PREFACE

When we were first approached by Elsevier to develop this *Encyclopedia of Movement Disorders,* it was not immediately evident to us how an encyclopedia would be different from existing textbooks on the same topic. Exploring the concept, we consulted the omnipresent mother of all modern encyclopedias, Wikipedia, where we found the following explanation of the origin of the word: encyclopaedia comes from the Greek ἐγκύκλιος παιδεία, transliterated 'enkyklios paideia'; 'enkyklios' meaning 'cyclical, periodic, or ordinary', and 'paideia' meaning 'education'. Together, the phrase literally translates as a '[well-] rounded education'. In Latin, the two words were unified into 'encyclopaedia', which subsequently became part of the English vocabulary. This etymologic detail, while interesting, did not provide us with a clearer vision of the project at hand, so we gathered existing encyclopedias and compared them to standard textbooks. This comparison revealed immediately that textbooks have tables of contents, and the content is separated into chapters and sections. The hierarchical format of a textbook pre-defines an order that is the core of a unified narrative that builds from page to page. In contrast, an encyclopedia is harnessed by an alphabetical order with cross referencing to related topics. This type of structure has not been previously presented for a work focusing on movement disorders and the printed and digital format options proposed by the publisher for this work convinced us that this project would be a novel and useful addition to the international literature.

Organization, structure, and digital innovations, however, are not enough to differentiate a textbook from an encyclopedia. We have developed this encyclopedia with the primary mission of providing up to date and easily accessible information. We have not developed the encyclopedia to infringe on the primary goal of a textbook as a teaching tool. Whereas a textbook is anchored as a progressive teaching program with its step-by-step development of chapters and prescribed order of presentation to instruct readers, our mission is the efficient delivery of information.

As a result, the *Encylopedia of Movement Disorders* is organized in alphabetical manner and contains 402 entries encompassing clinical and basic science topics relating to movement disorders, including anatomy, physiology, molecular biology, pharmacology, toxicology, genetics, pathology, epidemiology, behavioral neurology, neuro-ophthalmology, imaging, surgery, and psychiatry. Most entries are relatively brief and highly focused to allow the reader to hone in on the topic without needing to wade through introductory information. The cross references in the printed version and the search engine in the electronic version allow the reader rapid access to additional information in either a more general or a more specific format. This particular feature makes the encyclopedia accessible to anyone regardless of background knowledge, including students, general physicians, basic scientists, and movement disorder specialists. Each entry contains a 'further reading list' that will steer the reader to the most essential published works on the subject. In addition, cross references are offered throughout the work, to facilitate the reader's navigation between entries, zooming out from the more focused to the more general article, and zooming back in to related focused entries.

The discipline of Movement Disorders relies heavily on recognition of phenomenology. Therefore no Movement Disorder reference work is complete without video clips. Numerous authors have complemented their written work with visual testimonies that will greatly enhance the reader's learning experience. We are grateful for the authors' extra effort to make this possible and to their patients who consented to be videographed.

The remarkable pace of discovery in neurosciences and the scope of this work defy any attempt at being absolutely comprehensive. However, the dynamic nature of our on-line version allows for timely updates and makes this reference work conceptually and practically an ongoing work-in-progress.

We feel privileged to have worked with the authors, most of them world renowned, some at earlier stages of their careers, but all experts in their designated topics. We thoroughly enjoyed the opportunity to review their latest work and to communicate our editorial comments. When we started out, the freshly introduced electronic manuscript submission website (EMSS) may have caused initial hardship for some, but overall the ability to communicate through this website and to have a paper trail of different manuscript versions, figures, videos, and communications among author, associate editors, Elsevier, and us was an invaluable asset and we thank all participants for their persistence. We are indebted to our

Associate Editors who were instrumental in recruiting expert authors, and in the review and editing of the manuscripts in their respective areas of expertise. At the publisher, Elsevier, many people are responsible for the ultimate product currently resting in your hands, but we want to single out Developmental Editor Jason Mitchell whose optimism and professionalism never failed us.

Co-editing this work was greatly facilitated if not enabled by our close professional and personal relationship. At the occasional juncture on the long and windy road where one of us became discouraged, there was always the other to take the helm and bring the energy and determination to re-ignite the spark. The mutuality of that process has happily brought the *Encyclopedia of Movement Disorders* to its timely completion.

EDITOR'S BIO

Leonard Verhagen Metman earned his medical degree from the University of Leiden in the Netherlands in 1983. He moved to the United States in 1985 to work in the Artificial Heart Program at the University of Utah with Dr. Willem J. Kolff (1985–1987). He first pursued his interest in the Neurosciences by joining the Division of Restorative Neurology and Human Neurobiology at Baylor College of Medicine in Houston, Texas with Dr. Milan R. Dimitrijevic (1987–1988). Following an internship at Waterbury Hospital Health Center in Connecticut (1988–1989), he completed his Neurology residency at Thomas Jefferson University Hospital in Philadelphia, Pennsylvania under Robert J. Schwartzman (1989–1992). He then accepted a fellowship at the National Institutes of Health, in the Experimental Therapeutics Branch of the National Institute of Neurological Disorders and Stroke in Bethesda, Maryland under Thomas N. Chase (1992–1994). Upon completion he remained at the NIH as Visiting Associate and later as Visiting Scientist until 1999 when he joined the Movement Disorder Section of the Department of Neurological Sciences at Rush University Medical Center in Chicago, Illinois, directed by Dr. Christopher G. Goetz. In 2002 Dr. Verhagen received his Ph.D. from the University of Leiden based on his studies of motor response complications in Parkinson's disease. Over the past 10 years at Rush, Dr. Verhagen has served as Assistant Professor (1999–2000) and Associate Professor (2001-current) of Neurological Sciences. In addition, he established the Rush Movement Disorder Surgery Program and serves as its Medical Director. His clinical research interests include the development of new medical and surgical therapies for patients with advanced movement disorders. Dr. Verhagen is board certified in psychiatry and neurology (1994-present) and is a member of the American Academy of Neurology, the American Neurological Association and the Movement Disorder Society.

Dr. Kompoliti was born in Greece and completed her early education there, including Medical School. She graduated from the University of Patras, college of Medicine in 1988. She came to the United States in 1989, where she completed the rest of her medical education. She first trained in internal medicine (1990–1992) at St Francis Hospital, Evanston, IL. Following that she pursued her interest in neuroscience by completing a residency in Neurology at Northwestern University, Chicago, IL (1992–1995). After the completion of her residency she held a fellowship in Movement Disorders at Rush University Medical Center, Chicago, IL (1995–1997). She became Assistant Professor of Neurology in 1998 and Associate Professor in 2004. She is board certified in Neurology (1997-present) and is a member of the American Academy of Neurology, the American Neurological Association and the Movement Disorders Society. The author and coauthor of numerous publications, her clinical interests as a principal investigator have focused on several therapeutic areas of on-going research including studies to evaluate the safety and efficacy of new compounds to treat Parkinson's disease, Tourette syndrome, and Psychogenic Movement Disorders. Special interests of Dr. Kompoliti's include the gender differences in Parkinson's disease and other movement disorders, studies to define the effect of neuroleptics on weight, risk for diabetes and dyslipidemia in patients with Tourette syndrome, and define the current status of use of Complementatry and Alternative Medicine in patients with Tourette syndrome. Finally, Dr. Kompoliti has been conducting studies to assess therapeutic interventions for patients with functional movement disorders. Dr. Kompoliti is a member of the National Medical Advisory Board of the Tourette Syndrome Association and has given numerous lectures and Grand rounds around the country to increase public awareness in Tourette Syndrome.

3-Nitropropionic Acid

E Brouillet, URA CEA-CNRS 2210, Molecular Imaging Research Center (MIRCen), Fontenay-aux-Roses, France

Glossary

SDH (succinate dehydrogenase) – An enzyme that catalyzes the transformation of succinate into fumarate.
Succinate – A tricarboxylic acid that is an intermediate metabolite in the so-called tricarboxylic acid cycle (TCA cycle or Kreb's cycle).
TCA – Transforms and uses the energy that is 'stored' in the covalent bonds between carbon atoms through a number of reactions (including decarboxylation and dehydrogenation).

Definition and History

The neurotoxin 3-nitropropionic acid (3NP), a metabolite of 3-nitropropanol, was identified many decades ago in western United States of America as a toxic agent responsible for livestock poisoning. Animals intoxicated with leguminous plants (e.g., *Indigofera* or *Astragalus*) presented motor abnormalities consisting of general weakness and incoordination of the hindlimbs that evolved to paralysis. More recently, it was reported that accidental ingestion of sugar cane, contaminated with the fungus *Arthrinium* that produced 3NP was also the causal agent responsible for the development of acute encephalopathy in man. Most patients fall into a comatose state that can last several days. After coma, a large proportion of patients recovered completely without neurological alterations. However, a substantial number of subjects displayed a persistent neurological impairment characterized by delayed onset dystonia, torsion spasm, facial grimacing, and jerk-like movements. In these cases, computerized tomography (CT) and magnetic resonance imaging (MRI) examination usually indicate the presence of basal ganglia lesions mainly implicating the putamen, and less commonly, the caudate nucleus.

Pathogenesis/Pathophysiology

The dose-dependency of 3NP toxicity in man is unknown. Indeed, contamination of sugar cane is likely highly variable. The first controlled studies in mice and rats were performed in the early 1980s, suggesting that striatal degeneration was produced for acute doses in the range of 15–180 mg kg^{-1}. In nonhuman primates, the acute toxic dose is in the range of 20–30 mg kg^{-1} day^{-1}.

Biochemical studies have established that 3NP is a suicide inhibitor of succinate dehydrogenase (SDH), an enzyme located in the mitochondrial inner membrane and responsible for the oxidation of succinate to fumarate. The toxin irreversibly binds to the substrate site. This blocks the tricarboxylic acid (TCA) cycle (oxidative use of carbohydrates) and hampers the flow of electrons in the respiratory chain, reducing the capacity of mitochondria to produce ATP through namely 'oxidative phosphorylation.' Thus, the basic mechanism of 3NP is to produce impairment of energy metabolism.

How does 3NP trigger striatal neurodegeneration? Mitochondrial dysfunction produced by 3NP triggers oxidative stress and dysregulation of Ca^{2+} homeostasis. The increase in concentrations of Ca^{2+} in the cytosol and mitochondria activates a number of enzymes and intracellular signaling pathways that produce cell death resembling necrosis.

Certain mechanisms have been suggested to play an important role in the particular vulnerability of the striatum to 3NP toxicity. Some neurotransmitters and their receptors have been identified to play a key role, including glutamate and dopamine.

The links between brain lesion and symptoms can be underlined from in vivo imaging studies using CT scan and MRI in poisoned patients and from the observations in laboratory animal studies. General energy failure likely causes noninflammatory encephalopathy associated with coma, a phase that likely occurs in the absence of detectable tissue damage. After the period of coma, degeneration

of the putamen and the globus pallidus, two important structures of the basal ganglia, likely underlies most of motor symptoms. Postmortem studies of the brain of intoxicated patients have never been reported. From animal studies, it is known that the striatum is preferentially damaged. Neuropathological evaluation showed that medium-size spiny neurons are highly vulnerable. The globus pallidum, and sometimes, the hippocampus and substantia nigra pars reticula and substantia nigra pars compacta can also be found affected in acute intoxication.

Epidemiology/Risk Factors

In man, acute intoxication has been only reported in North China. Nearly 1000 cases of intoxication were reported between 1972 and 1989. The cause of intoxication is related to the fact that sugar cane is stored in humid and warm places where fungus proliferates very rapidly to produce high amounts of 3NP. The sugar cane was sold informally as sweets during the Chinese New Year celebration. Thus, the presence of the fungus in molded sugar cane could not be anticipated before the occurrence of overt intoxications.

Apart from environmental factors (food habits, warm climate, sugar cane storage), no other risk factors have been clearly identified. However, the Chinese neurologists who reported the cases of 3NP poisoning in man point to the fact that children are more commonly affected than adults. It is possible that children eat more contaminated sugar cane than adults do. Indeed studies in laboratory animals showed that adult animals (mice, rats, and monkeys) are in fact more vulnerable compared with young adolescents.

Differential Diagnosis

The striatum and the globus pallidus are known for their peculiar vulnerability to mitochondrial toxins (e.g., cyanide), hypoxia, and carbon monoxide intoxication. In the case of cyanide poisoning (suicidal ingestion), the poison can be detected. In the case of hypoxia, loss of consciousness occurs rapidly in the absence of major gastrointestinal signs. Carbon monoxide as 3NP might cause nausea, vomiting, headache, and drowsiness before coma. In the acute phase of 3NP poisoning, detection of normal levels of carboxyhemoglobin in venous arterial blood permits to rule out carbon monoxide intoxication.

Long-lasting neurological symptoms (in particular dystonia) can be found in many disorders associated with striatal degeneration. Certain aspects of Huntington's disease (HD), including choreiform involuntary abnormal movements and frontal-type cognitive symptoms and the selective pattern of cell death in the striatum, can be replicated in nonhuman primates, using chronic treatment with 3NP. Disorders associated with genetic mitochondrial defects can also lead to striatal degeneration and dystonia. However, absence of inheritance, absence of symptoms progression, record of an episode of gastrointestinal signs of acute intoxication followed by a period of coma, and suspicion of sugar cane ingestion can help to diagnose long-term neurological effects of 3NP poisoning and rule out genetic diseases.

Diagnostic Work-up/Tests

The first signs of intoxication are gastrointestinal signs (e.g., vomiting) and general weakness. The first signs of intoxication occur few hours after the ingestion of sugar cane. Gastrointestinal signs in the absence of fever might help to exclude viral origin. The absence of signs of brain inflammation (temperature change, nuchal rigidity, normal CSF) and gastrointestinal symptoms might help to diagnose poisoning. The neurological manifestations in children in the acute stage of 3NP poisoning indicate both diffuse and focal brain impairment. Chinese neurologists who reported these cases in children underline that the presence of convulsive attacks, coma, and bilateral extensor plantar responses suggest diffuse encephalopathy. They also report forced upward gaze, with deviation of the eyes and (horizontal or vertical) nystagmus. All these acute symptoms are reversible suggesting a general widespread brain dysfunction. When coma occurs, it lasts several days. Some of the comatose patients recovered completely without neurological alterations. In patients with delayed neurological manifestations, CT scan or MRI indicate the presence of basal ganglia lesions mainly implicating the putamen, and less commonly, the caudate nucleus.

The detection of *Arthrinium* in contaminated sugar cane should likely be the best proof of 3NP poisoning. Methods to detect 3NP in urine in animals have been reported but are not very sensitive and have to be set up and validated for helping diagnosis. Elevated nitrate levels in blood might also be indicative of 3NP poisoning. Improvement should be done to detect traces of 3NP in blood (for instance using mass spectroscopy).

Management

There is no particular management reported. During the initial phase of intoxication (at onset of gastrointestinal signs), hospitalization with an intensive health care follow-up is recommended. From animal studies showing

rapid elimination of 3NP in urine, it can be inferred that stomach washout and physiological serum venous perfusion to increase elimination immediately after 3NP ingestion should improve the prognosis.

There is no known antidote against 3NP in man. 3NP is rapidly eliminated through the urine as shown in animal studies. Apart from factors related to elimination, various pharmacological agents might be protective if given simultaneously or shortly after 3NP ingestion. Among these agents, for example, arginine, free radical scavengers, dopamine D2 receptor antagonists, and several agents reducing the entry of Ca^{2+} into neurons can prevent 3NP toxicity in cellular and animal models. Whether these findings could be extrapolated to the human condition is unknown. After the phase of acute encephalopathy and coma, when the presence of striatal lesions has been diagnosed using imaging, no treatment has been tested to reduce the severity of neurological symptoms. Since the lesions are stable and do not evolve toward aggravation, a partial recovery linked to neuronal plasticity can be expected. However no report of rehabilitation trial has been reported. Experimental results in nonhuman primates suggest that grafting of embryonic striatal neurons could have beneficial effects to improve symptoms. Clinical trials have not been carried out.

Prognosis

Approximately 10% of the intoxicated persons died from 3NP poisoning. Among the patients recovering from coma, ~10–15% displayed a persistent neurological impairment, while the others had no persistent symptoms. Neurological symptoms appearing after coma remain essentially stable thereafter.

6-OH Dopamine Rat Model

M Angela Cenci, Lund University, Lund, Sweden

Glossary

Dopamine – Dopamine is a neurotransmitter occurring in a wide variety of animals, including both vertebrates and invertebrates. In the brain, it can activate five types of dopamine receptors: D1, D2, D3, D4, and D5, and their variants. Dopamine is produced in several areas of the brain, but the largest aggregates of dopamine-producing neurons are found in two midbrain nuclei named 'substantia nigra' and 'ventral tegmental area.' Dopamine is also a neurohormone released by the hypothalamus. Its main function as a hormone is to inhibit the release of prolactin from the anterior lobe of the pituitary. Severe dopamine deficiency in the striatum is the prime cause of the motor symptoms typical of PD (in particular, slowness of movement, poverty of movement, difficulty in movement initiation, resting tremor, rigidity).

L-dopa (or levodopa) – L-dopa (3,4-dihydroxyphenyl-L-alanine) is a medication that is used to increase the amount of dopamine in the brains of patients with PD and other disorders (in particular, dopa-responsive dystonia). Dopamine as such cannot be administered systemically because it does not cross the blood–brain barrier, whereas the dopamine precursor, L-dopa is transported across the blood–brain barrier by an endothelial carrier system.

Motor complications – This term refers to motor fluctuations (i.e., rapid transitions between poor mobility and good motor function) and dyskinesia (i.e., abnormal involuntary movements) that usually occur after a few years of L-dopa therapy in patients with PD.

Nigrostriatal projection – Axon fibers that originate from neurons in the substantia nigra pars compacta

and reach the striatum. This projection uses dopamine as its primary transmitter.

Oxidative stress – Oxidative stress is caused by an imbalance between the production of reactive oxygen and a biological system's ability to readily detoxify the reactive intermediates or repair the resulting damage. The ensuing toxic effects are mediated by peroxides and free radicals that damage all components of the cell, including proteins, lipids, and DNA. Oxidative stress is believed to contribute to the death of nigral dopamine neurons in PD.

Striatum – The corpus striatum (commonly referred to as 'striatum') is a subcortical structure (i.e., located inside the telencephalon/cerebrum) consisting of two main components: the caudate nucleus and the putamen. These nuclei are the major input station of the basal ganglia system, and receive dense axonal projections from the entire cerebral cortex. The striatum plays a very important role in the selection and control of actions and movements. A ventral extension of the putamen, called nucleus accumbens, is now commonly referred to as 'ventral striatum.' This structure is part of the brain reward systems.

6-Hydroxydopamine (6-OHDA) is a naturally occurring, endogenous autooxidation product of dopamine that has been widely used as a catecholamine neurotoxin. When injected systemically, the toxin only affects sympathetic nerve terminals in the peripheral nervous system. When injected intracerebrally, 6-OHDA causes degeneration of central monoamine neurons with a pattern that depends on the dose, the route (intraventricular or intraparenchymal), and the coordinates of toxin injection. 6-Hydroxydopamine is efficiently taken up and accumulated by neurons that have a membrane transport mechanism for catecholamines (dopamine or noradrenaline), which accounts for the specificity of its action. High concentrations of the toxin, however, can produce nonspecific neuronal damage, as seen in close proximity to intraparenchymal injection sites. The neurodegenerative process induced by 6-OHDA is rapid, and mainly depends on the production of reactive oxygen species and oxidative stress. The toxin is indeed susceptible to nonenzymatic autooxidation associated with the formation of a number of reactive and potentially cytotoxic products. In addition, 6-OHDA inhibits mitochondrial complex I activity. Axon terminals are more sensitive than cell bodies to the cytotoxic action of 6-OHDA. The most common application of 6-OHDA in the scientific literature is related to Parkinson's disease (PD) research.

Rodent 6-OHDA Models in Studies of PD-like Neurodegeneration

Intracerebral injections of 6-OHDA can be used to study the mechanisms and consequences of catecholamine neuron degeneration. Rodents with 6-OHDA lesions remain the model of choice to address the biochemical and molecular consequences of the severe dopamine depletion typical of PD. In this sort of studies, injections of 6-OHDA in the nigrostriatal axon bundle are most commonly used because they cause acute death of nigral dopamine neurons and denervation-induced adaptations in striatal neurons that are complete within a few days. On the other hand, injections of 6-OHDA in the striatum are most commonly used to study mechanisms of nigral cell death and the effects of potential neuroprotective treatments. Intrastriatal 6-OHDA injections have been reported to produce a rapid loss of striatal dopaminergic terminals, and a biphasic pattern of dopamine cell death in the substantia nigra, where a first rapid phase of cell loss (1–2 days) is followed by atrophy and progressive loss of dopamine neurons continuing over 8–16 weeks. Programmed cell death with the morphology of apoptosis has been shown to occur in this model.

Rodent 6-OHDA Lesion Models in Behavioral-Pharmacological Research

Based on the observation that unilateral electrolytic lesions of the substantia nigra produce an asymmetric posture in the rat, with the head and tail deviating towards the side of the lesion, Ungerstedt and Arbuthnott developed a unilateral 6-OHDA lesion model where amphetamine administration is used to produce vigorous rotation towards the side of the lesion, and this behavior is quantified using automated 'rotometer' bowls. In the same animal model, dopamine receptor agonists induce rotation towards the side contralateral to the lesion. Since these seminal observations, drug-induced contralateral rotation in rats with unilateral 6-OHDA lesions has been the most commonly used animal model for screening drugs with antiparkinsonian potential. The success of the model greatly depends on its ease of execution and quantification, and on the well-documented relationship between the extent of drug-induced rotation and the severity of dopamine denervation in the nigrostriatal system. More recently, the specificity and predictive validity of contralateral rotation has been questioned because the effects of dopaminergic drugs on rotation do not correlate well with their capacity to improve spontaneous motor behaviors, and because some aspects of rotational behavior may predict motor complications rather than reversal of parkinsonism. Rats with unilateral 6-OHDA lesions have been

shown to exhibit qualitative and quantitative impairments in the limbs contralateral to the lesion during walking, climbing, reaching-and-grasping, postural adjustments, and other behaviors. Simple tests have been developed to measure these deficits, which can be applied in the preclinical assessment of PD treatments. A relatively novel application of unilaterally 6-OHDA lesioned rats is that related to L-dopa-induced dyskinesia. When treated with L-dopa, these animals exhibit abnormal involuntary movements that affect the limbs contralateral to the lesion, the trunk, and the orofacial musculature. These movements have the same time course as peak-dose dyskinesia in PD, and, like the human disorder, they disrupt physiological motor activities. Rating scales have been developed and validated to quantify treatment-induced abnormal involuntary movements in both rats and mice with unilateral 6-OHDA lesions. Rats subjected to bilateral 6-OHDA lesions of the nigrostriatal pathway display a bilateral parkinsonian-like syndrome including akinesia, gait abnormalities, hunched posture and other postural deficits, increased muscle resistance to passive stimuli, and tremulous jaw movements. The bilateral lesion procedure has been used parsimoniously in preclinical PD research mainly because animals subjected to this lesion require intensive postoperative care.

A

Abetalipoproteinemia (ABL)

R Zamel and R A Hegele, University of Western Ontario, London, ON, Canada

Glossary

Acanthocyte – Erythrocyte of thorn like-protrusion ('acantha' from Greek for thorn). Seen in patients with advanced liver disease, neuroacanthocytosis syndromes, postsplenectomy state.
Acanthocytosis – The presence of acanthocytes in the blood.
Apolipoprotein B-100 – A major transporter of lipids in plasma, it is secreted from liver, the full length is comprised of 4536 amino acids, and is the main constituent protein of VLDL and LDL.
Apolipoprotein B-48 – Apolipoprotein B-48 is secreted from the enterocytes. Apo B-48 is identical to 48% of the amino-terminal portion of apo B-100, and is the translational product of apo B-100 mRNA edited at amino acid position 2152 to form a termination codon. The editing enzyme is a cytidine deaminase that converts cytidine to uridine.
Microsomal triglyceride transfer protein (MTP) – A protein located in the lumen of endoplasmic reticulum, and acts as a chaperone that facilitates the transfer of lipid onto apoB. Failure of lipidation of apo B results in degradation of apoB, accumulation of partially assembled lipoproteins in the endoplasmic reticulum of enterocytes and hepatocytes, and subsequent deficiency of apo B containing lipoproteins 'LDL and VLDL' in plasma.
Retinitis pigmentosa – A type of inflammation of the retina. Characterized by; progressive loss of retinal responses, retinal atrophy, and clumping of the pigment.

Abetalipoproteinemia (ABL)

Definition and History

The syndrome comprising fat malabsorption, ancanthocytosis, Friedreich-like ataxia, and atypical retinitis pigmentosa was originally given the eponym 'Bassen–Kornzweig syndrome' in the 1950s. This syndrome was later linked to low plasma lipoproteins, leading to the redesignation as 'abetalipoproteinemia' in 1960. Improvements in analysis of plasma lipoproteins during the 1970s narrowed the fundamental defect in ABL to the inability to synthesize lipoprotein particles containing apolipoprotein (apo) B, namely chylomicrons, very low density lipoprotein (VLDL), and low density lipoprotein (LDL).

Pathogenesis and Pathophysiology

ABL has an autosomal recessive mode of transmission. Typically, obligate heterozygotes have normal plasma lipid levels. Disease frequency is <1 in 100 000. ABL is caused by mutations in the gene encoding the microsomal triglyceride transfer protein (MTP; MIM 157147) on chromosome 4q22–24. MTP is required for normal assembly and secretion of apo B-containing lipoproteins. MTP is a heterodimer composed of the multifunctional enzyme protein disulfide isomerase (PDI), and a unique 97-kDa subunit. PDI appears to be necessary to maintain the structural integrity of MTP, however, no mutations in PDI have been reported. In the absence of MTP, apo B cannot be properly lapidated, and undergoes rapid presecretory degradation.

Clinical and Pathological Features

At birth, infants with ABL are asymptomatic. Gastrointestinal symptoms typically develop shortly after birth. The initial presentation resembles celiac disease with diarrhea, vomiting, and abdominal swelling. Subsequently, the gastrointestinal signs subside in part because the patients learn to avoid fatty foods. Chronic malabsorption of lipids also leads to fat-soluble vitamin deficiency because the plasma transport and delivery of these vitamins to tissues depend almost exclusively (for vitamin E and β-carotene) or in part (for vitamins A, D, and K) on intact synthesis and secretion of apo B-containing lipoproteins.

Without intervention, the vitamin deficiencies result in neuro-opthalmologic complications by the third decade of life, which dominate the clinical picture, and determine the morbidity of ABL. However, there is heterogeneity in disease presentation. Almost all reported ABL patients >20 years of age who had not received vitamin E supplementation developed neuro-retinal complications. Some were blind and bedridden. In ~25% of reported cases, the diagnosis was made after the age of 20. This clinical heterogeneity is unexplained, although there may be some correlation with the severity of the molecular defect.

With a normo-lipidemic diet, steatorrhea is invariably present. This symptom reflects lipid malabsorption, and is attenuated or fully relieved after the introduction of a low-fat diet. Lipid malabsorption affects growth and may lead to secondary malabsorption of other nutrients. Endoscopic examination of the intestine reveals a 'gelee blanche' or white frosting appearance, which reflects infiltration of the mucosa by lipids. The fat engorgement of intestinal cells provided an early clue that the metabolic defect in ABL prevented the normal secretion of dietary fat from enterocytes into the plasma through the intestinal lymphatics.

As with the intestine, the liver in ABL subjects can show marked lipid accumulation. This hepatic steatosis is occasionally associated with elevation of transaminases either with or without hepatomegaly. Rarely, evolution to fibrosis occasionally progresses to cirrhosis, requiring transplantation.

The initial neurological sign is often diminution then loss of deep tendon reflexes followed by a progressive loss of position and vibration sensation, a spinocerebellar syndrome, and muscular weakness. Also, slowed intellectual development is present in up to one-third of the patients. Neuropathology reveals axonal degeneration of the spinocerebellar tracts and demyelination of the fasciculus cuneatus and gracilis. Vitamin E deficiency was first recognized in ABL patients in 1965, and is now considered to be the cause of the spinocerebellar degeneration. The myopathy results from both neural degeneration and an intrinsic myositis. Although the clinical course is variable without treatment, it leads progressively to impaired mobility, and some patients become wheelchair-bound or even bedridden. The severe effects on the central nervous system are the ultimate cause of death in most patients with ABL, which (before the introduction of high-dose vitamin E therapy) often occurred by the fifth decade. However, early administration of vitamin E has been shown to cause objective arrest of the usually progressive neuropathy and myopathy.

Initially, ABL patients complain of decreased night and color vision, followed by a decrease in visual acuity. The visual field shows a concentric contraction. If left untreated, virtual blindness occurs by the fourth decade. Fundoscopy shows atypical pigmentation of the retina. Pathologically, the retina shows reduced numbers of photoreceptor cells and accumulation of lipofuscin. In some cases, angioid streaks, opthalmoplegia, ptosis, and anisocoria have also been described.

Acanthocytes are speculated to result from membrane deformation stemming from decreased membrane fluidity caused by changes in lipid composition. In addition to acanthocytosis, patients with ABL may have a moderate to severe anemia that results from hemolysis and shortening of the erythrocyte half-life. Abnormalities in coagulation (elevated prothrombin time) caused by deficiency in vitamin K-dependent coagulation factors may also be seen in ABL patients. This may be symptomatic, leading to bruising or hemorrhage.

Management

Early diagnosis and treatment are essential to prevent growth retardation and neuro-opthalmological complications in ABL secondary to chronic lipid malabsorption and deficiency in fat-soluble vitamins.

The steatorrhea and vomiting caused by the lipid malabsorption lead to secondary deficiencies in carbohydrates and proteins. A low-fat diet allows for normal absorption of carbohydrates and proteins. To provide an adequate amount of total calories, the proportion of protein and carbohydrate in the diet must be increased to allow resumption of growth in height and weight. The lipid-poor diet should provide the daily requirements in essential fatty acids in the form of vegetable oils. Oral medium-chain triglycerides provide dietary fatty acids for absorption through the portal circulation, thus bypassing the defective MTP-mediated assembly of apo B-containing lipoproteins in ABL. However, this treatment has been suggested to induce hepatic fibrosis in rare cases.

Vitamin E is thought to prevent lipid peroxidation. Therefore, its deficiency in ABL leads to an increase in the peroxidation of polyunsaturated fatty acids in photoreceptor cells, myelin, and cell membranes in general. ABL subjects require lifetime therapy with vitamin E in large oral doses of 100–300 mg per kilogram per day to prevent this complication. Such high doses of vitamin E are absorbed through the hepatic portal vein. Plasma levels of vitamin E rarely exceed 10% of normal even after long-term therapy. Nevertheless, levels in fat, liver, and erythrocytes almost always increase with large doses of vitamin E.

Vitamin A is thought to stabilize photoreceptor membranes in epithelial cells of the retina. In ABL patients, vitamin A deficiency is easily corrected by oral supplementation because after intestinal absorption and transport to the liver, vitamin A has a lipoprotein-independent own transport system, unlike vitamin E. Daily doses up to four-fold increase over recommended doses are required to normalize the levels of vitamin A or its surrogate analyte, β-carotene.

Vitamin K administration whether orally or parenterally rapidly corrects the coagulation abnormalities in ABL. The deficit in vitamin K is exacerbated when large doses of vitamin E are absorbed, and therefore, it is important to administer vitamin K prophylactically when beginning vitamin E therapy.

Vitamin D deficiency is not classically described in ABL because the metabolism of vitamin D does not depend much on apo B-containing lipoproteins, since there is partial absorption via the portal path and specific vitamin D transport proteins. However, the development of rickets and osteomalacia has been reported, and therefore, prophylaxis should be instituted in infants during growth.

Prognosis

Thus, early treatment with Vitamin E and vitamin A appears to prevent the onset of neuroretinal complications of ABL. However, vitamin therapy does not typically reverse clinical features if it is initiated too late, and neurological and opthalmological signs have already become established.

Familial Hypobetalipoproteinemia (FHBL)

Homozygous FHBL displays most of the clinical attributes of ABL, with the main distinguishing feature being half-normal plasma concentrations of plasma apo B-containing lipoproteins in heterozygote parents, contrasted with normal levels in parents of ABL subjects. Homozygous FHBL is rare, occurring in less than 1 in 100 000 persons. As in ABL, homozygotes may be ascertained at a young age because of fat malabsorption and reduced plasma cholesterol levels. Fat malabsorption results from an inability to form chylomicrons in the intestine and a subsequent failure to absorb fats and fat-soluble vitamins. The failure to form chylomicrons is directly due to the absence of apoB. Cholesterol absorption is also impaired, since a transgenic mouse that lacks intestinal apoB expression and chylomicron formation. Fat malabsorption may lead to a progressive neurologic degenerative disease resulting from vitamin E deficiency. It may also cause retinitis pigmentosa and acanthocytosis. Despite the low plasma cholesterol levels, steroidogenesis appears to be normal except when demands are quite high. Homozygotes that produce enough of a truncated isoform of apoB to facilitate some fat absorption may have a milder phenotype.

FHBL segregates as an autosomal codominant trait. Homozygotes have clinical and biochemical findings similar to ABL, with virtual absence of LDL cholesterol. Heterozygotes have LDL cholesterol below the tenth percentile for age and sex. Apart from hypocholesterolemia, FHBL heterozygotes are healthy and usually have no difficulty absorbing fat. Genetic linkage analyses in the 1980s indicated that the defect in some cases of FHBL was within the *APOB* gene on chromosome 2p24, which was distinct from the ABL locus. The *APOB* gene defects were mostly truncation-producing mutations of apo B of the nonsense or frameshift variety, although there are some missense mutations in this gene also.

The treatment of homozygous FHBL is similar to that of ABL. No specific treatment is indicated for heterozygotes, but dietary supplementation with fat-soluble vitamins is reasonable. Heterozygotes should be informed that if their spouses also have a very low plasma cholesterol level, the possibility exists that offspring could have homozygous or compound heterozygous FHBL; in this situation, subjects should be referred to a lipid clinic for genetic counseling.

Summary

Homozygosity for a defect either in apo B or MTP cripples this process, and results in failure to secrete apo B-containing lipoproteins into the plasma leading to deficiencies of fat-soluble vitamins, with vitamin E deficiency underlying the characteristic neuropathy in ABL and FHBL. Early diagnosis and high-dose oral supplementation with fat-soluble vitamins has helped normalize life expectancy and quality of life in patients with these rare metabolic conditions.

Accelerometry

R J Elble, Southern Illinois University School of Medicine, Springfield, IL, USA

Glossary

Accelerometer – A motion transducer that is sensitive to the acceleration of motion and earth's gravity.
Gravitational artifact – The portion of an accelerometer output signal that is produced by earth's gravity.
Gyroscopic transducer – A motion transducer that is sensitive to the velocity of the rotation of a body (i.e., angular velocity).
Rotational motion – Motion of a body that produces a change in orientation in space (i.e., spinning or rotation).
Translational motion – Motion of a body without any change in its orientation in space (i.e., without any spinning or rotation).

Accelerometers are small motion transducers that are based on Newton's law of mass acceleration (Force = mass × acceleration) and Hooke's law of spring action (Force = spring constant × change in length of a spring). Piezoresistive, piezoelectric, and capacitance devices are the three types of accelerometers used in human applications. All three types contain a small mass attached to an elastic element, and the elastic element is stretched or compressed in proportion to the acceleration. Very small transducers are produced using microelectromechanical systems (MEMS) technology.

Accelerometers are made for many industrial applications such as the measurement of machine vibrations and vehicle crashes. Consequently, accelerometers are available in many sizes, shapes, sensitivities, and accuracies. Users should consult with a technician to make sure that an accelerometer is suitable for the desired biological application. Some accelerometers are capable of measuring accelerations of $< 0.01g$ ($1\,g = 9.807\,\mathrm{m\,s^{-2}}$, the static acceleration of gravity), and therefore, these devices are capable of measuring very small accelerations such as physiologic tremor. Other accelerometers are less sensitive and are capable of measuring pathologic tremor but not physiologic tremor (e.g., Kinesia™, www.clevemed.com/pdfs/products/Kinesia.pdf and Tremorwatch®, www.salusa.se/Filer/Produktinfo/Aktivitet/tremorwatch.pdf). Insensitivity to physiologic tremor is an advantage when physiologic tremor is of no interest or might confound the measurement of pathologic tremor.

Motion of a body part usually consists of translational motion and rotation in three-dimensional space. Postural tremor in the horizontally extended hand is predominantly rotational motion about the wrist. Most accelerometers are linear accelerometers with one to three orthogonal axes of recording. A linear accelerometer measures translational movement, and it records rotational movement only to the extent that it is mounted some distance away from the axis of rotation (**Figure 1**). For example, if a linear accelerometer is mounted precisely on the axis of rotation of the hand (i.e., the wrist), it will detect only translational wrist motion and gravitational artifact. It will not measure the variable of interest: angular acceleration of the hand.

Gravitational artifact is an important confounder in accelerometry. Many investigators assume incorrectly that gravitational artifact is constant and can be removed simply by numerical subtraction or AC coupling. To the contrary, gravitational artifact occurs at all frequencies of body rotation, except when the accelerometer's axis of sensitivity rotates solely in the horizontal plane. For example, in **Figure 1**, the vertical Z axis of the accelerometer contains gravitational artifact equal to $g \cos(\theta)$ where θ is the angle between the Z axis and the gravity vector. For small angles of rotation ($<25°$), the Z axis and the gravity vector are approximately parallel, resulting in a gravitational artifact that is nearly constant ($\approx 1g$). Thus, true inertial acceleration is approximately equal to the accelerometer signal minus $1g$. However, for large angles

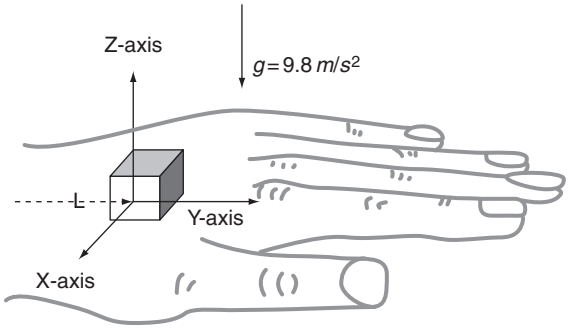

Figure 1 A triaxial accelerometer mounted on the dorsum of the hand will detect motion in the direction of its three axes of sensitivity. The accelerometer will detect translational motion and tilt with respect to gravity (g). The rotational acceleration is detected only when the accelerometer is located some distance L from the axis of rotation (e.g., the wrist). When $L = 0$, the accelerometer will simply spin in space, relative to gravity, making the output of the accelerometer pure gravitational artifact. Gravitational artifact can be as large as $\pm 1g$ at all frequencies of rotation.

of rotation, the gravitational artifact can vary as much as $\pm 1g$, at any frequency of rotation. This gravitational acceleration will, to some extent, obscure the inertial acceleration, which is the measurement of interest.

Except when an accelerometer simply moves up and down, more or less vertically, the task of separating the gravitational and inertial components of acceleration is impossible unless multiple accelerometers are used. Gravitational artifact will contaminate an accelerometer signal at all frequencies of rotational motion and in all planes of rotation except the horizontal plane. Biaxial and triaxial accelerometers are not a solution, because each axis of the accelerometer will contain gravitational artifact to the extent the accelerometer rotates or tilts with respect to gravity. At least six one-dimensional linear accelerometers must be strategically mounted on a body part to record translational and rotational movement of a body segment in three-dimensional space, and more than six accelerometers are needed in most instances.

Gyroscopic transducers (e.g., Kinesia™ and Motus® at www.motusbioengineering.com/index.htm) are not sensitive to gravity, and these devices are preferable to accelerometers when motion is predominantly rotational. Gyroscopic transducers are also constructed with MEMS technology, which makes them sufficiently small and lightweight for human applications. Gyroscopic transducers measure angular velocity, from which angular rotation and acceleration can be computed by numerical integration and differentiation respectively. Angular accelerometers are also commercially available (www.endevco.com/product/prodpdf/7302BM4.pdf). The technology of these devices is driven by industrial applications, but the manufacturers of these devices are increasingly in tune with biomedical applications (e.g., Xsens www.xsens.com/en/home.php).

Accelerometers and gyroscopic transducers require electrical filtering and amplification. Modern electronics enable these functions to be integrated with the transducer, forming a wireless portable device (Kinesia™, Tremorwatch®). Consequently, quantitative electrophysiologic study of movement disorders (e.g., tremor) is no longer restricted to a laboratory.

Acetylcholine

M Habibi, University of Illinois at Chicago, IL, USA

Glossary

Acetylcholinesterase inhibitors – Drugs that inhibit the break down of acetylcholine.
G protein – Cell membrane protein involved in the cellular signal transduction pathway.
Hydrophilic – Having strong affinity for water.
Lewy bodies – Abnormal aggregates of protein deposits in neurons.
Metabotropic receptors – G-protein coupled receptors.
Neuromuscular junction – A synaptic junction between a nerve and muscle cell.
Transmembrane receptors – Integral membrane proteins spanning the entire thickness of the membrane.

Introduction

Acetylcholine (Ach) is a neurotransmitter that is synthesized from choline and acetyl CoA by choline transferase enzyme and has a significant role in both the peripheral and central nervous systems. Acetylcholine is released at all preganglionic neurons, all parasympathetic postganglionic neurons, sympathetic postganglionic terminals of sweat glands, and neuromuscular junctions. Acetylcholine receptors are transmembrane (TM) receptors and are divided into two major groups: the metabotropic muscarinic receptors and the ionotropic nicotinic receptors.

Nicotinic Acetylcholine Receptors

The nicotinic acetylcholine (nACh) receptors are fast ionotropic receptors that are composed of distinct

subunits, α, β, δ, ε, and γ, and are arranged in different pentameric combinations around a ligand-gated excitatory ion channel permeable to Na^+, K^+, and Ca^{2+} ions.

All nACh receptor subunits have a large extracellular NH_2 terminal domain, three TM domains, a cytoplasmic loop in variable size and amino acid sequence, and a fourth TM domain with a short and variable extracellular COOH terminal. These subunits are further identified as α (alpha) or non-α (non-alpha) subunits based on the presence of a Cys–Cys pair near the TM1 entrance, which is required for the binding of the agonist. The nACh receptors are also subdivided according to whether their main site of distribution is muscle or nerve. Muscle nACh receptors consist of one α and four non-α (β, δ, ε, and γ) subunits. Neuronal subunits are formed in various combinations of α (α_2–α_{10}) and β subunits (β_2–β_4).

These subunits are widely distributed. For example, the mRNA of α_4 subunit is expressed in the thalamus, cerebral cortex, ventral tegmental area, and substantia nigra. Peripherally, these α_4 subunits are expressed in the trigeminal ganglion. The presence of α_6 subunits in striatum indicates their importance in locomotor activity. In addition to their presence in both the central and peripheral nervous systems, evidence exists that the neuronal subunits are also expressed by many nonneuronal cells, including cells of the digestive, pulmonary, and immune systems.

The binding site of ligands, such as nicotine, is in a hydrophobic pocket that is formed at the interface of adjacent subunits. The front side (positive site) of the binding site is formed by one of the following α subunits (α_1, α_2, α_3, α_4, α_6, α_7, α_9) with the Cys–Cys pair present, while the back site (negative site) of this binding site is formed by one of the following adjacent subunits (α_{10}, β_2, β_4, δ, ε, and γ). When a ligand binds the nACh receptor, it creates significant structural rearrangements throughout the receptor, which results in repositioning of the TM2 segment of each subunit, opening the ion channel in microseconds. The rotation of the TM2 segments plays a crucial role in supporting ion flow by temporarily replacing the hydrophilic barrier with hydrophilic residues and increasing the diameter of the channel.

Activation of nACh receptors by nicotine results in Na^+ influx, membrane depolarization, and activation of voltage-gated Ca^{2+} channels. Subsequently, stimulation of Ca^{2+} dependent kinases, including protein kinase C (PKC), protein kinase A (PKA), calmodulin-dependent protein kinase II, and extracellular signal-regulated kinases, occurs.

The activity of nACh receptors can be increased by nicotinic allosteric potentiating ligands (APLs) binding to the receptor at a site close to but distinct from the ACh binding site. For example, galantamine, an acetylcholinesterase inhibitor, improves synaptic transmission primarily by acting as an APL.

Muscarinic Acetylcholine Receptors

Muscarinic acetylcholine (mACh) receptors belong to the family of G-protein coupled receptors and consist of five different subtypes: M1, M2, M3, M4, and M5 receptors. These receptors are subdivided into two groups, based on their G-protein coupling properties. M1, M3, and M5 receptors couple to $G_{q/11}$ proteins, increasing formation of inositol-1,4,5-triphosphate, activating phospholipase C, mobilizing intracellular calcium, and increasing cAMP. On the other hand, M2 and M4 receptors exert their effects by binding primarily to $G_{i/o}$ proteins, inhibiting the activity of adenylyl cyclase and decreasing cAMP formation. The orthosteric binding site of these receptors is highly conserved and is located between TM helices 3, 5, 6, and 7.

M1 mACh receptors are highly expressed in the cerebral cortex, hippocampus, and striatum. This is consistent with their role in learning and memory. M2 mACh receptors are mainly located in the brainstem and thalamus; they are also found in the cortex, hippocampus, and striatum. Peripherally, these receptors play an important role in smooth muscle contractions. Compared with other muscarinic subtypes, there is less expression of M3 receptors in the CNS. Nonetheless, M3 receptors are highly expressed in the hypothalamus and have also been found in cerebral cortex and hippocampus. In the peripheral system, there is four times higher expression of M3 receptors in smooth muscle tissues compared with M2 receptors. Studies indicate a synergistic relationship between M2 and M3 receptors in contractions of smooth muscles. M4 receptors are found in the cortex, hippocampus, and on striatal projecting neurons. M4 agonists have shown to inhibit mesolimbic dopaminergic activity, suggesting antipsychotic properties. M5 receptors have been found in substantia nigra and ventral tegmental areas of the brain, indicating a probable role for these receptors in dopamine transmission. In the periphery, they are expressed at low levels in iris-ciliary muscle and salivary gland.

Physiological Properties

Cognition

Reduced function or expression of nACh receptors may play a significant role in the pathophysiology of the dementia seen in Alzheimer's disease (AD) or schizophrenia. The expression of $\alpha_4\beta_2$ nACh receptors is significantly decreased in AD. Different animal studies have also shown a decreased hippocampal expression of α_4 and α_7 nACh receptors with age. Similarly, studies in schizophrenia show a substantial reduction in α_7 nACh receptors in hippocampus and frontal cortex. Therefore,

preventing or decreasing the loss of nAChR function may be therapeutically beneficial. In human trials, use of nicotine showed little efficacy in the improvement of AD symptoms. This may have been related to the initiation of treatment after the diagnosis of symptoms.

The loss of cortical cholinergic neurons has been well-documented in Parkinson's disease (PD) dementia and Lewy body dementia. There is less expression of α_7 nACh receptors in the frontal cortex of patients with PD dementia and Lewy body dementia. The reduction of these receptors in the temporal cortex of patients with Lewy body dementia was associated with delusions and visual hallucinations.

Drugs that are currently approved for AD include the acetylcholine esterase inhibitors (AChE), galantamine, donepezil, and rivastigmine. These drugs have also been evaluated for the improvement of cognitive decline and negative symptoms of schizophrenia, as well as PD dementia.

It is also important to note that because of the high expression of M1 mACh receptors in the cortex and hippocampus, it is postulated that M1 mACh receptor agonists possess the highest potential for the treatment of AD. However, despite various preclinical candidates, no M1 mACh agonist is yet available for the treatment of AD. This is thought to be due to a lack of selectivity for M1 mACh receptors, since these compounds bind the highly conserved orthosteric ACh-binding site. Recent discovery of a new class of agonists, which selectively bind the allosteric M1 mACh receptor binding site, shows promise.

Movement

PD is a progressive neurodegenerative disorder caused by a loss of dopaminergic neurons in the substantia nigra. Several studies suggest that acetylcholine receptors play a critical role in PD. In several animal studies, nigrostriatal damage caused a significant loss in $\alpha_6\alpha_4\beta_2\beta_3$, $\alpha_6\beta_2\beta_3$, and $\alpha_4\beta_2$ nACh receptors, and postmortem studies showed a significant decline in the nicotinic Ach receptors in the striatum of PD patients.

Extensive studies have also shown the specific involvement of α_4 and α_6 containing nACh receptors in improving abnormal motor activity in rodents.

Nicotine can induce dopamine neurons to release dopamine. It is suggested that this release is mediated through the activation of presynaptic nACh receptors that are located on the cell body or terminal regions of dopaminergic neurons. Therefore, it has been postulated that nicotine or nicotine receptor agonists that cause dopamine release from nerve terminals may have a higher physiological efficacy in stimulating postsynaptic dopamine receptors compared with the administration of L-dopa or dopamine receptor agonists. It is also possible that combination therapy with a nACh receptor agonist and L-dopa may allow to decrease the dose of L-dopa and reduce the frequency and severity of adverse effects usually reported with the use of L-dopa. Few studies have investigated the use of nicotine patch and an investigational nicotinic agonist SIB 1508Y in PD; however, no significant improvement in the PD symptoms were noted with the doses and duration of treatment chosen. The use of higher doses was limited by the occurrence of intolerable side effects.

One future therapeutic option includes developing drugs that specifically act on α_6 subunits of nACh receptors, which may play a significant role in regulating dopamine release in the striatum.

Stimulation of nACh receptors may also play a role in neuroprotection and against nigrostriatal damage. Epidemiological studies showed that heavy smokers are ~50% less likely to have PD. However, the results of animal studies have been inconsistent.

In PD, the destruction of dopaminergic neurons results in a higher level of acetylcholine in the striatum. Anticholinergic drugs have long been used to restore the balance between the cholinergic and dopaminergic systems in PD; however, the extensive central and peripheral adverse effects caused by these medications have limited their use, especially in older individuals. PD tremor, in particular, may be improved with anticholinergic medications. Recent research suggests a role for more selective cholinergic antagonists. Several animal studies suggest a role for M4 mACh receptor antagonists to improve tremor in PD.

Dystonia is characterized by sustained, prolonged muscle contractions and can produce abnormal, twisting body movements and postures. Imaging and postmortem studies have linked dystonia with lesions and dysfunction of basal ganglia. There have been reports of significant reduction in dopamine level in the substantia nigra and striatum in dopa-responsive dystonia (DRD). Patients with DRD usually show a significant improvement when treated with small doses of L-Dopa. Anticholinergic drugs such as trihexyphenidyl have shown efficacy and resulted in a significant symptomatic improvement in patients with young-onset dystonia, segmental dystonia, and generalized and secondary dystonia. Botulinum toxin types A and B have shown efficacy in the treatment of dystonia. Both type A and type B botulinum toxic act at the neuromuscular junction and inhibit the release of ACh at the presynaptic membrane paralyzing the striated muscles.

Addiction

Chronic use and addiction to nicotine have been related to changes in function and expression of nACh receptors.

Continued nicotine administration results in upregulation of high-affinity $\alpha_4\beta_2$ nACh receptors. Several genetic studies in mice have shown the important role of α_4 nAChR subunits in nicotine addiction. A mutant form of this subunit showed a higher sensitivity to nicotine, and a lower concentration of nicotine was required to enhance the activity of this receptor. Other studies indicate that $\alpha 7$ nACh receptors may control withdrawal symptoms and that tolerance to nicotine administration may be induced by $\beta 3$ and/or $\beta 4$ subunits.

M5 mACh receptors are the main subtype in the ventral tegmental area of the brain, which is involved in drug reward and addiction. Several studies have shown that activation of these receptors will increase dopamine levels in the nucleus accumbens and other limbic areas, reinforcing drug dependency. On the other hand, selective M5 mACh receptor antagonists inhibit dopamine release and may provide a novel therapeutic approach in the treatment of drug addiction.

Actigraphy

R J Elble, Southern Illinois University School of Medicine, Springfield, IL, USA

Glossary

Accelerometer – A motion transducer that is sensitive to the acceleration of motion and earth's gravity.

Actigraph – A small portable motion transducer, usually an accelerometer, worn on the wrist or other body part for the purpose of recording the motor activity for one or more days.

Gravitational artifact – The portion of an accelerometer output signal that is produced by earth's gravity.

Gyroscopic transducer – A motion transducer that is sensitive to the velocity of the rotation of a body (i.e., angular velocity).

Rotational motion – Motion of a body that produces a change in orientation in space (i.e., spinning or rotation).

Translational motion – Motion of a body without any change in body orientation in space (i.e., without any spinning or rotation).

An actigraph is a small portable motion transducer that is worn on the wrist or other body part (e.g., ankle) for the purpose of recording the motor activity for hours or days. The motion transducer is usually an accelerometer with one to three axes of recording. These devices are about the size of a watch and contain integrated electronics for the processing and storage of digitized data. Data are downloaded from the actigraph to a digital computer for analysis.

The validity of these devices in recording a particular type of activity depends critically on the method used to process the accelerometric signal(s). Accelerometers are

extremely sensitive to all types of motion, including mechanical and gravitational artifact. Sudden jarring movements entail much larger accelerations than slow smooth movements, and the acceleration of repetitive movements (e.g., tremor) increases in proportion to the squared frequency of repetition (oscillation). Thus, the processing algorithm must take such issues into account when measuring motor activity, and the algorithm used in a particular device determines its utility and validity more than the characteristics of the accelerometer. An accelerometer on the wrist will detect the acceleration produced by all but very minute forces (muscle, gravitational, and external) acting on the wrist directly or indirectly through mechanical linkage with other body parts.

Actigraphy was first developed in the 1970s for analysis of rest–activity (sleep–wake) cycles. Sleep is deemed present when the quantity of movement (activity) per minute falls below an empirically defined threshold. Actigraphy is a reliable and valid method of detecting sleep in normal adults, but its reliability and validity are unestablished in patients with sleep disorders. The location of the actigraph has little, if any, effect on its reliability and validity.

Van Someren and colleagues developed an actigraph algorithm for long-term tremor recording, and this algorithm is incorporated into the Cambridge Tremorwatch (Cambridge Nanotechnology, www.camntech.com/h_aw_6.html). The integrated electronic algorithm in this device separates tremor from other movement by distinguishing the rhythmic high-frequency profile of tremor acceleration from the arrhythmic low-frequency profile of other movement. Tremor is quantified in terms of duration and amplitude. It has been validated in patients with Parkinson's disease but not other forms of tremor. The uniaxial accelerometer in this device is not sensitive enough to detect physiologic tremor, and the measurement of tremor amplitude is subject to the caveats discussed elsewhere.

The Cambridge Tremorwatch parses acceleration into tremor and nontremor activity. It is unclear to what extent this nontremor activity is a measure of bradykinesia or hyperkinesia in Parkinson's disease.

Salarian and colleagues developed an actigraph with gyroscopic sensors instead of accelerometers and were able to produce measures that correlated with the Unified Parkinson Disease Rating Scale (UPDRS) tremor and bradykinesia scores. Unlike accelerometers, gyroscopic sensors are not sensitive to their position on a body segment and are not subject to gravitational artifact.

Actigraphs are used in many other applications that are relevant to movement disorders. Kinetic energy is one-half the body mass times velocity squared, and velocity is the integral of acceleration. Thus, energy expenditure can be estimated with an accelerometric actigraph worn at the waist, near the body's center of mass. Actigraphs are also used to capture crude estimates of physical activity, postural sway, walking speed, walking cadence, limb motion during walking, and falls.

Actigraphs provide only crude measures of body motion regardless of the type of transducer used, because body motion usually consists of complex translational motion and rotation of multiple body segments in 3-dimensional space. Multiple transducers mounted strategically on multiple body segments are needed to quantify motion completely. The rhythmicity and frequency of pathologic tremors are useful in distinguishing tremor from other normal and abnormal movements. However, rhythmic normal movement, such as tooth brushing, can be mistaken for tremor. The complex movements produced by chorea, ballism, myoclonus, and dystonia cannot be distinguished with an actigraph.

In summary, users beware of the limitations of these devices! There is no actigraph that is suited for all applications, and actigraphs are becoming increasingly application specific. Transducer technology, data analysis algorithms, integrated electronics, wireless data transmission, and data analysis software are improving rapidly. Many options are available, and the internet is a good place to search for the best available option. Begin searching the internet using the following search parameters with and without your particular application (e.g., tremor, bradykinesia, falls) appended: actigraph, activity motor plus accelerometer, activity monitor plus gyroscope.

Akathisia

R M A de Bie, University of Amsterdam, Amsterdam, The Netherlands
A E Lang and S H Fox, University of Toronto, Toronto, ON, Canada

Glossary

Diurnal pattern – Symptoms and signs that vary or fluctuate in intensity over a 24 h period for example, better in the morning and worse in the evening.
Drug holiday – A planned period of time in which the person stops a medicine and then resumes it.
Tactile hallucinations – A perception of being touched in the absence of any stimulus, such as a feeling of insects/bugs crawling on the skin (known as formication).

Definition and History

Akathisia is a disorder characterized by a subjective report of inner restlessness with an inability to sit still, relieved by moving about. The patient usually has repetitive movements, which involve primarily the legs and trunk, that occur predominantly when the patient is sitting.

The first documented description of a syndrome resembling akathisia has been attributed to the British physician and anatomist Thomas Willis (1621–1675). The term akathisia (from Greek, literally 'not to sit') was coined by Lad Haskovec (1902) to describe two patients with restlessness and an inability to sit still. Haskovec distinguished the disorder from chorea and regarded it as a nonorganic psychiatric disorder, a tradition that continued for the next two decades. Due to the Sicard's and Bing's descriptions of akathisia in association with parkinsonism in 1923, akathisia was recognized as a symptom of idiopathic or postencephalitic parkinsonism. An influential statement came from Kinnier Wilson (1940) who wrote that even though Haskovec used the term akathisia for cases of 'hysterical or psychopathic nature,' it could be applied to parkinsonian patients.

In 1947, Sigwald reported drug-induced akathisia in a patient with Parkinson's disease (PD), who developed restlessness when treated with promethazine, a neuroleptic drug. After antipsychotic drugs became generally available, a number of reports appeared in the literature of patients being restless, unable to sit, and marching like soldiers to abate the restless feelings. The similarity with the akathisia syndrome of the preneuroleptic era was recognized. In the early 1960s, akathisia was accepted as an 'extrapyramidal' side-effect of neuroleptic medications with dopamine receptor blocking properties. It was demonstrated that akathisia could occur in psychiatrically normal individuals when treated with neuroleptic drugs.

In modern psychiatry, akathisia is used synonymously with drug-induced akathisia, but the term's origin in the preneuroleptic era makes it clear that the syndrome has multiple causes.

Pathogenesis

Although numerous risk factors for akathisia have been described, the exact pathophysiology of akathisia is still unknown.

Drug-Induced (Iatrogenic) Akathisia

The most frequent cause of akathisia is exposure to antipsychotic medications, both typical, such as phenothiazines, thioxanthenes, and butyrophenones (e.g., haloperidol), and atypical, such as olanzapine and quetiapine (patients 1 and 4). Antipsychotic medications primarily act as competitive antagonists of central dopaminergic receptors.

Akathisia due to the use of neuroleptics can occur shortly after starting the psychotropic drug, termed acute akathisia, or after long-term use, termed tardive akathisia. In the former case, akathisia usually starts within days of starting or increasing the dose of an antipsychotic. In the latter case, the syndrome can develop after long-term, stable, or even decreasing doses of antipsychotic drugs. The common characteristic of these drugs is that they block dopamine D2 receptors in multiple areas of the nervous system. In line with this, metoclopramide, an antiemetic drug that is not only used in psychiatry but also with dopamine D2 receptor blocking actions, also causes akathisia. In addition, dopamine depleting drugs, such as tetrabenazine (patient 3) and reserpine (the latter is no longer in clinical use), can cause akathisia, suggesting that the syndrome relates to decreased activity of central dopaminergic mechanisms, but can have pre- or postsynaptic causes of dopaminergic antagonism. Rarely, akathisia is associated with antidepressants, particularly the selective serotonin reuptake inhibitors (SSRIs (patient 5)) and less often with tricyclic compounds.

Akathisia can also be due to certain recreational drugs such as γ-hydroxy-butyrate (GHB), methamphetamine, and 3,4-methylendioxymethamphetamine (MDMA). All these agents potentially influence dopaminergic neurotransmission.

Akathisia Associated with Neurodegenerative Disorders

Akathisia can be seen in a variety of neurodegenerative forms of parkinsonism such as idiopathic PD, corticobasal degeneration (CBD), and multiple system atrophy (MSA). It can also occur in the context of postencephalitic parkinsonism. In PD, akathisia can develop in untreated patients or in treated patients in need of higher daily doses of dopaminergic medication. Among PD patients with a fluctuating medication response throughout the day, akathisia can be a cyclic and distressing form of 'off' effects that occur when the dopaminergic drugs are not working well. However, other studies (see below) found no correlation in symptoms of akathisia with response to levodopa.

Although these observations suggest that blockade or reduced stimulation of dopamine receptors, especially D2 dopamine receptors, can cause akathisia, the exact mechanism is probably more complicated. Beta blockers and anticholinergics can relieve akathisia, suggesting nondopaminergic influences. Anticholinergics may work indirectly to modify dopaminergic transmission because there are well-established compensatory balances between cholinergic and dopaminergic function in several areas of the central nervous system. Beta blockers antagonize norepinephrine, and the mechanism underlying efficacy of these drugs is less clear. In addition, a role of iron has been suggested based on phenomenological similarities between akathisia and restless legs syndrome (RLS). In RLS, unpleasant sensations in the legs occur that worsen at rest or periods of inactivity and are relieved by movement. These, however, are primarily nocturnal, which is not the typical pattern with akathisia. The association between low serum iron and RLS is established and serum iron may also be lower than normal in patients with antipsychotic medication-induced akathisia.

Epidemiology/Risk Factors

The prevalence of akathisia in neuroleptic-treated people ranges between 20 and 75%, occurring more frequently in the first 3 months of treatment. It is usually related not only to acute administration of a neuroleptic but also to rapid dose increase. Currently, clinicians use newer, atypical antipsychotics, but these drugs also induce akathisia, though to a lesser degree than the traditional neuroleptic drugs: risperidone, 6.7–50%; olanzapine, 2.8–16%; quetiapine, 2–5%; clozapine, 0–39%. One of the causes for the wide discrepancy in the reported prevalence of akathisia may be under-diagnosis. The presence and severity of drug-induced akathisia can be measured using the Barnes Akathisia Scale (see **Table 1**).

Lang and Johnson performed an interview study using a questionnaire in 100 patients with idiopathic PD and found evidence for akathisia in 26; 17 patients complained of general restlessness. Akathisia most often started after initiation of levodopa. Comella and Goetz studied 56 idiopathic PD patients using an 'akathisia questionnaire.' Akathisia was defined as feelings of restlessness associated with an urge to move. Based on this definition, they concluded that 45% of patients had akathisia and motor restlessness predominantly affecting the legs and feet. This high prevalence may be due to the inclusion of other causes of restlessness in these patients, such as muscle stiffness and immobility and possibly RLS. In a recent prospective study by Wadia and colleagues assessing the prevalence of restlessness in parkinsonism, 16% of idiopathic PD patients and 19% of patients with atypical parkinsonism (MSA, Progressive Supranuclear Palsy (PSP), CBD, and vascular parkinsonism) had restlessness not due to stiffness and immobility but thought to be due to akathisia, in contrast to 6% aged matched healthy controls. This observation demonstrates that akathisia likely affects individuals with atypical parkinsonism as well as PD.

Restlessness and psychomotor agitation may also occur in a wide variety of diseases, for example, due to metabolic disturbances secondary to liver or kidney disease. However, an iatrogenic cause should not be overlooked. In a recent prospective study, in which cancer patients were referred to an outpatient department of psychiatry, 20 of 420 (4.8%) patients had developed akathisia from prochlorperazine, an antiemetic drug.

Clinical Features and Diagnostic Criteria

The typical motor phenomena in akathisia include complex motor activities that are repetitive or stereotyped. These include repetitive crossing of legs, tapping of legs or feet, squirming in a chair, and truncal rocking back and forward. Arm movements may include repetitive rubbing of the face or scalp. Patients find it hard to sit still in a chair and therefore get up and pace. In addition, some patients prefer to lie down rather than sit. Vocalizations are often associated, especially in tardive akathisia, including moaning, groaning, and humming (patient 4). Akathisia rarely involves a single limb or body part. The movements and vocalizations can be transiently suppressed by the person if asked.

Patients describe an inner sense of restlessness, inner tension, or even torment as well as other abnormal sensations such as burning or pain. However, frequently, they cannot describe the sensation. The motor activity provides some relief from the abnormal sensation.

Akathisia may range in intensity from a mild sense of disquiet or anxiety (which may be easily overlooked) to a total inability to sit still, accompanied by overwhelming anxiety, malaise, and severe dysphoria (manifesting as an almost indescribable sense of terror and doom). Akathisia can exacerbate psychopathology and lead to suicide.

Table 1 Rating scale for drug-induced akathisia (by Barnes)

Patients should be observed while they are seated, and then when standing while engaged in neutral conversation (for a minimum of 2 min in each position). Symptoms observed in other situations, for example, while engaged in activity on the ward may also be rated. Subsequently, the subjective phenomena should be elicited by direct questioning.

Objective

0 Normal, occasional fidgety movements of the limbs

1 Presence of characteristic restless movements: shuffling or tramping movements of the legs/feet, or swinging of one leg while sitting, and/or rocking from foot to foot or 'walking on the spot' when standing, but movements present for less than half the time observed

2 Observed phenomena, as described in (1) above, which are present for at least half the observation period

3 The patient is constantly engaged in characteristic restless movements, and/or has the inability to remain seated or standing without walking or pacing, during the time observed

Subjective

Awareness of restlessness

0 Absence of inner restlessness

1 Nonspecific sense of inner restlessness

2 The patient is aware of an inability to keep the legs still, or has a desire to move the legs, and/or complains of inner restlessness aggravated specifically by being required to stand still

3 Awareness of an intense compulsion to move most of the time and/or reports a strong desire to walk or pace most of the time

Distress related to restlessness

0 No distress

1 Mild

2 Moderate

3 Severe

Global clinical assessment of akathisia

0 Absent

No evidence of awareness of restlessness. Observation of characteristic movements of akathisia in the absence of a subjective report of inner restlessness or compulsive desire to move the legs should be classified as pseudo-akathisia

1 Questionable

Nonspecific inner tension and fidgety movements

2 Mild akathisia

Awareness of restlessness in the legs and/or inner restlessness worse when required to stand still. Fidgety movements present, but characteristic restless movements of akathisia not necessarily observed. Condition causes little or no distress

3 Moderate akathisia

Awareness of restlessness as described for mild akathisia above, combined with characteristic restless movements such as rocking from foot to foot when standing. Patient finds the condition distressing

4 Marked akathisia

Subjective experience of restlessness includes a compulsive desire to walk or pace. However, the patient is able to remain seated for at least 5 min. The condition is obviously distressing

5 Severe akathisia

The patient reports a strong compulsion to pace up and down most of the time. Unable to sit or lie down for more than a few minutes. Constant restlessness that is associated with intense distress and insomnia

Akathisia may be difficult to distinguish from psychotic agitation or anxiety, especially if the person describes a subjective experience of akathisia in terms of being controlled by an outside force. If the akathisia is mistaken for psychosis, the antipsychotic drug dose may be increased leading to worsening of the condition. Another pitfall is that a patient may suffer from neuroleptic-induced hypokinesia and akathisia at the same time.

In the study of Lang and Johnson, akathisia most often started after initiation of levodopa but was not clearly related to either 'on' or 'off' phases of the levodopa-induced motor response fluctuations. The authors did not find a diurnal pattern. Drug holidays led to a transient resolution of symptoms in individual cases. In the study of Comella and Goetz, half of the patients reported an association between their akathisia symptoms and the timing of their antiparkinson drugs. About 40% of their patients had akathisia only at certain times of the day. The syndrome may also occur when antiparkinsonian drugs are reduced or discontinued.

Differential Diagnosis

In psychiatric patients on neuroleptic drugs and displaying motor restlessness, akathisia may be difficult to distinguish from psychotic agitation, anxiety, and tactile hallucinations, especially if the patient interprets the sensation in terms of being controlled by an outside force. This is complicated by the possibility that movements may be suppressed by the medication (hypokinesia). The inner restlessness may not

be expressed voluntarily, and for patients with intellectual disability, it may be difficult to describe the sensations.

In PD, akathisia should be distinguished from muscle stiffness and immobility as well as from drug-induced dyskinesia. In this respect, the presence of inner restlessness may be the clue. As noted above, akathisia in PD patients with response fluctuations may be associated with the timing of the antiparkinsonian drugs in different manners; during 'on,' 'off,' 'wearing off,' or the 'onset of drug effect' phases, in a similar way to levodopa-induced dyskinesia that varies in phenomenology (chorea and dystonia) in relation to levels of levodopa.

Akathisia shares a number of features with RLS. Both disorders are accompanied by an urge to move. Compared to drug-induced akathisia patients, those with RLS more often have sleep disturbances, periodic limb movements, paresthesias, and worsening of the symptoms at nighttime and less often have inner restlessness. Many patients with akathisia prefer the recumbent position over the sitting position, while lying down often worsens the symptoms of RLS.

Other rarer disorders that may be mistaken for mild akathisia include 'painful legs and moving toes'; although the movements here generally do not alleviate discomfort.

Diagnostic Work-Up/Tests

Akathisia can be diagnosed through a careful history, in particular, drug exposure and physical examination. Patients should be observed while they are seated and when standing and asked to describe any abnormal sensations especially when trying not to move. However, patients may be able to voluntarily stay still for a short period of time, so they should not be prompted to sit still. The clinical context, such as the use of neuroleptics or the presence of PD, is important in this aspect. There are no ancillary tests such as laboratory or imaging studies that assist in making the diagnosis. Small case series have reported lower serum iron and ferritin levels in patients with akathisia, although the finding is inconsistent.

Management

The optimal management of neuroleptic-induced akathisia is prevention rather than treatment. In this regard, it is preferable to use the atypical antipsychotics and standardize titration, although these can also result in akathisia. Treatment options include discontinuation or reduction of dose of the causative agent, if possible.

Most commonly, anticholinergics and propranolol (or other lipophilic beta-blockers) are recommended for neuroleptic-induced akathisia. The rationale for using anticholinergics is that acute akathisia may be an extrapyramidal side-effect similar to dopamine D2 receptor antagonist induced rigidity and hypokinesia, and therefore should be treated in the same manner. However, Cochrane reviews have concluded that there is insufficient data to recommend either anticholinergics or beta-blocking drugs for akathisia. Case reports have suggested that mirtazapine may be helpful, possibly due to an anticholinergic property as well as 5-HT_2 receptor antagonism. Other 5-HT_2 receptor antagonists such as mianserin and cyproheptadine have been tried in small studies. High dose vitamin B6 (1200 mg day^{-1}) has also been shown to significantly improve neuroleptic-induced akathisia.

There is little information on the treatment of tardive akathisia. Publications on successful treatments are mostly case reports and include the discontinuation of neuroleptics for a long period of time. Other options include lorazepam, anticholinergics, propranolol, moclobemide, clonidine, ropinirole, and electroconvulsive therapy.

In PD, it seems reasonable to determine the relationship between the occurrence of akathisia and the timing of the antiparkinson medication and adjust the medication schedule accordingly, analogous to the treatment of the motor symptoms.

Akinetic-Rigid Syndrome

O S Gershanik, Favaloro Foundation University Hospital, Buenos Aires, Argentina

Glossary

Akinesia – Difficulty initiating movement.
Basal ganglia – A group of brain nuclei including the striatum, globus pallidus, subthalamic nucleus, substantia nigra, and its corticothalamic connections.
Bradykinesia – Slowness of movement.
Festination – A peculiar type of gait; short-stepped, shuffling, and propulsive.
Hypomimia – Reduced facial expression.
Parkinsonism – Aka 'akinetic-rigid' syndrome, any disorder presenting with the combination of bradykinesia and rigidity, with or without tremor.
PET – Positron emission tomography: a functional neuroimaging technique that allows the visualization of radiolabeled fluorodopa within the nigrostriatal system.
SPECT – Single photon emission tomography; a functional neuroimaging technique that allows the visualization of radiolabeled tracers bound to the dopamine transporter in striatal dopaminergic endings.
Syndrome – A combination of signs and symptoms that collectively indicate or characterize a disease or group of diseases.

Definition and History

Akinesia and rigidity are derived from the Greek word 'akinesis,' the prefix 'a' meaning without, and 'kinesis' meaning motion, and the Latin word 'rigor' meaning stiffness. The term 'akinetic-rigid syndrome,' also designated as 'parkinsonism,' encompasses a variety of disorders that present clinically with the characteristic combination of difficulty in initiating movement and slowness in the performance of voluntary actions (akinesia/bradykinesia), hypertonicity, or muscular stiffness, with or without associated tremor. It may also include postural abnormalities, and depending on the etiology, associated features that help in making a differential diagnosis among the different diseases presenting with this syndrome. Parkinson's Disease (PD) is the most frequent and representative disease within the spectrum of the 'akinetic-rigid' syndromes.

In James Parkinson's original monograph of 1817, 'An Essay on Shaking Palsy,' we can find the first comprehensive description of this syndrome. Parkinson defines the shaking palsy as a combination of rest tremor, lessened muscular power, abnormal truncal posture, and festinant, propulsive gait, without any mention of the presence of rigidity. Although he did not distinguish weakness from slowness of movement, he specified the presence of disabilities affecting writing and feeding and referred to the failure of the hand to respond to the dictates of the will, which in fact constitutes the essence of akinesia. The recognition of rigidity as one of the main features of PD came in the second half of the nineteenth century, when the French neurologist, Charcot, recognized it to be an integral part of PD. Based on his observations, he was able to distinguish bradykinesia as a cardinal feature of the illness, separating it from rigidity. Charcot and his students described the clinical spectrum of the disease, recognizing two forms of presentation, the tremor predominant and the akinetic/rigid form. This is perhaps the first mention in the medical literature of the peculiar combination of akinesia and rigidity, causing impairment in motor function.

Pathophysiology

Loss of dopaminergic innervation of the nigrostriatal circuits, leading to changes in tonic and phasic activity of basal ganglia output pathways, transmitted via cortical motor areas, results in akinesia, bradykinesia, and rigidity. As a result of nigrostriatal denervation, there is reduced inhibition of the globus pallidus internal segment (GPi) neurons via the direct pathway and increased neuronal activity in the subthalamic nucleus via the indirect pathway, both leading to increased activity of GPi neurons and causing excessive inhibition of thalamocortical and brainstem motor neurons. In combination, these physiological changes are felt to underlie the development of parkinsonian features. Although these changes have been studied extensively in PD, similar involvement of basal ganglia circuits probably constitutes the pathophysiological basis of the majority of disorders presenting with an akinetic-rigid syndrome.

Clinical Features and Diagnostic Criteria

In patients with an akinetic-rigid syndrome, there is slowness and poor movement (bradykinesia) and often

difficulty in initiating movement (akinesia). This problem typically manifests as hypomimia (masked faces), micrographia (handwriting becomes smaller), and hypophonia (reduction in speech volume). Additionally, the speech becomes monotonous, there is a reduced blink rate, and impairment of associated movements such as reduced arm swing while walking. There is a reduction in the speed and amplitude of repetitive hand and foot movements; there may be progressive fatiguing, and brief arrests of ongoing movement. The demeanor and overall bodily attitude convey the sense of labored slowness in akinetc-rigid syndromes. Muscle tone is frequently affected with hypertonicity (rigidity) of variable distribution depending on the specific disorder. There may be postural abnormalities like generalized flexion in PD, extensor posturing of the head and neck in progressive supranuclear palsy (PSP), disproportionate antecollis in multiple system atrophy (MSA), or asymmetric limb dystonia in corticobasal degeneration (CBD). Gait may be involved early or late, depending on the specific disorder. In PD, it usually occurs late in the course of the disease and is characteristically slow, with short shuffling steps and a tendency to propulsion and festination. In PSP and MSA, gait disorders are an early manifestation of the disease, presenting as frontal disequilibrium in the former, and ataxia in the latter. Some of the secondary causes of the akinetic-rigid syndrome may also have gait disorders; in vascular pseudoparkinsonism, a peculiar short stepped gait ('*marche à petit pas*') is frequently observed, while in normal pressure hydrocephalus, there is often a mixed pattern gait disorder (frontal disequilibrium, parkinsonian, ataxic gait). Clinical criteria developed by the United Kingdom Parkinson's Disease Society Brain Bank are used to establish a firm diagnosis of PD, in which the presence of an akinetc-rigid syndrome, with or without rest tremor, in the absence of atypical features (exclusionary criteria, see **Table 1**), and in the presence of prospective supporting clinical elements (e.g., asymmetry, presence of rest tremor, progressive course, etc.), establishes it with a high degree of certainty. A number of diseases included in the category of akinetic-rigid syndrome are also diagnosed on the basis of established criteria.

Differential Diagnosis

Table 1 provides a list of disorders in which the akinetic-rigid syndrome is the sole or predominant clinical feature or one of many other clinical manifestations. As a general rule, only in primary or idiopathic parkinsonism (PD) is the akinetic-rigid syndrome present as the exclusive clinical manifestation of the disease. Drug-induced parkinsonism may also be a pure akinetic-rigid syndrome; however, it is often associated with signs and symptoms of tardive dyskinesia.

Diagnostic Work-Up/Tests

Clinical examination is performed through the observation of general body movement, gait, posture, and the performance of repetitive alternating movements of the limbs (akinesia/bradykinesia), together with manual examination of muscle resistance to passive limb displacement (rigidity). The unified Parkinson's disease rating scale (UPDRS) and its updated revision, sponsored by the movement disorder society (MDS-UPDRS) are used to evaluate severity, and overall functioning and disability in primary parkinsonism. Other scales have been specifically developed for the evaluation of other forms of the akinetic-rigid syndrome (e.g., PSP, MSA, etc.).

In routine clinical practice, diagnostic tests are generally used to rule out disorders other than PD from within the spectrum of the akinetic-rigid syndrome (e.g., CT and MRI may help in confirming the presence of hydrocephalus, vascular lesions, brainstem atrophy, cerebellar atrophy, tumors, etc.). Functional neuroimaging, such as fluorodopa positron emission tomography (PET) scans and dopamine transporter single photon emission tomography (SPECT) scans, not used in routine clinical practice, may help in confirming the presence of nigrostriatal denervation.

Management

Pharmacological treatment using dopaminergic agents (levodopa, dopamine agonists, MAOB inhibitors, and COMT inhibitors along with levodopa), amantadine, anticholinergics, and functional stereotactic surgery (pallidotomy, thalamotomy, pallidal, or subthalamic deep brain stimulation) are predictably effective in the management of primary parkinsonism (PD). Some of these drugs may be used in the treatment of other akinetic-rigid syndromes, but in most cases, the positive effects are less marked than in PD. In the case of drug-induced parkinsonism, withdrawal of the offending drug is the treatment of choice, whereas in hydrocephalus, a surgically implanted drainage device may be effective. Physical therapy and motor and speech rehabilitation may also be helpful.

Prognosis

On the basis of the diversity of diseases presenting with an akinetic-rigid syndrome, it is almost impossible to

Table 1 Akinetic-rigid syndromes

Disease	*Distinguishing features*
Primary	
Parkinson's disease (sporadic, genetic)	Asymmetric akinetic-rigid syndrome, rest tremor frequent, excellent response to levodopa
Secondary	
Drug-induced	Usually symmetric presentation; frequently associated with tardive dyskinesia
Infectious	Oculogyric crises, dystonia, myoclonus, choreoathetosis, seizures, altered sleep-cycle, cognitive impairment
Metabolic	Hepatocerebral degeneration (similar to Mn intoxication), Hypoxia (pyramidal tract signs, dysarthria, cognitive disturbances). Parathyroid dysfunction (seizures, cognitive disorders, oculomotor disturbances, chorea, calcifications on neuroimaging)
Tumor	Focal signs, positive imaging findings
Hydrocephalus	Cognitive deterioration, mixed pattern gait disturbance, urinary incontinence
Toxic	Mn (cock walk, postural tremor, T1 hyperintensities), Organic mercury (visual loss, ataxia, paresthesias, cognitive dysfunction CO (delayed-onset parkinsonism and dystonia)
Vascular	*Marche a petit pas*, signs of pyramidal tract involvement, pseudobulbar palsy, imaging studies reveal vascular lesions
Atypical parkinsonism (Parkinsonism-plus)	
Progressive supra-nuclear palsy	Supra-nuclear gaze palsy, cognitive involvement of the frontal type, frequent falls, discordant axial rigidity, early dysarthria, superior peduncular atrophy on imaging
Multiple system atrophy	Cerebellar signs, early dysarthria, early signs of autonomic failure, pontocerebellar atrophy on imaging
Corticobasal degeneration	Asymmetric limb involvement, cortical sensory loss, dystonic posture, myoclonus, alien limb phenomenon, asymmetric frontoparietal atrophy on imaging
Parkinsonism associated to other neurodegenerative diseases	
Alzheimer's disease	Early dementia (cortical type), amnestic, aphasia, apraxia, temporal atrophy on imaging
Lewy body dementia	Early dementia, visual hallucinations, cognitive fluctuations, early falls, autonomic dysfunction
Akinetic-rigid form of Huntington's disease	Oculomotor disturbances, cognitive and psychiatric involvement, gait ataxia, cortical, and caudate nucleus atrophy on imaging
Spinocerebellar ataxias	Ataxia, oculomotor disturbances, cerebellar atrophy on imaging
Pantothenate kinase associated neurodegeneration (PKAN)	Early-onset (first/second decade), progressive rigidity, dystonia, dysarthria, swallowing disturbances, cognitive deterioration; 'eye of the tiger' sign on MRI
Neuroacanthocytosis	Arreflexia, elevated CPK, acanthocytes on blood smear, orolingual dystonia, facial grimacing, bite lesions, self-mutilation, chorea
Wilson's disease	Cognitive and behavioral disturbances, flapping tremor, dystonia, rictus sardonicus, Kayser–Fleischer ring, basal ganglia or thalamic lesions on imaging
Other	
Dopa-responsive dystonia	Lower limb dystonia, gait disorders (walking on the balls of the feet), diurnal fluctuations, dramatic response to levodopa
Neimann-pick type C	Childhood-onset, progressive deterioration, ataxia, dystonia, seizures, spasticity, myoclonus, supranuclear gaze palsy, dementia, psychiatric manifestations
Pallido-pyramidal degeneration	Kufor–Rakeb syndrome. Early-onset (first/second decade), rapidly progressive, absence of tremor, spasticity, upgaze paresis, dementia, visual hallucinations, facial–faucial–finger mini-myoclonus, oculogyric crises
Rapid onset dystonia-parkinsonism	Unusually rapid evolution of symptoms (abrupt or subacute, hours or weeks), dystonic cramps, gait disturbances, dysarthria, dysphagia

make general statements regarding prognosis. PD and drug-induced parkinsonism are perhaps the only disorders that entail a rather benign prognosis. In the majority of the remaining disorders, the prognosis is poor due to their progressively disabling nature, and the lack of effective treatment.

Alexander Disease

B R Barton, Rush University Medical Center, Chicago, IL, USA

Glossary

Alexander disease (AD) – A rare, progressive, degenerative disorder of the central nervous system presenting with a broad range of signs and symptoms, in all age groups.
Glial fibrillary acidic protein (GFAP) – A major astrocytic intermediate filament protein, forming cytoplasmic aggregations as part of Rosenthal fibers.
Leukodystrophy – A group of inherited diseases characterized by progressive degeneration of central nervous system white matter, with primary pathology in myelin or myelinating cells.
Megalencephaly – Abnormal brain enlargement beyond the average for age and gender, usually related to abnormalities of neuronal proliferation.
Rosenthal fibers – The pathologic hallmark of AD: eosinophilic inclusions found in astrocyte cytoplasm composed of protein aggregates, including GFAP.

Definition and History

Alexander disease (AD) is a rare leukodystrophy characterized by progressive neurologic impairment, typically affecting infants and children but occasionally presenting in adults. The first case was characterized in 1949 by W. S. Alexander, who described developmental delay, megalencephaly, vomiting, and continuous screaming in a 15-month-old boy, with rapid progression to death. Brain pathology revealed hypertrophic astrocytes with protein aggregates, later identified as Rosenthal fibers. The eponym for the disease was later coined by Friede in his description of the sixth similar case in 1964.

Pathogenesis/Pathophysiology

AD is a genetically homogeneous disorder: ~95% of cases have glial fibrillary acidic protein (GFAP) gene mutations on chromosome 17p21, which is the only known genetic abnormality associated with AD. Nearly all forms of the disorder are caused by heterozygous, dominant, missense GFAP mutations. The exact function of the intermediate filament GFAP protein is not clear. Mutations of two GFAP residues account for over half of all cases. Almost all cases are sporadic, with de novo mutations discovered in almost all infantile cases, although autosomal dominant transmission in some familial cases has been reported. Dozens of different GFAP mutations have been associated with AD, mostly affecting the conserved regions of the gene, resulting in a gain of GFAP function.

The pathologic hallmark of AD, regardless of the phenotype, is abundant, widespread accumulation of Rosenthal fibers, which are eosinophilic protein aggregates found in the cytoplasm of hypertrophic astrocytes. Rosenthal fibers are composed of mutant GFAP, α β-crystallin, vimentin, and heat shock protein 27. Rosenthal fibers are not specific to AD, being also found adjacent to CNS tumors, multiple sclerosis plaques, syringomyelic cavities, and in a association with Parkinsonism. However, Rosenthal fibers in AD are distinctly concentrated in periventricular, perivascular, and subpial astrocytes. They also may be distributed throughout deep brain structures in younger-onset cases. Histologic brain tissue examination also demonstrates varying loss of myelin and neurons.

Epidemiology/Risk Factors

AD is rare, with fewer than 500 cases reported. Prevalence has not been published. Male predominance is suggested in infantile cases, while there are more females reported in the adult form. Environmental or sex-related risk factors are unknown.

Clinical Features

The clinical and pathological signs of AD vary widely depending on the age of onset, and have been divided into three subtypes:

Infantile AD

With onset of symptoms before age 2, infantile AD comprises the majority of reported cases (~63%). Progression typically follows a rapid, lethal course. Seizures, psychomotor delay, bulbar dysfunction, and megalencephaly are the most common symptoms; dysphagia, emesis, spasticity, and ataxia may also occur. Pathologic examination shows a pronounced absence of myelin in the frontal lobes. Accumulation of Rosenthal fibers may lead to aqueductal stenosis and obstructive hydrocephalus.

Juvenile AD

Onset between age 2 and 12 years defines juvenile AD, and accounts for about 24% of cases. The clinical course may present in a manner similar to that of infantile AD or may occur in the setting of normal early development, with more bulbar or pseudobulbar signs. Intelligence may be relatively intact, with lower incidence of frontal lobe involvement or macrocephaly.

Adult-Onset AD (AOAD)

While Previously considered the rarest manifestation of AD, case reports of AOAD have been growing since the availability of genetic testing. Symptoms begin after age 12, with more variable clinical and radiologic presentations. Common features of infantile forms are absent. In genetically confirmed AOAD cases, bulbar dysfunction, particularly lower brainstem signs, accounts for the most common symptoms, including dysphonia, dysphagia, dysarthria, and ataxia. Palatal tremor is present in 41% and can be an important clue for the diagnosis. Fluctuations of symptoms may occur. Urinary dysfunction, pyramidal involvement, scoliosis, and cerebellar dysfunction are often present, while dysautonomia, endocrine dysfunction, or sleep disturbances such as obstructive sleep apnea are less common. Cognition is typically well preserved.

Differential Diagnosis

Differential diagnosis is broad given the nonspecificity and diversity of symptoms, and depends on the individual clinical phenotype and the age of presentation. In young-onset cases, consideration should be given to other leukodystrophies, inborn errors of metabolism, or mitochondrial disease. Later-onset cases may mimic multiple sclerosis, cervical myelopathy, or brainstem tumors and may have overlapping signs with other neurodegenerative disorders, including motor neuron disease, multiple system atrophy, or spinocerebellar ataxia.

Diagnostic Work-up/Tests

Neuroimaging

Five diagnostic MRI criteria for AD were reported in 2001, four of which must be met for an imaging-based diagnosis: (1) extensive, symmetric, frontal-predominant cerebral white matter abnormalities (including atrophy, swelling, or cystic degeneration); (2) a periventricular rim of high signal on T1-weighted images and low signal on T2-weighted images; (3) signal abnormalities in the basal ganglia and thalami (atrophy or swelling); (4) brainstem abnormalities, particularly in the medulla or midbrain; and (5) contrast enhancement of select white and grey matter structures. In typical patients, MRI criteria lead to an appropriate diagnosis and correlate highly with histopathologic findings (**Figure 1**). Unusual variants in MRI findings have been reported, particularly in those with juvenile or adult onset. Typical MRI findings in later-onset patients include prominent atrophy and signal change in the upper spinal cord and medulla, no or minimal cerebral white matter abnormalities, and predominant or isolated abnormalities in posterior fossa structures (**Figure 2**). Review of MRIs by neurologists

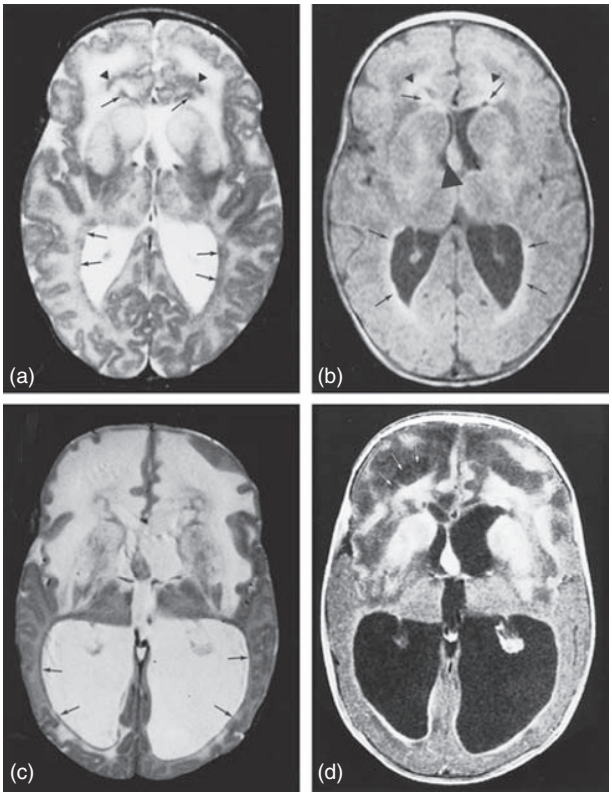

Figure 1 MR imaging of a patient with biopsy-confirmed infantile Alexander disease. (a and b): At the age of 1 1/2 months, the frontal white matter has a slightly higher signal intensity on T2-weighted images and slightly lower signal intensity on unenhanced T1-weighted images than does the remainder of the cerebral white matter, which has normal signal intensity for unmyelinated white matter. There is a periventricular rim of low signal intensity on T2-weighted images (arrows, a) and high signal intensity on T1-weighted images (arrows, b), with some extensions into the frontal white matter (arrowheads, a and b). The caudate nucleus and putamen have high signal intensity on T2-weighted images and are mildly swollen. (c and d): At the age of 3 months, a major increase in ventricular size is seen with extreme thinning of the posterior cerebral mantle. The frontal white matter has more abnormal signal intensity than the occipital white matter, appears markedly swollen, and shows early cystic degeneration (arrows, d). There is a thin periventricular rim of low signal intensity on T2-weighted images (arrows, c). The basal ganglia are now markedly atrophic. After contrast administration, enhancement occurs in the ventricular lining, caudate nucleus, putamen, frontal white matter, and parts of the frontal cortex (d).

or radiologists familiar with leukodystrophies is recommended before pursuing genetic testing.

Molecular Genetic Testing

GFAP gene testing is clinically available. Given the high rate of novel GFAP mutations reported in new cases, in many instances it may not be clear whether a novel coding change represents a benign polymorphism or a disease-causing mutation. In such situations, further familial genetic testing (best accomplished by testing both parents), comparison with control chromosomes, or assembly of abnormally expressed GFAP protein in cultured cells may provide further evidence that a particular coding change may cause AD pathology.

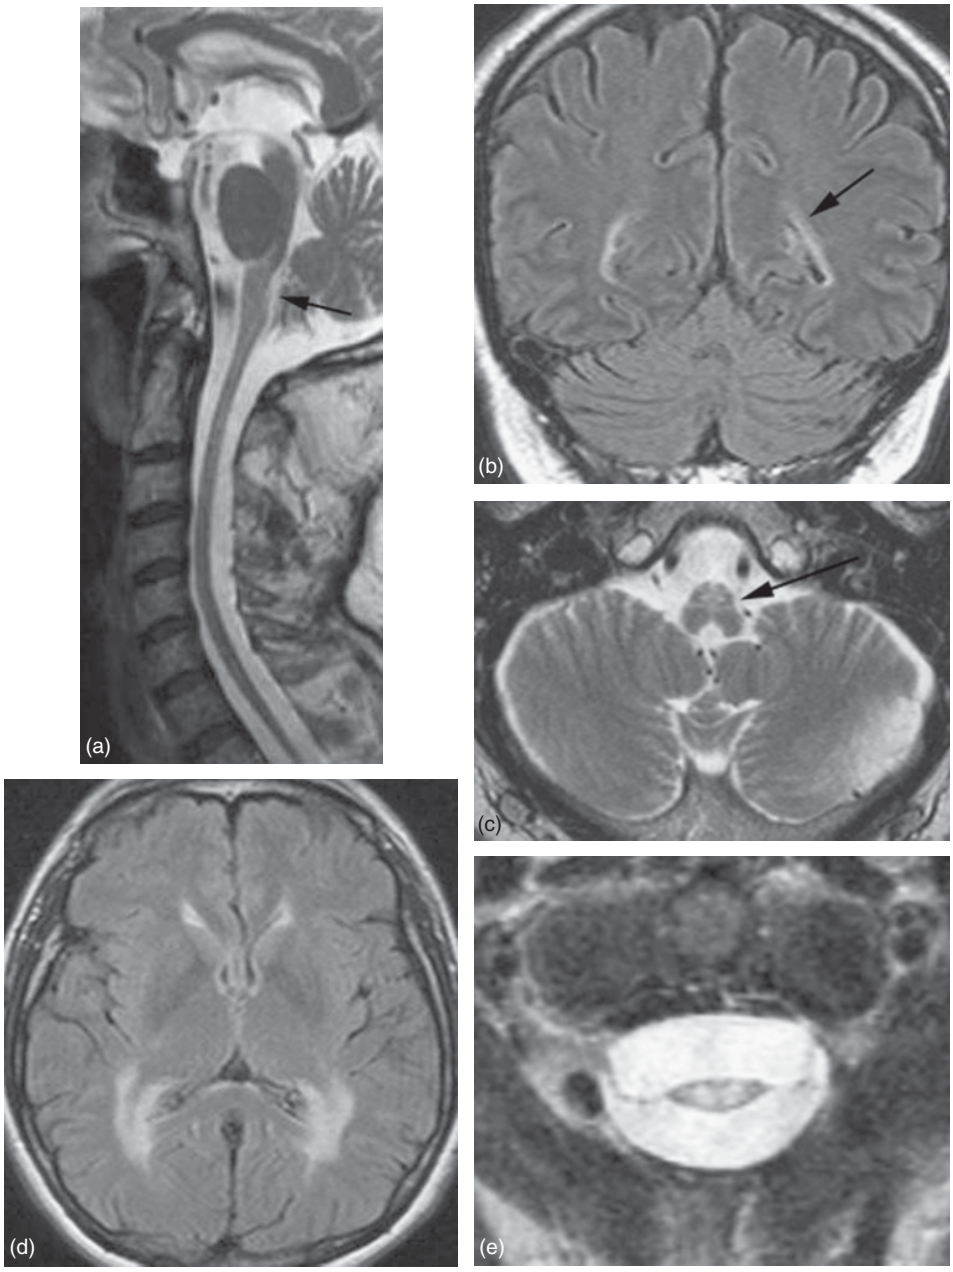

Figure 2 Representative MR images of characteristic lesions of AOAD from patients ranging in age from 43 to 64-years old. T2-weighted midline sagittal section shows (a) atrophy and signal abnormalities in the medulla oblongata (arrow); the hyperintensity fades away in the upper cervical spinal cord, whereas the entire spinal cord is also atrophic. Axial FLAIR image shows (b) increased signal intensity of the periventricular white matter, more extensive in the posterior regions. Coronal FLAIR section shows (c) very thin posterior periventricular abnormalities (arrow on the left) not detected by T2-weighted sequences (not shown). Axial T2-weighted section demonstrates (d) signal hyperintensities in the atrophic anterior part of the medulla oblongata (arrow). Axial T2-weighted section on the cervical spinal cord shows (e) severe atrophy and signal changes at C1–C2 level.

Histology

Before development of reliable MRI diagnostic criteria, definitive diagnosis was confirmed by the demonstration of astrocytic accumulation of Rosenthal fibers. Brain biopsy is now only indicated in atypical cases.

Management

Treatment is symptomatic as there are no curative or neuroprotective strategies. Bone marrow transplantation in one child did not change the disease course. Hydrocephalus may be treated with a VP shunt, and antiepileptic drugs help to alleviate seizures. Genetic counseling may be appropriate in later-onset cases. Secondary prevention of complications of disease may include screening for dysphagia and taking precautions for falls or complications of immobility. Physical, occupational, and speech therapy may assist with functional adaptation.

Prognosis

Prognosis is variable, with age of onset as an indicator of disease course. In infantile AD, death occurs within a decade, usually from respiratory complications, after an average of 3–4 years from symptom onset. In juvenile AD, progression is slower with a median interval to death of 8 years but some patients survive for decades. In AOAD, progression is highly variable, ranging from a few years to over 20 years.

Alien Limb

L C Shih and D Tarsy, Beth Israel Deaconess Medical Center, Boston, MA, USA

Glossary

Agonistic apraxia – Agonistic apraxia is the execution of an act by one limb when the contralateral limb is asked to perform the act.
Autocriticism – Negative or astonished attitudes toward the alien limb.
Corticobasal degeneration (CBD) – Neurodegenerative disease typified by prominent apraxia, myoclonus, parkinsonism, and cognitive decline; pathologically characterized by cortical and basal ganglionic gliosis and atrophy as well as tau-positive astrocytic plaques.
Diagonistic apraxia – Diagonistic apraxia conflict between the performed act and the desired act.
Intermanual conflict – The phenomenon of one limb acting at odds with the other.
Magnetic or repellent apraxia – Magnetic or repellent apraxia is grasping or avoiding postures.

Definition and History

Alien limb refers to the phenomenon of alteration of self-perception of one's own limb, combined with abnormal involuntary movements of that limb. There are currently no formal consensus diagnostic criteria, but one basic element thought to be essential for making the diagnosis

of alien limb is that the patient's perception of the limb is altered in some form. In the prototypic case, patients do not recognize their limb as belonging to them.

An early case described in the literature by Goldstein in 1908 involved a 57-year old woman describing a left hand behaving on its own will, at some points choking her with great force. Autopsy revealed multiple infarctions, including one involving the corpus callosum. Originally coined *la main étrangère* ('the foreign hand') by Brion and Jedynak in 1972 describing patients with corpus callosal tumors, the term evolved into alien hand syndrome in part due to erroneous translation of the term 'étrangère' and in part to imply the behavior of a hand with independent will. Since the original descriptions, a variety of structural lesions have been associated with these abnormal movements, including medial frontal lobe lesions, with or without involvement of the anterior corpus callosum, posterior corpus callosal lesions, thalamic infarcts as well as parietal-occipital atrophy associated with corticobasal degeneration (CBD). Other degenerative conditions, such as Alzheimer's disease and Creutzfeldt–Jakob disease, have occasionally been associated with alien limb although not to the same degree as with CBD. In addition, a lower extremity can be affected as well, thereby generating the broader term, alien limb.

Clinical Features and Anatomical Basis

Biran and Chatterjee classified three aspects of alien limb behavior: (1) apparent conflict of the will of the limbs involved, (2) abnormal involuntary movements, and (3) the subjective attitude of the patient to the abnormal limb. A wide variety of terms describe the various behaviors that can be seen with alien limb. *Diagonistic apraxia* refers to the conflict between the performed act and the desired act. *Agonistic apraxia* reflects the execution of an act by one limb when the contralateral limb is asked to perform the act. *Intermanual conflict* is seen when one limb acts at odds with the other.

Several types of involuntary movements can be seen with alien limb. *Magnetic* or *repellent apraxia* refers to posturing seen as grasping or avoiding. Compulsive manipulation of tools is sometimes seen as well. The term *anarchic hand* has been used to describe the autonomous behavior of a limb in the absence of denial of ownership. This type of behavior is thought to result from damage to the supplementary motor area via a failure to modulate externally generated action from ipsilateral premotor area.

The patient's attitudes toward the alien limb vary. Some patients fail to recognize the limb as their own and are astonished by the behavior of the limb, referred to in the literature as *autocriticism* or *interhemispheric autocriticism.* Denial of ownership of the limb is seen in prototypic cases, but this feature is uncommon and is not considered by many to be essential for the diagnosis of alien limb. Various combinations of alien limb behavior have been seen, but the common element of alteration of self-perception runs through different types of subjective attitudes of patients to adopt in relation to the limb.

Debate continues on subcategorizing the various patterns of involvement, and correlating them with affected neuroanatomic structures. Alien limb can be seen with a variety of anatomical lesions. Variations in the clinical signs may exist depending on the location of damage. Part of the confusion derives from cases of alien limb that result from anterior cerebral artery territorial infarctions which variably involve supplementary motor area and the anterior corpus callosum. There may be three forms of alien limb with different patterns of behavior, originating from either frontal damage, callosal damage, or from posterior or subcortical involvement as in CBD. This disorder may present with a unique type of motor posturing, described as a 'wayward' or 'wandering' hand. In CBD, an asymmetric involvement of parietal and frontal lobes seems to play a role in the genesis of the phenomenon. An interplay of approach and avoidance behaviors have been advanced to explain the differences in limb movements. Frontal lobe lesions may facilitate approach behaviors mediated by the parietal lobe such as grasp reflex, while parietal lesions allow frontal avoidance behaviors to predominate such as abnormal overextended posturing of the hand. Fitzgerald et al. identified a left-handed patient with autopsy-proven CBD with bilateral asymmetric alien hand. The greater proportion of parietal to frontal atrophy was seen to correspond with contralateral avoidance behavior, while the relatively more preserved parietal lobe in the right hemisphere was associated with an approach behavior which they termed *tactile mitgehen.* It still remains unclear whether this parietal-frontal interplay hypothesis holds true in other patients with CBD. In most cases, it is believed that alien limbs in CBD patients tend to display more levitation and posturing relative to the perseveration commonly seen in medial frontal lobe damage. In contrast, alien limb phenomenon seen with callosal damage manifests as more complex purposeful movements in the nondominant hand.

Epidemiology and Differential Diagnosis

Estimates of prevalence of alien limb phenomenon among the general population are unknown, but it is reasonable to conjecture that it is more common in the chronic stroke population. In a large multicenter case series of CBD patients, 42% had alien limb syndrome. Dystonia occurred in 71% in this series making it feasible that alien limb can be mistakenly identified as dystonia.

When prominent posturing is present, botulinum toxin injections can be administered to provide relief from pain and spasm, but the more complex automatic behavior is not readily treated by either botulinum toxin or oral medications. Other conditions resembling alien limb phenomenon include dystonia and arm levitation each occurring without alteration of self-perception, both of which can be seen in atypical parkinsonism syndromes such as progressive supranuclear palsy and pure limb apraxia which can be differentiated by the absence of involuntary movements. When abnormal limb movements are present, especially when limited to one limb, imaging is important to identify the underlying structural lesions such as stroke, tumor, or lobar atrophy due to neurodegenerative conditions.

Management and Prognosis

Rehabilitative strategies have been employed with little success, perhaps depending upon the etiology. Alien limb phenomenon can be distressing to the patient and others, and in general has a poor prognosis for recovery. In some situations, placing a barrier or a cover on the affected limb has been effective for minimizing intrusive automatic behaviors.

Alpha-2 Adrenergic Agonists in Tic Disorders

L Scahill, Yale University, New Haven, CT, USA

Glossary

Clonidine – This drug is used primarily to treat hypertension because of its action on central norepinephrine, but is also used to treat tic disorders and attention deficit hyperactivity disorder.
Guanfacine – This drug, pharmacologically similar to clonidine, but with distinct properties, is used primarily to treat hypertension because of its action on central norepinephrine, but is also used to treat tic disorders and attention deficit hyperactivity disorder.
Locus coeruleus – This brainstem nucleus is rich in noradrenergic cells.

Definition and History

The alpha-2 agonists were developed for the treatment of hypertension through their effect on noradrenergic receptors in the brain. Clonidine was introduced as a treatment for tic disorders in the late 1970s and for the treatment of attention deficit hyperactivity disorder soon thereafter. Guanfacine was introduced for these same indications in the 1990s. Currently, these agents are among the most commonly used medications in children with tic disorders. They are often used in combination with other medications such as stimulants or selective serotonin reuptake inhibitors. In September 2009, an extended release formulation of guanfacine was approved by the FDA for the treatment of children with attention deficit hyperactivity disorder (ADHD).

Mechanism of Action

Using clonidine as the model for the class, it has been shown that alpha-2 agonists reduce the firing of norepinephrine neurons in the locus coeruleus. The reduced firing of these neurons results in reduced norepinephrine

release in the prefrontal cortex. This regulatory effect on the noradrengeric system decreases arousal, resulting in decreased hyperactivity and impulsiveness. The introduction of guanfacine in the 1980s and a large body of preclinical data that followed prompted a revision in this proposed mechanism. Animal experiments and human studies have revealed important differences in clonidine and guanfacine. Although less potent than clonidine, guanfacine also reduces the firing of neurons in the locus coeruleus. In addition to indirect benefits on prefrontal function, guanfacine enhances prefrontal function through direct effect on alpha-2A receptors. According to this theory, prefrontal cortical dysfunction adversely affects attention, emotional regulation, and impulse control. Direct stimulation of alpha-2A receptors may improve attention, impulse control, and, perhaps, regulation of subcortical activity, including tics.

Clonidine for the Treatment of Tics and Attention Deficit Hyperactivity Disorder

Since it was introduced for the treatment of Tourette syndrome, clonidine had been evaluated in a few small randomized placebo-controlled and active comparator trials targeting tics. Taken together, these trials suggest that clonidine is modestly effective for tics, though results are not uniformly positive (**Table 1**).

There is more support for the efficacy of clonidine in children with ADHD. Two large scale trials have been conducted with clonidine, methylphenidate, their combination, and placebo in children with ADHD. In a sample of 136 children (age 7–14 years), the Tourette Study Group showed that each of the active treatments was superior to placebo on parent and teacher ratings of ADHD symptoms. The magnitude of benefit on ADHD outcomes was greatest for the combined treatment group. Tics showed modest improvement in all active treatment groups on average. However, in all treatment groups, including placebo, ~20% of subjects reported an increase in tics.

Using the same design in 122 children with ADHD uncomplicated by tic disorders, Palumbo and colleagues reported that neither clonidine alone nor methylphenidate alone was superior to placebo on the teacher ratings. After adjusting for the effect of placebo, combined treatment (clonidine plus methylphenidate) had a significant positive effect on teacher and parent ratings on ADHD. These two trials suggest that clonidine offers benefit of medium magnitude for children with ADHD (with or without tic disorders). Both trials showed additive benefit with the combination of clonidine and methylphenidate on ADHD outcomes. In the sample of children with tic disorders, clonidine, however, was not superior to placebo for tics.

Guanfacine

To date, only two placebo-controlled trials have been conducted with guanfacine in children with a tic disorder (Tourette Syndrome or Chronic Tic Disorder). Both trials were small and tic severity of these samples was relatively mild. Guanfacine was associated with about a 30% improvement in overall tic severity in both trials. This improvement was superior to placebo in the first trial but not the subsequent (smaller) trial (**Table 1**).

These two guanfacine trials also provided information on ADHD outcomes. Guanfacine was superior to placebo in an 8-week randomized controlled trial in 34 subjects with ADHD and a tic disorder on teacher measures of ADHD. In this trial, parent ratings of ADHD symptoms showed improvement, but were not significantly better than placebo. In the second trial involving 24 subjects (and only a subset met criteria for ADHD), guanfacine showed no difference from placebo on ADHD outcomes.

Adverse Effects of Alpha-2 Agonists

Clonidine is rapidly absorbed and, although it has a wide ranging half-life (6–24 h), peak effects occur as soon as 1 h after oral administration. Thus, some adverse effects can be tied to the time of administration. Common adverse effects include sedation, fatigue, lowered blood pressure and heart rate, irritability, and sleep disturbance (mid-sleep awakening). The sedative effects often reduce sleep latency, but the decline of peak effects after 3 or 4 h may contribute to mid-sleep awakening in some patients. Similarly, behavioral change across the day may coincide with peak and waning of acute drug effects. Slow upward dose adjustments and modifying the timing and dose increment is often required to achieve optimal benefit against minimal adverse effects. Abrupt discontinuation of clonidine is

Table 1 Dosing for immediate release alpha-2 agonists in children with tic disorders

Medication	*Starting dose (mg)*	*Rate of increase*	*Usual dose range (mg per day)*	*Doses (per day)*
Clonidine	0.025–0.05	every 4–5 days	0.15–0.30	3–4
Guanfacine	0.5–1.0	every 4–5 days	1.5–3.0	2–3

associated with a well-established withdrawal syndrome consisting of increased pulse and blood pressure, sweating, anxiety, and irritability. Findings by Daviss and colleagues suggest that concerns about cardiovascular adverse effects have been overstated. In healthy children with a negative cardiac history, no pretreatment medical testing appears necessary.

Guanfacine has a longer half-life ranging from 12 to 24 h and a slower rise to peak concentration. The longer duration of action and less marked peak effects often translates into fewer adverse events. However, decreased pulse and blood pressure sedation, fatigue, and mid-sleep awakening have also been reported with guanfacine and clearly influence the rate of dose increase. Studies in adults treated for high blood pressure show that abrupt withdrawal is less of a problem with guanfacine, but still should be avoided.

Special issues related to Guanfacine Extended Release formulation: A new extended release formulation of guanfacine has been developed, tested and approved for children with ADHD. In a study of 345 children aged 6–17 years with ADHD, (without a co-occurring tic disorder) children were randomized to one of four groups: placebo or guanfacine at 2, 3, or 4 mg per day for 5 weeks. Subjects randomized to active treatment were started on 1 mg per day for a week and then increased to 2, 3, or 4 mg in 1 mg increments each week. Thus, children on the 2 mg dose were observed for 3 weeks on stable dose, subjects on 3 mg were observed for 2 weeks, and subjects on 4 mg were observed for 1 week. Although each dose of active medication showed statistically significant improvement on the primary ADHD outcome measure at week 5, due to the design, the results provide few clinical implications. The most common adverse effects associated with guanfacine included sedation, abdominal pain, and fatigue. Most adverse effects were mild to moderate and time limited. Study withdrawal due to adverse events occurred in 9 of 87 patients taking 2 mg per day and 20 of 86 patients taking 4 mg per day.

Future Directions for Research

Clonidine and guanfacine have been used in clinical practice in children with tic disorders for many years. Thus, in many respects, their advantages and disadvantages are well known. Despite the common use of these drugs in clinical practice, however, it is remarkable that there are few large-scale trials in either drug focused on reducing tics in children with tic disorders. A large scale, so-called simple trial, might be considered as a way to confirm the validity of clinical practice.

Available data suggest that the alpha-2 agonists may be more effective for the treatment of hyperactivity, impulsiveness, and inattention than for tics. Clonidine has now been evaluated in two large-scale trials focused on ADHD outcomes. These trials show that the combination of clonidine and methylphenidate has advantages over either drug alone. Large-scale trials of guanfacine, especially the newer extended release product, are needed to evaluate the efficacy of guanfacine on ADHD outcomes and tic severity in children with tic disorders and ADHD. To be more clinically relevant, these trials should be longer than 5 weeks in duration and use flexible dose strategies.

Alpha-Synuclein

L Stefanis, University of Athens Medical School, Athens, Greece

Glossary

Chaperone-mediated autophagy – A selective, lysosomal receptor-mediated process of degradation of cytosolic proteins.
Fibrillization – The process in which a protein starts assuming a beta-pleated structure.
Lewy body – A cytoplasmic neuronal inclusion comprising a radial fibrillar halo and a dense core, which stains positively with antibodies against α-synuclein and ubiquitin.
Oligomerization – The process in which multiple molecules of a single protein or polypeptide interact covalently with each other forming a larger globular structure.
Protofibrils – Soluble intermediates in the process of α-synuclein aggregation.

α-Synuclein: Structure and Physiologic Function

α-Synuclein is a member of the family of synucleins, comprising α-, β-, and γ-synuclein. The α-synuclein protein consists of 140 amino acids. In the N-terminal region, there are seven imperfect repeats of KTKEGV with an apolipoprotein lipid-binding motif, which are predicted to form amphiphilic helices. The central region, denominated non-amyloid component (NAC), is hydrophobic, whereas the C-terminus is characterized by the presence of acidic stretches. The NAC and the C-terminal region differentiate α-synuclein from the other members of the synuclein family, as within these areas, there is substantially reduced homology compared to the N-terminal region.

α-Synuclein does not have a defined structure in solution, and is therefore termed a natively unfolded protein. However, upon binding to synthetic membranes or certain lipid surfaces, its structure assumes an α-helical conformation. It is expressed predominantly in the neuronal cells and in the mature nervous system, where it is widely distributed; it is one of the most abundant neuronal proteins with preferential localization to the presynaptic terminal. Although the exact function of α-synuclein is unknown, it is thought to control vesicular trafficking and release, possibly through transient interactions with lipid vesicular surfaces. Knockout mice for α-synuclein do not demonstrate any obvious anatomical or behavioral abnormalities, but at least in the nigrostriatal dopaminergic system, they show an enhancement of response to paired electrical stimuli, suggesting that, α-synuclein normally negatively controls neurotransmitter release. This is consistent with studies in the chromaffin cells, which upon overexpression of α-synuclein show reduced evoked dopamine release, presumably through an effect at the level of the presynaptic membrane, downstream of vesicle docking. This could occur through interactions with the soluble *N*-ethylmaleimidesensitive factor attachment protein receptor (SNARE) complex, which regulates presynaptic release. Indeed, α-synuclein has been found to rescue the disassembly of the SNARE complex and the degeneration of neuritic terminals associated with lack of the presynaptic protein CSP-α (cystein string protein-α), suggesting that, possibly through a chaperone-like function, it normally helps in the maintenance of this presynaptic complex. α-synuclein also binds and inactivates phospholipase D2, and could thus influence synaptic membrane biogenesis through phosphatidic acid metabolism.

α-Synuclein is upregulated during late embryonic and early postnatal life in rodents and also during maturation of primary neurons in cell culture. As evidenced by the lack of obvious phenotype in the knockout mice, it does not appear to have a role in synaptogenesis per se, but it does appear to have a role in plasticity responses, as demonstrated by the fact that it is often upregulated as an adaptive response to various injuries, and most notably, during the period of song-learning in birds.

α-Synuclein has also been shown to bind to a number of other proteins, mostly cytoplasmic. It shares homology and binds to members of the family of 14-3-3 proteins, which have chaperone function within the cytosol. It has been reported to bind to a number of targets of 14-3-3 proteins and to regulate their function. Notably, α-synuclein may bind to tyrosine hydroxylase (TH) and inhibit its activity through effects on its phosphorylation status, and may thus affect dopamine metabolism. The physiological significance of these findings, mostly ascertained through overexpression in cellular systems, remains to be established.

Genetic Data Linking *SNCA*, the α-Synuclein Gene, with Parkinson's Disease

The first connection between α-synuclein and Parkinson's disease (PD) was the discovery that a missense point mutation, A53T, in the *SNCA* gene, encoding for α-synuclein,

was found to segregate with the disease in Italian and Greek families with autosomal dominant PD. Although the pathogenicity of this mutation was originally doubted, the identification of two further missense point mutations, A30P and E46K, in the *SNCA* gene in families with similar inheritance patterns in different populations, has conclusively shown the link with PD. Furthermore, more recently, it was discovered that multiplications of the gene locus for the *SNCA* gene are also linked to PD in other families with autosomal dominant inheritance. In fact, a gene dosage effect exists, in that individuals with triplication of the *SNCA* locus manifest the disease earlier and in a more severe form compared to those with duplications. However, it has to be noted that these families are very rare and only account for a very small proportion of PD cases worldwide. Therefore, it is especially important that genetic data exist linking *SNCA* with PD even in the large majority of cases with sporadic disease. In particular, the length of tandem repeats within the Rep1 polymorphic region ~10 kB upstream of the *SNCA* promoter has been conclusively shown through a series of studies, including a large meta-analysis, to confer risk of PD in sporadic cases. Alleles that confer risk were associated with increased α-synuclein mRNA expression in neuronal cells in one study, but it may be that the observed effect reflects the linkage disequilibrium with other critical regions within the *SNCA* gene. In support of this idea, other population studies have shown association of other polymorphic regions within or close to the *SNCA* gene, including areas within the 3′ UTR, with PD risk.

α-Synuclein Deposition in the Brain: The Concept of Synucleinopathies

Shortly after the discovery that α-synuclein is genetically linked to PD, another major discovery was made by Maria Grazia Spillantini and colleagues that α-synuclein was a main constituent of Lewy bodies (LBs), the cytoplasmic inclusions that represent the pathological hallmark of the disease. α-Synuclein antibodies characteristically label the ring of the LBs. On electron microscopy, the identified structures correspond to the filaments that characterize these structures. α-Synuclein antibodies normally demonstrate by immunohistochemistry predominantly punctate neuropil staining, indicative of the physiological localization to presynaptic terminals. In PD tissues, apart from LB staining, there appears to be a general increase of cytosoplasmic immunostaining in the substantia nigra (SN), as well as labeling of dystrophic neurites, termed Lewy neurites. In advanced PD as well as in Lewy body dementia (LBD), α-synuclein immunohistochemistry also identifies LBs throughout the cortex. With aging, there appears to be a general increase of cytoplasmic α-synuclein immunostaining in the SN. Immunohistochemistry with α-synuclein antibodies is now considered the gold standard for the pathological identification of Lewy pathology, as it is more sensitive than ubiquitin immunohistochemistry.

Immunohistochemistry with α-synuclein antibodies was used systematically by Heiko Braak and colleagues in a cohort of tissues from their brain bank. They discovered that a number of brains demonstrated abnormal α-synuclein accumulation and aggregation in lower brainstem areas, without involvement of the SN. Based on these studies, they surmised that α-synuclein aggregation and deposition initially start from the dorsal motor nucleus of the vagus and the olfactory bulb, and at later stages, follow an ascending route, eventually involving, at a third stage, the SN dopaminergic neurons. At stages 4–6, there is progressive involvement of the limbic system and cortical regions. This staging scheme has not been universally accepted, but it does seem to hold true for the majority of patients with sporadic PD. The Braak staging reinforces the idea that α-synuclein aggregation is an early event in the development of PD, and that it could be the main pathogenetic factor.

Beyond PD, it is now clear that aberrant intracellular α-synuclein deposition occurs in various neurodegenerative conditions, most notably multiple system atrophy (MSA), in which deposition occurs predominantly within glial cells, the LB dementia, and pantothenate kinase-associated neurodegeneration. Although there is no genetic link with α-synuclein in these cases, it is surmised that common pathogenetic mechanisms may lead to α-synuclein deposition in these disorders, collectively termed synucleinopathies, and that reversing this phenomenon may have therapeutic value.

α-Synuclein Aggregation

Biochemical studies of brain tissue of PD patients, including partially purified LBs, have revealed the presence of poorly soluble forms of α-synuclein, mostly in the form of SDS-resistant oligomers, which may appear as insoluble smears on the top of SDS/PAGE gels or as discrete multimers of α-synuclein. This tendency of α-synuclein to form oligomers and aggregates is thought to be the core of its pathological function. The purified α-synuclein protein, when incubated in an aqueous environment at 37 °C, gradually loses its disordered structure, and starts assembling into beta-pleated sheets. By electron microscopy, various structures can be identified as transition intermediates between the monomeric protein and the fully fibrillar amyloid-like structures of the mature α-synuclein fibrils. These intermediates appear as ring-like (annular) or spherical or chain-like 'protofibrils', and correspond to soluble oligomeric α-synuclein. The similarity of the end-products of this in vitro process of α-synuclein aggregation with human neuropathology, the conceptual kinship with the amyloid hypothesis proposed for Alzheimer's disease, the temporal correlation between α-synuclein

aggregation and the conferred toxicity in various cellular models, and the protective effects of antiaggregation strategies, all indicate that this process of aggregation is critical for α-synuclein-mediated toxicity. However, it is a matter of intense debate as to exactly which species within this aggregation pathway may be toxic. A related unanswered question is how such species may confer toxicity.

Which are the Toxic Species?

There is evidence that the soluble oligomeric protofibrils, and not the mature fibrils, are the toxic species. In particular, (1) the presence of such species, when compared to frank fibrillar inclusions, correlates better temporally with death in cellular models; (2) in cellular and in vivo models, the presence of frank inclusions is not a good predictor of toxicity; (3) dopamine and its metabolites act as inhibitors of the conversion of protofibrils to fibrils, thus favoring protofibril accumulation; this could help explain in part the selective vulnerability of dopamine neurons to α-synuclein-mediated toxicity; and (4) in vitro, the A53T and A30P mutants both lead to enhanced protofibril formation, whereas they have opposing effects on mature fibrils, suggesting that the common denominator of the mutants is the accumulation of soluble intermediates; however, this notion breaks down in the case of the E46K mutant, which leads to enhanced conversion of protofibrils to fibrils, and therefore this issue is not yet settled.

Mechanisms of Aggregation-Dependent Toxicity

In solution, protofibrils have structures resembling those of bacterial pore-forming toxins, and it has therefore been suggested that they may have a similar function, forming pores on cellular membrane, leading to deleterious alterations in ionic exchange or conductance, or on intracellular organelles. The hypothesis that protofibrils, through this pore-like mechanism on vesicles, may cause leakage of vesicular dopamine into the cystosol is especially attractive and supported by cellular data. This could provide a link between α-synuclein protofibrils and increased cytosolic dopamine, and thus, oxidative stress, leading to selective nigral neuron loss. Alternatively, protofibrils may interact aberrantly with cellular constituents and interfere with their function. A case in point is the effect of select soluble oligomers of α-synuclein on the 26S proteasome. Protofibrils may be deleterious especially when localized at the presynaptic level, as they may interfere with normal synaptic transmission. In one study, the presence of such soluble oligomers, but not frank inclusions, correlated with synaptic degeneration in brains of patients with LBD. Larger fibrillar inclusions may also exert toxic effects, through blocking of axonal transport or by causing other mechanical problems through bulk effects, or by sequestering normal cellular constituents, leading to loss of their function in the appropriate cellular compartment.

Factors that Influence α-Synuclein Aggregation

Given the importance of α-synuclein aggregation, it is critical to consider the factors that may influence it. An obvious factor is the amount of α-synuclein. It is clear that the higher the protein levels, the more likely the process of aggregation. This, in conjunction with the genetic data, especially the cases with *SNCA* multiplication, and the human PD α-synuclein pathology, gives rise to the 'α-synuclein burden' hypothesis, according to which the critical factor in idiopathic PD pathogenesis is the accumulation of α-synuclein, either because of enhanced transcription or through reduced degradation. A corollary of this hypothesis is that reducing α-synuclein levels may be a valuable therapeutic target. Although the factors regulating α-synuclein transcription in vivo are not known, a number of regulating transcriptional elements are beginning to emerge from cellular studies. The issue of α-synuclein degradation has been controversial, but it now appears that the bulk of degradation of at least monomeric wild type (WT) α-synuclein in neuronal cell systems occurs through the lysosomal pathways of chaperone-mediated autophagy (CMA) and macroautophagy. We and others have proposed that dysfunction of these degradation pathways may be a contributing factor to PD pathogenesis.

Posttranslational modifications of α-synuclein can also alter its propensity to aggregate. α-synuclein is constitutively phosphorylated at S129 in certain cell types, but in vivo in the CNS, such phosphorylated conformations occur only within LBs. This has led to the idea that S129 phosphorylation, which has now been shown to be mediated by Polo-like kinase 2 (PLK-2), may drive α-synuclein aggregation. However, the data supporting this idea are conflicting, and it now actually appears that S129 phosphorylation reduces α-synuclein aggregation, at least in vitro. Nitratively modified α-synuclein also occurs within LBs, and both nitration and oxidation may lead to enhanced aggregation, whereas glycation may also play a role.

The general consensus in the field is that α-synuclein, either through genetic or epigenetic influences, acquires a tendency to aggregate and to cause inclusions. Something along this pathway confers neuronal toxicity and leads to PD.

Beyond Aggregation: Other Mechanisms of α-Synuclein Toxicity

α-Synuclein may have other pathogenic effects which may not be dependent on aggregation. Susan Lindqvist and colleagues have discovered that in yeast, α-synuclein disrupts ER–Golgi trafficking, presumably due to misfolding,

and that enhancing ER–Golgi trafficking through overexpression of Rab5a leads to protection against α-synuclein toxicity in mammalian neuronal cell models and in the fly model of α-synuclein overexpression. ER stress may thus contribute to α-synuclein-mediated toxicity. The A30P and A53T mutants, as well as the dopamine-modified WT α-synuclein, lead to the inhibition of CMA, the same selective lysosomal process that is responsible in part for α-synuclein degradation, thus creating a potential feed-forward loop of cellular dysfunction. Aberrant interactions of α-synuclein with cytosolic proteins leading to activation of proapoptotic pathways have also been proposed. It should be noted that there is evidence that WT α-synuclein may even have antiapoptotic effects. This may depend on the levels of expression.

Animal Models of α-Synucleinopathies

Based on the idea that α-synucleinopathies are due to a toxic gain of function, animal models of these disorders have been created based on α-synuclein overexpression. Species targeted include *Caenorhabditis elegans*, *Drosphila*, mice, rats, and nonhuman primates. These are models of neuronal-specific expression, but a model of MSA has been created in transgenic mice with overexpression in ologodendroglia. In most cases, cellular dysfunction with phenotypic manifestations has been demonstrated. In some cases, neuritic degeneration, without neuronal cell body loss, has been shown. With the possible exception of the fly model, it has not been possible to replicate the classical fibrillar LBs. A particular problem with the transgenic mouse models has been the inability to recreate the dopaminergic degeneration that characterizes PD, despite abundant expression of the transgene in SN neurons. Models with lenti- or adeno-associated virus (AAV)-mediated transduction of rodent ventral midbrain neurons have been much more successful in this regard, and have the advantage that they can be extended to nonhuman primates. They are, however, technically challenging, and this prevents their widespread establishment and utilization for preclinical studies.

Aluminum

E Cubo, Complejo Hospitalario Burgos, Burgos, Spain

Glossary

Dopamine – A neurotransmitter occurring in a wide variety of animals, including both vertebrates and invertebrates. In the brain, this catecholamine functions as a neurotransmitter, activating the five types of dopamine receptors – D1, D2, D3, D4, and D5, and their variants. Dopamine is produced in several areas of the brain, including the substantia nigra and the ventral tegmental area.

Lewy bodies – Abnormal aggregates of protein that develop inside neurons. There are two morphological

types: classical (brain stem) Lewy bodies and cortical Lewy bodies.
Neurofilaments – Filaments found specifically in neurons.
Neurotoxin – A toxin that acts specifically on the peripheral or central nervous system usually by interacting with membrane proteins such as ion channels.
α-synuclein – A protein of unknown function primarily found in neural tissue, where it is seen mainly in presynaptic terminals. It is predominantly expressed in the neocortex, hippocampus, substantia nigra, thalamus, and cerebellum. It is predominantly a neuronal protein but can also be found in glial cells.

Chemical Structure

Aluminum is a trivalent trace element that is found in aluminum silicate, oxide, or halide. It is a common metal in the earth mined from impure ore, bauxite, which contains aluminum oxide, water, and iron. Metallic aluminum does not occur in nature, it occurs only after the electrolytic processing of the oxide from the ore.

Environmental Exposure

Aluminum is found in many products such as cosmetics, surgical bone cement, antacids, and antiinflammatory creams. It is commonly found in drinking water and teas and is used in leavening and antisticking agents in the baking industry.

Exposure can be nonoccupational such as dialysis, drinking water, and food, and occupational, including dust and vapors from mining, smelting, foundry, and fabrication work. Chemical manufacturing plants use organoaluminums as catalysts. Welders are vulnerable to exposure, as are miners exposed to 'McIntyre Powder,' a dust consisting of finely ground aluminum as oxides and used as a prophylactic agent for silicosis.

Clinical Signs of Intoxication

Aluminum exposure is usually not associated with any neurological problems. Aluminum is highly reactive and not known to perform any enzymatic or other function in the body. However, neurotoxicity related to aluminum has been reported. Metal flux across the blood–brain barrier (the primary route of brain metal uptake) and the choroid plexuses as well as sensory nerve metal uptake from the nasal cavity have been described. The controversial role of aluminum in Alzheimer's disease suggests that brain aluminum uptake occurs by transferrin-receptor-mediated endocytosis and of aluminum citrate by system Xc(-) and an organic anion transporter, suggestive of transporter-mediated aluminum brain efflux. Neurologic manifestations of aluminum toxicity include 'potroom palsy,' an acute syndrome characterized by lack of coordination, poor memory, and impairment of abstract reasoning as well as depression. It was first described in smelter workers, with loss of balance as the most frequent complaint noted. Aluminum has been also implicated in a syndrome known as dialysis encephalopathy since it has been found in dialysis water and is part of the oral aluminum-containing phosphate binding gels used to control blood phosphorus levels. Clinical manifestations start with fatigue, drowsiness, and disturbances of concentration, cognition, and mental activity.

Aluminum may also have a role in the pathogenesis of neurodegenerative diseases, since elevated aluminum levels have been found in subjects with amyotrophic lateral sclerosis and parkinsonism dementia complex of Guam. Animal studies have found induction of spinal neuronal degeneration after the injection with aluminum. The incorporation and accumulation of aluminum ions in the cells may also have a role for the transmissible spongiform encephalopathies due to an 'iron-overload syndrome' which highly promotes formation of hydrogen peroxide, which can be a main factor in causing serious damages to DNA and proteins (oxidative stress).

In experimental animals, a low calcium and magnesium/high aluminum diet induces neurofibrillary pathology characterized by the accumulation of phosphorylated neurofilaments in the anterior horn cells and neuronal loss most concentrated in the dopaminergic neurons in the substantia nigra. This diet over a prolonged period of 11–31 months induced loss of neurons and occurrence of tau-immunopositive neurons in the cerebral cortex. These findings may have implications to amyotrophic lateral sclerosis and parkinsonism–dementia complex where combinations of degenerating neurons occur. The isolation of this syndrome to Guam suggests that environmental issues may underlie at least part of the pathogenesis of this neurodegenerative disease.

The relationship between aluminum and idiopathic Parkinson's disease (PD) is unclear. In the majority of cases, it is proposed that environmental agents, modulated by the individual's genetic susceptibility, can contribute to the etiopathogenesis of PD. Several studies have implicated environmental factors, especially pesticides and metals, including iron and aluminum. In those studies, compared with controls, increased concentrations of aluminum in the substantia nigra of PD patients have been found. In a study of 200 PD patients and 200 age- and sex-matched controls, a marked and statistically

significant higher incidence of ulcers (diagnosed by X-ray or surgery) in the PD patients compared with the controls (14% to 4%) was found. As a result, it has been speculated that aluminum-containing antacids may contribute to the pathogenesis of idiopathic PD. Recently, it has been reported in the preliminary studies that certain pesticides and metals could accelerate the formation of α-synuclein fibrils both individually and synergistically. In experiments using higher α-synuclein concentrations, micromolar amounts of aluminum stimulated the rate of fibril formation. Since these agents also induce a conformational change in α-synuclein, it is likely that this partially folded conformation is a critical precursor to association and fibrillation. These observations suggest a possible underlying molecular basis for association of aluminum and PD and related Lewy body diseases, where these interactions between α-synuclein and environmental agents, in this case aluminum, could play a role in the pathogenesis of nigrostriatal degeneration, and thus, in the etiology of sporadic PD.

Alzheimer's Disease and Parkinsonism

Z Arvanitakis, Rush University Medical Center, Chicago, IL, USA

Glossary

Alzheimer's disease – A common neurodegenerative disease of aging, associated with memory loss and cognitive decline, and motor decline including parkinsonism.

Episodic memory – Memory for learning and retention of specific events (episodes) embedded in an autobiographical, temporal context; deficit is the clinical hallmark of Alzheimer's disease.

Semantic memory – Previously acquired knowledge independent of the specific context in which the facts were learned.

Working memory – The ability to manipulate information held in short-term, limited-capacity, memory stores.

Consequences of Aging

The recent and marked increase in the detrimental impact, including personal, societal, and economic factors, of common conditions of aging on world populations is large and projected to worsen. Among the most common and disabling conditions of aging are neurologic conditions. In particular, two important consequences of aging are a decline in cognitive function and a decline in motor function. With the current demographic trends showing an increase in the life expectancy, age-related conditions, such as Alzheimer's disease, are increasingly common. Indeed, Alzheimer's disease is considered the most common cause of dementia.

Alzheimer's Disease

Important Public Health Issue

Over the last century, US national statistics show a trend of increasing life expectancy. In 2000, the average life expectancy at birth for all races and both sexes in the United States was 76.9 years of life. Because of the growing number of elderly persons, it has become increasingly crucial to understand and address the common diseases and problems experienced by this population group. One of the most prevalent diseases of old age is the neurodegenerative disease, Alzheimer's disease. Both the incidence and the prevalence of Alzheimer's disease are strongly related to age. Recent data estimate that Alzheimer's disease affects about 5 million Americans and that this will increase by slightly less than threefold by the year 2050. The annual number of incident cases of Alzheimer's disease is expected to more than double by 2050. Further, cognitive and motor impairments associated with aging will also become increasingly more common and become major public health concerns. Alzheimer's disease and cognitive and motor impairment are associated with greater morbidity and mortality. Because of the expected increase in the growth of the older age groups in the coming decades, the burden of cognitive and motor impairment, as well as other age-related conditions, is projected to increase dramatically for this sector of the population.

Clinical Features

Alzheimer's disease is characterized by an insidious onset and progressive decline in cognitive function. The most common early clinical manifestation is short-term memory loss, in keeping with a deficit in episodic memory. With disease progression, other cognitive systems are affected, including visuospatial abilities (resulting in disorientation and getting lost) and language abilities (with early anomia, and late global aphasia), and a full-blown dementia is observed.

In addition to decline in cognitive function, Alzheimer' disease is characterized by other clinical features. Patients have a decline in functional abilities, which may affect function in the work and home environment. Affect is often involved, with depression being common in the early stages of the illness. Behavior may become affected in the mid-late stages, with perseveration, apathy, and other abnormal behaviors. Significantly abnormal behavior, resulting in danger to the self or others (e.g., aggression), may result in institutionalization.

An increasingly recognized feature of Alzheimer's disease is the presence of parkinsonian signs. These manifest as bradykinesia, rigidity, and postural instability with inability to ambulate in late stages of the illness (see below).

Decline in Cognitive Function

Aging and Alzheimer's disease are characterized by progressive loss of memory and other cognitive abilities. Memory is the recording, retention, and retrieval of information and accounts for all knowledge gained through experience; it includes memories of specific events, knowledge of facts, and acquisition of skills. Although memory loss is recognized as the characteristic cognitive manifestation of Alzheimer's disease, extensive literature documents impairment in multiple other cognitive systems. Assessment of various cognitive systems is important, as risk factors may be associated with change in one or several systems, while showing little or no association with others. Such selective effects on cognitive function have already been found for various risk factors for Alzheimer's disease: genetic factors (e.g., apolipoprotein E ϵ4) and other factors (e.g., proneness to psychological distress) have been associated with decline in episodic memory, while vascular factors (e.g., diabetes mellitus) have been associated with decline in perceptual speed.

Episodic memory refers to learning and retention of specific events (episodes) embedded in an autobiographical, temporal context. Impairment of episodic memory is the clinical hallmark of Alzheimer's disease and may be the only clinically apparent deficit early in the disease. Recent studies suggest that persons with isolated episodic memory impairment (e.g., mild cognitive impairment) are probably exhibiting the earliest clinical manifestations of Alzheimer's disease. Semantic memory refers to previously acquired knowledge, independent of the specific context in which the facts were learned. It is represented primarily, though not exclusively, by language function. Working memory refers to the ability to manipulate information held in short-term, limited-capacity, memory stores. Perceptual speed refers to the speed with which perceptual comparisons can be made. Both working

memory and perceptual speed are involved, to some extent, in most forms of information processing. Both appear to decline with age independent of Alzheimer's disease.

Decline in Motor Function and Parkinsonism

Aging and Alzheimer's disease are also characterized by progressive loss of motor function. Age-related parkinsonian signs are common and changes in motor function, including gait disorder, rigidity, and bradykinesia, are often progressive. Both Alzheimer's disease and cognitive decline are associated with change in parkinsonian signs. Parkinsonian signs include signs of bradykinesia (e.g., slow, small amplitude, hesitant movements), gait disturbance (e.g., stooped posture, small tentative steps, postural instability), rigidity (e.g., stiff limbs), and tremor. Parkinsonian signs are associated with mortality in older persons with and without Alzheimer's disease. Parkinsonian signs are present in about half of people with Alzheimer's disease and become much more common as disease advances. Although parkinsonian signs progress in persons with Alzheimer's disease, the rate of this progression varies for the different signs, suggesting that risk factors may be associated with change in some signs but not others. Indeed, risk factors may be differentially related to change in one or several parkinsonian signs. Preliminary work suggests that some vascular factors common in aging and related to Alzheimer's disease are associated with change in parkinsonism signs, and may be related to some aspects of parkinsonism more than others. For instance, type 2 diabetes mellitus has been found to be associated with increasing rigidity and gait disturbance in older persons followed annually over about 6 years.

Relation Between Cognitive Decline and Parkinsonism

It has long been hypothesized that loss of cognitive function and progression of parkinsonian signs may share a common etiopathogenesis. For example, some diseases such as the Parkinsonian–Dementia Complex of Guam manifest clinically as cognitive impairment and parkinsonism. There is also data suggesting that age-related cognitive and motor impairment are related. First, about half of persons with Alzheimer's disease exhibit parkinsonian signs. Likewise, up to half of persons with Parkinson's disease develop dementia. Mild age-related parkinsonian signs are associated with risk of Alzheimer's disease. Further, in persons with and without Alzheimer's disease, rate of cognitive decline is associated with progression of parkinsonian signs. While many factors could account for the phenotypic overlap of cognitive decline and parkinsonian signs, including structural changes in cognitive and motor systems (e.g., cerebrovascular disease, Lewy bodies, neurofibrillary changes), shared mechanisms underlying selective vulnerability has also been hypothesized to play an important role, including oxidative stress and inflammatory processes, among others.

Recent studies have found that common age-related conditions, such as parkinsonism, increase the risk of dementia and Alzheimer's disease. Yet, little data are available on the relation of these conditions to neuropathology of dementia. Human postmortem data on a group of older community-dwelling persons with and without dementia who are well-characterized during life, allow for examination of potential mechanisms leading to dementia. Some clinical–pathologic data have suggested that neurofibrillary tangles (one of the key pathologies of Alzheimer's disease) in the substantia nigra (an anatomical location for pathology of Parkinson's disease) are contributing factors to gait disturbance and parkinsonism in old age. Further such studies are needed to examine the pathophysiologic basis of parkinsonism in old age and Alzheimer's disease.

Future Directions

Age-related conditions are increasingly common worldwide and are resulting in a large public health burden. Cognitive and motor impairment are among the most common conditions of aging. Identification of risk factors for decline in cognitive function and decline in motor function, particularly modifiable risk factors, could potentially have a large impact on our understanding of the underlying mechanisms of diseases of aging and on our ability to treat and, one day, prevent these conditions.

Amyotrophic Lateral Sclerosis/Parkinsonism-Dementia Complex of Three Pacific Isolates

J C Steele, Guam Memorial Hospital, Tamuning, Guam
P L McGeer and J Miklossy, University of British Columbia, Vancouver, BC, Canada

Glossary

ALS (amyotrophic lateral sclerosis) – A universal and progressive disease with amyotrophy and spasticity of bulbar and limb muscles. On Guam, it was distinguished by familial occurrence, high prevalence, and linear retinopathy. Otherwise, its clinical features and immunohistology were like classical ALS elsewhere. Occurring among Guamanians for 200 years, it has declined on Guam during the past 40 years, and is now rare.
ALS/PDC (amyotrophic lateral sclerosis/ parkinsonism–dementia complex) – A unique familial tauopathy of three Pacific places with three phenotypes of ALS, parkinsonism, and dementia.
Dementia – A progressive disorder which impairs cognition and alters behavior. On Guam, when dementia is associated with parkinsonism, it is termed the parkinsonism–dementia complex. When it occurs independently, it is referred to as Guam dementia (GD) or Mariana's dementia (MD). Its clinical features include those of Alzheimer's disease (AD) and frontotemporal dementia (FTD).
Guam – A tropical and high island of 200 square miles, southernmost of the Marianas archipelago in Central and Western Oceania. Guam was a Spanish possession after its discovery in the sixteenth century until it was ceded to United States in 1898. As a US Territory, it remained an undeveloped island of subsistence and a Navy coaling station until its occupation by Japan from 1941 to 1944 during World War II. Since the War, United States has rapidly developed Guam as a main military and tourist center at its western extent.
Parkinsonism – A generic term for diseases involving the extrapyramidal system. On Guam, it is distinguished by clinical heterogeneity which includes features of atypical parkinsonism like postencephalitic parkinsonism (PEP), Parkinson's disease (PD), progressive supranuclear palsy (PSP), and corticobasal degeneration (CBD).
Postencephalitic parkinsonism – A progressive tauopathy accumulating the same hyperphosphorylated tau isoform as ALS/PDC and Alzheimer's disease which was epidemic for several decades after acute pandemics of encephalitis lethargica and Spanish influenza in the 1920s.

History and Background

The neuropathologist, Harry Zimmerman, was the first to recognize that amyotrophic lateral sclerosis (ALS) was unusually common in the Chamorros of Guam in 1945. He confirmed that diagnosis by autopsy, but because it was familial and of young onset, he called it an 'obscure

malady' (**Figure 1**). Thereafter, teams of Navy physicians confirmed that ALS was endemic in all parts of this small tropical island of 200 square miles, and in 1953, epidemiologist Leonard Kurland calculated that its overall prevalence was 100 times greater than elsewhere. His colleague, neurologist Donald Mulder agreed the clinical illness of Chamorros was the same as classical ALS, and he learned it had affected successive generations of the 'Q' family in Umatac village of southern Guam for more than 150 years. He also identified a second neurological syndrome of parkinsonism and dementia that was common among Guamanian Chamorros. It resembled postencephalitic parkinsonism and occurred in the same families with ALS. The neuropathologist, Nathan Malamud, identified neurofibrillary degeneration (NFD) in the substantia nigra of a patient with ALS and parkinsonism in 1958, and his new finding led Zimmerman to encourage Asao Hirano to study the neuropathology of both syndromes. In 1960, after a year of studies on Guam, Hirano and his colleagues concluded that ALS, parkinsonism, and dementia were phenotypes of a single disease with the histological hallmark of Alzheimer-type NFD. They called it the ALS/parkinsonism–dementia complex (ALS-PDC) of Guam, and since then it is known worldwide by this appropriate designation. Chamorros refer to it as lytico-bodig. (**Figure 2**). Since 1957, the National Institutes of Health (NIH) have honored a commitment to longitudinal studies of ALS/PDC on Guam.

Figure 1 Guam, Mariana islands.

Once described, ALS/PDC was recognized in two other places. In 1975, neurologist Yoshiro Yase and neuropathologist Hirotsugu Shiraki described ALS with NFD among the residents of two clusters, each involving five small and adjacent mountain villages in the Kii peninsula of Honshu island. One cluster, along the Koza river, was called the Kozagawa focus, and the other cluster, 200 km away was the Hobara focus on the Iseji river. There were no cases of ALS in the villages between these two clusters, in other parts of the Kii peninsula, or in Japan. The disease there is called 'muro' and it is also familial. It was first recorded in a document of 1693, and its high prevalence was recognized by the pioneer neurologist Kinnosuke Kimura after he learned of ALS from Jean-Martin Charcot in Paris. Since 2001, neuropathologist Shigeki Kuzuhara and his colleagues at Mie University have confirmed that the epidemiology, clinical features, and immunohistology of ALS/PDC in Hobara are identical to those of ALS/PDC on Guam.

Figure 2 Chamorro patients with ALS (left) and the parkinsonism–dementia complex (right).

In 1982, Nobel Laureate Carleton Gajdusek described a syndrome of ALS and parkinsonism among 7000 head hunting tribes people living in riverside villages of coastal mud flats in West New Guinea. Although not pathologically verified, its clinical features and epidemiology are similar to ALS/PDC on Guam and in Japan.

Materials for this Review

This review article is based on 1093 probable cases of ALS/PDC in Guamanian Chamorros during 50 years. For 25 years and from 1957 to 1982, neurologists at the NIH Guam Research Center identified 389 ALS, 306 PDC, and 39 mixed ALS and PDC cases. During the next 25 years and from 1983 to 2008, Steele and his colleagues have identified 64 ALS, 282 PDC, and 13 mixed ALS and PDC cases by the same NIH criteria.

Clinical Manifestations

ALS/PDC is progressive and fatal. Its average duration is 3–4 years, but the disease may be fulminant with death in 6 months or prolonged for more than 25 years. ALS/PDC is more common in men than women and has the same ratio of 1.7:1 in both ALS and PDC phenotypes.

ALS is clinically and immunopathologically identical to classical ALS in other parts of the world. Its age of onset, in this series and by pathological confirmation is from 20 years (in 1951) to 71 years (in 2005). The last born case was in 1951 (Patient AG).

Parkinsonism usually manifests as progressive bradykinesia, flexion posture, postural instability, and symmetrical rigidity that does not respond to L-dopa. Tremor is seldom severe. Less often, and in early stages, Guam parkinsonism may mimic Parkinson's disease (PD) presenting with asymmetric or even unilateral signs with prominent rest tremor, and responsivity to dopaminergic drug treatment. A small number of Chamorros exhibit classical syndromes of progressive supranuclear palsy (PSP), first described by Tanner and Steele in 1987, and corticobasal degeneration (CBD), described by Gwinn Hardy in 2000. The onset of parkinsonism is later than ALS, and its age of onset in this series and by pathological confirmation is from 32 years (in 1956) to 82 years (in 1998). The last born case was in 1951 (patient BT).

The dementia of ALS/PDC is referred to as Mariana's dementia (MD) by some and Guam dementia (GD) by others. It may precede, accompany, or be independent of parkinsonism. Different examiners report different characteristics. Thus, Douglas Galasko of UC San Diego finds that GD is clinically indistinguishable from Alzheimer's disease (AD), but Thomas Bak of Cambridge University, using different psychometric tests, concludes that a combination of amnestic and frontal-executive symptoms distinguish GD from AD. In 2004, an NIH-sponsored community survey diagnosed 12.2% (243 cases) of Chamorros 65 years and older with all types of dementia. The majority (174 cases and 72%) were diagnosed with probable (128) or possible (46) GD. GD and parkinsonism (i.e., PDC) were present in only 29 (12%) of all 243 cases of dementia. The probable age of GD was 79.4 ± 7.1, and greater than the age of 76.0 ± 5.9 for PDC.

Since 1983, Steele has identified 96 cases of GD. The age of onset is later than ALS or PDC and is from 53 years (in 2001) to 89 years (in 2004). Its prevalence increases exponentially with age, and it is three times more common in women than men. The eldest case had characteristic changes of ALS/PDC at autopsy without AD or beta-amyloid deposits. The last born case in 1947 (Patient RY) has the youngest age of onset (53 years) and is still alive in 2008. Her diagnosis of GD is probable. She has a family history of ALS/PDC and has not developed parkinsonism during the 7 years of observation.

Latent ALS/PDC remains common among senescent Guamanian Chamorros, but it is rare in Chamorros younger than 65 and in those born after the 1940s. Forty years ago, in subjects dying between 1968 and 1974 without neurological symptoms, Leung Chen identified NFD in a few Chamorros in their 20s who were born in the 1950s (14%), and Anderson observed it in some subjects in their 30s who were born in the 1940s (29%). Both agreed the histopathology was like ALS/PDC and not AD, and both found that NFD was increasingly prominent and widespread as subjects were older and their year of birth was earlier. Daniel Perl in 2003 confirmed that latent ALS/PDC was also a cohort which was ending when he examined asymptomatic Chamorros dying between 1988 and 1996. At that time, and 20 years after the reports by Chen and Anderson, the youngest subject of his series was 41 years of age, there were far fewer subjects under 50 years, and NFD was less intense. Those subjects who were older than 50 years and born before the 1940s still showed greater prominence of NFD with advancing age.

Pathology

In 1963, Hirano visited Jerzy Olszewski and Clifford Richardson in Toronto as they were describing PSP, and agreed that its neuropathology was remarkably similar to ALS/PDC. Thirty years later, Jean Geddes and her colleagues compared ALS/PDC with PSP and postencephalitic parkinsonism (PEP), and found that the histopathology and topography of all three tauopathies were so similar that they could not distinguish between them (**Figure 3**). Most recently, in 2008, neuropathologist Judith Miklossy and Patrick McGeer confirm that tau deposition dominates the pathology of ALS/PDC, but Aβ, α-synuclein, ubiquitin, and TDP-43 proteins are also present and implicated in

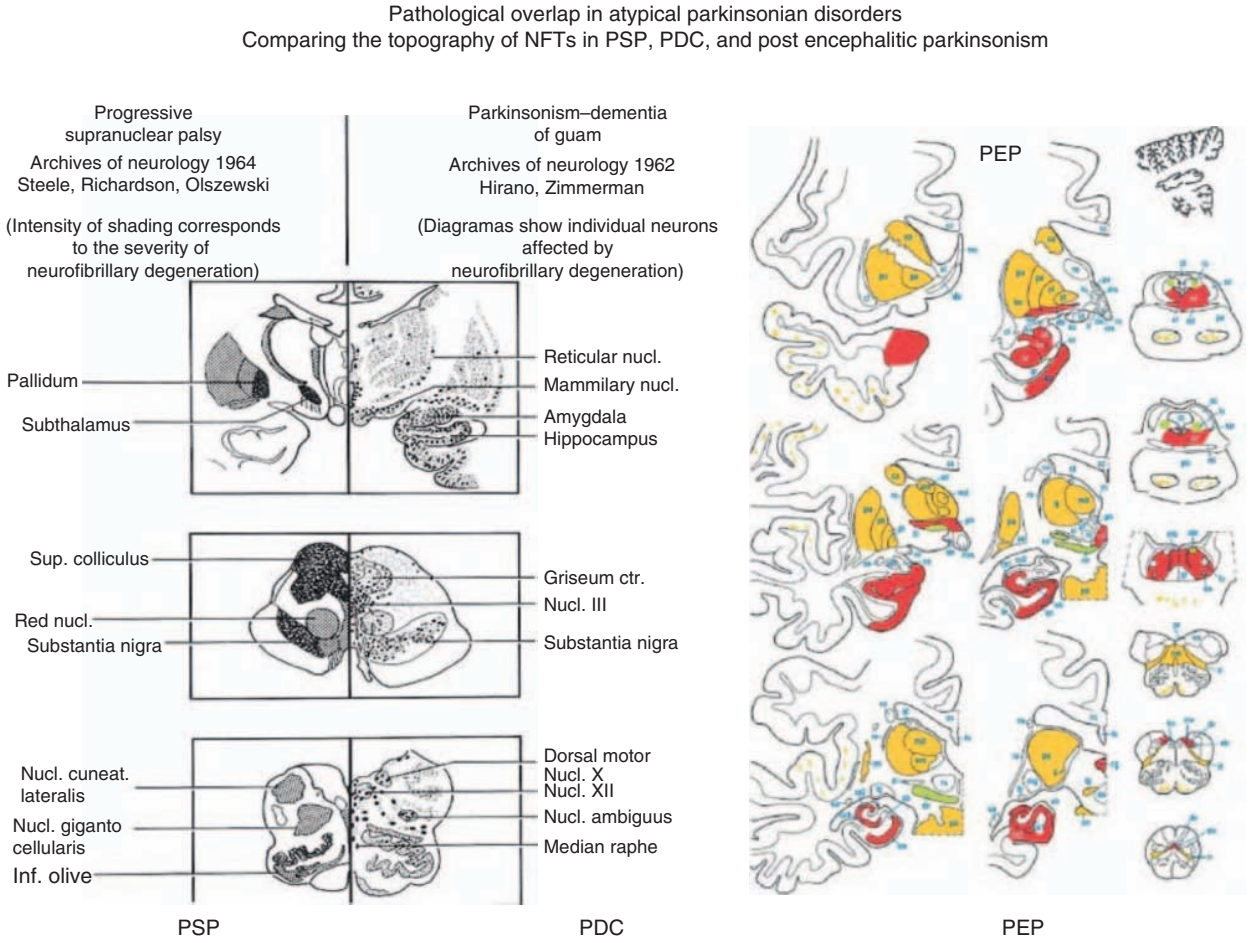

Figure 3 Pathological overlap in atypical parkinsonian disorders.

pathogenesis. The neurofibrillary tangle (NFT) pathology of ALS/PDC, first noted by Malamud and Hirano, shares similarities with AD and PEP, Lewy bodies are identical to those of PD, and the tau-positive glial pathology of ALS/PDC has similarities to PSP, CBD, and frontotemporal dementia (FTD). Tau-positive NFTs, coiled bodies, hazy granules, astrocytic plaques, thorn-shaped astrocytes, and the association of coiled bodies with hazy granules with nerve fiber tracts occur in all ALS/PDC phenotypes and confirm that they are likely variants of the same disease. In their immunohistological study of 35 ALS/PDC cases from 1946 to 2006, Miklossy and McGeer found that the qualitative features are the same in all cases, but they observed an increasing age of autopsy by 4.5–5 years per decade. They concluded that immunoproteins including ubiquitin, α-synuclein, and TDP-43 were not new but had always been involved in the neuropathogenesis of ALS/PDC.

Natural History

The etiology of ALS/PDC is not known, and it remains unclear if there is a single or multifactorial precipitant. It is, however, very clear that the phenotypic expression is age-dependent and that the age of onset can be from 20 years (ALS), to middle/late life (parkinsonism), to senescence (GD). The majority of cases are familial, and within a given family, siblings often express phenotypes of ALS, parkinsonism, and dementia that depend on the age of onset. (**Figure 4**).

During the past 50 years, the clinical and pathological features of ALS/PDC have remained the same, but there are no new cases of ALS, parkinsonism, or dementia in Chamorros born after 1951 or in non Chamorro migrants to Guam after 1956. Since that date and during the past 40 years, ALS/PDC has steadily declined, its age of onset has slowly increased, and its phenotypes have altered. Differences in the age of onset and latency of its different phenotypes are likely to account for these changes (**Figure 5**).

By example, ALS has the youngest age of onset (20 years) and affects the youngest siblings in families with ALS/PDC (**Figure 4**). Its longest latency, recorded by Ralph Garruto in 1980 is 34 years in a Chamorro who left Guam in 1935 and did not develop ALS until age 59 when in California. Because its onset is at the youngest age and its latency is the shortest, ALS was the first

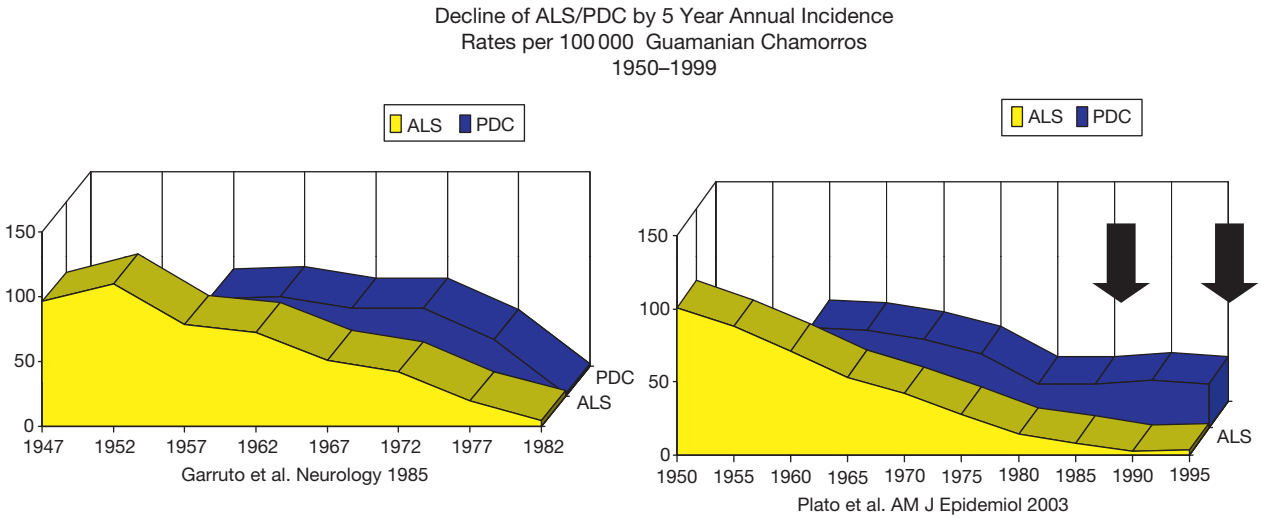

Figure 4 Three Chamorro families from different parts of Guam with ALS, PDC, and GD in siblings.

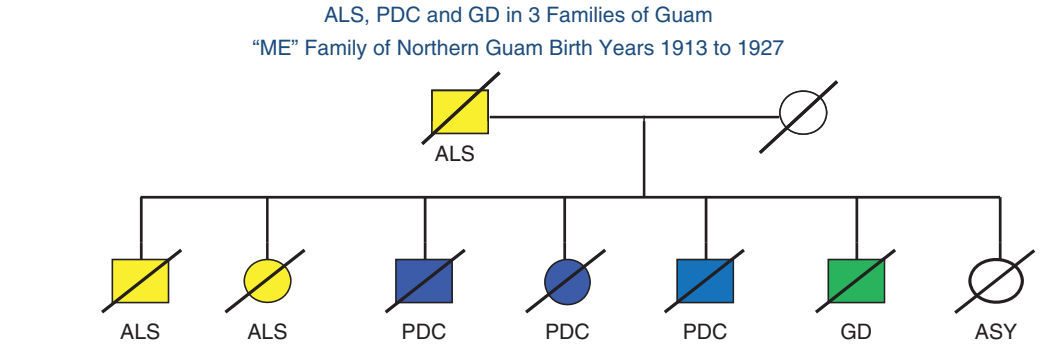

Family "M.E." northern Guam: years of birth 1913 through 1927. ALS, amyotrophic lateral; PDC, parkinson-ism dementia complex; GD, Guam Dementia, ASY, no neurological symptoms at time of death

Figure 5 Decline of ALS/PDC by annual 5 year incidence rates per 100 000 Guamanian Chamorros 1950–1999.

phenotype to show a steady decline in those born after 1951. By 2008, it is now rare.

Parkinsonism likewise is declining. The youngest age of onset of PDC is 32 years of age, 12 years later than ALS, and among affected siblings, it begins in middle or late life, and at a later age than ALS (**Figure 1**). In 1969, Eldridge reported a latency of 46 years in a Chamorro who left Guam in 1918 and lived thereafter in California until 1964 when he developed pathologically verified PDC. That latency is 12 years longer than the longest latency of ALS.

GD has been the last phenotype to alter. The youngest age of onset is 51 years, and it affects the eldest siblings in families with ALS/PDC (**Figure 4**). The NIH community survey, reported in 2007, indicates it is still common in senescent Chamorros.

Non Chamorros who migrated to Guam before 1957 are also apparently at risk for ALS/PDC. Majoor-Krakauer has recently identified American servicemen who were in Guam for only 1–2 months at the end of World War II, but who did not develop ALS until 1989–1991 when in New York City. Garruto has also reported Filipino construction workers migrating to Guam between 1946 and 1950 who developed ALS/PDC after long latencies. For example, ALS with NFD was identified in a Filipino beginning

17 years after arrival, and PDC is pathologically confirmed by Hirano, Perl, and Dickson in four cases whose onset was 20–55 years after arrival. Two nonmilitary Caucasians who went to Guam in 1952 and 1956 developed fulminant ALS 41 and 39 years later, and both were suspected to have ALS/PDC because of NFD by Hirano and Perl.

This ending of ALS/PDC in Chamorros born before 1952 and non Chamorro migrants coming before 1957, indicates the ending of its likely environmental cause which had been common and endemic in all parts of Guam for more than two centuries. Because ALS/PDC predominates in Chamorros and in families, its cause is likely to be in the traditional, pre-World War II subsistence life style of Chamorro families. But the cause must also involve genetic or other factors very specific to individual Chamorro families to explain why some are severely affected and others are spared, though they live in the same small village and share a common environment. Despite 60 years of intense study, Zimmerman first identified in 1945 that the disease remains an obscure malady.

Pathogenesis

In a review article of 2008 and correspondence that followed it, Steele and McGeer discuss the various hypotheses proposed for ALS/PDC during the past 60 years. These include genetic inheritance, neurotoxins of *Cycas circinalis* (cycad), seeds which may also be present in flying foxes, and geochemical deficiencies of calcium and magnesium. None is proven and each hypothesis is plagued by a mixture of supporting and refuting evidence. In 2009 evidence for genetic predisposition is provided by Sieh, Schellenberg and colleagues who find three susceptibility loci in Chamorros with ALS/PDC. Steele and some colleagues favor a postinfectious, immunologically mediated pathogenesis akin to postencephalitic parkinsonism. They notice the tau isoform of ALS/PDC, and its histology and topography are identical to PEP, the clinical phenotypes of parkinsonism and ALS are similar, and the long latency of ALS/PDC occurs also in PEP. Furthermore, the silent exposure and long latency of ALS/PDC very much resemble chronic cerebral infections like kuru, Jacob–Creutzfeldt's disease, and subacute sclerosing panencephalitis (SSPE).

Future Perspectives

In 1986, neurophthalmologist Cox reported a significant association between ALS/PDC on Guam and a unique linear retinopathy. It was present in one half of ALS/PDC patients and had the appearance of a worm migration in the retinal pigment epithelium. It was asymptomatic and detected only by indirect ophthalmoscopy. Three hundred sixty cases of this linear retinal pigment retinopathy (LRPE) are now identified in Guam since 1982. It does not alter over time, often precedes the onset of ALS/PDC, and may be the marker of its etiology. Yasumasa Kokubo in 2006 reports that it is also present in case of ALS/PDC in the Kii peninsula, but till date, it is not reported from any other part of the world. Knowing the cause of this unique retinopathy in these two places can advance understanding of the ALS/PDC pathogenesis.

Umatac village, the site of Guam's discovery and Ferdinand Magellan's landing in 1521, has been the epicenter of ALS/PDC for two centuries. In the 1950s, Kurland and Mulder observed ALS had 3–4 times the prevalence of adjacent villages. Now, 50 years later, most of its 33 residents of age 65 and older suffer dementia and some also have parkinsonism, but none is young or middle aged, and none has ALS. Like Rosetta town where the understanding of Egyptian hieroglyphics was revealed by the study of an ancient stone, Umatac village remains a place for neurological understanding and discovery. But time is running out and Oliver Sacks wonders; "Will the quarry, hotly pursued for fifty years now, with all the resources that science can bring, elude them finally, tantalizingly, by disappearing at the moment they are about to grasp it?".

Anticholinergics and Movement Disorders

R Katzenschlager, Department of Neurology, Donauspital/SMZ-Ost, Vienna, Austria

Definition and History

The anticholinergics are a class of drugs with antimuscarinic effects in the central nervous system. They were commonly used in the treatment of Parkinson's disease (PD), especially before the introduction of levodopa and other antiparkinsonian drugs. Currently, they are used, to a lesser degree, in PD although there is considerable geographic variability with respect to prescribing patterns. They are still used in the treatment of dystonia, especially in children.

Mechanism of Action

The exact mechanism of action of anticholinergic drugs in the relief of parkinsonian motor problems remains undetermined, although their effect is centrally mediated and they are believed to counteract the imbalance between striatal dopamine and the acetylcholine activities caused by the degeneration of dopaminergic nigrostriatal neurons. Anticholinergics are used for treating parkinsonism block muscarinic receptors. In addition, some agents have been shown to inhibit striatal dopamine reuptake in animal models of PD. In dystonia, the mechanism of action of anticholinergics is incompletely understood, but they are thought to work centrally within the basal ganglia circuits rather than at the neuromuscular junction.

Anticholinergics for the Treatment of Parkinson's Disease

Charcot was the first to note the beneficial effects of a belladonna alkaloid containing atropine on the parkinsonian motor signs. His observation was reported by his student, Ordenstein, in 1867. Subsequent investigators, including Gowers in the late nineteenth century, also found that antimuscarinic substances such as Indian hemp, scopolamine, and hyoscyamine were effective in mitigating tremor and muscular rigidity in patients with PD. Similarly, these drugs were used in the pandemic of encephalitis lethargica at the beginning of the twentieth century. In 1945, Feldburg discovered that acetylcholine is a central neurotransmitter abundant in the striatum at synaptic nerve terminals. He suggested a central effect for anticholinergic drugs. For over half a century, the belladonna alkaloids formed the mainstay of the medical management of PD. Since 1950s, these natural products have been replaced by synthetic substances, but anticholinergics remained the only drugs available for the symptomatic treatment of PD for nearly a century until the introduction of levodopa. The anticholinergics most commonly used in the treatment of PD are listed in **Table 1**.

Efficacy: Parkinsonian Motor Signs

A systematic review by the Cochrane Collaboration investigated the literature dealing with anticholinergics

Table 1 Most commonly used anticholinergics and their recommended daily doses in the treatment of PD

Substance	*Recommended daily dose in PD (mg)*
Benztropine	1–6
Benzhexol = trihexyphenidyl	2–15
Biperiden	2.5–15
Bornaprine	2–12
Orphenadrine	150–300
Procyclidine	5–20

for the treatment of PD and identified nine eligible randomized-controlled studies published between 1954 and 1986. The overall number of patients randomized into these studies was 221. Two studies dealt with benzhexol, three with bornaprine, one with orphenadrine, one with benztropine, and one with methixene; one compared benzhexol and benapryzine with a placebo. Seven studies investigated anticholinergics as an add-on to other antiparkinsonian drugs and two as monotherapy. Nearly all studies were double-blind; all were cross-over in design; and their duration ranged from 5 to 20 weeks. These studies were performed prior to the development of modern methodologies and each has significant limitations. Eight of the nine studies reported a significant improvement from baseline in at least one motor function or activity of daily living in patients on an active drug, but the magnitude of these changes was usually moderate. Only four studies reported whether the difference between drug and placebo was statistically significant. Despite limitations with respect to the quality of performing and reporting these clinical trials, the existing data provide evidence of a superior antiparkinsonian effect of anticholinergics as a group compared with a placebo in short-term application, both as monotherapy and as an adjunct to other antiparkinsonian drugs. There is no information from the literature on whether the use of anticholinergics as initial treatment of PD has any effect on the emergence of motor complications, which can be delayed by using dopamine agonists. There are also no long-term studies comparing the symptomatic effects of anticholinergics with other antiparkinsonian drugs.

There is a widespread belief among clinicians that anticholinergics have a more pronounced effect on tremor than on rigidity and bradykinesia and that the major benefit derived from their use is related to a tremorolytic effect. Although a small single-dose study found a better effect of benzhexol on tremor compared with pergolide, two recent systematic reviews indicate that data suggesting such a tremor-specific effect are inconclusive. In the Cochrane review performed on anticholinergics in PD, information on tremor as well as on other parkinsonian features was available from five studies. The results available from these studies do not argue in favor of a preferential effect of anticholinergics on tremor compared with other parkinsonian features such as rigidity and bradykinesia.

Anticholinergic drugs have been reported to alleviate dystonic spasms in PD associated with chronic levodopa administration, especially early-morning OFF dystonia. A challenge with procyclidine in nine fluctuating PD patients with OFF foot dystonia resulted in abolition of dystonia in six; amelioration in one; and no effect in two patients. In de novo-PD patients presenting with foot dystonia – as is sometimes seen in younger patients – the use of benzhexol has been reported to improve dystonia as an early motor sign.

The efficacy of anticholinergics in patients on long-term levodopa therapy with associated motor complications such as fluctuations or dyskinesias has not been investigated in randomized studies. Clinical experience suggests that there may be some benefit in this approach, and the use of anticholinergics as part of a combination regime in patients with advanced PD has been recommended by some authors, provided there are no contraindications, in particular with respect to age and cognitive function. The role of anticholinergics in the management of patients with advanced PD remains worthy of further research.

Other Manifestations of PD: Hypersalivation

Drooling and poor handling of saliva are frequent problems in PD. Despite the fact that drooling is primarily due to decreased swallowing and increased mouth opening, anticholinergics are occasionally used in an attempt to reduce saliva production. No randomized-controlled studies have investigated the systemic use of anticholinergics in this regard and the spectrum of adverse effects often precludes their use in patients with advanced disease. A small cross-over study using sublingual ipratropium bromide found a small subjective but no objective benefit compared with a placebo.

Comparison of Different Anticholinergic Drugs in Parkinson's Disease

Only one of the studies included in the Cochrane review involved two different anticholinergic drugs, benzhexol and benapryzine, in patients on levodopa therapy. The outcome measure was a total disability score based on functional disability, tremor, rigidity, akinesia, posture, and autonomic dysfunction. No significant improvement compared with placebo was found on using either drug.

Overall, there are insufficient data to draw conclusions on the differences among individual anticholinergic drugs, either in efficacy or in safety. It is likely that therapeutic differences among the various anticholinergics are minor, but some patients may tolerate one better than another.

Anticholinergics in the Treatment of Dystonia

The same range of anticholinergic drugs discussed for the treatment of PD have a role in the symptomatic management of many types of primary and secondary dystonia. One randomized-controlled cross-over study investigated benzhexol in 31 patients with various forms of primary or secondary dystonia. Improvement occurred in 22 patients. At doses up to 30 mg day^{-1}, the drug was better tolerated by patients below 19 years, whereas adverse effects

were dose-limiting in older patients. All other studies performed to date have been open-label or retrospective, but they support these findings. A large retrospective study reported good response in 43% of dystonic patients and again, younger patients being able to tolerate higher doses, with better efficacy and fewer side effects. As a rule, much higher doses can often be used in dystonia than in PD, because patients as a group are younger and usually cognitively intact. For example, most patients require a maximum dose of benzhexol of 40 mg day^{-1}, but in children, daily doses of up to 100–120 mg have been used and well tolerated. Overall, younger patients and patients with mild disease and short disease duration tend to show better responses to anticholinergic drugs. Both primary and secondary forms of dystonia may respond, and generalized and segmental dystonia tend to respond better than focal dystonia, which is often preferentially treated with botulinum toxin injections. There is some evidence that the initial effect of anticholinergics tends to wear off over months to years.

Safety and Tolerability of Anticholinergics

Clinical practice has shown that compared with some other antiparkinsonian drugs, anticholinergics carry a greater risk of adverse events. Side effects considerably limit their clinical use in many patients.

The abrupt withdrawal of anticholinergic drugs may lead to rebound effects with marked deterioration of parkinsonism and severe agitation in PD patients. In both PD and dystonic patients, these drugs should always be discontinued gradually over a period of weeks to months.

Due to their peripheral antimuscarinic action, anticholinergics are contraindicated in narrow-angle glaucoma. Caution must be exercised in elderly male patients with prostate hypertrophy, due to a high risk for urinary retention. They may cause blurred vision due to accommodation impairment, urinary retention, nausea, tachycardia, and dry mucous membranes. Gingivitis and caries, sometimes leading to loss of teeth, may occur, and reduced sweating may interfere with body temperature regulation. They impair gastrointestinal motility and may impair the absorption of other drugs, including levodopa. Constipation may occur, rarely leading to paralytic ileus. These effects are reversible with discontinuation of the drug, and can show some tolerance after prolonged exposure.

The most relevant limitation to the clinical use of anticholinergics is caused by their central anticholinergic effects. Effects on the cholinergic system, specifically in the nucleus basalis of Meynert, likely form the basis of the cognitive changes induced by anticholinergics. Impaired mental function, mainly involving immediate memory and memory acquisition, is a well-documented central side effect that resolves after drug withdrawal. Acute confusion, sedation, restlessness, poor concentration, and psychiatric disturbances, including hallucinations and psychosis, may also occur. Anticholinergics may lead to an exacerbation of frontal lobe dysfunction in patients with PD. These central adverse effects are more common in older and cognitively impaired patients, but they have also been demonstrated in patients without preexisting cognitive impairment. A recent small pathological study showed a significantly greater degree of Alzheimer-type pathology in PD patients who had been on long-term anticholinergic treatment. The findings have not yet been replicated, but in keeping with the clinical adverse effect profile, suggest that this class of drugs should be used with caution.

There are a few reports of dyskinesias brought on or increased by anticholinergics when used in PD, either when used as monotherapy or in combination with levodopa. Some dystonic patients will develop dyskinesia when anticholinergics are used to treat the dystonic symptoms.

Future Directions of Research

The available literature demonstrates a symptomatic effect of anticholinergics on PD and dystonia, but a clear delineation of the receptor populations involved in this benefit has not been accomplished. Further, pure centrally active anticholinergics that target only the needed receptors have not been developed, and therefore, many patients cannot tolerate these drugs because of central and peripheral side effects. Although anticholinergics are occasionally used in initial treatment in the early stages of PD and throughout the course of dystonia in many patients, they are no longer used as first line drugs for PD. There are no controlled data for anticholinergic use in the management of motor fluctuations in PD, but this area could be studied further in future research efforts. Anticholinergics are still sometimes recommended in patients in whom other therapies have failed to sufficiently control tremor. Definite data to confirm a special role for anticholinergics in the management of tremor are lacking, but the literature on this class of drugs dates back to times when performance and the reporting of clinical trials differed from today's standards, precluding firm conclusions. With the development of actigraphy and other automated tools to assess tremor longitudinally, very focused studies on tremor response to anticholinergics are feasible research programs for the future. Although the discussion of anticholinergics has focused on antimuscarinic agents, a second primary central cholinergic system involves nicotinic pharmacology. The development of pure nicotinic and antinicotinic agents would allow the study of the cholinergic/anticholinergic impact of nicotinic receptor manipulation in both PD and dystonia.

Antidepressants and Movement Disorders

M Danehy, Rush University, Chicago, IL, USA

Glossary

Apathy – Lack of emotion, as distinguished from depression.
Augmentation – Adding a medication to increase the response already achieved by another.
Mania – Increased energy and decreased need for sleep, often associated with irritability and agitation.
Remission – Lack of daily signs or symptoms of depression versus response, which is only an improvement.
Sexual side effects – Decreased libido, impotence, and difficulty in reaching orgasm or anorgasmia.
Suicidality – Thoughts of wanting to kill oneself, if a plan or intent exists the patient will likely need emergency psychiatric help.
Withdrawal effects – Most often flu-like symptoms with severely depressed mood, even suicidality.

Antidepressant Application Overview

Mood or behavioral symptoms are very common in movement disorders. Patients with Parkinson's disease are more likely than the general population to have depression and anxiety. Tourette's syndrome and obsessive–compulsive disorder are known comorbidities. Irritability is extremely common as one of the first psychological symptoms of Huntington's disease. Behavioral symptoms adversely affect the quality of life, as well as motor symptom-related disability and level of social support. Anxiety can result in more 'off' time in Parkinson's disease patients. A Huntington's disease patient with irritability can end up with little family support and be institutionalized sooner than would be necessary otherwise. Behavioral and mood problems in movement disorders may be under-recognized and undertreated. Whether for depression, anxiety, or irritability, the antidepressants may be useful for patients with movement disorders. Treatment helps more than just the psychological wellbeing of the movement disorder patient, but can often improve the physical manifestations of their illness.

Many of the antidepressants and other medications discussed here can cause movement disorders, usually of minor significance. These movement disorders are most commonly tremor or myoclonus, or rarely neuroleptic malignant syndrome. Please see the suggested reading and chapters on these subjects for further information.

Antidepressant Medication Classes

Serotonin Selective Reuptake Inhibitors

This class of medications includes fluoxetine, fluvoxamine, citalopram, sertraline, paroxetine, and escitalopram. The side effect common to the entire class and of similar frequency among each is sexual side effects. These sexual side effects consist of decreased libido, impotence, delayed orgasm, or anorgasmia. **Table 1** summarizes usual dosing, side effects, and other important considerations of these medications.

Choosing which SSRI

Serotonin selective reuptake inhibitors (SSRIs) are one category of antidepressants without life-threatening or organ-damaging side effects with normal use, although nearly every one has drug–drug interactions that can be serious. For this reason, they are agents of first choice for depression. There is controversy over their (and other antidepressant) use with Parkinson's medications of the monoamine oxidase inhibitor (MAOI) family, but combination can be done with close monitoring, preferably by both a psychiatrist and the neurologist. The choice of initial SSRI is based on desirable and undesirable side effect profiles, past history of efficacy with a particular drug, family history of drug efficacy, drug interaction potential, and cost. If one SSRI is not effective, there is a 75% chance another one may be effective. After two failures, a switch to another category of antidepressants is recommended.

SSRIs' interactions with movement disorders

While there were early concerns that SSRIs could worsen parkinsonism, this is not usually the case. SSRIs can worsen restless leg syndrome, but again, monitoring case by case seems to be the best approach.

The other concerns with SSRIs lie in the overall treatment of elderly patients. The anticholinergic effects of paroxetine, as well as particular other SSRI effects such as decreased appetite, sleep/wake disruption, and hyponatremia, are all concerns when using SSRIs in the elderly.

Serotonin Norepinephrine Reuptake Inhibitors

Serotonin norepinephrine reuptake inhibitors (SNRIs) include venlafaxine, duloxetine, and desvenlafaxine. Information on dose, adverse effects, and other features is contained in **Table 2**. These agents are serotonergic and noradrenergic. The noradrenergic component may be helpful in patients who experience apathy or emotional numbness from the SSRIs, those who do not respond to SSRIs, or for patients when poor energy and physical symptoms are chief symptoms of depression.

Norepinephrine and Dopamine Reuptake Inhibitor

The norepinephrine and dopamine reuptake inhibitor comes in two generic forms: budeprion XL and bupropion SR. Dosing information, common side effects, and other information are reported in **Table 3**. In particular, this type of medication counteracts apathy and enhances energy, attention, and wakefulness.

Table 1 Selective serotonin reuptake inhibitors

Drug	*Dose*	*Common side effects*	*Other information*
Fluoxetine	20–80 mg daily	Fatigue, weight gain, weight loss, apathy; sexual side effects, headaches	Calming; rarely causes agitation, akathisia more common than other agents
Fluvoxamine (only available as brand name Luvox CR)	100–300 mg daily	Insomnia, fatigue, sexual side effects, headaches	May be best SSRI for obsessive–compulsive symptoms, may need high doses, many drug interactions
Sertraline	100–250 mg daily	Initial anxiety, loss of appetite, insomnia, nausea, sexual side effects, headaches	Can be started at very low dose, benzodiazepine may be needed early in therapy
Paroxetine	20–60 mg daily	Sedation, weight gain, dry mouth, constipation, confusion, sexual side effects, headaches	Withdrawal rapid and severe, avoid in patients with poor compliance
Escitalopram	10–40 mg daily	Sedation, increased appetite, dry mouth, sexual side effects, headaches	Few medication interactions
Citalopram	20–80 mg daily	Minimal, weight and sleep neutral, headaches, sexual side effects	Not the generic for escitalopram and those on escitalopram may not respond

Table 2 Serotonin norepinephrine reuptake inhibitors

Drug	*Dose*	*Common side effects*	*Other information*
Venlafaxine	150–375 mg daily	Insomnia, anxiety, loss of appetite, hypertension, irritability (especially in Huntington's disease); sexual side effects and headaches	Not a good choice for noncompliant patients, withdrawal rapid and severe
Duloxetine	60–150 mg daily	Liver failure (rare), weight neutral, fewer sexual side effects	Calming, avoid in patients with ethanol abuse
Desvenlafaxine	50–100 mg	Similar to venlafaxine	Crumbles when cut, FDA approved only at 50 mg, minimal drug interactions

Noradrenergic and Specific Serotonin Antidepressant: α-2 Antagonist

Mirtazapine is a noradrenergic and serotonergic antidepressant that is also an α-2 antagonist. Mirtazapine is likely underused outside of the elderly population. However, it can be combined with other antidepressants and has a low incidence of sexual side effects. In the elderly population, the use of mirtazapine minimizes negative side effects and maximizes positive side effects of the antidepressants. Mirtazapine is given 15–75 mg once daily, usually at night. It may cause sedation, weight gain, dry mouth, and constipation and is very rarely associated with aplastic anemia. At low doses, sedation and weight gain may be significant. Mirtazapine has a calming effect, and its effects on insomnia and weight loss make it a very good choice in Parkinson's disease patients.

First Generation Antidepressants

A discussion of first generation antidepressants is very complicated. A selection of agents is discussed here. While there is evidence to support the use of amitriptyline and nortriptyline for treatment of depression in Parkinson's disease, current practice is to use newer agents with more favorable side effect profiles, especially in an older population. First generation antidepressants may be used to treat symptoms other than depression. For example, low-dose amitriptyline and trazodone are often used to treat sleep disturbances. Information on dose, side effects, and other salient features is included in **Table 4**.

Other treatment modalities

Monoamine oxidase inhibitors

The use of nonselective MAOI is quite complex and can be best managed by consultation with a psychiatrist or neuropsychiatrist. The three main monoamine oxidase inhibitors (MAOIs) in use by psychiatrists at this time are eldepryl, phenylzine, and tranylcypromine. The doses of MAOIs used in psychiatry are eldepryl: 10 mg orally and patch form in 6, 9, and 12 mg, phenylzine: 30–60 mg, and tranylcypromine: 20–60 mg. With phenylzine, tranylcypromine, eldepryl oral, and any eldepryl patch above 6 mg, careful dietary and medication precautions are required to prevent hypertensive crisis. These are irreversible MAOIs and 14 days must pass after use of any other antidepressants (5 weeks for prozac) and starting an MAOI or 14 days after the MAOI is stopped before starting another antidepressant. Dextromethorphan and meperidine are well known contraindicated medications with MAOIs, and levodopa/carbidopa are as well.

Table 3 Norepinephrine and dopamine reuptake inhibitor

Drug	*Dose*	*Common side effects*	*Other information*
Budeprion XL	150–450 mg daily	Insomnia, decreased appetite, fidgeting, tremor, risk of seizures – rare except if history of seizures, head trauma, or current electrolyte imbalance (purging in bulimia, renal)	Activating antidepressant, may activate mania in Huntington's disease, not very good for anxiety, irritability or impulsivity; generic XL may not be as reliable as brand name (Wellbutrin XL), lower seizure risk
Bupropion SR	200–400 mg daily in two divided doses	More likely to cause insomnia, remainder as above	Better choice than generic XL, higher seizure risk than brand name XL

Table 4 Selected first generation antidepressants

Drug	*Dose*	*Common side effects*	*Other information*
Amitriptyline	10–25 mg daily for insomnia 150–300 mg daily for depression	Excessive morning sedation, dry mouth, constipation, orthostatic hypotension, dizziness, arrhythmia, hyponatremia, seizures	Useful for sleep at low doses, can be useful in patients with pain at moderate doses, treats depression and anxiety at higher doses, second most fatal medication in completed suicides
Nortriptyline	75–150 mg daily	Dry mouth, sedation, orthostatic hypotension (less than amitriptyline)	Avoid grapefruit juice, longer half-life than amitriptyline, better tolerated in elderly
Clomipramine	100–250 mg daily	Weight gain, headaches, insomnia, sedation, arrhythmia, hyponatremia, seizures	Used for obsessive–compulsive disorder, most serotonergic of the first generation antidepressants
Trazodone	25–150 mg	Morning sedation, dry mouth, orthostatic hypotension	Works best in depression-altered sleep, higher doses do not increase efficacy for sleep, not very effective as antidepressant/antianxiety agent

Orthostatic hypotension, weight gain, edema, and, as in other antidepressants, sexual dysfunction are the more common and troublesome side effects. MAOIs are thought to be most helpful for the depression with hypersomnia, hyperphagia, and mood reactivity, and worse for bipolar depression.

Electroconvulsive shock therapy

Electroconvulsive Therapy is an alternative therapeutic strategy for depression. This therapy is usually outside the scope of neurological practice, and therefore, requires referral to a psychiatrist.

Other biological therapies

Other nonmedication biological therapies also exist. See additional reading for more information.

Maximizing Treatment with Antidepressants

Before moving from the first few categories to trying a first generation or MAOI antidepressant, there are other options that may be helpful and have fewer side effects. These can be referred to as 'boosters,' although in the psychiatric literature they are called 'augmentation strategies.' The difficulty, if the SSRIs, SNRIs, mirtazapine, or bupropion are not working, is in deciding whether it is better to increase the dose, use an augmentation strategy or combination, or switch antidepressants. The goal is complete remission from mood disorder. Without complete remission, patients can relapse sooner, and most often the relapse of depression will be more difficult to treat than the original episode.

Decision Making

Guidelines are generally stated as follows: if the patient is showing some decrease in symptoms of depression and at least 3–6 weeks have passed, the physician can increase the dose of the current medication (unless already at the suggested maximum dose in the earlier table). If there is no room for increasing the dose and the patient has only shown partial response, one can augment that current antidepressant (consultation with a psychiatrist may be helpful here, see Further Reading) or use a combination approach. If there has been little to no response over at least 8 weeks to the current antidepressant (dosed in the 'effective' dosing range as listed earlier), there are two options. If time permits, the physician can increase the dose of antidepressant once and wait 4 weeks, then, if no results, switch antidepressants or simply switching antidepressants is also reasonable.

The most commonly used combinations include mirtazapine or bupropion/budeprion combined with selective serotonin reuptake inhibitors or with SNRIs. Mirtazapine and bupropion/budeprion can also be added to tricyclic antidepressants.

Aripiprazole is the only FDA-approved augmentation agent for depression. Because of the risks of chronic antipsychotic therapy (drug-induced parkinsonism, tardive dyskinesias), it is not used except to manage treatment-resistant depression. In this context, psychiatric consultation can be very valuable.

Managing Side Effects

Another reason to switch antidepressants, or augment and keep the original medication dose lower, is that the patient suffers from significant side effects. Movement disorder patients with degenerative brain disorders are very sensitive to side effects in general. Often times, keeping doses of medications low, but using combinations or augmentation, can allow them to be fully treated with antidepressants.

Sexual side effects are the easiest to treat and very common in the usual patient. Common 'antidotes' used are bupropion/budeprion addition for sexual dysfunction in men and women, taken at usual dose daily; Buspirone can be added for sexual dysfunction in women at a dose of 15–30 mg bid; or Sildenafil or similar impotence medication for sexual dysfunction in men and women, taken as needed. Benzodiazepines can also be of assistance to treat other side effects.

Length of Treatment

In major depression, the recommendation is a full year of treatment dated from full remission before tapering a patients with no prior history of depression off of their antidepressant (although some say 6 months). Another area where patients/physicians make decisions about medication is the lowering of the dose of medication, augmenting agent, or antidepressant itself; however, this could be the same as removing it entirely. In addition, sometimes starting the same antidepressant regime again does not treat a new depression. Patients with degenerative brain disorders will likely be having fewer neurosubstrates to work with over time. Lifelong medication treatment, and frequently, increasing doses of medication over time or augmentation (rarely having to switch medications) are often necessary.

Follow-up

Being familiar with antidepressants adds to a neurologist's practice of medicine. Knowing when to start an antidepressant or when to consult a psychiatric colleague can be very helpful. It is a black box warning recommendation that patients started on antidepressants must be

monitored closely for emergence of clinical worsening, suicidality, or unusual behavior. The current standard of care in psychiatry is that patients are being seen between 2 and 3 weeks after they are started on an antidepressant. This could pose a difficult situation for a neurologist who usually follows patients on a less intensive schedule. However, if the physician takes the time to have the patient check in on the phone regularly, and can arrange for short-term monthly follow-up, the comfort of the patient being able to stay with their primary neurologist for treatment of mood or behavior is important for compliance. The initial follow-up appointment is only to check on side effects and suicidality or evidence of mania, and can usually be managed over the phone, if collateral information can be obtained from a family member.

Antidepressants do not start to work for 4–6 and sometimes 8 weeks after they are at an effective dose. It is important to see a depressed, anxious, or irritable patient who has been started on an antidepressant on a more frequent schedule initially, but once well treated and in remission, moving to an every 3–4 month appointment is acceptable. In the acute phase of treatment, when an antidepressant is first started, it might be necessary to use a psychiatrist, if only to follow the patient more closely, and then have the patient return to you for their psychiatric care once the crisis has passed and medication stabilization has been accomplished.

Conclusion

A neurologist who uses antidepressants in practice is making an excellent decision and patients with movement disorders are among the most psychiatrically ill of neurological patients. In addition to medication, the physician should also refer to the psychological elements of mood or behavioral treatment, such as social work assistance, counseling, or family, individual, or caretaker psychotherapy. Being familiar with the common side effects, effective dose ranges, and decision making involved in using antidepressants helps a physician to be more confident in treating this aspect of the patients' movement disorder. Consultation for full care or for assistance should be available from a psychiatrist for every movement disorders practice. Many movement disorders are neurodegenerative and little can be done for the patient's movement, but often the psychiatric aspects of the patient's disorder are a major factor and can be greatly helped by antidepressants.

Applause Sign

D R Williams, Monash University (Alfred Hospital Campus), Melbourne, Australia

Definition and History

The 'applause sign' describes an abnormal tendency for a patient to initiate an automatic program of applause when asked to imitate three claps. It is included in the spectrum of clinical signs that can be identified at the bedside in patients with frontostriatal cognitive dysfunction. It was originally described as a clinical sign that differentiates progressive supranuclear palsy from Parkinson's disease and frontotemporal dementia.

Bruno Dubois is the neurologist who has contributed most to the development and study of the applause sign. His work on cognitive neurology, with colleagues from the Hôpital de la Salpêtrière, has established him as an expert in the area of subcortical cognitive dysfunction. Some refer to this sign as 'Dubois' applause sign.'

Pathophysiology

The frontostriatal cognitive pathways subserve the motor and cognitive functions via circuits that involve the dorsolateral prefrontal cortex, orbitofrontal and cingulate regions of the prefrontal cortex, and basal ganglia. Lesions in any of these regions can produce a dysexecutive syndrome characterized by poor attention, decreased working memory, diminished planning and reasoning, and depression. Although anatomically different, the basal ganglia and the frontal lobes are so closely involved in executive function that extensive neuropsychological evaluation is required to demonstrate the neuropsychological differences between lesions in these areas. They do, however, differ in their control of motor acts: the frontal lobes are involved in the voluntary control of actions and subcortical structures intervene in more automatic components of action.

The applause sign probably reflects lesions in the subcortical structures, and is more often seen in patients with these lesions than in patients with predominantly frontal lobe dysfunction. Although unproven, this sign is thought to be caused through an inability to stop an automatic activity once it has been released (because of the dysfunction of the basal ganglia). Other explanations for this behaviour include frontal lobe problems of perseverative behavior or decreased ability to plan specific motor programs.

Clinical Features and Diagnostic Criteria

The sign is usually elicited as part of the cognitive bedside assessment. The examiner first says to the patient 'Clap three times after me' and then demonstrates three claps (in <1 s). The patient is observed and the number of claps produced is counted and scored. The performance of the subject is normal when he or she claps only three times (score $= 3$) or abnormal when he or she claps four times (score $= 2$), 5–10 times (score $= 1$), or when he or she initiates a program of applause that he or she cannot stop (score $= 0$).

Normal controls always clap three times. Patients with subcortical cognitive dysfunction clap more than three times. In patients with progressive supranuclear palsy, there was no correlation between the severity of cognitive dysfunction and the degree of abnormality in the applause sign. The applause sign has been studied in only small samples of patients with Parkinson's disease and no correlation with cognitive function (mini-mental state examination) was observed but a negative correlation with motor severity (Unified Parkinson's Disease Rating Scale, section III) was identified.

Differential Diagnosis

The applause sign has been shown to be a common clinical feature in patients with neurodegenerative parkinsonism, including corticobasal syndrome, progressive supranuclear palsy, and multiple system atrophy, and has been described in a patient with nondegenerative subcortical lesions. The applause sign occurs less often in Parkinson's disease, Huntington's disease, and rarely in frontotemporal lobar dementia syndromes. The sign is not sufficiently sensitive or specific to contribute to the differential diagnosis of patients with Parkinsonism.

Approximate Entropy

D E Vaillancourt, University of Illinois at Chicago, Chicago, IL, USA

Glossary

Autocorrelation – A method to quantify the correlation of a variable at one time with itself at another time.
Essential tremor – A movement disorder that primarily causes tremor of the extremities, and is considered the most prevalent movement disorder in the world. The tremor can occur during a posture, during movement, and when holding an object. The tremor does not occur when the limb is at rest.
Frequency – Frequency describes the number of cycles per second. Fourier analysis is a method that transforms a data time series into the frequency domain to determine which frequency content is within the data time series.
Parkinson's disease – A neurodegenerative disorder that causes motor symptoms such as tremor, rigidity, and bradykinesia.
Tremor – An involuntary, approximately rhythmic, and roughly sinusoidal movement that occurs in Parkinson's disease, cerebellar disease, essential tremor, and other movement disorders.
White Gaussian noise – Each data point in a time series is independent to the past and future data points. The power spectrum of white Gaussian noise is flat.

Definition and History

Approximate entropy (ApEn) is an algorithm that examines the structure of a data time series in the time domain. ApEn was originally developed by Steven Pincus. This was a seminal paper that has been cited 576 times as of writing this entry. In general, ApEn measures the regularity of a time series by examining the predictability of future values in a time series on the basis of previous values. For example, consider a sine wave where there are accurate short- and long-term predictions of future values in a time series. ApEn tends toward a value of 0. For a randomly generated signal such as white Gaussian noise, each value in the time series is generated independently of the other time series values. ApEn increases to a value near 2. Thus, the ApEn algorithm returns a value tending toward 2 for highly irregular signals, and becomes close to 0 for a more regular signal.

In the field of movement disorders, ApEn has been used to study tremor. This is because tremor in healthy individuals takes on a broad band of frequencies, but during pathology, tremor becomes more rhythmical at a fixed frequency. ApEn can be more sensitive than frequency at detecting tremor in Parkinson's disease. An example of the independence of ApEn in relation to the frequency and amplitude of tremor is shown in **Figure 1**. **Figure 1(a)** shows an accelerometer recording of tremor from the index finger of a healthy individual in the time domain (left), frequency domain (middle), and autocorrelation (right). In the middle figure, the classic peak ~10 Hz is observed, as is a high frequency peak between 20 and 25 Hz. This is consistent with the original description of healthy physiological tremor by Stiles. The signal in **Figure 1(a)** has a standard deviation (SD) of 0.38 and an ApEn value of 0.90. In **Figure 1(b)**, the time series was converted into the frequency domain, and the phases associated with each frequency were shuffled. The signal was then converted back into the time domain. This process randomizes the orderliness or regularity of the signal, but preserves the linear qualities of the signal. Thus, as shown in **Figure 1(b)**, the SD remains at 0.38 (left), the frequency spectrum remains very similar to **Figure 1(a)** (middle), and the autocorrelation looks very similar (right). The ApEn value has increased to 1.24. This demonstration illustrates why ApEn can be more sensitive than the other measures that rely on the first and second moments at detecting tremor.

ApEn is reduced in patients who have essential tremor and Parkinson's disease. Also, deep brain stimulation of the ventral intermediate nucleus of the thalamus increases the ApEn value of tremor in patients with essential tremor. Deep brain stimulation of the subthalamic nucleus increases the ApEn value of tremor in patients with Parkinson's disease. ApEn has also been used to study posture and force steadiness in other motor control studies. Although ApEn has not been used in electrophysiological studies of brain function, it is a very reasonable approach if one is interested in regularity. ApEn is beneficial because it can be calculated on time series that are short, with only a few hundred data samples. There is one cautionary point regarding ApEn. The ApEn value is dependent on the number of samples. Thus, if one wants to compare ApEn values across studies using the same type of time series (e.g., local field potential, tremor acceleration), the sampling rate and length of the recording need to remain constant. More recent developments which build on ApEn have been developed in the form of sample entropy.

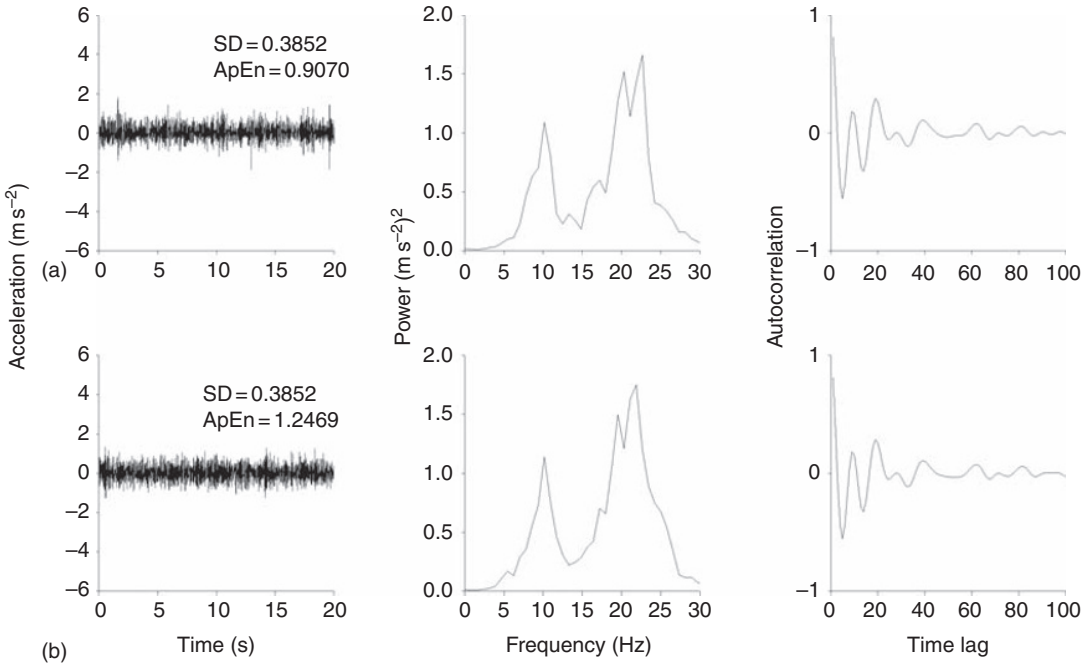

Figure 1 The figure shows a recording of physiological tremor from an accelerometer attached to the middle finger of a healthy adult. (a) The acceleration time series (left panel), power spectrum of the acceleration (middle panel), and autocorrelation of the acceleration (right panel). (b) The phase-randomized surrogate transformation of the acceleration signal in A. The surrogate time series (left panel), power spectrum of surrogate time series (middle panel), and autocorrelation of surrogate time series (right panel) all appear qualitatively similar to the original time series. As is shown in (a) and (b) left panel, the ApEn values distinguish the two signals whereas the SD does not distinguish the two signals.

Sample entropy is independent of the number of data samples.

The following steps are adapted from Slifkin and Newell and used in the calculation of ApEn. A more formal mathematical account of the required calculations is available in Pincus and Pincus and Goldberger.

Step 1: Two input parameters, m and r, need to be specified. The value of r is multiplied by the SD of the time series and, as is discussed in more detail, provides tolerance limits for assessing the nearness of adjacent data points in the time series. The m value represents a vector length comprising m consecutive data points. Typical values used in the literature include $r = 0.2 \times \text{SD}$ and $m = 2$.

Step 2: The calculation of ApEn begins with the identification of the first vector in the time series, $[u(1), u(2)]$, which comprises the first and second data points. This vector is termed as the template vector. The calculation of ApEn entails a determination of the similarity of other vectors in the time series to the template vector. Beginning with the first data point, $u(1)$, limits are established around it that extend across the time series. The limits are determined by multiplying r by the SD. If, for example, $r = 0.2$ and the $\text{SD} = 0.10$, a value of ± 0.02 around the first data point is established. These limits are extended over the entire length of the time series. Then, according to the same procedure, limits are established for the second element, $u(2)$.

Step 3: The next step is to identify all other vectors of adjacent m length points, $x(i) = [u(i), u(i+1)]$, in the time series that are close to the template vector, $[u(1), u(2)]$. The first element, u(i), in all other vectors, $x(i)$, is close to $u(1)$ if the element falls within the limits around $u(1)$. The second element, $u(i+1)$, of each vector is close if it falls within the limits around $u(2)$. Thus, all vectors that are close to $[u(1), u(2)]$ will have their first element within the boundaries of $u(1)$ and their second element within the boundaries of $u(2)$. These are called the conditioning vectors. The number of conditioning vectors becomes the denominator of a ratio that is the central calculation for ApEn. Another way of thinking about this procedure is that it identifies other vectors that are similar to the template vector, and the value of r determines the threshold or criterion for stating that other vectors are similar. For instance, decreasing the value of r decreases the range of the limits around template vector elements, and would result in fewer vectors qualifying as conditioning vectors.

Step 4: The next element of the template vector is identified, which in this example is $u(3)$. According to the procedure in Step 2, limits are constructed around it as previously described for $u(1)$ and $u(2)$. Then the

conditioning vectors with $u(i+2)$ values that are close to $u(3)$ – within the limits around $u(3)$ – are identified. The initial conditioning vectors, $u(\mathrm{i})$, that were close to the template vector, $[u(1), u(2)]$, and that still have $u(\mathrm{i}+2)$ values close to $u(3)$ of the template vector become the numerator of the ratio.

Step 5: The ratio forms a conditional probability of the likelihood that runs of two adjacent data points in the conditioning vectors that were close to the first two values of the template vector and will remain close to the template vector on the next incremental comparison – to $u(3)$. In other words, given the number of runs of adjacent values that are a similar distance away (A), what is the likelihood that those runs will still be similar when the number of values have been incremented to three (B)? The natural logarithm of the conditional probability, A/B, is then calculated. Thus, compared with a highly periodic process (e.g., a sine wave), white Gaussian noise will have a low probability of finding conditioning vectors in the time series that are close to the first two elements in the template vector, and that will still be close at the next incremental comparison.

Aprataxin

A Filla and F Saccà, Università degli Studi di Napoli ''Federico II'', Napoli, NA, Italy

Glossary

APTX – Gene coding for aprataxin, mutated in Ataxia with oculomotor apraxia type 1 (AOA1) patients.
Aprataxin – Protein implicated in DNA repair.
Ataxia – Symptom or syndrome consisting of abnormal coordination caused by an altered function of the cerebellum or its connections.
Base excision repair (BER) – Mechanism responsible for removing DNA damaged bases.
Oculomotor apraxia – Dissociation of eyes and head movements when looking toward a lateral target.
Single strand brake – DNA discontinuation in one filament produced during base excision repair or after reactive oxygen species (ROS) damage.

Definition and History

Ataxia with oculomotor apraxia type 1 (AOA1) was first described in Japanese and Portuguese families. AOA1 is characterized by early-onset ataxia, peripheral neuropathy, and oculomotor apraxia. Linkage analysis localized the causative gene to chromosome 9p13.3. The sequencing of the region revealed missense, nonsense, and frameshift mutations in the *FLJ20157* gene. Nucleotide changes were not found in unrelated and unaffected individuals. The gene was successively named *APTX* and the protein, Aprataxin (*APTX*).

Pathogenesis

DNA single-strand breaks (SSBs) are the most abundant DNA lesions produced by reactive oxygen species (ROS).

Experimentally, SSBs can be generated after UV irradiation and hydrogen peroxide (H_2O_2), methyl methane sulfonate (MMS), or camptothecin administration. SSBs are also produced during base excision repair (BER) as repair intermediates. BER is responsible for removing DNA bases that are oxidized or alkylated, which can occur during inflammation and UV light exposure, and after endogenous alkylating agents' exposure. The first step in BER is the recognition and removal of damaged bases and the incision in the phosphodiester bond operated by glycosylases. At this point, the DNA filament is opened and a SSB is generated. During SSB formation, abnormal 3′or 5′ terminals can arise, especially if SSBs are generated directly by ROS. To be correctly repaired and polymerized, they must be repaired to 5′-phosphate and 3′-OH. At this stage, the recognition of SSBs is operated by poly-ADP ribose polymerase-1 (PARP-1), which assembles the repair machinery interacting with DNA polynucleotide kinase–phosphatase (PNKP), XRCC1, polymerase-β, ligase-III, tyrosyl-DNA phosphodiesterase 1 (TDP1), and aprataxin.

APTX consists of 7 exons and is ubiquitously expressed in human tissues. Mutations have been reported in exons 5, 6, and 7. Lymphoblasts of patients carrying truncating mutations show reduced levels of APTX mRNA up to 57% of controls. Exon 3 is alternatively spliced, generating two transcripts. The longer, in frame transcript of 342 amino acids, is the major form found in human cell lines, whereas the shorter is present at lower levels. Aprataxin contains three functional domains: A N-terminal forkhead-associated (FHA) domain (exons 1–3), a central histidine triad (HIT) domain (exons 4–6), and a C-terminal divergent zinc-finger (exon 7). Aprataxin is also predicted to have a potential nuclear localization signal between the FHA and HIT domains. Aprataxin is believed to interact with PARP-1 and XRCC1 through its FHA domain, allowing a close interaction at BER sites. Aprataxin's HIT domain is able to catalyze the nucleophilic release of adenylate groups linked to 5′-phosphate termini, as well as the removal of 3′-phosphoglycolate and 3′-phosphate ends.

AOA1 lymphoblastoid cell lines (LCL) display an altered sensitivity to genotoxic stress. H_2O_2, MMS, and camptothecin, all SSB inductors, cause genomic instability and reduce cell survival compared with control LCL. Enhanced sensitivity to H_2O_2 can be reduced by transfecting AOA1 LCL with wild-type aprataxin. SSB repair is also impaired after UV light irradiation, resulting in cell death. Antioxidants have been shown to be useful in this model.

Together this information indicates an active role of Aprataxin in BER and SSB repair. Mutations may result in unrepaired SSBs and apoptosis, followed by neuronal loss and cerebellar atrophy.

Clinical Features

AOA1 is an autosomal recessive neurodegenerative disorder, first described in the Japanese and Portuguese population. Relative frequency, as estimated through molecular screening of non-Friedreich early onset (<25) progressive autosomal recessive ataxia, ranges from 6 to 9%, representing the most frequent recessive ataxia in the Japanese population. The most frequent AOA1 phenotype is associated with early-onset cerebellar ataxia with cerebellar atrophy, areflexia, and axonal sensorimotor neuropathy. The onset of the disease ranges from 2 to 18 years, although late onset (>25) has been reported. Hypoalbuminemia and hypercholesterolemia are variable and late features, and thus, not present in all patients. Choreic movements are frequent at onset, but often disappear during the course of the disease, except for those patients with A198V mutations that show persistence up to 10 years after onset. Mild cognitive impairment may also be present, and represents a frequent finding in Japanese families. In contrast, Portuguese and Tunisian families showed no mental deterioration despite long disease duration.

AOA1 presents with square wave jerks, saccadic pursuit, gaze-evoked nystagmus, and hypometric saccades. In addition, patients show normal vestibulo-ocular reflex (VOR), but cancellation is defective. Dissociation of eyes and head movements when looking toward a lateral target in the head-free condition is present in 80% of the patients. It closely resembles oculomotor apraxia (OMA).

Genome-wide analysis was performed in a family with ataxia and coenzyme Q10 deficiency, showing linkage to chromosome 9p13. *APTX* mutations were identified, indicating that coenzyme Q10 deficiency may contribute to the pathogenesis of AOA1.

Postmortem examination has revealed severe loss of Purkinje cells and degeneration of the posterior columns, spinocerebellar tracts, and anterior horn cells of the spinal cord. Nerve biopsies show marked loss of small and large myelinated fibers, with preservation of small unmyelinated fibers.

Brain MRI shows cerebellar atrophy in all patients. Cerebellar hypoperfusion was present in SPECT imaging. Dopamine transporter density was studied with (FPCIT)-SPECT in four patients. It showed a slight bilateral and uniform reduction of the average striatal DAT density, impairment that occurred even in the absence of extrapyramidal features, suggesting a subclinical involvement of the basal ganglia.

Differential Diagnosis

Differential diagnosis is usually made among Friedreich's ataxia (FA), ataxia-telangiectasia (A-T), chorea, and hereditary neuropathies. The absence of oculo-conjunctival telangiectasias, cancer predisposition, immunodeficiency, and normal α-fetoprotein levels can allow exclusion of A-T. FA patients show extensor plantar reflexes, altered electrocardiograms, and cardiomyopathy without marked cerebellar atrophy or OMA. The presence of involuntary movements in AOA1 may pose a differential diagnosis with other

choreas. Cerebellar atrophy at MRI and the presence of peripheral neuropathy may be helpful in the diagnosis.

Management

Coenzyme Q10 administration ($>600\,\mathrm{mg\,day^{-1}}$) to AOA1 patients was reported to be beneficial and well tolerated, but future clinical trials are warranted to confirm this finding. Idebenone, a Q10 synthetic analog used in Friedreich' ataxia, could also be proposed. Beneficial effects of antioxidants on SSBs in cellular models suggest that their clinical use should be studied.

Apraxia: Upper Limb

K M Heilman, University of Florida, Gainesville, FL, USA; North Florida/South Georgia Veterans Health System, Gainesville, FL, USA

Glossary

Apraxia – A loss of the ability to perform purposeful skilled movements that cannot be accounted for by weakness, sensory loss, abnormal movements, impaired comprehension, or cognitive disorders.

Body part as tool error – Patients with ideomotor rather than pantomiming tool use will often use their fingers and hands as the tool.

Callosal apraxia – Injury to the corpus callosum that prevents motor programs stored in one (dominant) hemisphere from reaching the other hemisphere (nondominant) such that the hand contralateral to the nondominant hemisphere has a loss of the ability to perform skilled purposeful movements.

Conceptual apraxia – A loss of mechanical knowledge including tool–object relationships, tool–action relationships, and mechanical advantage of tools.

Deftness-dexterity – Ability to make precise, independent, but coordinated finger–hand movements.

Dissociation apraxia – An inability to correctly use the upper limb in response to a stimulus of one type or in one modality (e.g., verbal command) with preserved ability to perform in response to stimuli in a different modality (e.g., vision).

Ideational apraxia – A loss of the ability to perform a correct sequence of acts leading to a goal.

Ideomotor apraxia – Making spatial and temporal errors when using tools, pantomiming or imitating purposeful acts.

Limb-kinetic apraxia – A loss of deftness. This disorder is also called innervatory apraxia.
Premotor areas (including supplementary motor area) – Regions in frontal lobe, anterior to motor cortex, that is thought to translate spatial temporal movement representations to motor programs.
Supramarginal gyrus – Portion of the inferior parietal lobe that, when damaged, often induces ideomotor apraxia. This area is thought to store movement representations.

Introduction

Only organisms that perform goal-directed actions have brains, and hence one of the most important functions of the brain is to program movements that will allow the organism to successfully alter the environment or themselves. In humans, it is primarily the upper extremity or forelimb that we use for performing these goal-directed actions. The joints and muscles of the human forelimb allow people to perform almost any type of movement, and the corticospinal system that activates specific motor units can mediate an almost infinite number of movements. Thus, in order to successfully interact with the environment, the corticospinal neurons in the cerebral cortex must be guided by instructions or movement programs. Disorders in the implementation of these programs are termed apraxia.

There are many forms of apraxia, and this term has been used to describe abnormal control of movements of the eyes, mouth (e.g., buccofacial apraxia and apraxia of speech), and the legs (e.g., apraxia of gait). We, however, confine our discussion to apraxia of the forelimbs. There are two major forms of forelimb apraxia: task specific and general. Task-specific apraxia includes dressing and constructional apraxia, which will not be discussed in this article. We discuss general forms of forelimb apraxia, which can impair almost all purposeful movements made by the forelimb.

Apraxia is defined both by what it is not and what it is. After Liepmann's seminal papers in the early part of the twentieth century, there was little interest in this disorder until Geschwind's classic paper on 'Disconnexion Syndromes,' in which he resurrected interest in this disorder. Geschwind defined apraxia as a disorder in which a person makes clumsy movements as a result of a neurological disease, but this disorder is not considered as an apraxia if clumsiness is caused by weakness, abnormal movements such as tremor, chorea, ballismus, and myoclonus, severe sensory-perceptual deficits, or cognitive impairments such as an impaired comprehension or attention. There are several types of general forelimb apraxia, which are characterized by the errors made by the patients. In this article, we discuss five different forms of general forelimb apraxia including (1) conceptual, (2) ideomotor, (3) ideational, (4) dissociation, and (5) limb-kinetic. In addition to briefly describing the clinical aspects of these five forms of limb apraxia, the pathophysiologic disorders that might account for these deficits are also briefly discussed.

The five forms of general limb apraxia, which are discussed in this article, can be induced by a variety of diseases. Some of these diseases cause focal damage, such as that caused by a cerebral infarction, but apraxia can also be associated with degenerative diseases where the brain pathology is more widely distributed such as Alzheimer's disease or corticobasal degeneration. The specific diseases that can induce apraxia, however, will not be fully discussed in this article.

Conceptual Apraxia

Clinical

When a person is presented with a situation that requires forelimb actions to alter either themselves, such as combing hair, or objects in their environment, such as fixing a flat tire, the first thing a person must do is to see what is needed. Although there are animals that use tools and rare examples of animals that actually fabricated tools, it is primarily humans who develop and use tools to alter themselves and their environment. There are, however, patients who, when presented with a problem that requires an action, sometimes cannot recognize the required action, the required tool, or both. In addition, there are also patients with conceptual apraxia who might not recall the type of actions associated with specific tools, utensils, or objects (i.e., tool–object action associative knowledge) and therefore, make content errors. For example, when asked to demonstrate the use of a screwdriver by either pantomiming or using the tool, the patient without a visual agnosia might pantomime a hammering or pounding movement or use the screwdriver as if it were a hammer.

Patients with conceptual apraxia might be unable to recall which specific tool (e.g., hammer) is associated with a specific object (e.g., nail), thereby revealing impaired tool–object associative knowledge and a loss of mechanical knowledge. For example, when attempting to drive a nail into a piece of wood, if there is no hammer available, the patient with conceptual apraxia might select a screwdriver rather than a wrench. In addition, since mechanical knowledge is also important for tool development, patients with conceptual apraxia are often unable to correctly develop tools.

Pathophysiology

While Liepmann thought that conceptual knowledge is stored in the caudal parietal lobe, DeRenzi and Luccelli

located these representations in the temporal–parietal junction. There are two forms of evidence that these representations are stored in the hemisphere contralateral to the preferred hand. Patients with a callosal disconnection demonstrate conceptual apraxia of the nonpreferred (left) of their left (nondominant) hand. Heilman et al. studied right-handed patients who had either right or left hemisphere cerebral infarctions and found that conceptual apraxia was more commonly associated with the left than the right hemisphere injury. Although these investigators attempted to learn the locus of injury that induced conceptual apraxia, no specific anatomic region appeared to be critical. This might be related to having an inadequate number of subjects, or that each subtype might have a different localization, or that in right-handed people, mechanical knowledge may be widely distributed in the left hemisphere. As mentioned, conceptual apraxia can be associated with diseases that cause focal brain damage, such as stroke, but it is commonly seen in patients suffering from Alzheimer disease.

Ideomotor Apraxia

Clinical

Patients with ideomotor apraxia (IMA) make primarily spatial errors that cannot be attributed to a loss of deftness (LKA). Three types of spatial errors can be observed: (1) postural or internal configuration errors, in which patients fail to put their hand and arm in the position that would enable them to correctly hold a tool or implement. Often, patients use their hand and fingers as the tool, and unlike normal subjects, will continue to use a body part as tool even when corrected; (2) spatial movement errors, in which patients either move the incorrect joint or joints or do not properly coordinate joint movements and therefore move the hand and arm incorrectly through space; and (3) spatial orientation errors, in which patients do not consistently orient the tool-implement at the target-object. The most sensitive test for IMA is asking patients to gesture (pantomime) to verbal command. Patients with IMA often perform more poorly with transitive ('Show me how you would scramble eggs with a fork') than intransitive acts ('Wave bye-bye.'). Although patients with IMA typically improve when imitating the examiner pantomime a transitive act, their performance often remains impaired. In addition, when using actual tools, their performance might improve even further, because they are provided with visual and tactile cues, but their performance often remains abnormal.

When one forelimb has an elemental sensorimotor disorder that would preclude meaningful testing, the opposite ipsilesional limb should be tested. When possible, both forelimbs should be tested. In addition to testing gesture to command, imitation, and use of actual objects, patients should also be tested to learn whether they can comprehend the examiner's pantomimes of transitive movements and the examiner should also perform correct and incorrect pantomimes to learn whether the patient can discriminate.

Pathophysiology

IMA is almost always induced by left hemisphere lesions in patients who are right-handed and is associated with injury to several structures, including the inferior parietal lobe and the premotor cortex (supplementary motor area and convexity premotor cortex) as well as the corpus callosum. Subcortical lesions that involve the basal ganglia, the thalamus, and the white matter connecting these areas with the cortex can also be associated with IMA.

Callosal disconnection

Liepmann and Maas reported Ochs, a right-handed patient with a lesion of his corpus callosum, who was unable to correctly pantomime to commands with his left arm. Unfortunately, this patient's right hand could not be tested because he had a right hemiparesis from a pontine lesion. Paul Broca had demonstrated that in people who are right-handed, the left hemisphere is dominant for mediating language. Although Ochs' inability to pantomime to verbal command with his left hand could be attributed to a disconnection between language mediated by the left hemisphere and the right hemisphere's motor areas (a language–motor disconnection), a language–motor disconnection could not explain why this patient could not imitate or use actual tools. Instead, Liepmann and Maas suggested that the left hemisphere of right-handed people contains movement formulas (i.e., the spatial temporal patterns required to make purposeful skilled movements) and that the callosal lesion disconnected these movement representations from the right hemisphere's motor areas.

Watson and Heilman, as well as Graff-Radford and colleagues, reported patients similar to Ochs, who could not correctly pantomime or imitate transitive acts, but unlike Ochs, these patients had infarctions limited to the corpus callosum. These patients did not have weakness of their right hand and performed tasks such as pantomiming to command, imitation, and the use of actual objects, flawlessly with their right hand. These patients' behaviors suggest that not only language but also spatial-temporal movement representations (movement formula) were stored in the left hemisphere, and callosal injury disconnected these movement representations from the right hemisphere.

Left hemisphere injury

Liepmann studied a population of right-handed patients who had damage to either the left or the right hemisphere. While none of the patients with right hemisphere damage

had apraxia, about 50% of the patients with left hemisphere injury had IMA. Many patients with IMA are also aphasic, and some have thought that both aphasia and apraxia are symptoms of asymbolia, an inability to use signs. Liepmann noted, however, that some apraxic patients did not have aphasia and some aphasic patients were not apraxic. These behavioral dissociations provide evidence against the postulate that apraxia is a form of asymbolia.

Parietal lobe

Liepmann noted that many patients with IMA had injury to the inferior parietal lobe, especially, the supramarginal gyrus. In order to explain why lesions in this region would induce IMA of both hands, Geschwind posited that, the lesions in the left hemisphere could induce a disconnection syndrome. Thus, when a patient is given a command to perform a gesture, the incoming verbal message is decoded in Wernicke's area, but this message must then be transmitted to the left premotor convexity cortex for the command to be implemented by the left primary motor cortex. According to Geschwind, the lesion of the supramarginal gyrus injures the white matter pathway that connects Wernicke's area, located in the posterior–superior temporal lobe, with the left hemisphere's convexity premotor cortex. The left hemisphere's premotor cortex connects with the motor cortex of the left hemisphere as well as the premotor cortex of the right hemisphere. According to Geschwind, when carrying commands with the right hand, people use the former pathway and when using the left hand, the latter pathway; interruption of this pathway in the parietal lobe would cause IMA of both hands.

When attempting with either hand to imitate or use actual objects patients who have IMA from left inferior parietal lesions are impaired. Although the left hemisphere disconnection hypothesis of Liepmann–Geschwind can account for failure to correctly pantomime to command, this disconnection hypothesis cannot account for these imitation and actual tool-use disorders. Although the left hemisphere lesion might have also disconnected visual association cortex from motor areas, these patients' right hemispheric connections (between the anterior motor areas and the posterior visual areas) are intact and these patient should be able to normally imitate and use tools and implements with the left forelimb.

An alternative hypothesis was advanced by Heilman et al. and Rothi et al., who suggested that, in right-handed people, the movement formula or representations that contain the spatial and temporal parameters of purposeful actions are stored in the left parietal lobe. If these movement representations are degraded or destroyed, not only should there be deficits of pantomiming to command, imitating, and using actual objects, but these patients should also have gesture/pantomime comprehension deficits and a loss of the ability to discriminate between correctly and incorrectly performed purposeful actions. In order for these spatial temporal movement representations to guide-program purposeful actions, they have to have access to the premotor and motor cortex. Thus, injury to the projections from these movement representations to the premotor cortex or injury to the premotor cortex would be expected to also induce IMA. However, unlike left hemisphere inferior parietal lesions that destroy the movement representations, the anterior lesions should not induce gesture comprehension and discrimination disorders. To test this hypothesis, Heilman et al. and Rothi et al. tested patients with anterior and posterior left hemisphere cerebral lesions by attempting to learn whether they had IMA and whether they had a disorder of pantomime comprehension and discrimination. We found that while both the anterior and posterior groups of patients had the production deficits typical of IMA, only the patients with damage to the inferior parietal lobe had comprehension and discrimination disturbances.

Halsband and coworkers replicated Heilman et al. and Rothi et al.'s findings. In addition, Haaland et al. studied the localization of lesions that induce and those that do not induce apraxia. They found that, in addition to patients with frontal convexity lesions, patients with IMA most often had lesions in the region of the intraparietal sulcus (the top of the supramarginal gyrus), but also in the superior parietal lobe (Brodmann's area 7). Haaland et al. also found that many of their patients had subcortical damage that disconnected the pathways between the occipital and frontal cortex. However, these patients were able to normally imitate. Convergent evidence for the postulate that the left inferior parietal lobe stores movement representations comes from functional imaging studies performed with normal right-handed subjects.

Supplementary motor area

The movement representations that are stored in the left inferior parietal lobe are probably stored in a three-dimensional supramodal (temporal, visual-spatial and temporal kinesthetic-spatial) code. Before the neurons in the motor cortex are properly activated, the stored spatial-temporal movement representations have to be transformed into a motor program. The supplementary motor area receives projections from parietal neurons and projects directly to the motor cortex (Brodmann's area 4). Studies have revealed that neurons in the supplementary motor cortex (SMA) discharge before neurons in the primary motor cortex. The SMA also projects to convexity premotor cortex, the basal ganglia, and directly to the motor neurons in the spinal cord. Functional imaging studies of cerebral blood flow, an indicator synaptic activity, have revealed that simple repetitive movements increase the activation of the contralateral primary motor cortex. In contrast, complex movements increase flow in contralateral motor cortex and in the supplementary

motor area. When subjects remain still and think about making complex movements, however, the blood flow to the SMA increases but not to the primary motor cortex. Watson et al. reported several patients with IMA from left-sided medial frontal lesions that included the supplementary motor area. These patients with SMA lesions, unlike patients with left inferior parietal lesions, could both comprehend pantomimes and discriminate between correctly and incorrectly performed pantomimes.

Convexity premotor cortex

While Liepmann did not believe that injury to the convexity premotor cortex induced IMA, Geschwind posited that when a person pantomimes to command, the information from Wernicke's area travels to the convexity premotor cortex via a white matter pathway that parallels but is superior to the arcuate fasiculus. Faglioni and Basso, however, mention that they had difficulty in finding well-documented cases in which patients suffered from apraxia because of injury to the convexity premotor region; Kolb and Milner, Barrett et al., and Haaland et al. did report patients with frontal premotor injury who appeared to have an apraxia.

In Haaland et al.'s study, the investigators used the lesion overlap method for localization of the premotor lesions that are associated with IMA and found that the middle frontal gyrus appeared to be the critical area. Freund and Hummelsheim studied patients with convexity premotor lesions and also found that these patients were apraxic but had limb-kinetic, rather than IMA.

Basal ganglia and thalamus

Although IMA is most commonly associated with cortical lesions, there have been reports that IMA can also be associated with subcortical lesions. Pramstaller and Marsden performed a meta-analysis of 82 cases of apraxia that were reported to be induced by subcortical lesions and concluded that lesions confined just to the basal ganglia (putamen, caudate nucleus and globus pallidus) rarely, if ever, cause apraxia.

In many of these studies reviewed by Pramstaller and Marsden, the subjects were tested with imitation and scored as correct versus incorrect, which may have limited the qualitative analysis of errors. To better elucidate the role of the basal ganglia in the production of learned skilled movements, Hanna-Pladdy et al. compared patients with cortical and subcortical strokes. Both groups made apraxic errors, but the patients with cortical lesion were more severe and had discrimination deficits. The subcortical group made more postural errors, but the patients with cortical lesions made more sequencing and content errors. These behavioral dissociations suggest that the subcortical structures make an independent contribution to the praxis processing system.

There have also been several case reports of patients who developed apraxia from lesions of the left thalamus in the region of the pulvinar nucleus. This nucleus is strongly connected with the inferior parietal lobes and this thalamic cortical network might be important for normal parietal lobe functions.

Dissociation Apraxia

Clinical

Patients with dissociation apraxia are unable to carry out a transitive act in response to stimuli in a certain modality, but are able to normally respond when the stimulus is presented in another modality. For example, Heilman described three patients who when asked to pantomime to verbal command, looked at their hand but failed to perform any recognizable actions. However, when shown the implement or tool, they had no trouble correctly performing the transitive pantomime. They also had no trouble while imitating the examiner or using actual tools and implements. As mentioned, patients with IMA have impairment even when they see the tool or object upon which this tool works as well as with imitation and use of objects. Subsequently, DeRenzi et al. reported patients similar to those reported by Heilman, but also patients who did not have a visual agnosia but who could not perform correctly when seeing a tool. However, they performed normally to verbal command. Other blindfolded patients had a similar modality-specific defect in the tactile modality.

Merians et al. described a patient with a left ventral temporal occipital lesion, who was impaired at imitation, but not pantomiming to command, suggesting another form of dissociation apraxia, which has also been called 'visuo-imitative apraxia' and 'conduction apraxia.' The patients described by Heilman and DeRenzi et al. demonstrated this modal-specific apraxia in both hands; Geschwind and Kaplan as well as Gazzaniga et al. described patients who could not perform normally to verbal command with their left hand but who could perform normally with their right hand. Unlike patients with callosal IMA described earlier, these patients could normally imitate and use actual objects with their left hand. Thus, these patients with callosal disconnection had a 'verbal callosal dissociation apraxia.'

Pathophysiology

We have suggested that the patients with verbal callosal dissociation apraxia have their brains organized differently than those patients who have an IMA of their left forelimb induced by injury to the corpus callosum. Whereas in the former patients (verbal callosal dissociation apraxia), their left hemisphere mediates speech-language, and their movement representations are stored

bilaterally. In contrast, the right-handed patients who have both language and movement formula represented in their left hemisphere may show a combination of verbal disassociation and IMA of their left forelimb as a result of a callosal lesion. Hence, when asked to pantomime with their left hands, they may look at them and perform no recognizable movement (disassociation apraxia), but when imitating or using actual tools and objects, they may demonstrate the spatial and temporal errors seen with IMA. The patients reported by Heilman and DeRenzi and associates who had dissociation apraxia of both hands probably had left hemisphere injury that induced either a hemispheric language-movement formula disconnection, a vision-movement formula disconnection, or somesthesic-movement formula disconnection. Thus, depending on the location of the lesion, stimuli from one of these modalities (e.g., speech-language) were not capable of activating the movement representations, but stimuli in other modalities (e.g., vision) were able to activate these representations. Unfortunately, the anatomic loci of the lesions that cause many of these intrahemispheric disassociation apraxias remain unknown.

Ideational Apraxia

Clinical

The term ideational apraxia has been used to label many different disorders. For example, it has been used for the syndrome we now call dissociation apraxia. It has been used for patients with what we now call conceptual apraxia and finally patients with IMA who are impaired when they use actual tools and implements. In this article, as proposed by Leipmann, this term will be used for the disorder, first described by Marcuse and Pick, in which patients have an inability to correctly sequence a series of acts, an ideational plan. Thus, the most important test for making the diagnosis of ideational apraxia is having the patient perform a task that requires several sequential motor acts (e.g., making a sandwich).

Pathophysiology

Most often, the patients with ideational apraxia have some form of degenerative dementia. This disorder, however, has not been systematically studied in the various forms of degenerative dementia. Liepmann thought that lesions in the left occipital parietal region induced this disorder, but support for this hypothesis is not strong.

Injury to the prefrontal regions, especially in the left hemisphere, is commonly associated with temporal and sequencing processing deficits, but as mentioned, the critical anatomic focus of dysfunction in ideational apraxia remains unknown.

Limb-Kinetic Apraxia (Melokinetic Apraxia, Innervatory Apraxia)

Clinical

In addition to understanding the nature of the problem that requires action, having the knowledge of the tool required to successfully perform this action as well as the knowledge of the postures, joint movements, speeds, and forces that are needed to perform the purposeful act, a person needs to have the ability to make precise, independent, coordinated movements (dexterity or deftness). A loss of this deftness has been called limb-kinetic apraxia by Liepmann.

There are many tests of deftness or dexterity, but we have found the coin rotation task, in which the patient is asked to rotate a nickel between their thumb, index, and middle fingers, as rapidly as possible for 20 revolutions, to be easy to perform and very sensitive. Typically, patients with hemispheric damage have a contralateral loss of deftness. However, Heilman, Meador and Loring, as well as Hanna-Pladdy and colleagues have found that people with right hand preference are more likely to have an additional ipsilateral loss of deftness (LKA) with left than right hemispheric injury.

Pathophysiology

Liepmann thought that the lesion that induces limb-kinetic apraxia includes the primary sensorimotor cortex. More recent support for this postulate comes from the work of Lawrence and Kuypers, who demonstrated a loss of precision grasp in monkeys with corticospinal tract lesions. However, several studies have suggested that portions of the convexity premotor cortex are also important for programing deft movements. Freund together with Hummelsheim as well as Fogassi and colleagues showed that damage to the premotor cortex is associated with LKA. Nirkko and coworkers provided converging evidence, using fMRI, demonstrating that discrete unilateral distal finger movements were associated with activation of the convexity premotor cortex.

As mentioned, left hemisphere injury in right-handed people can induce ipsilateral LKA and patients with right hemisphere dysfunction have LKA primarily limited to their left hand. These observations suggest that the left hemisphere might have stronger ipsilateral control of spinal motor neurons than does the right hemisphere. While physiological studies appear to support this postulate, it remains unclear whether this control is mediated by ipsilateral corticospinal pathways or via the corpus callosum.

Summary

This article describes the clinical characteristics that define the five forms of forelimb apraxia and also discusses

the possible neural mechanisms. Based on this information, we have proposed an anatomically distributed modular network that is responsible for mediating purposeful skilled movements. When a person determines that something needs to be altered, he/she must decide whether a tool is needed, and if so, what tool can best accomplish this goal. The person must also know what action that tool performs. When the correct tool is not available or a new tool is needed, the person also needs to know the mechanical advantage that tools afford and how this could be accomplished by alternatives. A loss of this knowledge is called conceptual apraxia. In right-handed people, this knowledge is stored in the left hemisphere, but the exact locations of these representations are unknown. After a person selects a tool, he/she has to have the knowledge of the posture needed to hold and use this tool as well as the egocentric movements that permit this tool to be properly moved through space and the allocentrically oriented movements that allows the tool to work on objects that require action. In this model, movement (temporo-spatial) representations are stored in the left parietal lobe, and degradation of these movement representations or damage to the premotor cortex that translates these spatial-temporal representations into motor programs induces IMA. These movement representations have to be activated by auditory (speech), visual, or kinesthetic systems input. If one of these input modalities cannot activate these movement representations, there is a modality-specific deficit in performing these learned skilled acts, and this disorder is called dissociation apraxia. The motor program formulated by the premotor cortex must be implemented by the motor cortex that activates the motor neurons in the spinal cord. Injury to the corticospinal system induces a loss of deftness, which is called limb-kinetic apraxia. Many goals require a series of independent acts that must be performed in a specific temporal sequence; an inability to correctly sequence a series of acts to achieve a goal is called ideational apraxia, which might be a sign of frontal-executive dysfunction.

Aromatic Amino Acid Decarboxylase Deficiency

R Pons, University of Athens, Athens, Greece

Glossary

Aromatic L-amino acid decarboxylase (AADC) – Enzyme that catalyzes the conversion of 5-hydroxy-tryptophan and levodopa into serotonin and dopamine, respectively.
Biogenic amines – Naturally occurring monoamines that act primarily as neurotransmitters. They include serotonin and catecholamines (dopamine, epinephrine, and norepinephrine).
Oculogyric crisis – Paroxysmal dystonia characterized by eye deviation associated or not with axial and limb dystonia. It is characteristic, thought not exclusive, of inherited disorders leading to dopamine deficiency.

Pediatric neurotransmitter diseases – Group of genetic disorders involving the metabolism of neurotransmitters.

Definition and History

Aromatic L-amino acid decarboxylase (AADC) deficiency is an autosomal recessive inborn error of metabolism that involves the biosynthesis of monoamine neurotransmitters. This disorder was first described in 1990 by Hyland et al. in two twin boys who presented early in life with motor, extrapyramidal, and autonomic symptoms; decreased monoamine metabolites in cerebrospinal fluid (CSF), and severely reduced AADC activity in plasma. Since then, ~75 patients have been diagnosed. In 1998, the first mutations in the AADC gene were reported and it became evident that the spectrum of mutations is heterogeneous.

Pathophysiology

Monoamine neurotransmitters include serotonin and the catecholamines dopamine, adrenaline, and noradrenaline. These compounds have multiple functions including modulation of psychomotor function, cardiovascular, respiratory and gastrointestinal control, sleep mechanisms, hormone secretion, body temperature, and pain.

AADC plays an important role in the synthesis of monoamines. It is a pyridoxal-phosphate-dependent enzyme that converts levodopa to dopamine and 5-hydroxytryptophan to serotonin. The catabolism of monoamines leads to the formation of 5-hydroxyindolacetic acid (5-HIAA) from serotonin, homovanillic acid (HVA) from dopamine, and 3-methoxy-4-hydroxyphenylethyleneglycol (MHPG) from norepinephrine (**Figure 1**).

Decreased activity of AADC leads to decreased production of the monoamine neurotransmitters and to the accumulation of their precursors 5-hydroxytryptophan and levodopa. It also leads to the accumulation of 3-*O*-methyldopa, which is the result of methylation of levodopa (**Figure 1**).

The clinical manifestations in AADC deficiency derive from the deficiency of monoamine neurotransmitters in the developing brain and in the peripheral nervous system. Reduced levels of dopamine are thought to be the origin of the motor symptoms. Norepinephrine and epinephrine deficiency are responsible for the manifestations of autonomic sympathetic dysfunction, while serotonin deficiency is associated with sleep disturbances. Yet, some manifestations cannot be attributed to one specific neurotransmitter deficit, such as cognitive and behavioral

disturbances. Given the role of monoamines in hormonal function, evidence of endocrine dysfunction is also characteristic. Other factors implicated in the pathophysiology of this disorder are neurotransmitter imbalance and changes in receptor sensitivity.

Epidemiology

Currently, ~75 patients have been diagnosed with AADC deficiency. Over half of the total patients are in Asia. The largest single population is in Taiwan, with ~30 patients. A common splicing mutation has been identified in 81.3% of patients from Taiwan, and haplotype analyses have been consistent with a common ancestral origin. The calculated allele frequency for this mutation among the Taiwanese population is 1:508.

Clinical Features and Diagnostic Criteria

Clinical onset occurs within the first months of life, with more than half of patients presenting some symptoms during the neonatal period, including feeding difficulties, hypotonia, autonomic dysfunction, and/or hypoglycemia.

The majority of patients come to medical attention due to motor symptoms and paroxysmal events. The motor symptoms include axial hypotonia with fluctuating appendicular tone, decreased spontaneous movements with poor facial expression, and delayed motor development. The latter is so severe that patients fail to make any motor acquisition. Although tremor is not often seen in these infants, their striking hypokinesia and their fluctuating limb tone with rigidity, at times, are consistent with infantile parkinsonism.

The majority of patients develop paroxysmal dystonic events within the first months of life. These events are oculogyric crises. They are characterized by eye deviation upward, convergent, or to the side, that may occur on and off from minutes-to-hours. They may be associated with prolonged dystonic posturing of the limbs and/or the trunk. During these events patients are conscious but distressed. Seldom, some patients with AADC deficiency suffer from generalized tonic–clonic seizures.

Often, AADC-deficient patients show other types of movement disorders, especially dystonia, in particular limb, stimulus-induced and segmental cranial dystonia. They may also show prominent startle, myoclonus, and distal chorea. Less often patients develop choreoathetosis, nonepileptic flexor spasms or tremor.

Aggravation of neurologic symptoms late in the day and/or improvement by sleep is noted in many patients. Additionally, the occurrence of oculogyric crises is mainly in the afternoon or in the evening.

The majority of patients show some feature of autonomic dysfunction including ptosis and miosis, excessive diaphoresis, nasal congestion, temperature instability, and gastrointestinal dysmotility. Recurrent episodes of cardiorespiratory arrest with painful stimuli, hypersensitivity to exogenous cathecolamines and cardiac arrhythmias may also occur.

Sleep disturbances including increased sleeping time, frequent awakenings at night and insomnia are often noted. Also common are dysphoric mood with inconsolable cry, irritability, and moodiness. The majority of patients are nonverbal, though they are often able to interact with the environment. Cognitive testing in the more functional patients indicates mild-to-moderate mental retardation. Seldom, autistic syndrome and features of pervasive developmental disorders have been identified.

Although endocrine dysfunction is not documented very often, AADC-deficient patients can show recurrent episodes of hypoglycemia early in life, probably due to the lack of catecholamines as anti-insulinergic hormones. Delayed bone maturation and short stature reported in some patients is considered to be due to the lack of induction of growth hormone by catecholamines. Hyperprolactinemia due to dopamine deficiency is also documented.

Other features include failure to thrive, small hands and feet, hypersensitivity to light stimulation, tendency to breath-holding and apneic spells.

There have been occasional reports of patients with variable milder phenotypes. A few patients showed development of axial control by 2–3 years; while one showed independent gait by at 2½ years of age with remarkable fatigability.

Differential Diagnosis

The differential diagnosis of AADC deficiency includes neuromuscular disorders given their profound hypotonia and hypokinesia. The possibility of congenital myasthenia was raised in a mild case with ptosis, fatigability, and weakness of the cranial musculature.

Prolonged oculogyric crises associated with limb and/or axial dystonia may be misdiagnosed as seizures, while temperature instability during the neonatal period may be considered as an early sign of a serious infection. Hypoglycemia early in life may raise the diagnosis of an inborn error of intermediary metabolism, while prominent startle response may raise the diagnosis of hyperekplexia.

The clinical manifestations of other pediatric neurotransmitter disorders may be very similar. The pattern in CSF of monoamine metabolites and pterins, together with enzymatic and molecular analysis, points to the precise diagnosis.

A CSF pattern suggesting AADC deficiency has been detected in some patients with a severe infantile epileptic encephalopathy due to pyridoxamine 5′-phosphate oxidase deficiency. This disorder leads to decreased production of the biologically active form of pyridoxine; consequently the pyridoxine-dependent enzyme AADC is secondarily affected.

Diagnostic Work Up

The measurement of monoamine metabolites in peripheral fluids is generally uninformative, while their levels in CSF reflect the turnover of serotonin and catecholamine neurotransmitters within the brain. So, when there is clinical suspicion that a patient suffers from a pediatric neurotransmitter disease, a spinal tap is necessary. The diagnosis of AADC deficiency is based on the pattern of monoamine metabolites in CSF showing reduced levels of HVA, 5-HIAA, and MHPG; increased levels of the precursors levodopa and 5-hydroxytryptophan; and increased levels of 3-*O*-methyldopa (**Figure 1**).

Urine organic analysis searching for elevation of vanillactic acid, the result of 3-*O*-methyldopa transamination, may be used to further support the diagnosis. Amino acid analysis in blood is usually noninformative in AADC deficiency. However, if differential diagnosis with disorders of tetrabiopterin metabolism is raised, measurement of phenylalanine levels and analysis of tyrosine and phenylalanine levels after a load of phenylalanine may be of help.

Definite diagnosis with the analysis of AADC activity in plasma is done in a few laboratories, while molecular analysis of the AADC gene is more easily available in research and commercial laboratories. Analysis of AADC activity in plasma reveals residual activities ranging from undetectable to 8% of control values. When enzyme analysis is not available, diagnosis can be made with molecular analysis of the AADC gene. Screening of the gene has led to the identification of a number of mutations and the majority correspond to missense mutations. Patients are either homozygous for a given mutation or compound heterozygous. Recently, a common splice site mutation has been detected in a group of patients from Taiwan.

Neuroimaging studies are often normal, though in some cases they may show brain atrophy. F-18 Dopa positron emission tomography scan has shown virtually absent uptake of tracer. EEG studies are either normal or they show nonspecific findings. Epileptiform discharges have been reported in patients with epilepsy.

Treatment

The main goal in the management of AADC deficiency is to potentiate monoaminergic transmission. The main drugs used are dopamine agonists and monoamine oxidase (MAO) inhibitors, often administered in combination. Early patients were treated with the dopamine agonists bromocriptine and pergolide. Given the potential adverse effects associated with these medications (severe fibrotic reaction), more recently ropirinole and pramipexole have been used instead. MAO inhibitors include the nonselective inhibitors tranylcypromine and phenelzine and the MAO B inhibitor selegiline.

Treatment with levodopa is not given, since deficient AADC activity precludes monoamine production and administration of levodopa would promote further accumulation of the precursor. However, levodopa provided a favorable response in three siblings who had a mutation in the AADC gene that involved the enzyme-binding site for levodopa.

Because pyridoxine is a cofactor of AADC, patients are generally supplemented with pyridoxine. However, no significant clinical response is usually noted.

A number of other of therapeutic strategies have been used erratically in AADC-deficient patients, including anticholinergics, melatonin, buspirone, serotonin reuptake inhibitors, indirect cathecholaminomimetics, amine reuptake inhibitors, ergotamine and local sympathomimetics.

Some patients show elevated plasma homocysteine and low CSF 5-methyltetrahydrofolate levels due to reduced methylation capacity, since *S*-adenosylmethionine is the methyl donor for the methylation of levodopa to 3-*O*-methyldopa. For this reason, folate supplementation is given in some patients.

Finally, because of the risk of cardiac arrhythmia and abnormal responses to pressors in AADC-deficient patients, anesthesia procedures in these patients should be conducted with close cardiac and hemodynamic monitoring.

Prognosis

Treatment with dopamine agonists and/or MAO inhibitors offers variable degrees of improvement in tone and hypokinesia, reduces the frequency and duration of oculogyric crises and improves autonomic dysfunction. In general, response to the other therapeutic strategies has not been encouraging, because of poor clinical response or poor tolerance.

Many patients, despite the improvements noted above, are not able to make meaningful motor development; while a few are able to make significant developmental progress, become verbal, ambulant, and responsive to educational interventions.

Earlier series of AADC-deficient patients suggested better response to treatment and prognosis in males than in females, but this has not been supported with the description of further cases. It appears that patients with

milder presentations show better response to treatment; thus neurological status at the time of diagnosis is an important prognostic factor.

Early onset of treatment appears to be a favorable prognostic factor. However, numerous patients who started treatment early in life show poor motor progress. On the other hand, tolerance to treatment also has prognostic implications. Patients may show drug-induced dyskinesias such as chorea or dystonia; or they may develop prominent adverse effects. Generally these patients show a poorer clinical outcome and it is unclear whether they would have shown a favorable response if they had been able to tolerate higher doses of medication, or whether they represent a subtype of AADC deficiency with a worse clinical phenotype.

Monoamine metabolite concentration in CSF and residual AADC activity in plasma do not appear to correlate with prognosis. It is unknown if there is any correlation between specific mutations and the severity of the clinical manifestations.

Acknowledgments

The author would like to thank Lisa Flint for providing unpublished data on the frequency of AADC deficiency reported worldwide.

Asterixis

L B Bahroo and E A Shamim, Georgetown University Hospital, Washington, DC, USA

Glossary

Asterixis – An involuntary jerking movement typically considered to be a form of subcortical negative myoclonus and characterized by variable rhythmic EMG-silent periods without any detectible standard electroencephalographic (EEG) correlate.
Miniasterixis – A variant of asterixis with jerk rates of 6–12 Hz.
Myoclonus – Shock-like movements that can be generated at the spinal cord, brainstem, or cortex from a variety of causes including toxic-metabolic, drug effects and neurodegenerative diseases.
Negative myoclonus – A form of myoclonus involving lightning-like jerks due to rapid loss of postures.

Clinical Syndrome

Asterixis is derived from the Greek words 'a' meaning 'not' and 'stērixis' meaning 'fixed position,' and was used to describe the rhythmic motor phenomenon reported by Adams and Foley in 1949 for a bilateral flapping tremor of

3–5 Hz in the setting of hepatic encephalopathy. Although the frequency is known to be highly variable, it is best described as a momentary lapse of sustained posture. The movement is asynchronous and typically involves the wrist, metacarpophalangeal joints, hip joints, and feet. Asterixis can also involve muscles of the face and tongue. In its most dramatic presentation, asterixis of the lower extremities results in drop attacks and falls without loss of consciousness. Asterixis in the upper extremities can be elicited when the arms are held in extension with the wrists dorsiflexed like a 'stopping traffic' posture. A transient loss of extensor tone results in the flexion of the wrist and the fingers. It can be elicited in the lower extremities when the hip and the knees are flexed and slightly abducted. The loss of adductor tone in the legs results in an intermittent abduction of the lower extremities.

Over time, the phenomenon has been described in the setting of many metabolic encephalopathies, as a side effect of medications and as a result of structural lesions. A variant with faster rates of 6–12 Hz with postural lapse may be referred to as 'mini asterixis' by some people. The precise neuroanatomic details of asterixis remain unclear. Case studies and electrophysiologic studies have shed light on the role of the central and peripheral nervous systems in asterixis. It is classified as a type of negative myoclonus.

Negative myoclonus can be classified clinically or etiologically. It is divided into four clinical categories: asterixis, physiologic negative myoclonus, postural lapses, and epileptic negative myoclonus (ENM). Based on etiology, negative myoclonus is divided into three distinct entities: asterixis seen with metabolic derangements, unilateral asterixis noted with focal neurological lesions, and ENM.

Anatomy and Pathophysiology

Asterixis by itself provides poor neuroanatomic localization, and much of the information on the possible pathways involved in the generation of asterixis is ascertained from case reports. It can be associated with a variety of lesions in the neuraxis. As a general rule, discrete structural lesions produce unilateral asterixis, while metabolic or toxic causes generally result in bilateral asterixis. Lesions of the posterior fossa and subcortical and cortical structures have also been reported to produce this phenomenon, which is generally believed to be subcortical in origin.

Negative myoclonus can be localized to the subcortical areas, including the brainstem, pons, thalamus, and internal capsule. Cortical regions such as the parietal and medial frontal areas can also be involved, and the frontal circuitry likely includes the supplementary and premotor regions. It is believed that this circuitry receives input from the inhibitory motor suppression regions. In the brainstem, there is input into the circuit from the reticular activating system, which likely accounts for the altered mentation frequently seen with asterixis.

The underlying mechanism for asterixis is extrapolated from the neuropathologic effects of hepatic and renal dysfunction, as both conditions are frequently associated with asterixis. Fluid shifts cause swelling of Alzheimer type II astrocytes and metabolic derangements, leading to compromise in the blood–brain barrier, upregulation of peripheral benzodiazepine receptor, and the production of neurosteroids. The exact mechanism of how the metabolic derangements lead to asterixis and why this circuitry is particularly vulnerable are unclear.

Since its initial description in patients with hepatic encephalopathy, asterixis has been reported in numerous metabolic encephalopathies, including uremia, sepsis, cardiac, or pulmonary dysfunction, and electrolyte abnormalities. It has been reported in malabsorption syndromes such as Whipple's disease when electrolyte abnormalities or nutritional deficiencies occur. Asterixis has even been reported in the setting of bariatric surgery and Wernicke's encephalopathy due to nutritional deficiency. In addition, it has been reported in acute alcohol withdrawal. Asterixis can be present concomitantly with positive myoclonus in the setting of anoxic encephalopathy (Lance Adams Syndrome).

Medications and toxins can also produce asterixis. The most common are sedatives such as benzodiazepines and barbiturates, and anticonvulsants such as phenytoin, carbamazapine, valproic acid, and gabapentin. Phenytoin is the most prominently reported antiepileptic culprit. Asterixis due to phenytoin is referred to as 'phenytoin flap.' Phenytoin can unmask latent unilateral asterixis due to structural lesions. Lithium is associated with asterixis at both toxic and therapeutic plasma drug levels. Asterixis occurring in patients with Parkinson's disease, hallucinations, and high levodopa doses usually remits with lower levodopa. Ceftazidime, a third generation cephalosporin, has been associated with truncal asterixis in the setting of renal failure. Asterixis likely relates directly to ceftazidime, because a case history demonstrated that it remitted when the antibiotic was discontinued even though renal function continued to worsen. The penetration of ceftazidime into the central nervous system has been postulated to be responsible for asterixis in this setting.

Unilateral asterixis is generally due to focal lesions, most commonly of the thalamus. Other lesions involve the internal capsule, corona radiata, anterior cerebral artery territory, primary motor cortex, and parietal lobe lesions. In the posterior fossa, cerebellar and midbrain lesions are implicated in asterixis. A prominent case has been reported of a mesencephalic stroke producing bilateral asterixis.

Electrophysiology

Asterixis is typically considered a subcortical negative myoclonus and characterized by rhythmic EMG silent periods without any detectible standard electroencephalographic (EEG) correlate. Jerk-locked back-averaging techniques and measurement of silent period-locked back-averaging have been applied to studying asterixis, but these studies typically have not demonstrated any associated cortical phenomenon. Early components of cortical potentials, measured by standard somatosensory evoked potentials, also appear to be un-enhanced in asterixis. Coherence studies averaging the EEG and EMG signals in patients with asterixis have demonstrated the presence of giant sensory evoked potentials and C reflex in some situations, but overall, the evidence of cortical involvement is uncommon. Electrical stimulation of the internal capsule can produce negative myoclonus.

Treatment

In order to treat asterixis effectively, it is paramount to treat the underlying condition. For example, in situations where hepatorenal dysfunction appears to be the culprit, effective treatment of the dysfunction slowly leads to the resolution of the motor phenomenon called asterixis.

Ataxia

J G Goldman, Rush University Medical Center, Chicago, IL, USA

Glossary

Anticipation – Increased symptom severity and earlier onset of symptoms in subsequent generations.
Dysdiadochokinesia – The breakdown or decomposition of coordination of different single-joint movement components when performing rapidly alternating or fine repetitive movements.
Dysmetria – Inaccuracy in judgment of distance of the trajectory of a body part during active movement, in range, direction, and speed. Hypermetria involves overshooting the target, and hypometria, undershooting the target.
Dyssynergia or asynergia – Often referred to as decomposition of movement, disruption of normal coordination and execution of a voluntary movement, particularly with multijoint movements.
Trinucleotide repeat disorders or polyglutamine disorders – Disorders due to CAG repeat expansions that encode the repeat of the amino acid glutamine in the disease protein; includes SCA1 2, 3, 6, 7, and 17, Huntington disease, spinobulbar muscular atrophy, and dentatorubropallidoluysian atrophy.

Definition and History

Historical Concepts

Early concepts of the cerebellum date back to Galen's time (130–200 CE). Galen proposed that the cerebellum was a valve that controlled the animal spirits flowing from spinal and cranial nerves, and was the site from which cranial nerves and the spinal cord originated. The English physician, Thomas Willis (1621–1675), discussed cerebellar control of involuntary movements as well as cardiac and respiratory functions. Subsequent animal experiments furthered our knowledge of cerebellar function

and pathology. For example, after partial removal of the median lobe of the cerebellum in a goat, Luigi Rolando (1773–1831) observed that the animal swayed and fell to one side or the other. Ablative lesions in the cerebellum in animals demonstrated irregular and clumsy movements, lack of muscular coordination, and changes in gait with functional recovery in some. In the nineteenth century, gait ataxia and tremors were observed in humans and discussed by Charcot and his students in France, Hammond in America, and Gowers in Britain. Much attention was focused on the distinction between cerebellar and sensory (proprioceptive) ataxia with the latter resulting from posterior column sclerosis as in tabes dorsalis. Patients with cerebellar ataxia were noted to have a staggering gait, jerky and irregular movements, but intact sensation and less postural sway with eyes closure than those patients with sensory ataxia. At the turn of the nineteenth century, the French neurologist, Babinski (1857–1932) introduced several terms that are still used today to characterize cerebellar abnormalities. He described asynergia, dysdiachokinesia, hypermetria, and deficits in acceleration and deceleration of movements. Holmes (1876–1965), an Irish neurologist, examined the effects of acute cerebellar injuries and wounds in World War I soldiers and observed hypotonia ipsilateral to the cerebellar lesion, rebound and loss of check. These clinical observations provide a basis for our neuroanatomical and phenomenological understanding of cerebellar disease and ataxia.

Cerebellar Neuroanatomy

This section briefly reviews cerebellar neuroanatomy as related to clinical findings. The cerebellum is located in the posterior fossa and consists of two large hemispheres and a midline structure, the vermis. The hemispheres are involved in motor planning and limb control, whereas the midline structures or vermis control motor execution, balance and gait, and ocular movements. The cerebellum consists of three main parts – the flocculonodular, anterior, and posterior lobes. In addition, the lobes are subdivided into lobules which carry several different names. Based on phylogenetic and embryological studies, the archicerebellum (oldest part) corresponds to the flocculonodular lobe, paleocerebellum consists of the anterior and posterior parts of the vermis except the nodulus, and the neocerebellum (newest part) corresponds to the hemispheres and the middle vermis.

Afferent projections from the vestibulocerebellum (originating from vestibular nerve and nuclei), spinocerebellum (originating from the dorsal and ventral spinocerebellar tracts), and pontocerebellum (originating from the contralateral hemisphere) correspond to the projections areas of the archicerebellum, paleocerebellum, and neocerebellum, respectively. Anatomic designation based on the efferent projections from the cerebellar cortex to the cerebellar nuclei divides the cerebellum into three longitudinal zones – medial (vermis) projecting to the fastigial nucleus, intermediate (paravermal) projecting to the interposed nuclei (globose and emboliform nuclei), and lateral (lateral hemisphere) zone projecting to the dentate nucleus. From the deep cerebellar nuclei, efferent fibers from the fastigial nucleus project to the vestibular nuclei and reticular formation via the inferior cerebellar peduncle, and are concerned with balance and ocular movements. From the interposed nuclei, efferent fibers project to the contralateral thalamus and red nucleus via the superior cerebellar peduncle and are involved in execution of movements and gait. Other efferent fibers travel from the dentate nuclei to the contralateral thalamus and then primary motor and frontal/prefrontal cortex as well as to the contralateral red nucleus and then spinal cord via the superior cerebellar peduncle and are involved in motor planning and limb coordination. Furthermore, the cerebellar cortex is somatotopically organized with two inverted homunculi (leg representation anteriorly in the anterior lobe and posteriorly in the posterior lobe).

The output neuron of the cerebellum, the Purkinje cell, is inhibitory to cerebellar nuclear neurons and uses γ-aminobutyric acid (GABA) as its neurotransmitter, whereas Purkinje cells receive indirect input from many excitatory granule cells via their input from mossy fibers, excitatory climbing fibers (mainly from the inferior olive) connect directly with Purkinje cells. Neurotransmitters in the cerebellum primarily include GABA, glutamate, norepinephrine, serotonin, histamine, and acetylcholine. Disruption of the cerebellar blood supply (posterior inferior cerebellar artery, anterior inferior cerebellar artery, and superior cerebellar artery) leads to distinct neurological deficits and stroke syndromes.

Clinical Definitions

The cerebellum functions primarily to modulate and coordinate movements. Cerebellar disease is often characterized by limb and gait ataxia, clumsy and irregular movements, and decreased coordination and balance. Ataxia means literally, without order from the Greek, *taxi* (order). Abnormalities in the cerebellum lead to interruptions in speed, direction, timing, amplitude, and target accuracy of movements. These disturbances reflect difficulties in initiating and terminating movements, gauging target distances and timing, changing directions, and maintaining postural reflexes.

Clinically, limb or appendicular ataxia is exemplified by dysdiadochokinesis, dysmetria, or dyssynergia (see Glossary entries and Clinical examination section). Movements may appear slowed due to either the underlying cerebellar disorder or attempts by the patient to improve accuracy of movement by slowing his movements. Tone may be reduced, and reflexes may be pendular.

Kinetic or intention tremor is also a feature of cerebellar limb dysfunction, in contrast to the rest tremor of parkinsonism. Titubation and poor truncal control when seated or standing demonstrate axial involvement. Ataxic gait is characterized by a wide-based stance, irregular stride, unsteadiness when walking or turning, and difficulty performing tandem gait.

Cerebellar disease also can affect extraocular movements, speech, and cognition. Abnormalities in eye movements include nystagmus (gaze-evoked, rebound, and sometimes down-beating), square-wave jerks, abnormal saccades (hypo- or hypermetric saccades), jerky or saccadic smooth pursuit, ocular flutter, and opsoclonus. Speech disorders in cerebellar disease often have a 'scanning' quality and are described as dysarthric, hesitant, or slow. Many speech abnormalities have been described including deficits in articulation, phonation, respiration, timing, pitch, volume, and prosody. With bulbar musculature involvement, differences in labial, lingual, and palatal sounds may be seen. Patients with cerebellar disease have been shown to have deficits in motor learning, perception, and cognitive function. In some, systemic and other neurologic signs and symptoms are present and may include gastrointestinal problems, autonomic dysfunction, dizziness, spasticity, neuropathy, dystonia, and parkinsonism.

Pathogenesis/Pathophysiology

The pathogenesis of the ataxias is not surprisingly broad due to the many different types of ataxias recognized under the umbrella term of 'ataxia.' Much of our current understanding about the ataxias is rooted in genetics. As a result, the ataxias have often been classified as congenital, hereditary (autosomal dominant (AD), autosomal recessive (AR), X-linked, mitochondrial), or sporadic. Over the past two decades, researchers have identified specific gene mutations in many of the ataxias which provide insights into the pathogenesis of some of the hereditary ataxias. With increased understanding of the molecular basis of some of the ataxias, organization schemes that focus on disease mechanisms have been proposed, thereby classifying the ataxias as disorders of trinucleotide repeat or polyglutamine expansions, 'gain' or 'loss' of function, channelopathies, defective DNA repair, mitochondrial dysfunction, and metabolic abnormalities. This section will highlight several mechanisms of the ataxias; many of these ataxia disorders are discussed in further detail in separate entries in the encyclopedia.

Abnormal Protein Folding and Degradation: Trinucleotide or Polyglutamine Expansion Disorders

Several autosomal dominant spinocerebellar ataxias (SCAs) are caused by trinucleotide or polyglutamine expansions (CAG repeat expansions that encode the repeat of the amino acid glutamine in the disease protein), particularly in coding regions. The family of polyglutamine repeat disorders includes SCA1, 2, 3, 6, 7, and 17 as well as Huntington disease, spinobulbar muscular atrophy, and dentatorubropallidoluysian atrophy (DRPLA). Clinically, these SCAs share features such as anticipation and an inverse correlation of CAG repeat length to onset age. There may be an earlier age of onset with paternal transmission. These disorders also are thought to share a common toxic gain-of-function mechanism leading to the aggregation and deposition of misfolded proteins and subsequently, neuronal dysfunction and cell death. The polyglutamine aggregates form nuclear or cytoplasmic inclusions that may contain ubiquitin, HSP70, or transcription factors. Although these aggregates constitute neuropathological hallmarks of those SCAs due to repeat expansions, it is not known whether the toxicity results directly from the aggregate or is a byproduct of other ongoing processes.

There are other abnormal repeat expansions in SCA 12, 8, and 10. SCA12 is also caused by a CAG repeat expansion, similar to SCA1, 2, 3, 6, 7, and 17; however, the CAG repeat is located in the untranslated region of the *PPP2R2B* gene on chromosome 5, encoding a brain-specific regulatory subunit of the protein phosphatase PP2A. Since the polyglutamine expansion lies outside of the open reading frame, pathogenesis seems less likely to relate to a toxic gain of function. SCA8 is caused by a CTG repeat expansion in the 3′ untranslated region on chromosome 13. In contrast, SCA8 expansions vary greatly between generations, and correlations between repeat length and disease severity are less. Furthermore, the CTG repeat occurs as part of the natural antisense RNA of the Kelch-like 1 gene which may act in the formation or maintenance of Purkinje cell dendritic function. SCA10 is caused by an unstable ATTCT pentanucleotide repeat expansion in *E46L*, a novel gene of unknown function.

Channelopathies

Several ataxias, such as SCA6 and the episodic ataxias (EAs), are due to mutations in genes involved in calcium or potassium channel function. For example, SCA6 is caused by a CAG repeat expansion on chromosome 19p13 in the *CACNA1A* gene. The *CACNA1A* gene encodes the P/Q type voltage-gated calcium channel complex which is abundantly expressed in the cerebellum and also presynaptic neuromuscular junction. Proposed pathogenetic mechanisms include a toxic 'gain of function' or increased calcium entry into cerebellar cells. Mutations in the *CACNA1A* gene on chromosome 19 are allelic with EA type 2 (EA2) and familial hemiplegic migraine (FHM). EA-2 is caused by a point mutation in the calcium channel

gene *CACNA1A* on chromosome 19p13. Most mutations in EA2 involve point mutations causing truncated proteins, but missense mutations have been reported. In addition, a missense mutation in *CACNB4*, the calcium channel β4 subunit gene, has been identified in a family with EA-2. Episodic ataxia-1, EA-1, is caused by a missense mutation in the potassium channel gene *KCNA1* on chromosome 12p13. This was not only the first known ion channel mutation in the brain but also the first report of a mutation in the human potassium channel gene. The KCNA1 protein is widely expressed in the cerebellum and nodal regions in peripheral nerves. Several different missense mutations in *KCNA1* have been identified. Mutations may alter potassium channel function by reducing channel expression or affecting channel gating.

Mitochondrial Dysfunction

Friedreich's ataxia (FRDA) is often considered a prototype for an ataxia due to abnormal mitochondria oxidative metabolism. FRDA, the most common AR ataxia, is caused by a GAA repeat expansion in the intron of the *frataxin* gene on chromosome 9q13. This expansion accounts for about 96% of patients with FRDA; the remainder (4–5%) is heterozygous and has a point mutation in the *frataxin* gene. Larger repeat expansions are associated with earlier onset of disease and more severe phenotype. However, expansions >50 repeats form sticky DNA and may be pathological. Expanded GAA repeats suppress *frataxin* gene expression. Since the frataxin yeast homologue plays a role in iron, it has been proposed that decreased frataxin leads to abnormal iron accumulation in the mitochondria, increased reactive oxygen species, and disruption in mitochondrial function. Knockout models and yeast experiments suggest that frataxin is involved in iron–sulfur cluster assembly and that the impaired iron–sulfur cluster assembly may precede the iron accumulation in FRDA. Abnormal mitochondrial function forms the basis for therapeutic studies with idebenone and other free-radical scavengers.

Defective DNA Repair

Several recessive ataxias such as ataxia-telangiectasia (AT), xeroderma pigmentosum (XP), Cockayne syndrome, and ataxia with oculomotor apraxia types 1 and 2 (AOA1, AOA2) are thought to relate to defective DNA repair. In AT, truncating mutations occur in the ataxia telangiectasia mutated (*ATM*) gene. The ATM protein carries a region similar to the lipid kinase phosphatidylinositol-3 kinase (PI-3K), a signal transduction mediator, and another region similar to yeast proteins involved in DNA repair. Thus, although exact mechanisms of the *ATM* mutation have not been elucidated, ATM may have a role in DNA damage detection, cell checkpoint control, and intracellular growth factor signaling.

Both XP and Cockayne syndrome involve multiple mutations with defective DNA repair or reduced RNA synthesis after ultraviolet damage. AOA1 is caused by missense and truncating mutations in the *aprataxin* (*APTX*) gene. The *APTX* gene is a member of the histidine family and may affect DNA repair by interacting with repair proteins and affecting cellular response to stress. AOA2, which is due to mutations in the *SETX* gene, which codes for senataxin, a protein with RNA and DNA helicase activities.

Epidemiology/Risk Factors

Since the etiologies of ataxia are heterogeneous, many epidemiological studies focus on specific types of ataxia in the population (e.g., SCA types, FRDA, multiple system atrophy (MSA)). However, with genetic testing, the ability to diagnose patients and recognition of broader clinical phenotypes has increased; therefore, published frequencies may represent conservative estimates. This section will highlight the prevalence rates and geographic distributions for several different types of ataxia.

Prevalence rates reported for the AD SCAs range from 0.9 to 3 per 100 000. Of the SCAs, SCA2, SCA3, and SCA6 appear to be the most common. Differences in geographic region and ethnic origin occur. For example, SCA3 is one of the most common SCAs, ranging from about 20% in the US to 50% in German, Japanese, and Chinese series. SCA2 has been described in Cuban and Indian kindreds. SCA3 is frequently associated with descendants from the Azorean islands or Portuguese missionaries in Asia, from whom the disease was initially identified. SCA10 has been reported in Mexican and Brazilian kindreds, with the combination of ataxia and epilepsy described only in the Mexican families.

FRDA, an AR ataxia, is found predominantly in Caucasian populations (rare in non-Caucasian), with an incidence of 1 in 30–50 000. FRDA accounts for about 50% of the hereditary ataxias and 75% of those before age 25. AT is the second most common recessive ataxia with an incidence of 1 in 80–100 000 live births.

Regarding the sporadic ataxias, the prevalence of MSA has been reported to be 1.9–4.9 cases per 100 000 population in the US, with lower estimates from United Kingdom and France population studies. Diagnostic distinctions between MSA and idiopathic Parkinson's disease, pure autonomic failure or other atypical parkinsonian disorders, however, may be difficult, and these rates may not provide true estimates. About 29–33% of patients with isolated late-onset cerebellar ataxia are thought to develop MSA. Some studies have reported high prevalences of antigliadin antibodies in patients with sporadic and hereditary cerebellar

ataxia, thereby challenging our understanding of gluten ataxia as a distinct disorder. For example, the prevalence of antigliadin antibodies in hereditary ataxias was 14%, sporadic idiopathic ataxia 41%, MSA-C 15%, and normal controls 12% in one study, and in another, prevalent in 37% in AD ataxias and 27% in sporadic ataxias.

Clinical Features and Diagnostic Criteria

AD Ataxias

The autosomal dominant cerebellar ataxias (ADCA) were initially classified according to phenotype and accompanying signs by Harding. ADCA I consisted of cerebellar ataxia along with variable pyramidal, extrapyramidal, and neuropathic signs. ADCA II presented with cerebellar ataxia and retinal degeneration, and ADCA III manifested as a pure cerebellar ataxia (**Table 1**). Genetic advances have led to modification of these criteria as specific genes, and mutations responsible for cerebellar ataxias have been discovered and phenotypic heterogeneity has been observed. This section describes the clinical features of AD ataxias: selected SCAs, dentatorubral-pallidoluysian atrophy (DRPLA), and selected EAs.

Spinocerebellar Ataxias (SCAs)

SCA1

SCA1 is characterized by cerebellar ataxia (gait ataxia, dysarthria, slow saccades, and nystagmus), corticospinal tract signs, and neuropathy, as well as later ophthalmoplegia and bulbar dysfunction (dysphagia, tongue fasciculations). Extrapyramidal signs may be seen, but cognitive deficits are not typically present. The age of onset varies from adolescence to late adulthood with the average age of onset around third to fourth decades. Clinically, nerve conduction studies may reveal sensory axonal neuropathy, and brain magnetic resonance imaging (MRI) reveals atrophy involving the cerebellum, brainstem, and cervical spinal cord. Pathology reveals marked cerebellar atrophy with loss of Purkinje cells in cerebellar cortex and vermis in particular, atrophy of the pons and inferior olives as well as spinal cord spinocerebellar tracts and posterior columns. In addition, neuronal loss in cranial nerves III, X, and XII is seen, and ubiquitin-positive nuclear inclusions can be seen.

Table 1 Classification of autosomal dominant cerebellar ataxias (ADCA), modified from Harding

Type	*Clinical phenotype*	*Common genotypes*
ADCA I	Cerebellar ataxia plus other symptoms: extrapyramidal symptoms, neuropathy	SCA 1, 2, 3, 4, 12, 17, 21, 23, 25, 27, 28
ADCA II	Cerebellar ataxia plus retinal degeneration	SCA 7
ADCA III	Cerebellar ataxia – pure	SCA 5, 6, 8, 10, 11, 14, 15, 16, 22, 26, 30

SCA2

SCA2 clinically appears similar to SCA1, as it was described in a large Cuban kindred that phenotypically resembled SCA1 but lacked the same genetic mutation. However, SCA2 is distinguished by prominent slow saccades. Other clinical symptoms in its wide phenotype include ataxia, dysarthria, neuropathy, initial hyperreflexia followed by hyporeflexia, cerebellar tremor, and ophthalmoplegia. Parkinsonism, with levodopa response in some, has been reported in the literature. In other cases, myoclonus, chorea, corticospinal tract signs, and executive dysfunction have been reported. The age of onset is typically in the third or fourth decade. Sensory axonal neuropathy is present in nerve conduction studies, and neuroimaging reveals more severe cerebellar and brainstem atrophy than in SCA1 and SCA3. Neuropathology includes loss of Purkinje cells and other cerebellar neurons, neuronal loss in the brainstem including inferior olives, degeneration in the substantia nigra, and loss of spinal cord neurons in spinocerebellar tracts, posterior columns, and anterior horn cells though neuronal inclusions are not seen. Clinically, there is no curative treatment, but parkinsonian features may respond to levodopa. Median survival after disease onset is about 25 years.

SCA3/Machado–Joseph disease

SCA3 and Machado–Joseph disease MJD are now known to be synonymous, sharing a genetic mutation on chromosome 14q24.3–q32. Historically, reports in the 1970s described several Azorean kindreds in the United States with dominantly inherited but clinically variable neurodegenerative conditions. Three distinct phenotypes were reported in these kindreds: Type I – early onset (<30 years), rapid progression, symptoms of spasticity, rigidity, myokymia, facial-lingual fasciculations, dystonia; Type II – intermediate onset age (age 30s), ataxia, spasticity, and extrapyramidal features; Type III – later onset (age 40–60s), ataxia, neuropathy, and variable amyotrophy. Another type, Type IV, has been described with older onset, predominantly parkinsonian phenotype with possible levodopa response, and neuropathy.

SCA3/MJD has a broad phenotype with ataxia, neuropathy, parkinsonism, dystonia, spasticity, rigidity, ophthalmoplegia, bulging eyes, facial-lingual fasciculations, amyotrophy, and sleep disturbances, such as restless legs syndrome. Dementia is not typically seen. The average age of onset is in the third to fourth decades but ranges from childhood to 70s. Death usually occurs within 20–25 years after disease onset due to complications of immobility and respiratory dysfunction. Studies reveal axonal neuropathy

on nerve conduction studies and cerebellar and brainstem atrophy on neuroimaging. Marked dilatation of the fourth ventricle may be seen, and atrophy of the frontal and temporal lobes, as well as globus pallidus may be evident. Neuropathology reveals degeneration of the cerebellar tracts, spinocerebellar tracts, substantia nigra, and motor cranial nuclei with sparing of the cerebellar cortex and inferior olives in contrast to other SCAs. Neuronal inclusions, staining for ubiquitin, are widespread in the pons but also present in substantia nigra and brainstem.

SCA4

SCA4 is a rare spinocerebellar ataxia that manifests clinically as cerebellar ataxia, sensory axonal neuropathy, and pyramidal tract signs. Symptoms begin in the fourth to fifth decade with gait ataxia, followed by impaired fine motor function, dysarthria, hypo- or areflexia, and neuropathy (particularly vibratory and joint position sense loss). Limb weakness and extensor plantar responses may be present. Although known previously as Biemond ataxia (initially reported in 1954), genetic linkage to chromosome 16q22.1 was discovered in a large Scandinavian family in Utah with similar symptoms. More recently, a pure cerebellar ataxia syndrome in six Japanese families linked to the SCA 4 gene locus was described and may represent a phenotypic variation of the same disease.

SCA5

SCA5 is largely a pure cerebellar syndrome, consistent with phenotypic ADCA III classification. Onset ranges from 10 to 68 years of age, but typically occurs in the third or fourth decade with symptoms of gait and limb ataxia and dysarthria. Extrapyramidal, corticospinal, and cognitive dysfunction are not seen. One-third of patients report mild sensory deficits. Its course is relatively slowly progressive and mild with normal life span in adult cases. However, in childhood onset, bulbar atrophy and corticospinal tract abnormalities may lead to a more rapid course. Neuroimaging reveals marked cerebellar cortical atrophy but without involvement of the brainstem, basal ganglia, or cerebral hemispheres. Pathological studies are limited but show predominantly cortical cerebellar degeneration.

SCA6

SCA6 has been considered to be a relatively pure cerebellar ataxia with a slowly progressive course, although extracerebellar features may occur. Clinical manifestations include gait and limb ataxia, dysarthria, downbeat or gaze-evoked nystagmus, and oculomotor findings. Unlike SCA1, 2, and 3, saccade velocity is normal. Saccades are dysmetric and smooth pursuit, optokinetic responses, and vestibular suppression, impaired. Later in the course, dysphagia, mild sensory neuropathy, corticospinal tract signs, and occasional parkinsonism or dystonia can occur. The age of onset is typically in the fourth or fifth decade, with slow progression. Brain MRI typically reveals midline cerebellar atrophy. Neuropathology demonstrates cerebellar degeneration with predominant loss of Purkinje cells and presence of cytoplasmic and nuclear polyglutamine aggregates. Based on improvement in EA2, acetazolamide, a carbonic anhydrase inhibitor, has provided modest symptomatic improvement in SCA6.

SCA7

SCA7, classified as ADCA II, is a progressive ataxia distinguished by retinal degeneration. The earliest sign of retinal dysfunction may be blue–yellow dyschromatoptia, followed by central vision loss (predominant macular involvement), and progression to bilateral vision loss and blindness. Other symptoms include cerebellar ataxia, dysarthria, corticospinal tract signs, hyporeflexia, decreased vibration, dysphagia, sphincter dysfunction, and ophthalmoplegia and slow saccades. The age of onset is typically in the third or fourth decade (range from infancy to over age 70). Anticipation and inverse correlation with repeat length and age of onset occur. Early-onset patients may present with visual symptoms preceding or coinciding with ataxia onset. Juvenile cases, marked by larger repeat sizes (>200) due to paternal transmission, may have cardiac involvement and seizures in addition to retinal dysfunction. Clinical tests reveal dyschromatoptia and abnormal fundoscopy with mottling of macula pigment and loss of foveal reflex. Nerve conduction studies may show subclinical sensory neuropathy. Brain MRI demonstrates marked cerebellar atrophy, especially in the superior vermis and brainstem, and moderate cortical atrophy. Neuropathology of the retina reveals degeneration of photoreceptors, bipolar and granule cells in foveal and parafoveal areas, and patchy loss of retinal epithelial cells. Brain pathology includes marked degeneration in the cerebellum (vermis greater than hemispheres) and inferior olives as well as pons, basal ganglia, and spinal cord.

SCA8

Clinically, SCA8 presents as a slowly progressive limb and gait ataxia with dysarthria and abnormal eye movements (impaired smooth pursuit and nystagmus). Neuropathy (reduced vibratory sensation), tremor, spastic dysarthria, and upper motor neuron findings, such as spasticity and hyperreflexia may occur. The age of onset is from infancy to over 60 (mean onset in the fifth and sixth decades). Neuroimaging typically reveals marked cerebellar vermian and hemispheric atrophy with relative sparing of the brainstem. Neuropathological reports are not available to date.

SCA10

SCA10 ataxia has been reported in Mexican and Brazilian families; only the Mexican families, to date, have had epilepsy. Symptoms include limb and truncal ataxia, dysarthria,

dysphagia, abnormal eye movements (saccadic pursuit, ocular dysmetria). About 20–60% have recurrent seizures, mostly generalized motor but also complex partial seizures. Other features have included mild cognitive dysfunction, mild sensory neuropathy, and hepatic dysfunction. The age of onset ranges from 14 to 45 years. Neuroimaging reveals generalized cerebellar atrophy and EEGs, cortical dysfunction, or epileptiform discharges. Neuropathological findings are unknown presently. Although there is no known treatment for the ataxia, seizures can be managed with antiepileptic medications.

SCA11

SCA11 is a relatively mild, cerebellar ataxia mapped to chromosome 15q14. Symptoms include limb and gait ataxia, dysarthria, saccadic pursuit, nystagmus, and hyperreflexia. The mean age of onset in the one British family with linkage to chromosome 15q is 25 years. Life expectancy appears normal.

SCA12

Clinical manifestations of SCA12 include cerebellar ataxia and action tremor. Other features include dysarthria, nystagmus, hyperreflexia, axial dystonia, bradykinesia, neuropathy, psychiatric symptoms, and dementia (in cases with older age onset). The age of onset ranges from 8 to 55 years, typically in the fourth decade. Families described are German-American or Indian. Neuroimaging demonstrates generalized cortical and cerebellar atrophy. Possible treatments address specific symptoms, such as tremor, parkinsonism, and psychiatric features.

SCA13

SCA13 has been reported in French families with cerebellar ataxia and mild mental retardation. Other features include dysarthria, nystagmus, hyperreflexia, urinary urgency (2 cases), and absence seizures (1 case). The age of onset is usually in early childhood but ranges from infancy to 40s. Neuroimaging in two cases revealed cerebellar and pontine atrophy.

SCA14

Clinical presentations of SCA14 as described in Japanese and English-Dutch families and one sporadic case include cerebellar ataxia, nystagmus, dysarthria, possible hyperreflexia, and axial myoclonus especially in earlier onset cases. The age of onset ranges from 10 to 59 years, mean fourth and fifth decades. Brain MRI reveals atrophy in the cerebellum vermis and hemispheres. Neuropathology demonstrates reduced staining for protein kinase C, gamma and ataxin-1 in Purkinje cells.

SCA15

SCA15 has been described in an Australian family with a slowly progressive, pure cerebellar ataxia. Patients are ataxic but remain ambulatory. The age of onset ranges from 10 to 50 years, mean 25 years. Brain MRI reveals superior vermis atrophy and nerve conduction studies are normal.

SCA16

SCA16 has been reported in a Japanese family as predominantly a slowly progressive, pure cerebellar syndrome accompanied by constant gaze-evoked nystagmus, dysarthria, and head tremor in some. The age of onset ranges from 20 to 66 years, mean 40 years. Anticipation was not seen in the Japanese kindred. Brain MRI reveals cerebellar atrophy and sparing of the brainstem.

SCA17

SCA17 is characterized by cerebellar gait ataxia and dementia with development of limb ataxia, bradykinesia, and hyperreflexia over several decades. Eye movements are normal. The age of onset ranges from 19 to 48 years, mean 33 years. SCA17 has been described in Japanese, German, and Italian families. Others have reported similarities to Huntington's disease due to the presence of dementia, psychiatric features, and chorea. Brain MRI reveals marked cerebellar atrophy and mild cortical atrophy. Neuropathology reveals moderate cerebellar degeneration, neuronal intranuclear inclusions, and mild-to-moderate changes in the basal ganglia and cortical regions.

SCA18

SCA18 has been designated sensorimotor neuropathy with ataxia (SMNA) and may not truly represent spinocerebellar ataxia. Features of dysmetria, hyporeflexia, muscle weakness, muscle atrophy, neuropathy with decreased vibration and proprioception, and pes cavus in some were described in a five generation American-Irish kindred. The age of onset was from 13 to 27 years. Progression was slow with normal lifespan and wheelchair use in later years. Brain MRI revealed cerebellar atrophy, electrodiagnostic studies showed sensory axonal neuropathy and denervation, and muscle biopsy revealed neurogenic atrophy.

SCA19

SCA19 has been described in a Dutch kindred with symptoms of mild ataxia, postural tremor, myoclonus, cognitive impairment, variable reflexes, and neuropathy. The age of onset was between 20 and 45 years. SCA19 has been mapped to chromosome 1p21–q21. Since another form of FHM links to this locus, possible disease mechanisms may relate to mutations in ion channels. Brain MRI reveals marked atrophy of cerebellar hemispheres and mild atrophy of the vermis and cerebral cortex.

SCA20

SCA20 has been reported in an Anglo-Celtic family with relatively pure, AD spinocerebellar ataxia. Symptoms

include dysarthria, gait and limb ataxia, hypermetric saccades, mild nystagmus, mild corticospinal tract signs, palatal myoclonus, and had slow progression. The age of onset ranges from 19 to 64 years, mean 45 years. Head CT scans have revealed prominent dentate calcifications in all nine patients imaged.

SCA21

SCA21 has been reported in a French family with slowly progressive gait and limb ataxia, as well as variable parkinsonian signs, hyporeflexia, and cognitive impairment. The age of onset ranges from 6 to 30 years, mean 17 years. Brain MRI reveals cerebellar atrophy without brainstem involvement. More study is likely needed to define and assess parkinsonian features of SCA21 and responses to dopaminergic agents.

SCA22

SCA22 represents a pure AD cerebellar ataxia described in a Chinese Han family. Hyporeflexia was also present and course was slowly progressive. The age of onset ranges from 10 to 46 years. Brain MRI reveals cerebellar atrophy.

SCA23

SCA23 has been described in a Dutch family with a slowly progressive gait and limb ataxia accompanied by abnormal eye movements (slow saccades, ocular dysmetria), neuropathy, and corticospinal tract signs (hyperreflexia, extensor plantar responses). The age of onset was later, ranging from 43 to 56 years. Brain MRI revealed cerebellar atrophy, and pathology demonstrated cerebellar, brainstem, and spinal cord atrophy with cell loss in Purkinje cells, dentate nuclei, and inferior olives.

SCA25

SCA25 involves cerebellar ataxia along with variable nystagmus, hyporeflexia, neuropathy, urinary urgency, and gastrointestinal symptoms. SCA25 has been described in a large Southeastern French family. The age of onset was from 17 months to 39 years. Brain MRI reveals cerebellar atrophy and nerve conduction studies, absent sensory nerve action potentials.

Dentatorubral-pallidoluysian atrophy (DRPLA)

DRPLA is an AD ataxia with phenotypic similarities to progressive myoclonic epilepsy, spinocerebellar ataxia, and Huntington's disease, depending on the age of onset. Ataxia and dementia are present regardless of the age of onset. Inverse correlation between the age of onset and CAG repeat length and anticipation, particularly with paternal transmission, occur. The age of onset is variable, ranging from childhood to late adulthood but on average, age 30. Patients with symptom onset less than age 20 share a phenotype with progressive myoclonic epilepsy with additional seizures and myoclonus. Those patients with symptom onset after age 20 are more likely to resemble either SCAs or Huntington's disease due to chorea and neuropsychiatric symptoms.

DRPLA is relatively common in Japan with a prevalence rate of 0.2–0.7 per 100 000 and is present in the United States as a variant, Haw River syndrome that has been reported in African-American kindreds in North Carolina. DRPLA is caused by a trinucleotide CAG repeat mapped to chromosome 12p, encoding atrophin-1; abnormal alleles range from 49 to 88 repeats, whereas normal alleles typically have less than 30 repeats. Neuropathological examination reveals degeneration in the dentate, red nucleus, subthalamus, and globus pallidus and accumulation of atrophin-1 in neuronal nuclei. Useful laboratory studies include brain MRI, EEG, and genetic testing. Epilepsy requires anticonvulsant treatment, but other therapies are only for symptomatic effects.

Episodic ataxias

The EAs are a group of AD ataxias with intermittent symptoms and different genetic mutations. To date, seven EAs have been described (EA1–EA7), with mutations identified in four genes.

In EA-1, patients have sudden episodes of dysarthria and truncal and gait ataxia with normal eye movements. Episodes are brief, lasting from seconds to a few minutes, and often triggered by startle, emotional factors, or exercise. Preceding auras with weakness, dizziness, and blurred vision may occur. Interictal examination is normal except for myokymia, particularly in periorbital areas and fingers, and seen either clinically or by electromyography (EMG) only. The age of onset ranges from 3 to 20 years. Episodes decrease with age and may remit in teenage years. Families with EA-1 may have different types of epilepsy. Episodes may respond to acetazolamide.

In contrast, EA-2 is characterized by longer episodes of ataxia lasting for hours. Symptoms include ataxia, vertigo, nausea, emesis, and headaches, and examinations reveal cerebellar ataxia, dysarthria, and nystagmus. Episodes can be triggered by stress, exercise, alcohol, and caffeine. Interictal examination may show gaze-evoked nystagmus, downbeat nystagmus, and mild truncal ataxia. The age of onset is similar to EA-1, ranging from 3 to 30 years. Brain MRI often reveals cerebellar atrophy, particularly midline. Acetazolamide may decrease the severity and frequency of episodes by stabilizing the ion channel.

AR Ataxias

Although there are numerous AR ataxias described in the literature, this section will focus on a few selected ataxias. The AR ataxias can be divided into three primary phenotypes: (1) a Friedreich ataxia (FRDA)-like phenotype without cerebellar atrophy (e.g., FRDA, ataxia

with vitamin E deficiency, abetalipoproteinemia, and Refsum's disease), (2) a FRDA-like phenotype with cerebellar atrophy and possibly other neurological findings (e.g., cerebrotendinous xanthomatosis (CTX), late-onset Tay–Sachs disease, mitochondrial ataxia syndromes, and spinocerebellar ataxia with axonal neuropathy), and (3) an early-onset ataxia with cerebellar atrophy phenotype (e.g., AT, ataxia with oculomotor apraxia 1 and 2, AR ataxia of Charlevoix-Saguenay, infantile-onset spinocerebellar ataxia, Cayman ataxia, and Marinesco-Sjogrens syndrome).

Friedreich ataxia

FRDA clinically presents with gait instability and clumsiness or scoliosis diagnosed in adolescence. Neurological features include a mixed sensory and cerebellar ataxia, gait and limb ataxia, dysarthria, dysphagia, ocular fixation difficulty with square-wave jerks, areflexia, proprioceptive sensory loss, weakness, and extensor plantar responses. Cognition remains intact; optic atrophy and sensorineural hearing loss occur in some. On average, patients require a wheelchair 10–15 years after disease onset. Nonneurological abnormalities include musculoskeletal changes of kyphoscoliosis and pes cavus or equinovarus, hypertrophic cardiomyopathy (inverted T waves on electrocardiogram, symptoms of shortness of breath and palpitations), diabetes mellitus or glucose intolerance, and autonomic disturbances. In FRDA, evaluation reveals nerve conduction studies with sensory axonal neuropathy and absent sensory nerve action potentials (SNAPs), abnormal evoked potential studies (visual, brainstem, motor, and somatosensory), and atrophy of the cervical spinal cord rather than cerebellum on neuroimaging. Neuropathology demonstrates degeneration of posterior columns of the spinal cord and spinocerebellar tracts, the sensory tracts projecting to the brain and cerebellum; loss of large primary sensory neurons in the dorsal root ganglia; and mild cortical cerebellar atrophy late in the course.

Although onset is usually in adolescence, before age 20, late onset variants can occur. Late-onset FRDA (LOFA) can occur even after age 50–60; it is associated with shorter repeat lengths, and clinically may have intact reflexes, fewer skeletal deformities, and a more benign, slower progression. Another variant is FRDA with retained reflexes (FARR) which also may be milder in phenotype, and as its name suggests, patients have intact reflexes.

Ataxia with isolated vitamin E deficiency

Ataxia with isolated vitamin E deficiency (AVED) shares a phenotype with FRDA – progressive cerebellar ataxia, areflexia, proprioceptive sensory loss, and corticospinal tract signs with spastic gait and extensor plantar responses. Symptoms occur in the absence of fat malabsorption or gastrointestinal syndromes. Affected individuals may have retinal pigmentary changes but rare oculomotor signs, skeletal deformities such as pes cavus and possibly scoliosis, and hypertrophic cardiomyopathy only in about 19%. Patients become wheelchair bound after an average of 11 years. The age of onset typically is before 20 years but has been reported in the fifth decade. AVED, due to a mutation in the α-tocopherol transfer protein (αTTP) on chromosome 8q13.1–q13.3, is a relatively rare AR ataxia with the largest group of patients found in North Africa sharing a common mutation. Since α-TTP is involved in the transfer of vitamin E into circulating lipoproteins, the mutation results in the failure of incorporation of vitamin E into very low density lipoproteins in the liver. Diagnostic tests include vitamin E levels (typically $<2\,\mathrm{mg\,l^{-1}}$) and confirmatory genetic testing; other tests, such as complete blood count, creatine kinase, hepatic enzymes, copper studies, lipoproteins electrophoresis, peripheral smear for acanthocytes, and tests for steatorrhea are normal. Treatment with vitamin E at doses of $800\,\mathrm{mg\,day^{-1}}$ can reverse or slow down the ataxia.

Abetalipoproteinemia

Abetalipoproteinemia (also known as Bassen–Kornzweig disease) is a rare condition whose neurological manifestations are due to underlying vitamin E deficiency. As a result, abetalipoproteinemia clinically resembles AVED in the setting of a gastrointestinal malabsorption syndrome. Clinical features include cerebellar ataxia, proprioceptive sensory loss, areflexia, weakness, retinal degeneration, as well as steatorrhea, fat malabsorption, celiac syndrome, and acanthocytosis. Onset typically occurs in adolescence. Abetalipoproteinemia is caused by mutations in the gene coding a subunit of the microsomal triglyceride transfer protein (MTP) on chromosome 4q22–q24. Since MTP is necessary for lipoprotein assembly, the mutation impairs synthesis of apoB peptide of low density lipoprotein and very low density lipoprotein; this leads to impaired fat absorption and in turn, vitamin E deficiency. Levels of cholesterol and triglycerides are extremely low and apolipoprotein B-containing lipoproteins are absent. Treatment involves supplementation of fat soluble vitamins including vitamin E.

Refsum disease

Refsum disease, in its classic form, manifests as cerebellar ataxia, demyelinating sensori-motor polyneuropathy, and retinitis pigmentosa. Non-neurologic features include icthyosis, deafness, multiple epiphyseal dysplasia, and cardiac arrhythmias. Onset typically occurs before the age of 20. Diagnostic studies include elevated serum phytanic acid, reduced oxidation of phytanic acid in fibroblasts, demyelinating neuropathy on nerve conduction studies, and elevated cerebrospinal fluid protein. Neuropathology demonstrates large onion bulbs and decreased myelinated axons on nerves and decreased Purkinje cells in cerebellum and neurons in inferior olive and vestibulocochlear nuclei. Refsum

disease is a peroxisomal disorder due to an inability to degrade phytanic acid, a branched-chain fatty acid, with mutations in the gene coding phytanoyl-CoA hydroxylase on chromosome 10pter–p11.2. As a result, phytanic acid accumulates in body tissues. Treatment involves dietary restriction of phytanic acid to less than 10 mg day^{-1}. Dietary measures may improve ataxia and neuropathy but not vision and hearing loss.

Cerebrotendinous xanthomatosis

CTX is a rare AR ataxia that involves both neurologic and systemic features. CTX typically presents after puberty with progressive cerebellar ataxia, neuropathy, pseudobulbar dysfunction, parapesis, and myoclonus and dementia, in some. Systemically, premature atherosclerosis, cataracts, and xanthelasma with thickened tendons (cholesterol deposition) occur. Nerve conduction studies reveal axonal loss and biopsies demonstrate axonal loss with demyelination in some patients. Laboratory testing is diagnostic, revealing increased serum cholestanol and increased urinary bile alcohol. Plasma cholesterol concentrations are low normal in CTX. The defect in CTX is due to mutations in the *CYP27A1* gene on chromosome 2q33–qter, which is involved in bile acid synthesis pathway. Treatment involves administration of chenodeoxycholic acid to compensate for the pronounced deficiency of chenodeoxycholic acid in the intrahepatic pool. Some series of CTX patients have revealed improvement in neurological features (ataxia, neuropathy, dementia) in patients after at least 1 year of treatment. Management of atherosclerosis with HMG-CoA reductase inhibitors may also be necessary.

Ataxia-telangiectasia

AT, caused by a mutation in the *ATM* gene on chromosome 11q22–23, manifests itself as a progressive cerebellar ataxia, also complicated by systemic features. Neurologic signs and symptoms include limb and gait ataxia, oculomotor apraxia, choreoathetosis, dystonia, dysarthria, hyporeflexia, sensory loss, distal muscular atrophy, and impaired cognition. Nonneurologic features include oculocutaneous telangiectasias (occur after neurologic symptoms), impaired humoral and cellular immunity resulting in sinopulmonary infections, high incidence of malignancy, such as leukemia and lymphoma, radiosensitivity, infertility, and diabetes mellitus. Onset begins around age 1–2 years with truncal ataxia and oculomotor problems. Children may be wheelchair bound by age 10 and death occurs between 20 and 30 years of age. Adjunctive diagnostic studies include elevated serum α-fetoprotein and carcinoembryonic antigen, abnormalities in immunoglobulins (particularly absence or low level of serum IgA), neuroimaging revealing cerebellar atrophy, and genetic testing. No specific pharmacologic treatment for neurologic symptoms exists, but ongoing trials are assessing α-lipoic acid and PARP-1 inhibitor. Patients should be monitored for infections and malignancy; antibiotics should be used for sinopulmonary infections but treatment of malignancies with radiation may be problematic due to radiosensitivity.

Ataxia-ocular apraxia (AOA) types 1 and 2

Ataxia-ocular apraxia Type 1 (AOA1), caused by mutations in the APTX protein located on chromosome 9p13, is a slowly progressive, childhood disorder with limb and gait ataxia, oculomotor apraxia, motor and sensory neuropathy, and extrapyramidal features, such as dystonia and hypomimia. In addition, hypoalbuminemia and hypercholesterolemia may occur. The mean age of onset is 5 years. Epidemiology reveals a Portuguese and Japanese predominance. Laboratory studies support axonal neuropathy on nerve conduction studies, mild loss of myelinated axons on nerve biopsy, and cerebellar atrophy with possible brainstem involvement on neuroimaging.

Ataxia-ocular apraxia Type 2 (AOA2), caused by a mutation in the senataxin protein on chromosome 9q34, presents later than AOA1 with the age of onset from10 to 22 years and with severe gait ataxia, variably present oculomotor apraxia, slow saccades, choreoathetosis and dystonia, sensory-motor neuropathy, areflexia, and extensor plantar responses. Serum α-fetoprotein and creatine kinase may be elevated, but chromosomal instability and radiosensitivity are absent.

Spastic ataxia of Charlevoix-Saguenay (ARSACS)

ARSACS, caused by mutations on chromosome 13q12 in the *sacsin* gene, is characterized by cerebellar ataxia, spasticity, and prominent retinal myelinated fibers. Onset is typically around age 1–2 years with gait ataxia and lower limb spasticity, increased cerebellar signs around adolescence, motor axonal polyneuropathy in the third decade, and loss of ambulation around age 40. Other features include pes cavus or equinovarus, saccadic smooth pursuit, and distal amyotrophy, but absence of cardiac disease as in FRDA. ARSACS is prevalent in Charlevoix-Saguenay, a region in Northeastern Quebec. Diagnostic studies reveal abnormal fundoscopy, early demyelination and axonal neuropathy on nerve conduction studies, neurogenic atrophy of muscle biopsy, loss of large myelinated axons on nerve biopsy, and cerebellar atrophy of the superior vermis and later hemispheres on neuroimaging. No specific treatment is available for the ataxia but antispasticity medications may be considered.

X-Linked Ataxias

Fragile X-associated tremor-ataxia syndrome

The clinical syndrome of fragile X-associated tremor-ataxia syndrome (FXTAS) includes progressive gait

ataxia, action tremor, parkinsonism, cognitive decline/executive dysfunction, polyneuropathy, and autonomic dysfunction. The features typically occur in males over age 50, who are often the male grandparents of patients with FMR syndrome. Many patients have been previously diagnosed as having essential tremor, parkinsonism, or MSA. Neuroimaging reveals increased T2 signal in middle cerebellar peduncles and adjacent white matter. Neuropathology in mice and humans demonstrates eosinophilic, ubiquitin-staining, intranuclear inclusions in neurons and astrocytes throughout the brain and hippocampus. Treatments so far include symptomatic therapies for tremor, parkinsonism, and cognitive dysfunction.

Fragile X is caused by a CGG repeat expansion in the 5′ untranslated region of the fragile X mental retardation 1 (*FMR1*) gene with full mutation expansion lengths >200 CGG repeats. Instead, FXTAS is due to premutations in the *FMR1* gene with CGG repeat lengths of 55–200. The frequency of the premutation is 1/259 in females and 1/813 males in the general population. In FMR, the CGG repeat expansion leads to methylation and transcriptional silencing of the *FMR1* gene. In premutation carriers, however, levels of *FMR1* mRNA are elevated thereby, suggesting a possible toxic 'gain of function' mechanism. FMR protein production is reduced due to reduced translational efficiency of *FMR1* mRNA. CGG repeat length appears to influence FMR1 mRNA levels (elevated in premutation carriers) and position of transcription start (farther upstream with increasing repeats).

Sporadic or Nonhereditary Ataxias

Sporadic ataxias may be diverse in etiology. Differential diagnosis is influenced by the tempo of the ataxia and presence of systemic or neurologic abnormalities. Causes for sporadic ataxia include MSA, autoimmune disorders such as glutamic decarboxylase (GAD) antibodies, infections such as viral or prion disease, endocrine dysfunction such as hypothyroidism or hypoparathyroidism, gastrointestinal disorders such as celiac ataxia or Whipple's disease, paraneoplastic syndromes, toxins, trauma, neoplastic, and vascular events, among others.

Multiple system atrophy

MSA is a progressive neurodegenerative disorder with elements of parkinsonism, cerebellar ataxia, and autonomic dysfunction. Although previously classified as striatonigral degeneration, Shy-Drager syndrome, and olivopontocerebellar atrophy (OPCA, sporadic), MSA is currently defined by the predominant clinical presentation with parkinsonism (MSA-P) in 80% or cerebellar ataxia (MSA-C) in 20% of patients. Clinical features of MSA-P include: parkinsonism with tremor (more commonly action or postural than rest tremor), akinesia, and rigidity, often symmetrical; autonomic disorders with lightheadedness, recurrent syncope, urinary incontinence or incomplete emptying, and impotence; and cerebellar dysfunction with limb and gait ataxia, nystagmus, and tremor. Other manifestations include corticospinal tract signs with hyperreflexia and extensor plantar responses, inspiratory stridor, antecollis, myoclonus, rapid eye movement (REM) behavior disorder, facial dystonia, and cold or dusky hands. Clinical features of MSA-C include: impaired balance with ataxia, nystagmus, tremor, dysarthria; autonomic dysfunction with lightheadedness and syncope, bladder dysregulation and impotence; parkinsonism, and corticospinal tract signs. Patients typically have a poor and nonsustained response to levodopa although some benefit initially. Late-onset cerebellar ataxia and sporadic OPCA both may represent forms of MSA-C. Of patients diagnosed with OPCA followed longitudinally, about 25% developed MSA. The mean age of onset for MSA-P and MSA-C is around 50 years of age and survival, about 10 years. Average incidence rate for MSA is 3 new cases/100 000 person-years.

Diagnostic criteria for MSA have been established by Quinn et al., Gilman et al., and recently revised by Gilman et al. with possible, probable, or definite MSA designations. Definite MSA requires neuropathological demonstration of α-synuclein-positive glial cytoplasmic inclusions in the central nervous system with neurodegenerative changes in striatonigral or olivopontocerebellar structures. Probable MSA requires a sporadic, progressive, adult-onset disorder meeting criteria for autonomic failure and poorly levodopa-responsive parkinsonism or cerebellar ataxia. Possible MSA also requires a sporadic, progressive, adult-onset disorder with parkinsonism or cerebellar ataxia but at least one feature suggesting autonomic dysfunction plus either a clinical or neuroimaging abnormality. Neuroimaging with MRI may be helpful when characteristic findings are present. In MSA-P, putaminal hypointensity with a lateral hyperintense rim on T2 weighted images may occur. In MSA-C, the 'hot cross bun' sign with cerebellar atrophy and increased T2 signal in the pons may be seen. Variable sensitivity and specificity has been reported. PET imaging reveals decreased cerebral glucose metabolic rates in the striatum in MSA-P and brainstem and in the cerebellum in MSA-C. Studies related to autonomic failure indicate a preganglionic defect in MSA; cardiac SPECT imaging with [^{123}I] metaiodobenylguanidine (MIBG) which labels postganglionic adrenergic neurons may reveal significant decreases of uptake in PD but not in MSA due to its preganglionic deficit. Rectal sphincter EMG is a sensitive measure for denervation but may be abnormal in PD. Neuropathology of MSA includes degeneration of the striatum, substantia nigra, locus ceruleus, inferior olives, brainstem, cerebellum, interomedial cell columns, and Onuf's nucleus. The pathological hallmark is the glial cytoplasmic inclusion, an α-synuclein and ubiquitin staining inclusion found in oligodendrocytes in the cortex, striatum, brainstem, and interomedial cell column.

Gluten ataxia

Neurological features of celiac disease or sprue, a gluten-sensitive enteropathy due to T cell mediated immune responses to ingested gluten in genetically susceptible populations, including ataxia, peripheral neuropathy, myopathy, and headaches. White matter changes on MRI have been reported. Cerebellar dysfunction manifests as truncal or gait ataxia, dysarthria, and oculomotor signs with a mean age of onset of about 50–60 years. Gluten sensitivity may present with neurological dysfunction in the absence of gastrointestinal or systemic symptoms. Diagnostics tests include IgG and IgA antibodies to gliadin, but antiendomysial, and tissue transglutaminase antibodies may offer greater specificity despite being less common in neurological dysfunction alone. Duodenal biopsy typically reveals absent villi with hyperplastic crypts and inflammatory and lymphocytic infiltration. Cerebellar atrophy may be present on brain MRI. Treatment involves a gluten-free diet; however, unlike gastrointestinal symptoms, improvement in ataxia may not be as robust.

Cerebellar syndrome with anti-GAD antibodies

Cerebellar ataxia with anti-GAD antibodies is a variant of stiffperson syndrome (SPS) which presents as a slowly or subacutely progressive cerebellar ataxia involving the limbs and trunk, nystagmus, and dysarthria. Stiffness is less prominent than in SPS, occurring in about 15%, and the brainstem is unaffected. Similar to SPS, autoimmune diseases, such as diabetes mellitus, thyroiditis, and polyendocrine syndrome may be present. Paraneoplastic syndromes should be excluded. The age of onset ranges from 20 to 75 years with a female predominance. Laboratory tests reveal high titers of anti-GAD antibodies and also anti-parietal cell antibodies. Neuroimaging may be normal or exhibit cerebellar atrophy. There are no specific treatments for the cerebellar syndrome but case reports or series cite some response to steroids and intravenous immunoglobulin.

Paraneoplastic syndromes

Ataxia may be a presenting feature of a paraneoplastic cerebellar degeneration syndrome (PCD). Paraneoplastic antibodies are thought to react with antigens in the cancer and nervous system, targeting antigens on Purkinje cells in cases with cerebellar ataxia. Onset typically precedes the neoplasm by months to even years. Symptoms of limb and gait ataxia, dysarthria, nystagmus, and oculomotor dysfunction may progress rapidly over weeks to months and then plateau.

PCD has been described most often with cancers of the lungs (small cell), ovaries, breast, and lymphoma, but other cancers have been reported. Specific paraneoplastic antibodies associated with PCD include: Hu – small cell lung cancer, Yo – ovarian or breast cancer, Ri – breast cancer, Tr and metabotropic glutamate receptor R1 (mGluR1) – Hodgkin's lymphoma, Ma – breast, colon, or large cell lung cancer, Ma2 – testicular cancer, CV2 (CRMP5) – small cell lung cancer or thymoma, voltage gated calcium channels (VGCC) – small cell lung cancer, and Zic4 – small cell lung cancer. Diagnostic studies focus on serum antibodies and detection of underlying cancer. Increased protein, IgG synthesis, oligoclonal bands, and paraneoplastic antibodies may be found in cerebrospinal fluid. MRI, however, may not demonstrate cerebellar atrophy initially. Pathology reveals degeneration of cerebellar Purkinje cells, inflammatory infiltrates, and Purkinje cells that stain for specific paraneoplastic antibodies. Treatment usually involves cancer management but responses to intravenous immunoglobulins or plasmapheresis have been reported, particularly with Lambert–Eaton myasthenic syndrome, paraneoplastic encephalomyelitis or sensory syndromes, and in cerebellar degeneration. However, despite decreased titers of paraneoplastic antibodies with cancer resection and treatment, improvement of ataxia may be disappointing due to neuronal destruction.

Prion disease

Cerebellar ataxia may be a component of prion diseases and has been described in familial and sporadic Creutzfeldt–Jacob disease (CJD), Kuru, and familial Gerstmann–Straussler–Sheinker disease (GSS). Clinical features associated with CJD include progressive cerebellar ataxia, myoclonus, corticospinal tract and extrapyramidal signs, visual disturbances and oculomotor dysfunction, as well as dementia and behavioral problems. Patients with sporadic CJD carrying the valine–valine (VV) or methionine–valine (MV) polymorphism at codon 129 of the prion protein gene (*PRNP*) and PrP^{Sc} type 2 may present with a cerebellar form of CJD. In addition, sporadic CJD patients with MV polymorphism and type 1 PrP^{Sc} may demonstrate ataxia and sensory deficits before cognitive decline. Point mutations on chromosome 20 in familial CJD (P102L) and GSS (G131V or H187R) may present as a classical ataxic forms. Diagnostic tests include detection of 14–3–3 protein in cerebrospinal fluid, periodic sharp wave activity on EEG, hyperintense signal in the basal ganglia on MRI, and possible biopsies of tonsils and brain, although these tests vary in sensitivity and specificity for prion disease. More recently, genotype–phenotype correlations can be made by evaluating different polymorphisms at codon 129 in the PRNP and different types of PrP^{Sc}. Neuropathology of prion diseases reveals spongiform encephalopathy but specific patterns of spongiform degeneration, astrogliosis, and neuronal loss depends on the subtype of CJD.

Differential Diagnosis

See **Table 2** for salient SCA features.

Diagnostic Work-Up/Tests

When approaching a patient with ataxia, an organized, stepwise process is important (see **Figure 1**). There are several key components in addition to a comprehensive neurological examination that will aid in developing a differential diagnosis and in some cases, deciding on acute medical intervention. The clinician must first 'localize the lesion' and determine whether the ataxia is due to cerebellar disease or to other neurologic problems such as in the vestibular or sensory/proprioceptive systems. If the deficits result from cerebellar dysfunction, one should then assess whether the syndrome is purely cerebellar or has other associated neurologic or systemic features ('cerebellar-plus'). A detailed family history is necessary. Further investigation may require supplemental neuroimaging, electrophysiological studies, laboratory tests, and genetic tests.

Table 2 ADCAs classified by presence of neurologic signs and symptoms

Pure cerebellar ataxia	SCA 5, 6 (see ***Table 1***)
Peripheral neuropathy	SCA 1, 2, 3, 4, 18, 25
Corticospinal tract signs	SCA 1, 3, 6, 7, 8, 12
Parkinsonism	SCA 2, 3, 12, 21
Dystonia	SCA 3, 12, 17
Chorea	SCA 1, 17; DRPLA
Myoclonus	SCA 2, 14, 19; DRPLA
Ophthalmoplegia	SCA 1, 2, 3
Slow saccades	SCA 1, 2, 3, 7
Nystagmus (downbeat)	SCA 6
Pigmentary retinopathy	SCA 7
Cognitive impairment/ dementia	SCA 2, 13, 17, 19, 21; DRPLA
Seizures	SCA 10, 17; DRPLA
Dentate calcifications on CT	SCA 20

Clinical History

Key features in the history of a patient with ataxia include: the onset age, time course and progression, and medical, social, and family history. In children, congenital ataxias, metabolic disorders, infectious/acute cerebellitis, posterior fossa tumors, and hereditary ataxias are often part of the differential diagnosis, whereas in adults, the sporadic and hereditary ataxias predominate. The time course of the ataxia is important. Acute ataxias are more likely to be vascular, metabolic/toxic, infectious, inflammatory, or traumatic in origin. Subacute causes may include metabolic/toxic, infectious, inflammatory, or paraneoplastic, tumor processes. Chronic ataxias are more likely genetic or degenerative. Accompanying symptoms such as headache, nausea, or vomiting may signify an acute cerebellar hemorrhage or increased intracranial pressure as in childhood posterior fossa tumors. Systemic signs such as weight loss, gastrointestinal symptoms, autonomic dysfunction, skin changes or other neurological signs, such as parkinsonism, dystonia, spasticity, neuropathy may be present. The course of the ataxia may be stable, progressive, or episodic. Medications such as anticonvulsants (phenytoin, barbiturates), lithium, immunosuppressants (methotrexate, cyclosporine), or antineoplastic agents (fluorouracil, cytarabine) may contribute to ataxia symptoms. Other medical problems such as cancer, infections,

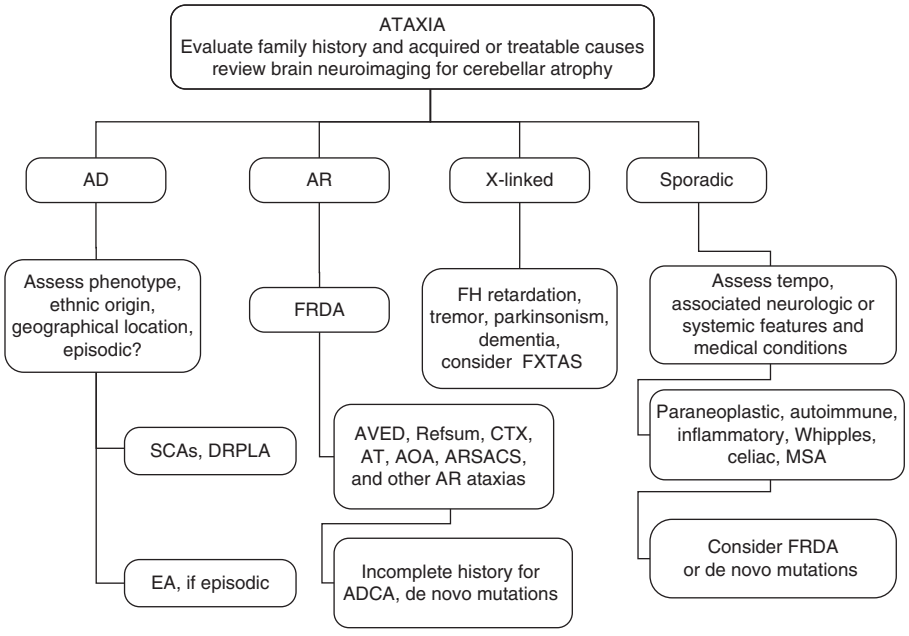

Figure 1 Proposed diagnostic algorithm for evaluating ataxia patients.

HIV, thyroid disease, gastrointestinal disease (malabsorption, celiac), or multiple sclerosis may be the cause of ataxia. Ascertaining the patient's history of alcohol or substance use and toxin exposures (heavy metals, solvents, thallium) is important. Lastly, obtaining a detailed family history is imperative. The presence of ataxia, similar symptoms, or other neurologic disease should be recorded for at least three generations to best determine the mode of inheritance and identify phenotypic heterogeneity.

Clinical Examination

In addition to the general physical and neurological examination, one should pay attention to several specific elements of cerebellar function: speech, ocular movements (nystagmus, smooth pursuit, hypo or hypermetric saccades), limb coordination, tremor, stance, and gait. Cerebellar function, especially appendicular function, can be tested at the bedside with the following maneuvers: for dysmetria (finger–nose–finger, heel–knee–shin), dysdiadochokinesia (rapid alternating movements of tapping the palmar and dorsal surfaces of the hands), dyssynergia (tapping of hands, fingers, feet, and other multijoint movements), rebound (application of a downward tap on the patient's outstretched arm which produces a rapid, excessive upward displacement), and impaired check (sudden release of the patient's flexed arm which leads to the inability of the patient to stop the movement). Tremor is more typically present with action and increases as the limb approaches the end-point or target (intention tremor). Tremor may be slow (2–5 Hz) and more proximal with wide amplitude. One should assess the patient's sitting position for titubation, stance (typically wide based), and ability to perform tandem gait, single leg stance, and stand with and without eye closure. Furthermore, the comprehensive neurological examination should include evaluation of mental status, cranial nerves (vision, bulbar involvement, asymmetry), tone (hypotonia, rigidity, spasticity), strength, reflexes, sensation (presence of neuropathy), and movement disorders (parkinsonism, dystonia, myoclonus, chorea, tremor). Abnormalities in these other neurological systems may provide diagnostic clues (vision loss in SCA7, ophthalmoplegia and/or parkinsonism and/or dystonia in SCA3, arreflexia and neuropathy in FRDA, etc.). General physical examination should include assessment of blood pressure for orthostatic hypotension (MSA), thyroid, eyes, cardiac (FRDA), endocrine, skin (AT), nail changes, and skeletal system.

Rating Scales

Specific ataxia rating scales can be used to monitor ataxia for both clinical management and research studies. The International Cooperative Ataxia Rating Scale (ICARS) rates gait, kinetic functions (limb ataxia), speech/dysarthria, and oculomotor findings, with scores ranging from 0 to 100; the ICARS demonstrates high-reliability as well as high test–retest reliability and internal consistency but has several overlapping, interdependent items that may affect its practicability. The Scale for the assessment and rating of ataxia (SARA) is a short, quick, semiquantitative scale that evaluates gait, stance, sitting, speech, and limb kinetic functions, but not oculomotor function; scores range from 0 to 40. The Unified Multiple System Atrophy Rating Scale (UMSARS) is a longer scale validated for MSA; it includes a historical interview, motor and autonomic examination, and global disability scale. Scales proposed for FRDA including the Friedreich Ataxia Rating Scale (FARS) which combines scores for ataxia, activities of daily living, and neurological examination. Other scales for tremor and parkinsonism (e.g., Unified Parkinson's Disease Rating Scale) may be useful. Details and clinimetric properties of these scales are discussed in other encyclopedia entries.

Studies of Potential Utility in Patients With Ataxia

This section describes tests that may be useful in the evaluation of a patient with ataxia. However, pursuit of these tests should be guided by the patient's history, family history for inheritance patterns, and examination, among other factors, particularly since many of the specialized tests are very expensive.

Laboratory studies to be considered (depending on clinical situation) include: thyroid function, vitamin B12, vitamin E, vitamin B1, heavy metal screen, antigliadin antibodies, GAD antibodies, serum cholesterol and plasma lipoprotein profile, peripheral blood smear for acanthocytes, serum lactate and pyruvate, very long chain fatty acids, hexosaminidase A or B, paraneoplastic antibodies, toxicology screen, α-fetoprotein and immunoglobulins, serum ceruloplasmin and 24 h urinary copper, and phytanic acid. Cerebrospinal fluid analysis may be used to assess protein, oligoclonal bands, 14–3–3 protein, GAD antibodies, or paraneoplastic antibodies. Many genetic tests are now commercially available, and some are available on a research basis. To date, genetic tests include SCA1, 2, 3, 5, 6, 7, 8, 10, 13, 14, 17, 27 (for SCA5, 13, 14, and 27, the analysis is of the entire coding region: sequence analysis, whereas the other SCAs have targeted mutation analysis); DRPLA; FRDA; Ataxia with oculomotor apraxia types 1 and 2 (APTX and senataxin); Fragile X DNA; Rett syndrome; X-linked sideroblastic anemia and ataxia; ataxia telangiectasia; ARSACS (targeted mutation analysis); *TTPA* gene for ataxia with vitamin E deficiency; SIL1 for Marinesco–Sjogren syndrome; mitochondrial recessive ataxia syndrome (MIRAS)-specific POLG1; and EAs type 1 and 2 (sequence

analysis). Tissue biopsies of muscle, skin, rectum, bone marrow, tonsil, or brain may be considered in appropriate circumstances.

Neuroimaging with MRI of the brain and possibly, cervical spine may be useful in excluding structural causes, multiple sclerosis, or assessing regional atrophy (i.e., in the cerebellum, brainstem, or cervical cord). In some cases, magnetic resonance spectroscopy may be helpful. Electrodiagnostic tests such as nerve conduction studies and EMG may be used to evaluate neuropathy which is often associated with the ataxias or other neuromuscular abnormalities; electoencephalography, evoked potentials, electronystagmography, or electroretinography may be considered in selected circumstances. Tests of autonomic dysfunction for tilt-table tests, sympathetic skin responses, cardiac I^{123}-MIBG-SPECT scans, or anal sphincter EMG, particularly in MSA. Ophthalmologic examination may be targeted for pigmentary retinopathy, macular degeneration, cataracts, Kayser–Fleischer rings.

Management

Treatment of cerebellar ataxias encompasses both pharmacologic and nonpharmacologic strategies and in some cases, depends on the specific etiology of the ataxia. Some of the management issues have been previously discussed in the individual ataxia sections and where available, specific trials will be noted. In addition to management of neurologic systems, one must pay attention to systemic disorders affecting cardiac, endocrine, gastrointestinal, and skeletal systems as well as underlying neoplasms. Trials of medications for cerebellar ataxia mainly consist of open label studies or case reports, and better therapeutics and double-blind, placebo-controlled trials are needed. Lastly, genetic counseling is an important aspect of the management of hereditary ataxias.

Pharmacologic Strategies

First, treatable causes of ataxia will be mentioned. Although not curative, high doses of vitamin E can improve neurologic symptoms in ataxia with vitamin E deficiency (AVED) and Abetalipoproteinemia. Phytanic acid should be restricted to less than 10 mg day^{-1} in Refsum disease. Gluten ataxia may improve with restriction of wheat and products containing gluten. Ataxia due to CTX should be treated with chenodeoxycholic acid and possibly other cholesterol medications. Of course, ataxia due to infectious (including Whipple's disease) or vascular etiologies may have disease-specific treatments. Paraneoplastic cerebellar syndromes may respond to treatment of underlying cancer and immunotherapies, such as intravenous immunoglobulin, plasmapheresis, and steroids. However, due to cerebellar neuronal damage, the ataxia symptoms may have modest response to these treatments. Cerebellar ataxia with GAD antibodies has been reported to respond to immunotherapies. EAs, particularly EA-1, 2, and 4, are acetazolamide-responsive. A recent open label trial of the potassium channel blocker 4-aminopyridine (4-AP) in three EA-2 patients reported prevention or decreased attacks during treatment and recurrence when 4-AP was stopped.

For FRDA, treatment focuses on rehabilitation and orthopedic interventions for gait and limb difficulty and skeletal deformities and cardiac and endocrine monitoring. Idebenone, a free radical scavenger, as other antioxidants such as vitamin E, coenzyme q10, and selenium have been studied in FRDA. Most trials with idebenone have been open label although a recent randomized, placebo-controlled study has been reported. Unfortunately, despite reduction of oxidative stress markers and decreased cardiac hypertrophy in some studies with idebenone, significant improvement in ataxia largely has been lacking.

Management for MSA is generally tailored to specific symptoms. Dopaminergic medications may provide some improvement in parkinsonian features (bradykinesia, rigidity, or rest tremor), particularly early in the course. Improvement, however, is not as dramatic or sustained as in idiopathic Parkinson's disease. Orthostatic hypotension can be managed with increased salt and caffeine intake, pressurized stockings, and elevation of the head of the bed. Several trials including double-blind studies have assessed fludrocortisone and midodrine in orthostatic hypotension, but the use of these medications is limited by supine hypertension. A prospective open label trial by Singer et al. evaluating the acetylcholinesterase inhibitor, pyridostigmine, in the treatment of neurogenic orthostatic hypotension in patients with MSA, PD, and diabetic, amyloid, or idiopathic autonomic neuropathy demonstrated significant improvement in orthostatic blood pressure, peripheral resistance index, and orthostatic symptoms with only a moderate and nonsignificant increase in supine blood pressure. Bladder frequency and urgency may be treated with agents, such as oxybutynin and tolterodine. REM behavior disorder responds well to clonazepam.

The neurochemistry of the cerebellum has led to investigations of serotonergic, dopaminergic, GABAergic, and cholinergic treatments in cerebellar ataxias, although symptomatic benefits have been modest. Several studies have examined buspirone, a 5HT1A serotonin agonist with weak dopaminergic properties, in the cerebellar ataxias. An open label trial by Lou et al. with 20 patients with mixed cortical or OPCA received buspirone 60 mg day^{-1} for 8 weeks followed by a washout period; nine patients with mild or moderate symptoms had significant improvement in clinical and subjective ratings but not in motor function or posturography and few patients with severe symptoms showed improvement. Trouillas et al. performed a double-blind, placebo controlled study with buspirone in 19 patients with cortical cerebellar atrophy for 4 months found improvement only in subscores such

as intensity of body sway and time of standing and kinetic score. A double-blind, placebo-controlled study by Botez et al. with amantadine (200 mg day^{-1}), an NMDA antagonist with some dopaminergic properties, was performed with 27 patients with FRDA and 39 patients with olivopontocerebellar ataxias for 3–4 months. Improvement was greater in the olivopontocerebellar ataxia group with improvement in visual and auditory reaction time and movement time. Other studies with amantadine have shown less positive results. An open label trial by Gazzula et al. with gabapentin, a GABAergic medication, in 10 patients (seven with sporadic cortical cerebellar atrophy and three with an unknown ADCA) reported a significant improvement in ataxia scores after single doses of 400 mg day^{-1} and 4 week treatment with 900–1600 mg day^{-1}. Double-blind, placebo-controlled, crossover studies have investigated the cholinergic system with physostigmine, an acetylcholinesterase inhibitor, and L-acetylcarnitine, a cholinomimetic agent, in mixed ataxia populations without any effect on ataxia in the former and significant improvement in coordination but not total ARS score in the latter trial.

Several trials have addressed specific pharmacologic treatments in the SCAs, using a variety of agents but with mixed results. These reports include: zolpidem in five SCA2 patients; buspirone, a 5HT1A serotonin agonist with weak dopaminergic properties, in a single SCA3 patient; tandospirone, also a 5HT1A agonist, in case reports and open label studies in SCA3; fluoxetine in open label study of 13 SCA3 patients; trimethoprim–sulfamethoxazole in a double-blind, placebo-controlled crossover trial in 22 genetically confirmed SCA3 (no effect); acetazolamide in open label studies in small numbers of SCA6 (mixed results in clinical measures and posturography sway); and intravenous lidocaine in a case report of SCA6. More recently, Zesiewicz and Sullivan reported three patients with SCA3 and SCA14 who had improvement in ataxia symptoms with varenicline, a partial agonist selective for $\alpha4(\beta2$ nicotinic acetylcholine receptors and prescribed for smoking cessation. Based on a recent SCA1 knockout mice study in which lithium improved motor function and learning, a safety trial with lithium in SCA1 is currently underway.

Nonppharmacologic Strategies

Although clinical studies are lacking for nonpharmacologic treatments of ataxias, these modalities can be helpful. Physical and occupational therapy may be useful in gait and balance training, safety mechanisms, decreasing spasticity or rigidity, and reducing musculoskeletal problems such as contractures. Occupational therapists may help patients find adaptive devices to improve functional use of upper extremities. Speech therapists can evaluate dysphagia with bedside tests or more formal radiographic studies and teach swallowing techniques, modify diets, and work on dysarthria. Social services and supportive care also are important aspects.

Genetic Counseling

Genetic counseling is extremely important in the management of hereditary ataxias. Patients and families need to be counseled on underlying inheritance and risks of developing disease. Genetic counselors are valuable allies when discussing genetic testing; ethical concerns; potential social, medical, or insurance issues; and family planning with patients and families. Presymptomatic testing in adults, in general, is not routinely performed. In a study on the impact of presymptomatic genetic testing in 50 subjects with hereditary ataxias and neuromuscular disease, testing was reported as helpful in 84%, but increased anxiety at some point in the study occurred in 18 subjects with persistence at follow up and depression occurred in three (of whom two had negative results) in post-test period. Reasons for genetic testing included explanation for symptoms, emotional relief, and family planning.

Ataxia (Familial Cerebellar) with Muscle CoQ_{10} Deficiency

M Hirano and C Quinzii, Columbia University Medical Center, New York, USA

Glossary

Coenzyme Q_{10} – Abbreviated CoQ_{10}, a lipophillic molecule present in cell membranes which transports reducing equivalents (electrons) in the inner membrane of mitochondria.
Primary CoQ_{10} deficiency – Deficiency of CoQ_{10} due to mutations of a gene required for CoQ_{10} biosynthesis.
Respiratory chain – A set of four multisubunit enzymes (complexes I–IV) embedded in the mitochondrial inner membrane that transfers reducing equivalents (electrons) to generate a transmembrane proton gradient.
Secondary CoQ_{10} deficiency – Deficiency of CoQ_{10} that is not due to mutations in a CoQ_{10} biosynthesis gene.

Definition and History

Coenzyme Q_{10} (CoQ_{10}) is comprised of a benzoquinone ring and a tail comprised of 10 isoprenyl units and is synthesized within mitochondria. A major function of CoQ_{10} is to transport electrons from complexes I and II to complex III in the respiratory chain, which reside in the mitochondrial inner membrane (**Figure 1**). In addition, CoQ_{10} is an antioxidant, a cofactor for de novo pyrimidine synthesis, electron transporter of plasma membranes and lysosomes, and modulator of apoptosis.

Deficiency of CoQ_{10} (MIM 607426) was originally described by Ogasahara and colleagues who reported two sisters with an encephalomyopathy characterized by a triad of recurrent myoglobinuria, brain involvement, and ragged-red fibers. Three other major clinical phenotypes have been associated with primary CoQ_{10} deficiency: (1) infantile multisystemic disease typically with prominent nephropathy and encephalopathy; (2) cerebellar ataxia with marked cerebellar atrophy; and (3) pure myopathy. Primary CoQ_{10} deficiencies are due to mutations in ubiquinone biosynthetic genes while secondary CoQ_{10} deficiencies are caused by mutations in genes not directly related to ubiquinone biosynthesis.

Pathogenesis and Pathophysiology

Primary CoQ_{10} deficiency has been molecularly proven by the identification of CoQ_{10} biosynthetic genes in

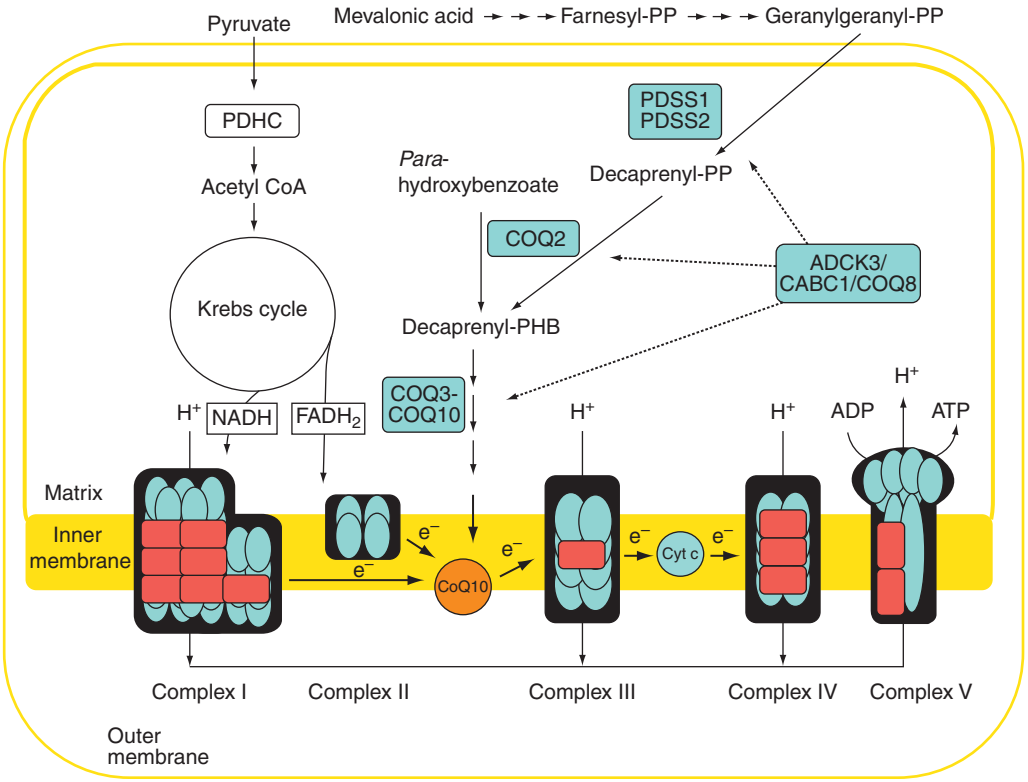

Figure 1 Mitochondrion showing the human CoQ_{10} biosynthetic pathway and the respiratory chain enzyme complexes.

8 patients (6 families) with infantile-onset diseases and in 11 patients (7 families) with cerebellar ataxia. In 2006, Quinzii and colleagues identified the first missense mutation in the *COQ2* gene (p.297Y>C), encoding *p*-hydroxybenzoate-polyprenyl transferase (**Figure 1**), in two siblings of consanguineous parents with infantile steroid-resistant nephropathy, encephalomyopathy in the older child, and deficiency of CoQ_{10} in muscle and fibroblasts in the younger child. Subsequently, *COQ2* mutations were identified in an additional patient with infantile multisystemic disease and two children with early-onset nephrotic syndrome. In addition, mutations in both subunits of decaprenyl diphosphate synthase (**Figure 1**) were identified in three patients with infantile-onset multisystemic diseases; one with fatal Leigh syndrome and nephrotic syndrome due to compound heterozygous *PDSS2* mutations and two siblings with early-onset deafness, encephaloneuropathy, obesity, livedo reticularis, and valvulopathy due to a homozygous missense mutation in *PDSS1*. In all of the infantile multisystemic syndromes, levels of CoQ_{10} were decreased in muscle and fibroblasts.

Finally, mutations in *ADCK3* (also called *CABC1*), a mitochondrial kinase involved in ubiquinone biosynthesis, have been described in 11 patients from 7 families with a cerebellar phenotype. All patients presented with childhood-onset cerebellar ataxia, variably associated with exercise intolerance that improved with years, mild psychomotor delay, and neuropathy. None had kidney disease. Partial CoQ_{10} deficiency was documented in muscle and in some patients' fibroblasts.

Secondary CoQ_{10} deficiency has been genetically proven in the cerebellar and myopathic phenotypes. In 2001, Musumeci and colleagues reported for the first time six patients presenting with cerebellar ataxia, pyramidal signs and seizures, and low level of CoQ_{10} in muscle and fibroblasts. In the three of those patients who were siblings, we found a homozygous W279X mutation in the *APTX* gene, encoding aprataxin, a protein involved in DNA single-strand break repair and known to be the cause of ataxia-oculomotor-apraxia 1 (AOA1). Le Ber and colleagues confirmed that aprataxin gene mutations are associated with decreased CoQ_{10} levels in muscle and that the decrease correlates with the genotype. They noted low levels of CoQ_{10} in muscle from five unrelated patients with AOA1 and the lowest levels of CoQ_{10} were seen in the patients with the homozygous W279X mutation. The CoQ_{10} deficiency was not correlated with duration, severity, and/or progression of the disease or with biological measures, indicating that CoQ_{10} deficiency is not the primary or the only cause of neurological decline in AOA1; nevertheless, patients improved considerately after CoQ_{10} supplementation.

In addition, secondary CoQ_{10} deficiency has been associated with pure myopathy due to mutations in the *ETFDH* (electron-transferring-flavoprotein dehydrogenase) gene, previously associated with glutaric aciduria

type II. A single patient with cardiofaciocutaneous syndrome due to a *BRAF* gene mutation also had CoQ_{10} deficiency and improvement with CoQ_{10} supplementation. All of the patients showed dramatic improvements after CoQ_{10} supplementation.

Despite the aforementioned advances, primary and secondary CoQ_{10} deficiencies have been defined biochemically and genetically in less than half of the reported patients, and their pathogenic mechanisms remain unclear. In skeletal muscle of patients, CoQ_{10} deficiency has been associated with variable defects of the mitochondrial respiratory chain, increased apoptosis, and upregulation of antioxidant defenses.

CoQ_{10} deficiency has variable effects on bioenergetics, oxidative stress, and antioxidant defenses. *PDSS2* mutant fibroblasts with severe CoQ_{10} deficiency (12% of normal) and decreased complex II+III activity showed reduced ATP synthesis without reactive oxygen species (ROS) production, signs of oxidative stress, or increased antioxidant defense markers. In contrast, *COQ2* mutant fibroblasts have milder reductions of CoQ_{10} (30% of normal) and complex II+III activity with moderate defects in ATP synthesis, but significantly increased ROS production and oxidation of lipids and proteins. In addition, *COQ2* mutant cells required uridine to maintain growth and proposed that deficiency of CoQ_{10} caused a defect of pyrimidines biosynthesis because of the dependence of dihydro-orotate dehydrogenase on ubiquinol. Thus, lack of CoQ_{10} may cause human diseases by one or multiple processes including reduced respiratory chain activity; enhanced ROS production, increased ROS susceptibility, or both; or impairment of de novo pyrimidines synthesis.

Epidemiology/Risk Factors

CoQ_{10} deficiencies are rare conditions due to autosomal recessive mutations.

Clinical Features and Diagnostic Criteria

CoQ_{10} deficiency has been associated with four major clinical phenotypes: (1) an encephalomyopathic form characterized by mitochondrial myopathy, recurrent myoglobinuria and central nervous system signs, associated with decrease of complex I+III and complex II+III activity and CoQ_{10} in muscle; (2) a pure myopathic form, with lipid storage myopathy and respiratory chain dysfunction; (3) a cerebellar form, with cerebellar ataxia and atrophy variably associated with other manifestations as neuropathy, seizures, mental retardation, muscle weakness, hypogonadism; and (4) a multisystemic infantile form. Moreover, CoQ_{10} deficiency has been reported in two adult sisters with Leigh syndrome, encephalopathy, growth retardation, infantilism, ataxia, deafness and lactic acidosis, and with cardiofaciocutaneous syndrome. In most of these phenotypes, family history suggests an autosomal recessive mode of inheritance because siblings are often affected while parents are typically unaffected; parents are sometimes consanguineous.

Cerebellar ataxia and atrophy is the most frequent phenotype associated with CoQ_{10} deficiency and is not rare. In a study of 135 patient with genetically undefined cerebellar ataxia (i.e., without spinocerebellar ataxia or Friedreich ataxia gene mutations), about 10% had CoQ_{10} deficiency in muscle.

Differential Diagnosis

The differential diagnosis of cerebellar ataxia due to CoQ_{10} deficiency includes other genetic forms of cerebellar ataxia including Friedreich ataxia, spinocerebellar ataxia, and other mitochondrial diseases such as myoclonus epilepsy with ragged-red fibers (MERRF), neuropathy ataxia retinitis pigmentosa (NARP), and ataxias due to mitochondrial polymerase γ mutations.

Diagnostic Work-up/Tests

Screening patients for cerebellar ataxia due to CoQ_{10} deficiency should begin with routine blood tests including complete blood count, serum electrolytes, liver function tests, blood urea nitrogen, creatinine, lactate, and pyruvate. Nevertheless, blood lactate and pyruvate are often normal in patients with cerebellar ataxia and CoQ_{10} deficiency. Screening for proteinuria may reveal signs of nephrotic syndrome, particularly in infants with the multisystemic disease due to CoQ_{10} deficiency.

In most cases, CoQ_{10} deficiency has been diagnosed by muscle biopsy. In patients with the myopathic forms, elevated serum creatine kinase, and the coexistence of ragged-red fibers and increased lipid in muscle are clues to the diagnosis of CoQ_{10} deficiency, whereas in patients with the ataxic form, muscle morphology is minimally affected. Skin fibroblasts may show CoQ_{10} deficiency, particularly in the ataxic and infantile-onset forms, whereas serum or plasma measurements of CoQ_{10} are not reliable to diagnose CoQ_{10} deficiency.

Management

No treatment for the genetic defect is currently available. Patients often show dramatic clinical improvements or stabilization with high-dose oral coenzyme Q_{10} supplementation (up to 3000 mg daily in adults and 30 mg kg^{-1} day^{-1} in children).

Prognosis

Because ataxia with CoQ_{10} deficiency is a relatively novel syndrome, the long-term prognosis of patients is unknown; however, CoQ_{10} supplementation often produces clinical improvements suggesting that treatment may improve outcome.

Ataxia with Isolated Vitamin E Deficiency

C Mariotti, Istituto Neurologico Carlo Besta, Via Celoria, Milano, Italy

Glossary

Ataxia – An inability to coordinate voluntary muscle movements.

Autosomal Recessive – Describes a trait or disorder requiring the presence of two copies of a gene mutation (one inherited from the mother and the other from the father) at a particular locus in order to express observable phenotype. The parents are usually asymptomatic.

Gene – The functional and physical unit of heredity passed from parent to offspring. Genes are pieces of DNA, and most genes contain the information for making a specific protein.

Gene mutation – Any alteration of a gene from its natural state.

Retinitis pigmentosa – Progressive degeneration of the neuroepithelium of the retina characterized by night blindness and progressive contraction of the visual field.

Vitamin – A general term for a number of unrelated organic substances that occur in many foods in small amounts and that are necessary in trace amounts for the normal metabolic functioning of the body. They may be water-soluble or fat-soluble.

Ataxia with Isolated Vitamin E Deficiency

Clinical Characteristics

Ataxia with vitamin E deficiency (AVED, OMIM 277460) is a very rare genetic neurodegenerative disorder, mostly detected in the Mediterranean populations. The disease is transmitted as an autosomal recessive trait. Clinical

features closely resemble those of Friedreich ataxia (FRDA) patients. However, the concomitant presence of specific neurological symptoms and very low levels of plasma vitamin E, in the absence of other clinical conditions commonly associated with fat malabsorption, can guide differential diagnosis. The neurological features include progressive gait and limb ataxia, dysarthria, lower-limb areflexia, loss of proprioceptive and vibration sense, and extensor plantar response. Frequently, the patients have head titubation (44%) and retinopathy (12%). The majority of the patients present the first neurological symptoms between 4 and 18 years of age. AVED patients rarely have cardiac involvement.

Electrophysiological examination shows normal motor and sensory conduction velocity (MCV–SCV) and normal muscle action potential (MAP) amplitude, while the sensory action potential is usually markedly decreased particularly in the lower limbs. Somatosensory evoked potentials demonstrate increased central conduction time and increased latencies at median and tibial nerves. Brain MRI findings include cerebellar atrophy and dilatation of the cisterna magna. Pathology studies demonstrated mild loss of Purkinje cells, atrophy of spinal sensory neurons, dying back-type degeneration of the posterior columns, neuronal lipofuscin accumulation in the third cortical layer of the cerebral cortex, thalamus, lateral geniculate body, spinal horns and posterior root ganglia, and retinal atrophy.

Biochemical Findings

The biochemical hallmark of the disease is a very low level of vitamin E in plasma, in the absence of intestinal fat malabsorption and abetalipoproteinemia. In fact, AVED patients have normal intestinal absorption of α-tocopherol (vitamin E) and normal incorporation into chylomicrons, but they have an impairment of the α-tocopherol incorporation into very low density lipoproteins (VLDL). In 1995, Ouahchi et al. demonstrated that AVED is caused by mutations in the gene coding for the α-tocopherol-transfer protein (*TTPA*). This cytosolic liver protein is able to select among the eight different dietary-derived vitamin E isomers (α,β,γ,δ tocopherols and α,β,γ,δ tocotrienols) and preferentially binds the RRR-α-tocopherol to VLDL proteins, which are then released into the circulation. Thus, the *TTPA* is responsible for the maintenance of normal vitamin E plasma concentrations. No universal normal range of plasma vitamin E concentration can be given, since it depends on the specific method used and varies between laboratories. In individuals with AVED, the plasma α-tocopherol concentrations are generally $<4\,\mathrm{mmol\,l^{-1}}$ ($<1.7\,\mathrm{mg\,l^{-1}}$). Since oxidation of α-tocopherol by air might invalidate test results, precautions should be taken soon after venipuncture to protect the blood sample from air and light. Levels of vitamin E in plasma of heterozygotes are generally within the normal range.

Molecular Genetics

The disease is caused by mutations in the *TTPA*, the gene encoding α-tocopherol transfer protein. Since 1995, when the genetic basis of the disease was elucidated, more than 50 AVED families and ~18 different mutations in the *TTPA* gene have been described. In North-African populations, the mutation most frequently responsible for the disease is the 744delA mutation, while in AVED families of North European origin, the 513insTT mutation has been often identified.

Sequencing the five exons and flanking intron sequences of *TTPA* genomic DNA detect mutations in more than 90% of individuals with AVED. Sometimes, mutations in intron sequences create a cryptic splice site that can cause abnormal splicing, leading to abnormal RNA transcripts and thus to abnormal proteins. These kinds of splice site mutations might be overlooked if sequencing is only done on the exon and flanking intron sequences, on the genomic DNA level. Most individuals are homozygous or compound heterozygous for one of the known mutations. For mutational screening, genomic DNA is extracted from blood samples using standard procedures. The DNA region corresponding to the five exons and to intron–exon boundaries of the *TTPA* gene is amplified by PCR, and direct sequence analysis of the PCR products is performed by automated sequencing system.

Natural History

The phenotype and disease severity vary widely between families with different mutations. Although age of onset and disease course tend to be more uniform within a given family, symptoms and disease severity can vary between siblings. AVED generally manifests in late childhood or early teens between 5 and 15 years of age. Individuals of Japanese descent with the H101Q mutation tend to manifest later between ~20 and 50 years of age. Initial symptoms include progressive ataxia, clumsiness of the hands, and loss of proprioception, especially of vibration and joint position sense. Handwriting deteriorates, and equilibrium in walking is impaired. In many individuals, cerebellar signs such as dysdiadochokinesia and dysarthria with a scanning speech pattern are present. One third of the individuals have a characteristic head tremor (head titubation). In some persons, psychotic episodes, intellectual decline, and dystonic episodes have been described. Most individuals become wheelchair bound because of ataxia and/or leg weakness between 11 and 50 years of age.

No clear genotype–phenotype correlations have been identified, except for two mutations: the 303T >G mutation that is associated with late onset (>30 years of age), mild course, and increased risk for pigmentary retinopathy (mainly described in individuals of Japanese descent); and the 744delA, associated with early onset, severe course,

and increased risk for cardiomyopathy (mainly observed in individuals of the Mediterranean or North African descent).

Management

The treatment of choice for AVED is lifelong high-dose oral vitamin E supplementation. Some symptoms (e.g., ataxia, mental deterioration) can be reversed if treatment is initiated early in the disease process. In older individuals, disease progression can be stopped, but deficits in proprioception and gait unsteadiness generally remain. With treatment, plasma vitamin E concentrations can become normal. Daily doses range from 800 to 1500 mg (or 40 mg kg^{-1} body weight in children).

The vitamin E preparations used are either the chemically manufactured racemic form (*all-rac*-α-tocopherol acetate) or the naturally occurring form (RRR-α-tocopherol). During vitamin E therapy, plasma vitamin E concentration should be checked at regular intervals (e.g., every 6 months), especially in children. Ideally, the plasma concentration of vitamin E should be in the high normal range. Vitamin E treatment should also be initiated in presymptomatic individuals (e.g., younger siblings of an index case), to prevent the onset of neurological deficits.

Genetic Counseling

Ataxia with vitamin E deficiency is an autosomal recessive disorder. The parents of an affected child are obligate asymptomatic heterozygotes and therefore carry one mutant allele. All children of heterozygotes parents have a 25% chance of being affected, a 50% chance of being asymptomatic carriers, and a 25% chance of being unaffected and not carriers. Carrier testing for at-risk family members is available on a clinical basis once the mutations have been identified in the proband.

The moderately lowered plasma vitamin E concentrations in heterozygotes are not sensitive enough to distinguish between heterozygous carriers and noncarriers. Because vitamin E treatment initiated in presymptomatic individuals can prevent the findings of AVED, testing of at-risk family members (particularly younger siblings of the proband) is appropriate.

Prenatal diagnosis for pregnancies at increased risk is possible by analysis of the DNA extracted from fetal cells obtained by amniocentesis or chorionic villus sampling. Mutations in the affected family member must be identified before prenatal testing can be performed.

Ataxia-Telangiectasia

M Scavina, DuPont Hospital for Children, Wilmington, DE, USA

Glossary

ATM gene – Ataxia-telangiectasia mutated (ATM) gene, located on chromosome 11q23 and associated with AT. Functions to sense double-stranded DNA breaks and coordinates cell cycle checkpoints involved in DNA repair.

Choreoathetosis – Involuntary movements of the body characterized by a combination of chorea

(irregular, random, flowing movements) and athetosis (slower, writhing movements).
DNA cycle and repair – Processes which occur in a cell that lead to the replication and repair of damaged DNA.
Oculomotor Apraxia – Difficulty in the initiation of voluntary eye movements.
Purkinje Cells – Neurons in the cortex of the cerebellum which are GABAergic in nature.
Telangiectasias – Dilated blood vessels which appear as tiny, red 'spider veins' on the surface of the skin and in the corners of the eyes.

Definition and History

Ataxia-telangiectasia (AT), first described in 1926 by Syllaba and Henner, is a genetic, degenerative disorder that is characterized by progressive cerebellar ataxia, oculomotor apraxia, telangiectasias, immune dysfunction, and a predisposition to malignancies. Individuals are also abnormally sensitive to ionizing radiation such as X-rays and γ-rays. The gene responsible for the disorder is the ataxia-telangiectasia mutated (ATM) gene, and it is located on chromosome 11q23. Mutations in the gene lead to abnormalities in DNA function and stability. Inheritance is autosomal recessive. Although there is no current cure for the disorder, survival has greatly improved over the last 10–20 years.

Pathogenesis

There are a number of factors that contribute to the AT phenotype. The ATM gene encodes a protein that helps control cell division and DNA repair. Lack of this protein product causes cell instability, leading to increased DNA breakage and death. Previous studies have shown that chromosomal recombination rates in skin fibroblasts from patients with AT are higher than those from controls. Regulation abnormalities of the cell cycle have been found which interfere with DNA repair and proper downstream signaling pathways. Specifically, the G1-S checkpoint of the cell cycle has been found to be absent in AT cells, leading to aberrant DNA formation. In the central nervous system, loss of Purkinje and granule cells in the cerebellum leads to progressive ataxia.

Epidemiology/Risk Factors

AT is an inherited autosomal recessive disorder. The prevalence is 1 in 40 000 to 1 in 100 000 people worldwide. There is no specific cultural predisposition, and males and females are affected equally. Approximately 1% of the population in the United States is felt to be a carrier for AT. Carriers have been found to be at increased risk of developing cancer, particularly breast cancer, as compared to the general population. Carriers also may be at increased risk of developing heart disease and diabetes.

Clinical Features

Clinical signs of AT usually begin in early childhood (typically between ages 1 and 4 years) with delays in motor milestones, progressive ataxia, oculomotor apraxia, and the appearance of telangiectasias. Truncal ataxia tends to occur before appendicular ataxia. Oculomotor apraxia may precede the appearance of telangiectasias and is progressive in nature. The telangiectasias or 'spider veins' can appear in the corner of the eyes as well as on the surface of the ears and cheeks, and appear between 3 and 5 years of age. Although they are characteristic of the disorder, they may not be present. Diagnosis is based on clinical features including the progressive ataxia and oculomotor apraxia with supportive laboratory tests.

Progression of the ataxia usually leads to an inability to ambulate independently and the need for a wheelchair in late childhood or early teen years. Choreoathetosis, myoclonus, dystonia, and intention tremors can be seen in addition to the ataxia. The choreoathetosis is seen in the majority of individuals, while myoclonus and intention tremors are present in approximately 25% of individuals. Deterioration in muscle strength and development of contractures, particularly in distal musculature, occur as the disease progresses. Deep tendon reflexes may initially be present but are diminished or absent by late childhood. Overall, cognitive function is intact, although some report slowed motor and verbal responses or mild learning difficulties.

In addition to the progressive neurological and skin manifestations, individuals with AT are predisposed to infections and the development of malignancies. The immune system is weak, and recurrent sinopulmonary infections may occur. Approximately 38% of individuals also develop cancer. The most common types are leukemias and lymphomas. Acute lymphocytic leukemia is often seen in younger children with AT. Other types of cancers which have been reported include breast, ovarian, gastric, and skin. Individuals with AT are also more sensitive to ionizing radiation such as medical X-rays and γ-rays.

Differential Diagnosis

A thorough history, including family history, physical examination, neuroimaging, and laboratory studies are

all part of the evaluation of a child with ataxia. The early onset of AT and lack of features such as oculomotor apraxia and telangiectasias at initial presentation can make the diagnosis challenging. A diagnosis of cerebral palsy is often made in cases in which ataxia and dysarthria may be part of the clinical picture. Other diagnoses to consider include structural lesions, particularly of the cerebellum, vitamin, and metabolic deficiencies such as B12 and biotinidase, and genetic forms of ataxia. Included in the long list of inherited ataxias would be Friedreich's ataxia, ataxia with vitamin E deficiency (AVED), ataxia with oculomotor apraxia type I (AOA1), ataxia with oculomotor apraxia type 2 (AOA2), and infantile onset SCA (IOSCA). Lysosomal enzyme deficiencies and mitochondrial disorders would also be considered in the differential. An AT variant known as Nijmegen Breakage syndrome is not characterized by ataxia but it is associated with cell radiosensitivity and increased risk of infections. Important findings that would make AT less likely include a nonprogressive ataxia and severe mental retardation.

Diagnostic Studies

A number of supportive tests are available in the evaluation of a child with AT. Neuroimaging, laboratory and chromosomal studies, protein assays, cell stability assays, and gene testing can all be used to confirm the clinical diagnosis of AT. Brain magnetic resonance imaging (MRI) may be utilized to look for evidence of cerebellar atrophy and to rule out other structural lesions or processes. The α-fetoprotein level is elevated in over 95% of individuals with AT. Immunoglobulin levels may show a decrease in IgA levels as well as other immunoglobulins. Karyotyping should be done to evaluate for translocations, particularly 7;14, which are seen in AT. Lymphoblastoid cell lines may be established for immunoblotting to determine whether ATM protein is present or absent. Approximately 90% of individuals with AT have no detectable ATM protein, 10% have trace amounts, and 1% have normal levels but lack ATM protein kinase activity. Colony Survival Assay is an in vitro assay that determines survival of lymphoblastoid cells following irradiation. The test usually takes several months to complete. Sequencing of the ATM gene is clinically available and detects 90% of alterations of the gene.

Management

Although there is no cure, treatment of neurologic and other manifestations is possible to optimize survival and quality of life. Physical, occupational, and speech therapy are important in addressing the functional needs of the individual with ataxia, dysarthria, dysphagia, and progressive weakness.

Although there is a lack of formal clinical trials and data to support their use, agents which have been tried include vitamins and antioxidants. Specifically, vitamin E and α-lipoic acid have been used. Intravenous immunoglobulin (IVIG) also has been utilized in individuals with frequent infections. Proper nutrition is important in maintaining health and decreasing risk of infections.

Given the increased risk for developing malignancies, regular surveillance is important for early detection. Use of radiation should also be minimized and monitored, as standard doses may be deleterious or even lethal to patients with AT.

Prognosis

AT is a progressive disorder for which there is no cure at this time. However, survival continues to improve with better supportive therapy and management. Life expectancy is now past 25 years of age for many patients. There have been reports of individuals in their forties and fifties with AT as well. In older individuals, pulmonary failure seems to be a major source of morbidity and mortality.

Ataxin

P Opal, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Glossary

Ataxin-1 – The protein involved in spinocerebellar ataxia type 1 (SCA1).
High-throughput yeast two-hybrid screen – A molecular biology technique used to discover protein–protein interactions in yeast.
PODs – PML oncogenic domains – nuclear domains, associated with the nuclear matrix, disrupted in human acute promyelocytic leukemia cells.
Polyglutamine disorders – A group of genetic disorders in which the mutation results in the expansion of a triplet sequence (CAG) that codes for the amino acid, glutamine; includes several of the SCAs as well as Huntington's disease among others.
Spinocerebellar ataxia – A term often used to describe a group of autosomal dominant neurodegenerative diseases characterized by progressive motor incoordination typically starting in mid-life.

Ataxin-1 Protein (*ATAXIN-1* Gene)

Ataxin-1 is the protein mutated in the autosomal dominant disease spinocerebellar ataxia type 1 (SCA1; OMIM 164400). *ATAXIN-1* is the gene encoding this protein situated on the chromosome 6p23. The specific mutation in SCA1 is a CAG trinucleotide repeat expansion within exon 8 of the *ATAXIN-1* gene. Because the repeat expansion occurs in the coding region of the gene and because CAG encodes for glutamines, the mutation results in a glutamine repeat expansion in the protein product. As such, SCA1 belongs to the family of polyglutamine repeat disorders. As in other polyglutamine diseases, a longer expansion results in earlier disease onset in patients (i.e., anticipation) and a worse severity of the disease.

Ataxin-1 is ubiquitously expressed. At a subcellular level, ataxin-1 is primarily localized to the nucleus in neurons including Purkinje cells, those neurons most affected by SCA1 toxicity. In peripheral tissue, ataxin-1 has been reported as being mainly cytoplasmic. Ataxin-1 demonstrates a molecular weight of ~100 kDa (with ~800 amino acids). The exact size is determined by the length of the glutamine repeat. In patients, the repeat length varies between 39 and 82 residues, with a tendency for the repeats to expand over generations. The instability of the repeat is especially pronounced with paternal transmission of the expanded allele. Even in normal individuals, the glutamine repeat shows variability in length (6–44 repeats). When the CAG repeat is long in asymptomatic individuals, it is usually interrupted by 1–3 CAT residues (trinucleotides that encode histidine), that presumably stabilizes these long alleles from expanding. The role of the normal polyglutamine tract is still a puzzle, given that the tract can be virtually nonexistent in other mammalian species (e.g., mouse ataxin-1 has only two glutamines).

The function of wild-type ataxin-1 is largely unknown. Because ataxin-1 is developmentally regulated (peaking in expression at postnatal day 14 in the mouse), ataxin-1 likely plays a developmental role, particularly as a transcriptional regulator. Despite the dearth of knowledge of ataxin-1's normal function, studies in genetically engineered mice suggest that SCA1 is predominantly a gain of function disease. This inference can best be summed up by the findings that transgenic or knockin mice with expanded ataxin-1 recapitulate the key features of this disease, while mice lacking SCA1 do not demonstrate ataxia or Purkinje cell degeneration. Indeed, ataxin-1 null mice are essentially indistinguishable from wild-type littermates by home-cage behavior. They do, however, display subtle defects on electrophysiological, behavioral, and locomotor assays. Some of these defects are presumed to occur because ataxin-1 serves a transcriptional role, modulating transcription affecting the dopaminergic pathway.

SCA1 transgenic and knockin mouse models have led to a better understanding of the pathology. They have revealed, for instance, the dual contributions of the expanded glutamine tract and mutant protein expression levels to toxicity. For example, knockin mice that express mutant ataxin-1 with 78 glutamines develop a mild phenotype – most likely because the life-span of the mouse is too short to allow for an accumulation of damage required for overt toxicity. However, knockin mice with a single copy of the *ataxin-1* gene expanded to encode 154 glutamine repeats ($SCA1^{154Q/2Q}$; Q = glutamine) display a robust, early-onset ataxic phenotype. In transgenic mouse and drosophila models, high expression of ataxin-1 with even a wild-type human CAG repeat length produces a mild version of SCA1.

SCA1 mouse models have also led to a detailed analysis of the pathology, which has been confirmed in the limited tissue available from human patients. For instance,

immunohistochemical studies on Purkinje cells show that ataxin-1, a protein that normally displays a diffuse nuclear staining pattern, relocates into a single ~2-μm structure called the nuclear inclusion that is thought to be a fibrillar proteinaceous aggregate. Recent studies suggest that inclusions form because ataxin-1 is misfolded and is poorly cleared by the ubiquitin–proteasomal proteolytic (UPP) system acting in concert with cellular chaperones. In fact, the evidence that the inclusions contain cellular components such as ubiquitin, proteasomal components of the proteasome, and chaperones suggested the role of misfolding and protein-clearance in the disease. In addition, the inclusions sequester ataxin-1 binding proteins. Although the role of inclusions is still debated, several studies suggest that it is the accumulation of soluble, misfolded ataxin, and not the inclusions per se, that causes toxicity. Inclusion formation and recruitment of chaperones have also been demonstrated in transfected cells. These inclusions can even form if wild-type ataxin-1 is overexpressed. The ataxin-1 inclusions are typically incorporated into the nuclear matrix associated with the PML oncogenic domains (PODs).

Ataxin-1 has several important domains or amino acid residues. It has a nuclear localization sequence on the C terminal domain that appears essential for toxicity; a self-aggregation domain – a region spanning residues 495–605 – that is important for dimerization (and aggregate formation); and a domain called the AXH (ataxin-1 and HMG-box protein 1). This domain (spanning amino acids 570–689) encompasses the self-association region, made up of several charged residues well-designed for protein–protein interactions and appears crucial for toxicity. This domain also has an oligonucleotide binding fold motif that might explain why ataxin-1 has a tendency to bind RNA. The binding to RNA has been shown to be inversely related to the length of the polyglutamine tract.

Ataxin-1 interacts with several proteins including LANP, 14–3–3, coilin, PQBP-1, SMRT, BOAT, capicua, RBM17, Gfi-1/senseless, Tip-60, and Sp1. Yet, other interactors have been identified by high-throughput yeast two-hybrid screening, but many of these are still largely poorly characterized. There is evidence to suggest that a significant amount of endogenous ataxin-1 is complexed to other proteins. There are at least two biochemically and functionally distinct complexes of ataxin-1. In the normal state, ataxin-1 is shared between these complexes. In the mutant state, expanded ataxin-1 drives the formation of one (defined by RBM17) at the expense of another (defined by capicua). The RBM17 complex appears to be toxic, given that excess RBM17 in SCA1 mouse models is toxic. The Capicua complex appears to be protective, given that overexpressing capicua thwarts degeneration. These interactions lead to the dissection of both the normal functions of ataxin-1 and a delineation of pathological intracellular pathways. Remarkably, many of these interactors appear to regulate gene expression. Thus, these interactions might help explain why transcriptional abnormalities are among the first phenotypic derangements to be noticed in mouse models of SCA1. In addition to these interactors, ataxin-1 also interacts with itself and a close homologue (ataxin-1-like; or atxnl-1). Indeed, wild-type ataxin-1 and atxn1-l protect against toxicity in the context of modulating the levels of these proteins genetically, presumably by competing with ataxin-1 for components of the complexes.

Ataxin-1 also undergoes several posttranslational modifications. As noted earlier, ataxin-1 is ubiquitinated, a modification involved in clearance. Ataxin-1 is sumoylated at multiple residues, although the precise role of this modification is still unclear. In addition, ataxin-1 undergoes phosphorylation. Phosphorylation at serine 776, appears to modulate binding to the protein 14-3-3, and regulates the stability of ataxin-1. In fact, ablating this phosphorylation renders expanded ataxin-1 incapable of causing toxicity. Intriguingly, RBM17 – the protein that defines the toxic ataxin-1 binding complex – has been shown to bind to ataxin-1 in a glutamine repeat dependent and phosphorylation dependent manner, suggesting that phosphorylation may act along with the glutamine expansion as an important mediator of toxicity. More recently, another phosphorylation site has been identified on serine 239. The significance of this phosphorylation and the kinase involved is unclear.

Athetosis

F Cardoso, Internal Medicine Department, The Federal University of Minas Gerais, Belo Horizonte, MG, Brazil

Glossary

Athetosis – Sinuous, slow, irregular, and involuntary movements affecting distal limbs.
Proprioception – Sense of position of joints.
Pseudoathetosis – Writhing finger and/or toe movements due to loss of proprioception.

Definition and History

The term athetosis ('without fixed posture') describes sinuous, slow, irregular and involuntary movements affecting distal limbs, particularly the arms. The term was coined by Hammond in the late nineteenth century, when describing a movement disorder in an alcoholic patient with onset following an episode of *delirium tremens*. Shortly afterward, Shaw also used the word athetosis to describe a similar sinuous movement disorder in a patient with cerebral palsy. The term has also been applied to movements seen in subjects with dysfunction of proprioception, but because the movements are a consequence of sensory abnormalities, this syndrome is called 'pseudoathetosis.' This latter term remains in the current medical literature, despite the sharp decline of the use of the term 'athetosis' in the last decades. The reason behind this decline is the realization that athetosis is better defined as dystonia occasionally associated with some degree of chorea. There are authors, however, who continue to advocate the usefulness of athetosis as a distinct type of hyperkinesia.

Etiology and Pathogenesis

Athetosis is usually associated with cerebral palsy caused by kernicterus, that is, lesions of the central nervous system due to severe jaundice in the new born. However, cerebral palsy of any etiology may cause this movement disorder. In the few patients who came to autopsy, there are reports of lesions in the putamen or caudate. (Please refer to the entry on Dystonia in this Encyclopedia for further details on the pathogenesis of athetosis).

In pseudoathetosis, the movements are thought to result from the inability of the fingers or toes to remain still because of the loss of proprioception. Traditionally, this movement disorder is associated with peripheral neuropathy. However, it may also result from central nervous system lesions causing impairment of sense of position. There are many reports of pseudoathetosis caused by lesions of spinal cord and, less commonly, thalamus. The causes listed in these reports are vascular lesions, B12 vitamin deficiency, and syringomyelia.

Epidemiology

There are no epidemiological studies of athetosis. It is possible to speculate, however, that it is becoming a much rarer condition nowadays. The main reason for the decline of its frequency is the improvement of obstetric care with the reduction of the number of cases of cerebral palsy. Traditionally, pseudoathetosis is considered as a rare condition. It is uncertain, however, if this is true since many patients may remain without diagnosis because of the lack of functional impairment caused by this movement disorders.

Clinical Features and Diagnostic Criteria

Athetosis is characterized by sinuous, slow, irregular, and involuntary movements affecting distal limbs, especially the arms. The phenomenology is usually characterized by a combination of dystonia and chorea, but myoclonus and spasticity are also common. Similarly, pseudoathetosis is characterized by slow, distal, writhing movements of the fingers or toes, which tend to worsen with the suppression of visual input. Invariably, these patients have proprioceptive sensory loss and often a Romberg sign. There are no formal diagnostic criteria for these conditions. However, a history of perinatal injury in athetosis and peripheral neuropathy or central loss of propriopception in pseudoathetosis are highly useful to make the diagnosis.

Differential Diagnosis

Athetosis and pseudoathetosis should be distinguished from other hyperkinetic movement disorders affecting distal limbs. Chorea is unpredictable; myoclonus has a shock-like nature, with a brief duration, usually less than 200 ms; and tremor is characterized by its rhythmic and oscillatory nature. The most important treatable condition with progressive athetosis is Wilson's disease, due to abnormal copper metabolism.

Diagnostic Work-Up

The investigation of patients with athetosis should follow the guidelines to work up patients suspected to harbor a secondary dystonia. Of note, all patients should undergo tests for Wilson's disease (serum ceruloplasmin, serum copper, 24 h urine copper, liver function tests, and search for Kayser–Fleischer ring) and magnetic resonance imaging of the brain. Focused attention should be placed on the basal ganglia. In patients with pseudoathetosis, electromyography and, in case it is normal, magnetic resonance imaging of the spinal cord and even the brain are useful.

Management

No treatment is required for pseudoathetosis since it does not cause significant functional impairment. The situation is different, however, in athetosis where many patients are significantly disabled by the dyskinesia. Unfortunately, as a rule it is often resistant to all available therapeutic options. A few patients may improve with levodopa, clonazepan, baclofen, anticholinergics, or tetrabenazine. Most of them, however, are refractory to clinical treatment and even surgical treatment has not been successful. There are recent reports describing failure or poor results of baclofen pump or deep brain stimulation of the globus pallidus internal in alleviating dyskinesias in patients with cerebral palsy.

Prognosis

As a manifestation of static encephalopathy, athetosis usually remains stable along the time. However, as well described in the literature of cerebral palsy, some patients may develop worsening of the movement disorder at later age. The course of pseudoathetosis depends on the underlying cause: if there is improvement of the proprioception, the movement disorder may also decrease.

ATM Gene

K Nakamura and R A Gatti, UCLA School of Medicine, Los Angeles, CA, USA

Glossary

Antisense morpholino oligonucleotides – A molecule used to modify gene expression using antisense technology to block access of other molecules to specific sequences within nucleic acids.

Apoptosis – A process of programmed cell death which eliminates cells in an organized manner without releasing harmful substances into the surrounding area.

Ataxia – Loss of balance or dysfunction of neural pathways that coordinate movements; a neurological sign for loss of coordination of muscle movements.

Autosomal recessive – A genetic condition that appears only in individuals who have received two mutated copies of an autosomal gene, one copy from each parent.

Double strand break (DSB) – Damage in both strands of DNA double helix.

Leucine zipper – Protein structural motif in which repeats of leucines are evenly spaced every seventh residue in the helical region and involved in DNA binding and protein–protein interaction.

Protein Kinase – An enzyme that modifies proteins by chemically adding a phosphate group.

Radiosensitivity – The relative susceptibility of cells, tissues, organs, and organisms to the effects of radiation.

Telangiectasia – Abnormal dilation of capillary blood vessels.

ATM Gene

The ATM gene is defective in patients diagnosed with ataxia-telangiectasia (A-T). A-T is a rare autosomal recessive disorder characterized by progressive cerebellar ataxia, ocular motor apraxia, dilation of blood vessels (telangiectasia), immunodeficiency, elevated levels of serum α-fetoprotein, and by an increase susceptibility to cancer, especially leukemia/lymphoma. A-T patients are usually diagnosed in their first few years of life and are usually wheelchair bound by age 10. The incidence is ~1 per 40 000–100 000 live births. At the cellular level, A-T is characterized by chromosomal instability, defects in cell-cycle checkpoint, premature senescence, accelerated telomere shortening, elevated oxidative damage, and extreme sensitivity to ionizing radiation and radiomimetic drugs.

In 1988, ATM was mapped to chromosome 11q22–23 by genetic linkage studies using large numbers of A-T families. However, it was not until 1995 that the gene was finally cloned by positional cloning, thereby offering a way to understand the disorder and develop possible therapeutic strategies (see **Figure 1**). Sequence analysis revealed that this gene includes about 150 kb of genomic DNA and encodes a major transcript of ~13 kb with a 9168 bp open reading frame (ORF) consisting of 66 exons. The main promoter of this gene is bidirectional and is shared by ATM and another gene, E14/NPAT/CAND3, whose function is not fully understood. The amino acid sequence of the ATM gene contains 3056 residues which results in an ~350 kDa protein that is localized mainly in the nucleus of all cells.

This ubiquitously expressed large protein belongs to the protein family of phosphatidylinositol 3-kinase (PI3K)-related protein kinases (PIKKs), which includes mammalian target of rapamycin (mTOR/FRAP), ATM-and-Rad3-related protein (ATR), TRAF and TNF receptor associated protein (TTRAP), DNA-dependent protein kinase catalytic subunit (DNA-PKcs) and the recently identified human homolog of *C. elegans* SMG1. All of these proteins are involved in cellular responses to DNA damage and some of them play regulatory roles in cell-cycle progression and/or damage induced cell-cycle checkpoints. The catalytic PI3 kinase domain of PIKK family members consists of about 300 amino acids located near the C-terminal end of the protein and is flanked by a domain called FAT (FRAP (mTOR), ATM, TTRAP) and a FATC (FAT at C-terminal) domain (**Figure 2**). The functions of the FAT and FATC domains are still largely unknown. Several regions distant from the PI3 kinase domain have been identified to have protein-binding activity. Recently Tip60 histone acetylase, which is essential for ATM activation, was shown to bind to the FATC domain of ATM.

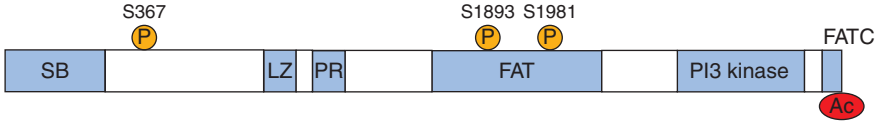

Figure 1 Schematic representation of ATM protein. Domains are shown in boxes. ATM autophosphorylation sites and acetylation site are also shown. SB, substrate binding region (1-246 a.a.); LZ, leucine zipper (1218-1238 a.a.); PR, proline rich (1373-1382 a.a.); FAT (1961-2566 a.a.); PI3 kinase (2712-2962 a.a.); FATC (3024-3056 a.a.).

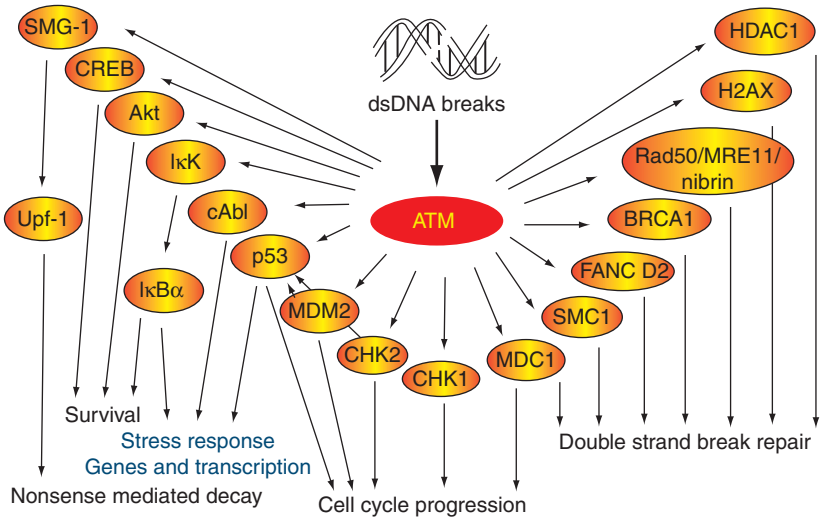

Figure 2 ATM targets.

At the N terminus, residues 1–246 act as binding sites for NBS, p53, and BRCA1 and are required for their activation in response to DNA damage (**Figure 2**). Regions within residues 811–1283 have been reported to bind β-adaptin, and a proline rich region (residues 1373–1382) has been shown to interact with c-Abl tyrosine kinase through its SH3 domain. While a putative leucine zipper motif at codons 1218 to 1238 has been identified in the ATM protein, this region has not yet been shown to be a site of protein–protein interaction and appears not to mediate the formation of ATM dimers.

ATM Activation and Functions

The complexity of the A-T disease symptoms is perhaps best reflected by the multitude of cellular roles played by the ATM protein. In vitro, ATM exists as an inactive dimer in undamaged cells. In this configuration, the FAT domain of one ATM monomer conceals the kinase domain of the other monomer, helping to keep ATM inactive. Following DNA damage, in particular in the form of double strand breaks (DSBs), ATM dimers are dissociated and the ATM monomers autophosphorylate each other on amino acid residues S1981, S367, and S1893 (**Figure 1**). In addition, acetylation is mediated by Tip60 acetylase; this is also required for the ATM protein to become fully active. Following the binding of activated MDC1 to DSB sites, the sensing proteins MRE-11/RAD50/NBS1 (MRN complex) are recruited and they bind DNA as a heterotetramer, to hold the two broken DNA ends together. This binding of the MRN complex is thought to recruit ATM to the site of the DSBs to form an expanding protein complex around the broken DNA ends. In the presence of DSB damage, activated ATM phosphorylates and transactivates a variety of protein targets involved in stopping the cell cycle, to allow DNA repair. These ATM targets include: p53, SMC1, FANCD2, H2AX, BRCA1, and Chk2 proteins (**Figure 2**). This activation process can be reset by the dephosphorylation of ATM by protein phosphatase 2A (PP2A), which also plays a pivotal role in modulating ATM's function(s) since inhibition of a PP2A-like protein phosphatase activity by the specific inhibitor okadaic acid (OA) induces the rapid accumulation of phosphorylation of ATM on Ser 1981. These results suggest that constitutive dephosphorylation of ATM by PP2A maintains ATM in an inactive state. This inactivation apparently serves to prevent unnecessary activation of cellular functions in the absence of genotoxic stress.

ATM Mutations and Heterozygous Carriers

Most A-T patients are compound heterozygotes, that is, they carry different paternal and maternal mutations in the ATM gene. Over 500 unique ATM mutations have been reported to date, and mutations are detected over the entire coding region of the gene, with no hot spots clearly identified. Approximately 85% of these mutations are predicted to produce premature termination codons (nonsense mutations), or secondary termination of translation caused by frameshifts mutations, insertions, deletions, or abnormal splicing defects. Thus, the majority of A-T patients produce either an unstable truncated ATM protein or none at all. Missense mutations account for <10% of all reported mutations in A-T patients and occasionally have small amounts of ATM protein and some of these have milder disease.

The frequency of A-T heterozygotes is estimated to be ∼1%, and heterozygotes display decreased levels of ATM (∼40–50%) and exhibit reduced ATM kinase activity. In addition, previous reports suggest that A-T carriers have a 4-fold increase risk for breast cancer and exhibit a slightly increased radiosensitivity over healthy controls. However, heterozygotes display no apparent A-T phenotype. Furthermore, the spectrum of ATM mutations observed in heterozygotes with breast cancer and no family history of A-T is very different from the mutations identified in individual with A-T.

Conclusion

ATM plays a critical role(s) in multiple biological pathways. Understanding the roles of ATM will lead us to explain how a single gene defect in A-T patients can cause so many deleterious symptoms in different organ systems. Within the 10 years after ATM gene was cloned, over 700 potential ATM protein targets for phosphorylation have been identified. However, in order to make more definitive functional predictions, we also need to understand the mechanistic and physiological relevance of phosphorylation of targets by ATM and other posttranslational modifications. At present there is no therapy available to cure or prevent the neurological deterioration of A-T. Aminoglycosides that help to read through premature stop codons have been reported to increase functional ATM protein levels in cells from A-T patients with nonsense mutations. Recently, it was reported that antisense morpholino oligonucleotides targeted to specific splicing mutations can restore normal splicing and produce functional ATM protein. It is also possible to alleviate some of the symptoms associated with immunodeficiency with intravenous γ-globulin treatment. Antioxidants reduce DNA damage from oxidative stress. Insight into ATM interacting proteins and ATM substrates, functional dissection of the ATM molecule and screening mutations may assist in the development of new and effective therapies for A-T.

Atrophin-1

M Fanto, Dulbecco Telethon Institute, DIBIT-San Raffaele Scientific Institute, Milan, Italy
B Charroux, IBDML, Marseille, France

Glossary

Aggregates – Stable accumulation of a protein in a specific area of the cell, usually due to the self interaction property of the protein.
Chromatin – Three-dimensional complex between the DNA and a number of different proteins that modify the accessibility of the genetic sequence and thus gene transcription.
Dentatorubral-pallidoluysian atrophy (DRPLA) – A neurodegenerative disorder of the central nervous system, causing motor deficits and dementia.
Domain – Part of a protein having a well-defined three-dimensional structure often emerging from a conserved amino acidic sequence.
Drosophila melanogaster – Fruit fly, the most amenable organism for genetic research, which is widely used to model neurodegenerative conditions.
Polyglutamine diseases – A family of neurodegenerative diseases having a common molecular origin in the expansion of glutamine stretches in the proteins causing the pathologies.

Definition and History

The human *atrophin-1* (*ATN1*) gene was identified in 1994 in the search for a candidate gene responsible for dentatorubral-pallidoluysian atrophy (DRPLA), a neurodegenerative disorder with genetic anticipation, characteristic of an unstable expansion of trinucleotide repeats. Indeed, the expansion of a CAG repeat tract within the coding sequence of *ATN1* (chromosomal location: 12p13.31) was identified in a series of DRPLA patients. In such individuals, the (ATN1) protein is expected to carry an abnormally long polyglutamine (polyQ) domain, classifying DRPLA as a polyglutamine disease. This group of autosomal dominant disorders includes Huntington disease (HD) and a number of spinocerebellar ataxias (SCAs). They have common features such as progressive neurodegeneration, ubiquitous expression of their respective gene product, and intracellular accumulation of a polyQ-expanded fragment of the protein into neuronal aggregates (cytoplasmic or nuclear). The latter characteristic is the hallmark of polyglutamine diseases. Nevertheless, the brain regions that are found degenerated in post-mortem DRPLA, HD, and SCAs patients are distinguishable as are their clinical features.

A trinucleotide expansion of *ATN1*, identical to the one found in DRPLA patients, was identified in a large family of African American with Haw River Syndrome (HRS), a neurological disorder with clinical and neuropathological features similar to those in DRPLA patients. Thus, DRPLA and HRS correspond to the same disease.

Epidemiology

DRPLA has been reported to occur mostly in Japan with an estimated frequency of 0.2–0.7 in 100 000 individuals. Remarkably, individuals with 20–35 CAG repeats, a mutable normal allele, are more common in the Japanese population in comparison with the Caucasian people. DRPLA is not exclusive to Japan, because few cases have been described in Europe (Portugal) and North America. Studies of two intragenic SNPs (single nucleotide polymorphisms) in introns 1 and 3 of *ATN1* have led to the conclusion that a founder DRPLA haplotype of Asian origin was introduced in Portugal to account for the high incidence of this disease in that country. Most cases recorded in Asian, Caucasian, and Afro-Americans can be traced to three haplotypes, one for each ethnic group.

Diagnosis Work-up/Tests

The diagnosis of DRPLA relies on the description of appropriate clinical features, a positive family history, and on the identification of an abnormally long CAG repeat tract within the *ATN1* gene. Molecular genetic testing is clinically available and corresponds to either a polymerized chain reaction (PCR) analysis of the CAG expansion or a Southern-blot analysis, when PCR is problematic.

Molecular Genetics

The CAG repeat length for the *ATN1* gene ranges from 6 to 35 CAG in unaffected individuals and from 48 to 93 in DRPLA patients, with a significant negative correlation between the length of the CAG repeat and the age of onset. Moreover, the clinical features of DRPLA, like those of SCA3, are influenced by the dosage of the expanded *ATN1* allele. This contrasts with HD, in which, patients homozygous for the pathogenic allele are clinically indistinguishable from heterozygous ones. Studies of CAG repeat size from single sperm DRPLA patients have revealed the amazing instability of the *ATN1* trinucleotide repeat, which displays a high variation in size compared with other polyglutamine diseases such as SCA3, HD, and spinal and bulbar muscular atrophy. In agreement with this observation, the genetic anticipation on the paternal transmission of DRPLA is the most prominent among CAG repeat diseases.

Molecular Aspects

The ATN1 protein is a 1185-amino acid polypeptide with an apparent molecular mass of approximately 200 kDa. It is

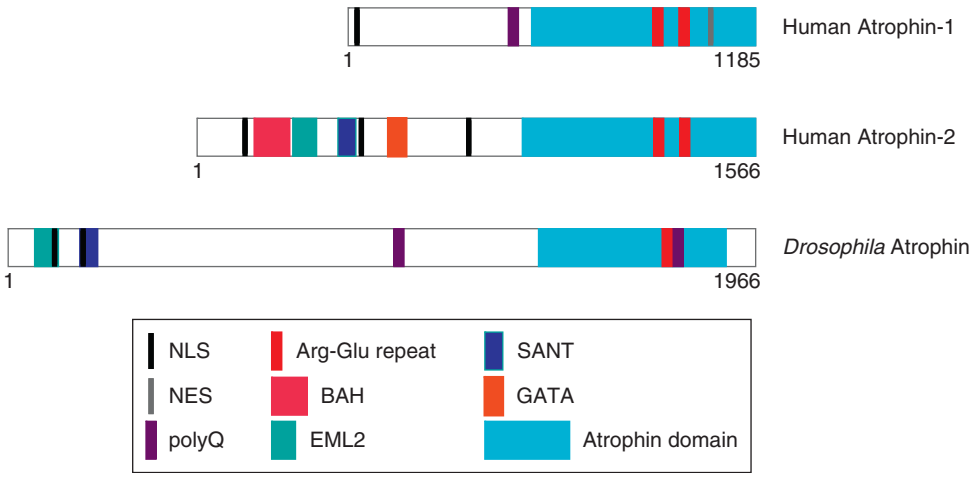

Figure 1 Protein architecture of Atrophins. Human Atrophin-1 and *Drosophila* Atrophin contain respectively one and two polyglutamine region (polyQ, purple box). The N-terminus of human Atrophin-2 is homologous to MTA-2, containing BAH, ELM2, SANT, and GATA domains (pink, grey blue, dark blue and orange box, respectively). The N-terminus of *Drosophila* Atrophin contains both an EML2 and a SANT domain. The C-terminus region common to both human and *Drosophila* Atrophins (light blue box) is the Atrophin domain. Human Atrophin-1 contains both a NLS (dark box) and a NES (grey box), while human Atrophin-2 and *Drosophila* Atrophin have respectively three and two NLS but no NES. NLS: Nuclear Localization Signal; NES: Nuclear Export Signal; BAH: Bromo Adjacent Homology; ELM2: Egl-27 and MTA-1 homology 2; SANT: SWI3, ADA2, N-CoR and TFIIIB Bd″ domain; GATA: DNA-binding domain that recognizes a six base-pair sequence with a GATA core.

ubiquitously expressed and detected both in the nuclear and cytoplasmic compartments of all cells analyzed so far. ATN1 is expected to shuttle between these two compartments, since it contains both a nuclear localization signal (NLS) and a nuclear export signal (NES). Interestingly, the cleavage of ATN1 occurs naturally and truncated fragments containing the expanded polyQ tract, but missing the NES, accumulate into the neuronal nuclei of animal models and in the human DRPLA brain tissue. This suggests that ATN1 toxicity is confined to the nucleus.

Human and mouse genomes have two *atrophin* genes: *ATN1* and *Atrophin 2* (*ATN2*), also called Arg–Glu repeat-encoding (*Rere*). Atrophin 2 (ATN2) was first described as an ATN1-related protein that physically interacts with ATN1, through a RERE repeat domain. The *ATN2* locus encodes two distinct polypeptides: a short (ATN2S) and a long (ATN2L) version of ATN2, the latter possessing additional conserved domains in the N-terminal region such as the BAH, ELM2, SANT, and GATA. These domains are disposed in a similar configuration to those found in MTA-2, a protein that contributes to the formation of the NURD (nucleosome remodelling and histone deacetylation) complex, a chromatin remodeling entity that represses transcription. ATN1 lacks these domains and resembles ATN2S more, the two proteins sharing 67% of homology in their C-terminal region (see **Figure 1**).

The *Drosophila* genome has a single *Atrophin* (*Atro*) gene that encodes a protein resembling full-length human ATN2 plus two polyQ motifs. Genetic studies in *Drosophila* have revealed that *Atro* acts as a co-repressor in several developmental processes such as the segmentation of the embryo, planar cell polarity, and imaginal disc patterning via the negative regulation of the EGFR (epidermal growth factor receptor) signaling pathway.

Although, in *C. elegans*, the product of *egl-27* gene has been described as an Atrophin orthologue, it resembles rather the MTA genes, lacking the most typical C-terminal domain of Atrophins.

Several lines of evidence indicate that the misregulation of transcription is the molecular mechanism underlying the pathogenesis of DRPLA. First, studies of the *Drosophila* Atro orthologue indicate that it participates in the developmental process acting as a co-repressor of transcription, via a direct interaction with well-known transcriptional repressors. Second, human ATN1 has been shown to physically interact with the nuclear receptor of the TLX family and with the transcriptional repressors ETO/MTG8 to ensure proper repression of their specific target genes. Third, a series of co-repressor factors such as Sin3a, Mi2, and HDAC colocalize with polyQ-expanded ATN1 nuclear aggregates. Furthermore, human ATN1 was recently described to operate as a potent transcriptional activator, demonstrating that the contribution of ATN1 to transcriptional regulation is rather complex and requires further investigations.

Little is known, however, about the consequences of polyQ expansion on ATN1 function. In one report, polyQ-expanded ATN1 was described to interact with the cAMP response element-binding protein (CREB)-binding protein (CBP), resulting in the suppression of CREB-dependent transcriptional activation and reduced neuronal survival and plasticity.

Animal Models of DRPLA

Mice expressing human ATN1 with an expanded polyQ domain exhibit ataxia, tremors, seizures, and premature death, a phenotype similar to the juvenile form of human DRPLA. Such animals have revealed the existence of nuclear fragments (120 kDa) of mutant ATN1, whose abundance increased with age and phenotype severity. This is in agreement with other reports that established that these fragments are particularly toxic and may underlie the pathogenesis of the disease. In addition, DRPLA mice exhibited age-dependent intergenerational and somatic instabilities of expanded CAG repeats similar to those observed in DRPLA patients.

A DRPLA Drosophila model, which relies on the expression of human or *Drosophila* polyQ-expanded Atrophins in fly neurons, can reproduce several characteristics of DRPLA disease: nuclear aggregates of polyQ containing Atrophin proteins, progressive degeneration of neurons, locomotor defects, and reduced viability. Recent data indicate that the misregulation of autophagy, a cellular mechanism that controls cell homeostasis, could account for the degeneration observed in the DRPLA fly model.

Autonomic Dysfunction

L Norcliffe-Kaufmann and H Kaufmann, New York University School of Medicine, New York, NY, USA

Glossary

Autonomic failure – Failure of the autonomic nervous system results in orthostatic and postprandial hypotension, bladder and bowel motility disturbances, impaired thermoregulation, anhidrosis and sexual dysfunction.
Autonomic synucleinopathies – Autonomic failure is a prominent feature of the LB disorders and MSA. These diseases are caused by accumulations of the protein α-synuclein in intracellular inclusions in neurons, glial cells. Thus the moniker autonomic synucleinopathies.
Lewy body (LB) disorders – LB are characteristic cytoplasmic eosinophilic neuronal inclusions first described by Frederic Heinrich Lewy in 1912. The LB disorders include three distinct but overlapping phenotypes: PD, DLB, and PAF. Autonomic dysfunction is a major feature of all three phenotypes.
Multiple system atrophy (MSA) – MSA is a term introduced by Graham and Oppenheimer in 1969. MSA includes disorders previously known as sporadic olivopontocerebellar atrophy (OPCA), with predominant cerebellar symptoms, striatonigral degeneration (SND), with predominant parkinsonian features, and the Shy–Drager syndrome (SDS), with predominant autonomic involvement.
Pure autonomic failure (PAF) – PAF was first described by Bradbury and Eggleston in 1925 as idiopathic postural hypotension. It is a sporadic, adult onset, slowly progressing, neurodegenerative disorder that is mostly confined to peripheral autonomic neurons. Although PAF is not a movement disorder, neuropathological data showing the presence of LB suggest a close connection with PD.

Introduction

The autonomic nervous system innervates almost all organs of the body. Impaired autonomic innervation results in characteristic clinical signs and symptoms

according to the affected viscera. These include orthostatic and postprandial hypotension, bladder and bowel motility disturbances, impaired thermoregulation, anhidrosis, and sexual dysfunction.

Disabling autonomic failure is the hallmark of two of the most prevalent neurodegenerative diseases: the *Lewy body disorders*, which includes Parkinson's disease (PD), dementia with Lewy bodies (DLB), and pure autonomic failure (PAF), and *multiple system atrophy* (MSA), which includes a parkinsonian and cerebellar phenotype. Both the LB disorders and MSA are caused by abnormal intracellular deposits of the protein α-synuclein; hence, the moniker *autonomic synucleinopathies* has been proposed to describe them.

Synucleinopathies can present clinically either with a movement disorder, cognitive impairment, or autonomic failure. As the disease progresses, these features are usually combined. There is, however, one synucleinopathy, PAF, in which involvement of the autonomic nervous system is the sole clinical feature (**Table 1**).

The LB Disorders

The LB disorders get their name from the characteristic cytoplasmic eosinophilic neuronal inclusions first described by Frederic Heinrich Lewy in 1912 found in the brain and peripheral autonomic neurons of affected patients. It is postulated that PD, DLB, and PAF are three different but overlapping phenotypes of a single neurodegenerative disorder, in which α-synuclein accumulates in LB. In patients with PD, the neurodegenerative process occurs mostly in the substantia nigra and other brain stem nuclei and to a lesser extent in peripheral autonomic neurons. Clinical findings are dominated by motor impairment with varying degrees of autonomic involvement. In DLB, there is extensive cortical degeneration as well as involvement of brain stem nuclei and autonomic ganglia, the clinical picture is dominated by severe cognitive impairment, although patients also have parkinsonian features and autonomic impairment. In PAF, the neurodegenerative process is mostly restricted to peripheral autonomic neurons, and autonomic failure is the sole clinical finding. These three distinct but overlapping phenotypes are likely the result of the specific anatomical distribution of the neurodegenerative process and sequential accumulation of LB. Clinically, all three LB disorders entail loss of postganglionic autonomic neurons and characteristic autonomic failure.

Parkinson's Disease

Around 90% of patients with PD have one or more symptoms of autonomic failure. These include constipation, urinary urgency or incontinence, orthostatic or postprandial lightheadedness and syncope, heat intolerance, and erectile dysfunction in men.

In most patients with PD, clinically significant autonomic failure occurs late, but there is a subset of PD patients in whom autonomic failure occurs early on in the disease process.

In addition to the prominent neuronal loss in the substania nigra, which accounts for the movement disorder, other brainstem nuclei including the dorsal motor nucleus of the vagus and locus coeruleus are affected in PD. These abnormalities together with degeneration of postganglionic autonomic nerves and enteric neurons explain the autonomic dysfunction in PD.

Cardiovascular abnormalities

Orthostatic hypotension (OH) is defined as a fall of at least 20 mmHg systolic and 10 mmHg diastolic BP accompanied by symptoms of cerebral hypoperfusion within 3 min of standing. In the autonomic synucleinopathies, OH is typically caused by impaired sympathetically mediated vasoconstriction in the systemic circulation, a reflex response that normally compensates for the gravitational fluid shifts to the lower body when in the upright position

Table 1 Neuropathological and phenotypic characteristics of the autonomic synucleinopathies

	MSA	*PD*	*DLB*	*PAF*

Autonomic failure	+++	+/–	+	+++
Movement disorder	+++	+++	++	–
Cognitive impairment	–/?	+/++	+++	–

MSA, multiple system atrophy; PD, Parkinson's disease; DLB, dementia with Lewy bodies; PAF, pure autonomic failure; LB, Lewy bodies. + denotes presence and – denotes absence. Number of + denotes severity: +++, severe; ++, moderate; +, mild.

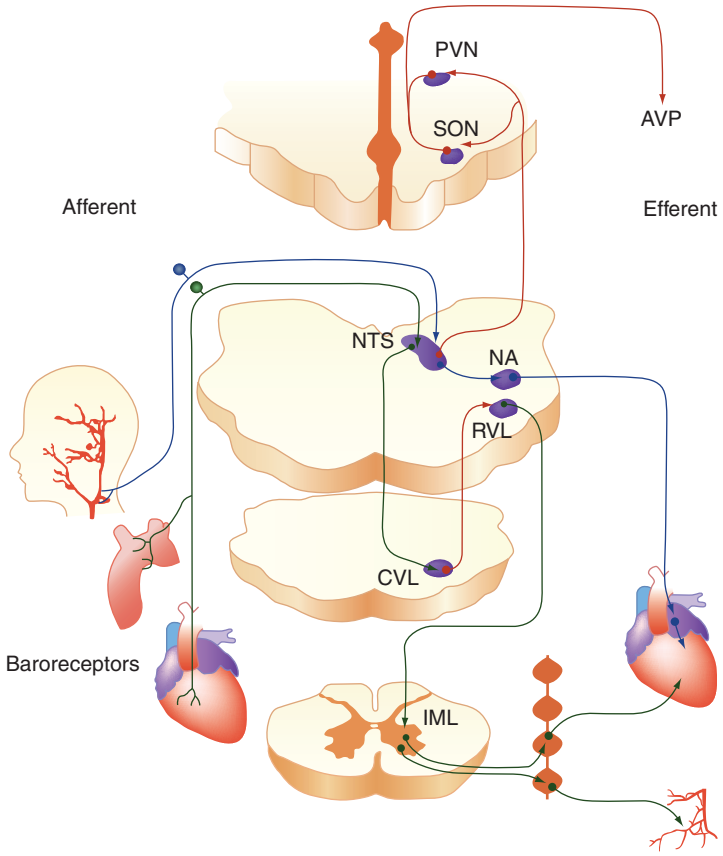

Figure 1 A schematic diagram of the baroreceptor reflex. The baroreflex is a negative feedback loop that regulates arterial BP. Arterial baroreceptors are located in the walls of the carotid sinus, aortic arch, and coronary vasculature and relay sensory information to the CNS through the glossopharyngeal (IXth) and vagus (Xth) nerves. These afferent neurons have their cell bodies in the petrosal (IXth) and nodose ganglia (X). The first synapse of the baroreflex is in the medulla, at the nucleus tractus solitarii (NTS), where baroreceptive information is integrated with inputs from other cardiovascular brain centers including the area postrema. Excitatory inputs project from the NTS to neurons in the caudal ventrolateral medulla (CVL). In turn the CVL provides an inhibitory influence to the rostroventrolateral medulla (RVL), which contains pacemaker neurons that generate sympathetic tone. RVL neurons project caudally through the spinal cord to synapse with preganglionic sympathetic neurons in the IML column. Axons from preganglionic sympathetic neurons leave the spinal cord to synapse in peripheral ganglia with postganglionic sympathetic neurons, which release norepinephrine at target organs. This results in arteriolar vasoconstriction, venoconstriction, tachycardia, and an increase in cardiac contractility. Parasympathetic tone is also modulated by the baroreflex. Projections from the NTS to the nucleus ambiguus (NA) excite preganglionic cardiac parasympathetic nerves. In addition, neurons in the NTS project rostrally to the supraoptic (SON) and paraventricular nuclei (PVN) of the hypothalamus and control vasopressin (AVP) release. An increase in systemic BP stretches arterial baroreceptors and increases the firing rate of afferent fibers. This activates NTS and CVL neurons, which in turn inhibits RVL neurons and 'withdraws' sympathetic outflow. Activation of the NTS also results is activation of the NA and an increase in parasympathetic outflow together with inhibition of vasopressin secretion. The end result is systemic vasodilatation, bradycardia and a decrease in cardiac contractility, which restores BP back to 'baseline' levels. In general, sympathetic withdrawal is accompanied by parasympathetic activation and vice versa. Sympathetic activation to different organs is not homogenously distributed and depends on the stimuli and afferent pathways involved. For example, mental stress induces sympathetic activation and increases BP, but causes vasodilatation in the forearm vasculature.

(**Figure 1**). Around 40% of patients with PD have OH. In patients with PD who have OH, beat-to-beat recordings of BP and heart rate during prolonged upright tilt reveal a progressive decline in BP with a smaller than normal increase in heart rate (**Figure 2**). If cerebral perfusion is significantly reduced syncope occurs. BP recordings during the Valsalva maneuver are also characteristically abnormal. The normal overshoot in BP after release of the strain (i.e., phase IV) is absent (**Figure 3**). This characteristic profile distinguishes OH due to autonomic failure from OH due to other causes, such as dehydration.

OH in PD is related to the duration and severity of the disease and is often worsened by treatment with levodopa and dopaminergic agonists. However, neither of these drugs is the primary cause of OH in PD.

Gastrointestinal abnormalities

Impaired gastrointestinal motility is the most frequent autonomic problem in PD. LB have been found in neurons in the Auerbach and Meissner plexuses throughout the gastrointestinal tract, from the esophagus to the colon. *Excessive drooling*, common in patients with PD, is caused

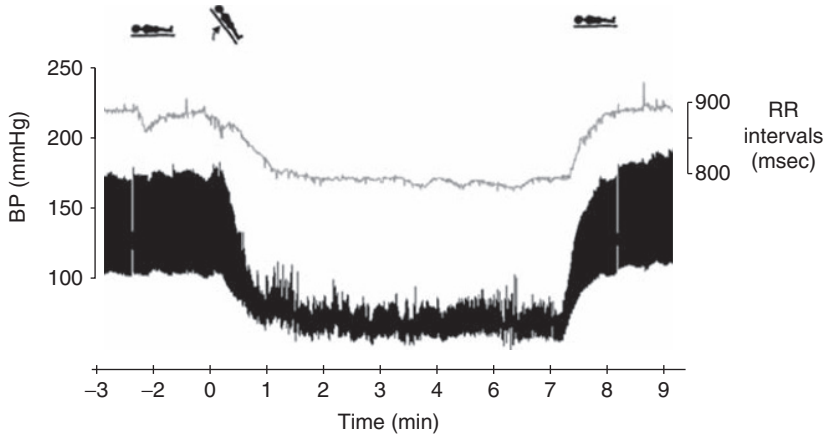

Figure 2 Beat-to-beat BP and electrocardiographic RR intervals during passive head-up tilt in a patient with autonomic failure. Note hypertension when supine and a precipitous fall in BP upon head up tilt. There is little shortening of RR intervals despite the pronounced fall in BP. Figurines denote posture.

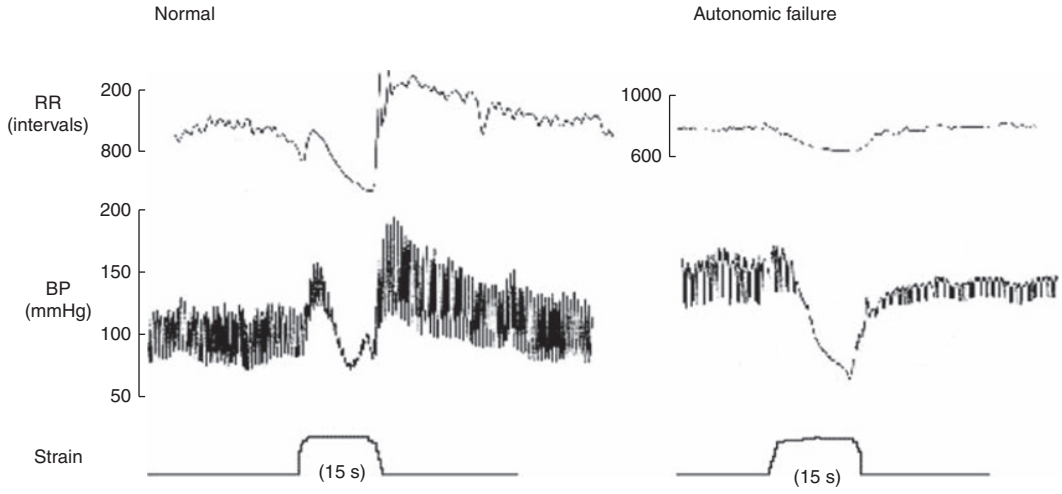

Figure 3 Beat-to-beat BP and electrocardiographic RR intervals during a Valsalva maneuver in a patient with autonomic failure and a healthy control. Note the absence of BP 'overshoot' after release of the strain in the patient with autonomic failure.

by a decrease in swallowing frequency rather than increased production of saliva. Treatment with anticholinergics is ineffective. Botulinum toxin injections in the salivary glands reduce drooling, but it increases the risk of dysphagia as the toxin diffuses into nearby muscles.

Dysphagia occurs in up to 50% of PD patients and is related to the severity of the disease. All three phases of swallowing: buccal, pharyngeal, and esophageal can be affected. Dysphagia is often more severe during an 'off' period and improves when the dose of levodopa becomes effective again. This suggests that impaired supranuclear control of oropharyngeal muscles may account for the abnormal swallowing in PD. Swallowing studies can be helpful in defining the phase of swallowing that is most affected and if there are silent aspirations. Soft diets and eating only during 'on' times help most types of dysphagia and reduce the risk of aspiration. Gastrostomy tubes and jejunostomies are a last resort but can be beneficial to allow adequate food, fluid, and medication intake.

Nausea and vomiting are common side effects of treatment with levodopa and direct dopaminergic agonists caused by stimulation of dopamine receptors in the area postrema of the brainstem located outside the blood–brain barrier. Carbidopa, a reversible inhibitor of Dihydroxyphenylalanine (DOPA) decarboxylase that prevents dopamine formation outside the brain effectively prevents nausea and vomiting associated with levodopa treatment. Domperidone, a dopamine antagonist with particular affinity for the D_2 subtype receptors in the peripheral nervous system is used successfully to reduce these symptoms.

Delayed gastric emptying is frequent in PD, resulting in early satiety, nausea, and abdominal distension. Delayed gastric emptying can also affect the clinical response to

levodopa. Delayed gastric emptying slows the delivery of levodopa into the absorptive sites of the duodenum and reduces its bioavailability, which leads to levodopa response fluctuations. Patients who experience motor fluctuations have been shown to have greater gastric retention 1 h after eating a meal than patients without fluctuations. Direct delivery of levodopa into the duodenum can markedly improve motor fluctuations. Frequent, small meals are recommended as a first line therapy.

Muscarinic receptor agonists such as bethanechol and carbachol produce a prokinetic effect by stimulating M3 receptors in intestinal smooth muscle. Unfortunately, their symptomatic benefit is limited at best and side effects such as nausea, vomiting, increased salivation, abdominal cramping, diaphoresis and flushing are common. D_2 receptor blockers also increase gastric motility. Metroclopramide, the most effective, cannot be used as it readily crosses the blood–brain barrier and worsens parkinsonism. Domperidone, which acts mostly on peripheral dopamine receptors, is an effective prokinetic agent but is not available in the US. Serotonin-4 receptor agonists such as cisapride and tegaserod stimulate the release of acetylcholine from enteric neurons and can improve gastric motility. Both agents were removed from the market in the United States as they prolong electrocardiographic QT interval.

Constipation is the most frequent autonomic problem in patients with PD. Loss of enteric and extrinsic parasympathetic neurons disrupt the normal peristaltic contractions of smooth intestinal muscle. Thus, colonic motility is reduced and stool transit time is prolonged, reducing the frequency of defecation. Pelvic floor dyssynergia and failure to relax or paradoxical contraction of the puborectalis muscle may also contribute to abnormal defecation. Megacolon and intestinal pseudoobstruction have been reported in PD. Patients should be encouraged to drink at least eight glasses of water a day, avoid low fiber foods such as baked goods and bananas, include high fiber raw vegetables in two meals per day to stimulate the gastrocolic reflex and increase physical activity. If necessary, stool softeners (e.g., docusate) at mealtimes may be used. Ten to 20 g of lactulose per day may also be beneficial in some cases. Discontinuing anticholinergics may increase bowel motility. Laxatives and weekly enemas may be required as part of an overall bowel regime. Treatment with mosapride, a serotonin-4 agonist and partial serotonin-3 antagonist, can improve constipation in PD. It also acts as an antiemetic by blocking serotonin receptors in the chemoreceptor trigger zone. Mosapride, in contrast to cisapride, does not block K channels or D_2 dopaminergic receptors, but is not yet available in the United States.

Urinary dysfunction

'Irritative' symptoms of urinary dysfunction such as urgency, frequency, and incontinence are frequent in patients with PD and are caused by uninhibited detrusor contractions. In contrast, urinary abnormalities in patients with MSA are usually retention and voiding difficulties, frequently requiring self-catherization.

Sexual dysfunction

Sixty percent of men with PD have erectile dysfunction together with impaired sexual arousal, lack of sex drive, and failure to orgasm. The cause of erectile dysfunction in PD is unknown, but may involve dopamine deficiency, as dopamine plays a role in libido and penile erection with arousal. Several drugs can cause sexual dysfunction. A thorough medication history is useful. Intracavernous injections or transurethral suppositories of alprostadil, a synthetic prostaglandin E1, induce penile erection, but their use is cumbersome. Sildenafil, an orally active inhibitor of the type V cyclic guanine monophosphate phosphodiesterase (the predominant isoenzyme in the human corpus cavernosum) has improved erectile dysfunction in small clinical trials of patients with PD. Patients with MSA, however, developed severe hypotension with this drug. Men using subcutaneous injections of apomorphine to treat motor fluctuations in PD noted that the treatment benefited their sexual function and induced penile erection. Drug trials to assess the effect of sublingual apomorphine to treat erectile dysfunction had promising results, although nausea occurs in a proportion of the patients. Some patients on high doses of antiparkinsonian therapy become hypersexual, despite inability to perform.

Sweating and thermoregulatory disturbances

Patients with PD can have increased, decreased or normal sweating. Based on studies using the quantitative sudomotor axon reflex test (QSART), postganglionic sympathetic cholinergic nerves innervating sweat glands appear to be intact in PD. In contrast, studies using skin humidity, electrical conductance, and body temperature as indices of sweat production have shown conflicting results.

Pure Autonomic Failure

Although PAF is not a movement disorder, neuropathological data showing the presence of LB suggest a close connection with PD. PAF was first described by Bradbury and Eggleston in 1925. It is a sporadic, adult onset, slowly progressing, neurodegenerative disorder that is mostly confined to peripheral autonomic neurons. PAF is characterized clinically by severe OH with varying degrees of autonomic impairment in other organs, but no other neurological abnormalities, specifically no parkinsonism or cerebellar ataxia. Men typically present with erectile dysfunction. Anhidrosis, dry mouth, constipation and problems with urination may occur. The typical age at onset is 60 years.

There are few neuropathology reports of patients with PAF. All reports have shown LB in autonomic nerves and, in some cases, in the brain stem as well. This suggests that PAF, despite the absence of parkinsonian features or dementia, is a neurodegenerative disorder related to PD and DLB.

Dementia with LB

DLB is the most frequent cause of degenerative dementia after Alzheimer's disease. The mean age at onset of DLB is 75 years, and has a slight male predominance. The majority of patients have cognitive or psychiatric manifestations as their initial presentation, but they may also present with parkinsonian or autonomic features alone. Whether DLB and PD with dementia are the same or two distinct disorders is controversial.

Neuropathology shows LB throughout the cortex, substania nigra and other brainstem nuclei, scattered within the spinal cord and in abundance in autonomic ganglia and in sympathetic neurons.

Autonomic abnormalities are a supportive feature in the diagnosis of DLB. Typically, dysautonomia occurs after the development of cognitive impairment; however, this is not always the case. Urinary incontinence and constipation occur frequently and OH with repeated falls and syncope is common and can precede other deficits by several years. Erectile dysfunction in men is common and often goes unnoticed or is wrongly dismissed as 'normal aging.'

Autonomic testing shows severe OH, lack of BP overshoot in phase IV of the Valsalva maneuver and decreased heart rate variability. Imaging of cardiac sympathetic terminals shows decrease amine uptake in cardiac postganglionic sympathetic neurons in DLB but not in Alzheimer's disease.

Multiple System Atrophy

The second type of neurodegeneration with prominent autonomic failure is MSA. MSA is a sporadic progressive neurodegenerative disorder that causes parkinsonism, cerebellar, pyramidal, and autonomic dysfunction. MSA affects neurons in the cerebellum, basal ganglia, brain stem, and spinal cord, but in marked contrast to LB disorders spares postganglionic autonomic neurons. MSA has two phenotypes: parkinsonian (designated MSAp) and cerebellar (designated MSAc) according to the predominant movement disorder. Autonomic failure occurs similarly in both phenotypes. There are no known genetic mutations responsible for MSA.

Age of onset is usually in the early 1950s, with men more commonly affected than women. MSA can present with either a movement disorder or autonomic deficits. Erectile dysfunction is common in men and half of female patients report decreased genital sensitivity. Rapid eye movement (REM) behavior disorder, characterized by violent movements during dreams, often precedes motor symptoms. Dementia is very unusual but emotional lability is frequent. Common features include marked postural instability, dysarthria, laryngeal stridor and antecollis, focal reflex myoclonus, Raynaud's phenomenon, dysphagia, snoring, and inspiratory sighs. Life expectancy is much shorter in MSA than in PD. The disease is usually rapidly progressive and survival is typically 6–9 years after diagnosis.

Neuropathology

The discovery of α-synuclein-containing inclusions in the cytoplasm of glial cells from patients with MSA provided the pathological hallmark for this disease. These glial cytoplasmic inclusions (GCI) are the equivalent of LB in PD. Degeneration of neurons at several levels of the central nervous system (CNS) impairs sympathetic and parasympathetic reflexes, while postganglionic neurons remain intact. Brainstem and cerebellar degeneration results in dysarthria, uncoordinated swallowing, and abnormal breathing particularly during sleep and recurrent aspirations. Postmortem examination shows depletion of tyrosine hydroxylase immunoreactivity in the rostral and caudal ventrolateral medulla (CVL), and intermediolateral columns (IML) of the spinal cord. There is also loss of dopamine-β-hydroxylase and tyrosine hydroxylase in the locus ceruleus, the main source of norepinephrine in the brain.

Cerebellar and Parkinsonian Phenotypes

Eighty percent of patients with MSA present with parkinsonian features (MSAp) while the remaining 20% first develop cerebellar deficits (MSAc). Patients with MSAp frequently have postural tremor, generalized akinesia, and rigidity, but the typical 'pill-rolling' resting tremor of patients with PD is rarely seen. Involvement is usually bilateral, but asymmetric symptoms are not infrequent. In MSAc cerebellar deficits predominate with gait and limb ataxia, pronounced scanning dysathria and oculomotor abnormalities. As the disease progresses, cerebellar and parkinsonian features are usually combined. Cerebellar abnormalities may be difficult to recognize when parkinsonism is pronounced.

Cardiovascular Abnormalities

In the majority of patients with MSA, postganglionic sympathetic neurons are intact. Lesions within central baroreflex pathways prevent the appropriate reflex activation (or inhibition) of postganglionic sympathetic neurons.

Failure to appropriately increase sympathetic activity with standing and after meals results in disabling orthostatic and postprandial hypotension. Likewise, a failure to suppress sympathetic outflow when supine results in, often severe, supine hypertension. Patients with MSA often have enhanced postganglionic sympathetic outflow to the vasculature, as revealed by the large fall in BP following ganglionic blockade with trimethaphan.

Autonomic testing reveals blunted baroreflexes characterized by progressive severe hypotension with upright tilt and a failure of the BP overshoot after release of the strain of the Valsalva maneuver.

Patients with MSA also have abnormal circadian rhythms of BP and heart rate. During the night, BP and heart fail to decrease, as it normally occurs in healthy subjects. Although hypertension only occurs when patients with MSA are supine, it does result in end-organ damage, including left ventricular cardiac hypertrophy. Elevation of the head of the bed on blocks is an effective treatment for nocturnal hypertension, as it reduces nocturia and helps expand intravascular volume.

Bladder Dysfunction

Dysuria, with or without chronic retention, is an early symptom in patients with MSA. It is frequently associated with a hypoactive detrusor and low urethral pressure. In contrast, patients with PD have urgency to void, with or without difficulty voiding, but without chronic retention, associated with detrusor hyperreflexia and normal urethral sphincter function. The striated muscle of the external anal and urethral sphincter is innervated by fibers that originate in the Onuf nucleus in segments S2–S4 of the spinal cord. This nucleus is particularly vulnerable in patients with MSA, but not in those with PD. Neuronal loss in the Onuf nucleus is reflected by signs of denervation and chronic reinnervation on EMG of anal and urethral sphincter muscle. Eventually most patients require daily selfcatheterization.

Sleep Disturbances

Sleep disturbances in MSA include sleep fragmentation, periodic limb movements, REM behavior disorder, sleep apnea, and excessive daytime sleepiness. Some of these disturbances can occur early in the course of the disease or may precede the development of the movement disorder, particularly REM sleep behavior disorder.

Vocal Cord Palsy

Vocal cord palsy is frequent in MSA and may lead to aspiration. Early recognition and treatment for laryngeal stridor may reduce mortality. In 104 patients with MSA, stridor was observed in 36. In 70% of the cases stridor occurred within the first 4 years; in 10 cases it developed in the first year of the disease. Laryngeal stridor was frequently accompanied by dysphagia and hoarseness.

Treatment

Treatment of Orthostatic Hypotension

OH can be effectively treated with a combination of nonpharmacological and pharmacological interventions. Patients should first sit when going from a supine to standing position. Straining during bowel movements or performing Valsalva-like maneuvers during isometric exercise reduces venous return to the heart, worsens OH and may trigger syncope, thus constipation should be treated aggressively. The use of physical countermaneuvers when upright such as leg crossing, standing on tip toes and muscle tensing increases venous return to the heart and enhances orthostatic tolerance. Eating frequent small meals is often effective in lessening postprandial BP falls. Custom-made full-length elastic stockings can be useful in preventing pooling in the lower extremities. Unfortunately, patients with movement disorders find them difficult to tolerate. Patients should liberalize their dietary salt intake and drink at least 2 l of water a day. Elevating the head of the bed 30° during the night reduces overnight sodium and water excretion by the kidney and lessens OH in the morning.

Treatment with fludrocortisone, a synthetic mineralocorticoid, when combined with a high salt intake raises BP. Potassium supplementation may be needed, because fludrocortisone increases renal potassium excretion. Octreotide and acarbose, reduce postprandial hypotension. Vasoconstrictor agents such as the selective α1-adrenoreceptor agonist midodrine increase BP and improve symptoms of OH. Side effects of midodrine include pilomotor reactions, pruritus, supine hypertension, and urinary retention.

Drugs that release norepinephrine from sympathetic nerve terminals may be effective in patients with MSA, since these patients have intact sympathetic terminals. Dihydroxyphenylserine (DOPS, droxidopa) is converted into norepinephrine after oral administration and has been used successfully in small trial of patients with autonomic synucleinopathies. All vasoconstrictor agents may lead to significant hypertension when the patient is supine. Treatment with recombinant erythropoietin and iron supplementation to correct the anemia, common in autonomic failure, increases upright BP and improves symptoms of OH. Acetylcholinesterase inhibitors (pyrostigmine) have been used, but their pressor effects are very modest.

Treatment of Supine Hypertension

Hypertension when supine is common in patients with autonomic failure. Patients should be instructed to avoid

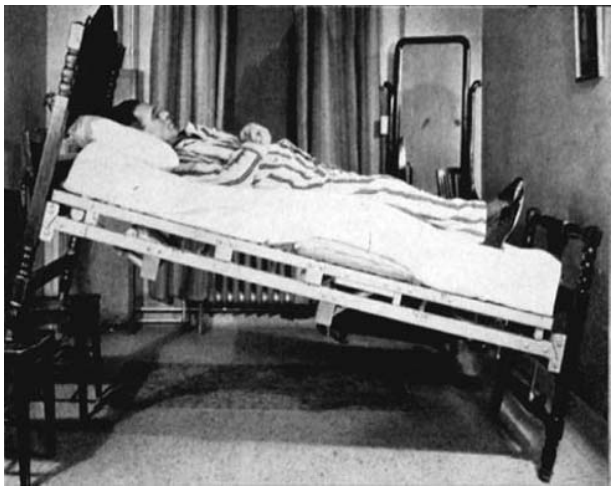

Figure 4 The 'head-up' bed as originally published by Maclean and Allen in 1940. Reproduced from Maclean AR and Allen EV (1940) OH and orthostatic tachycardia, treatment with the 'head up' bed. *Journal of American Medical Association* 115: 2162–2167.

being supine at all times and avoid taking antihypotensive agents before bed. Sleeping with the head of the bed elevated lessens nocturnal hypertension (**Figure 4**). The use of short acting antihypertensive agents such as transdermal nitroglycerin ($0.1–0.2\,mg\,h^{-1}$), oral nifedipine (30 mg) or hydralazine (50–100 mg) at night has been suggested. Unfortunately, these agents do not prevent nocturia and can, in the case of nifedipine, worsen nighttime sodium loss.

Differential Diagnosis among the Synucleinopathies

The two main diagnostic problems among the synucleinopathies are (1) the distinction between PAF and early 'premotor' MSA, PD, or DLB, and (2) the distinction between PD with autonomic failure and MSAp.

PAF versus Early 'Premotor' MSA, PD or DLB

When a patient presents with symptomatic OH and no other apparent neurological deficits and is thus presumed to have PAF it should first be ascertained whether the OH is neurogenic, that is, the result of dysfunction of the baroreflex. This can be accomplished with noninvasive autonomic testing showing lack of BP overshoot during Valsalva maneuver and lack of appropriate increase in heart rate when the BP falls. Simple bedside measurements can be helpful. For example, a marked increase in heart rate accompanying OH suggests volume depletion and 'rules out' autonomic failure. A careful drug history is important, as antihypertensive or antidepressants agent may be the culprit for OH. A detailed clinical history may reveal constipation, decreased sweating, bladder, and erectile dysfunction suggesting widespread autonomic denervation.

A careful neurological examination may uncover subtle parkinsonian or cerebellar signs indicating that, rather than having PAF, the patient is in the early 'premotor' stages of MSA. If no central neurological deficits are uncovered and peripheral neuropathies or autoimmune causes are ruled out, the most likely diagnosis is PAF. Early in the disease course, the diagnosis of PAF is always made tentatively because after a few years a patient who appeared to have PAF may develop extrapyramidal or cerebellar deficits and turns out to have MSA, or less frequently PD or DLB.

PD with Autonomic Failure versus MSAp

A patient that presents with parkinsonism and autonomic failure may have PD or MSAp. The distinction between these two disorders is challenging. A history of severe autonomic symptoms preceding motor deficits is much more frequent in MSA than in PD. Subtle cerebellar findings indicate that the patients has MSAp as they do not occur in PD, pyramidal tract features are more frequent in MSAp than PD and typical 'pill-rolling' asymmetric hand tremor strongly suggests PD. Contrary to PD, patients with MSAp have poor or no therapeutic response to levodopa. However, around half of MSA patients have at least some initial improvement, albeit transient. Patients with MSAp can develop axial levodopa induced dyskinesias, even in the absence of beneficial motor effects. Early urinary dysfunction, vocal cord palsy, early dysarthria, dysphagia, dystonia (including antecollis), focal reflex myoclonus, vasomotor changes in the hands ('purple hands'), laryngeal stridor, snoring, inspiratory sighs, pseudobulbar crying or laughing, early severe postural instability with wheelchair dependence all suggest MSAp, as their presence is rare in PD. Dementia is most severe and relentless in DLB; it occurs in the latter stages of PD, but not in MSA. Emotional incontinence, however, is frequent in MSA.

Sympathetic Neuroimaging in the Differential Diagnosis

Sympathetic cardiac neuroimaging has the potential to simplify the differential diagnosis among the synucleinopathies. Sympathetic neuroimaging using metaiodobenzylguanidine (MIBG) single photon emission computed tomography (SPECT) or fluorodopamine positron emission tomography (PET) consistently show that patients with LB disorders, including PAF, PD, and DLB have decreased amine uptake in postganglionic sympathetic neurons innervating the heart. In contrast patients with MSA have preserved amine uptake in these neurons.

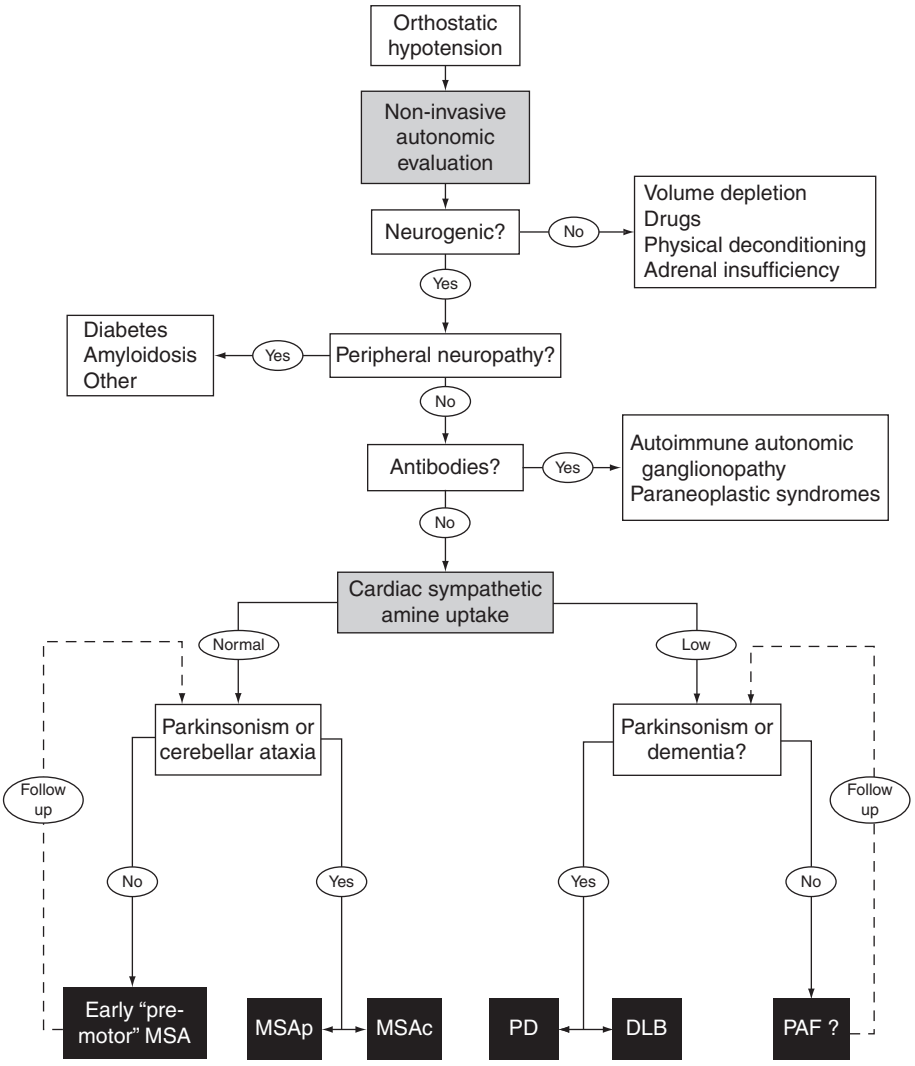

Figure 5 A proposed algorithm for the differential diagnosis of the autonomic synucleinopathies. See text for details. MSA, multiple system atrophy; MSAc, multiple system atrophy with predominant cerebellar ataxia; MSAp, multiple system atrophy with predominant parkinsonism; PD, Parkinson's disease; DLB, dementia with Lewy bodies; PAF, pure autonomic failure.

These findings reflect degeneration of postganglionic sympathetic neurons in LB disorders and sparing of these neurons in MSA.

Figure 5 shows a proposed algorithm for the differential diagnosis of the synucleinopathies. In a patient with neurogenic OH in whom a peripheral neuropathy or an autoimmune cause has been excluded, if myocardial amine uptake is low and the patient does not have parkinsonism or cognitive impairment, the most likely diagnosis is PAF. As previously mentioned, the diagnosis of PAF is tentative as this may be the initial presentation of PD or MSA, which will become apparent after a few years.

If a patient with neurogenic OH has normal myocardial amine uptake and parkinsonism or cerebellar ataxia, the diagnosis is MSA. If neither parkinsonism nor cerebellar ataxia are present, it is likely that he is in the early 'premotor' phase of MSA.

Basal Ganglia

A Galvan and Y Smith, Emory University, Atlanta, GA, USA

Glossary

Dopamine – Major neurotransmitter used by many neurons in the central nervous system. It mediates its effects through activation of two major families of receptors called D1 and D2 receptor families. It plays an important role in reward and addiction. Dopaminergic neurons in the substantia nigra pars compacta degenerate in Parkinson's disease.

Parkinson's disease – Second most common neurodegenerative disease after Alzheimer's disease characterized by the severe loss of dopaminergic neurons in the substantia nigra was first described by James Parkinson in 1817. The main symptoms are slowness of movements, muscular rigidity, rest tremor, and postural instability. Some patients also suffer from nonmotor symptoms such as depression and cognitive deficits.

Striatum – Large mass of subcortical gray matter located in the telencephalon considered as the main input station of extrinsic information to the basal ganglia circuitry. It is made up of the caudate nucleus, putamen, and nucleus accumbens.

Substantia nigra – Subcortical brain structure located in the mesencephalon made up of two parts called the pars compacta (dopamine neurons) and pars reticulata (GABAergic neurons). This structure plays a role in addiction, reward, and motor control.

Subthalamic nucleus – Small almond-shaped subcortical brain structure located ventral to the thalamus in the caudal part of the diencephalon. It is a key structure of the basal ganglia that plays a major role in Parkinson's disease pathophysiology. It is one of the main targets for surgical therapy in Parkinson's disease.

Definition and History

The basal ganglia are a group of subcortical brain nuclei, first described by the seventeenth century neuroanatomist Thomas Willis. They were originally named based on their location in the basal regions of the cerebral hemispheres. Although the modern view of the basal ganglia includes functionally connected structures in the basal forebrain, namely the striatum and the globus pallidus (GP), they also comprises other structures, such as the subthalamic nucleus (STN) and substantia nigra located more caudally at the basis of the diencephalon and ventral midbrain, respectively. As a crucial part of the extrapyramidal motor system, these nuclei are involved in the control of voluntary movements, but also participate in high order cognitive and limbic functions. As such, basal ganglia diseases such as Parkinson's and Huntington's diseases traditionally known as motor disorders are, in fact, much more complex disturbances that reveal motor, cognitive, emotional, and neuropsychiatric symptoms. Tourette's syndrome, obsessive compulsive disorders (OCD), and attention deficits, which likely result from neurochemical changes in the basal ganglia, are also characterized by complex motor and nonmotor deficits.

The basal ganglia are phylogenetically conserved in all vertebrates, having evolved more conspicuously in amniote species (reptiles, birds, and mammals). In birds and reptiles, these nuclei exert their influence on motor functions mostly via outputs to the midbrain, while the mammalian basal ganglia mediate their motor and nonmotor effects mainly through regulation of thalamocortical neurons linked to motor and prefrontal cortices.

Components of the Basal Ganglia

In primates, the components of the basal ganglia are the dorsal striatum (caudate nucleus and putamen), the ventral striatum (nucleus accumbens), the external and internal

segments of the globus pallidus (GPe and GPi, respectively), the STN, the substantia nigra that comprises the pars reticulata and pars compacta (SNr and SNc, respectively), and the ventral tegmental area (VTA). In rodents, the caudate nucleus and putamen form a single structure commonly called the caudate–putamen complex, while the GP and the entopeduncular nucleus (EPN) correspond functionally to the primate GPe and GPi, respectively. As for many other anatomical terms, the names of these structures are derived from Latin and usually indicate a remarkable structural feature of each brain region. For instance, striatum means 'to present a striated appearance.' The scarcity of cells in the GP gives this structure a faint aspect in comparison with surrounding structures, and thus the name 'pale globe.' The term 'substantia nigra' (black substance) is derived from the presence of the dark pigment neuromelanin in these neurons. Finally, the complex formed by the putamen and GP is called 'lenticular or lentiform nucleus' (lens-shaped body) because in coronal sections, it appears as a double lens.

Parallel and Segregated Cortical–Basal Ganglia Loops

The basal ganglia are part of neural circuits that involve the cerebral cortex and thalamus. According to the functions of the cortical regions from which they originate, three main functionally segregated loops can be identified: sensorimotor, limbic, and associative. In each of these circuits, functionally related cortical areas project topographically to specific areas of the striatum (see **Figure 1**). Thus, the sensorimotor loop involves the putamen posterior to the anterior commissure, which receives its main inputs from the somatosensory, primary motor, premotor, and supplementary motor areas of the cerebral cortex. The associative loop involves the head and tail of the caudate nucleus and parts of the putamen rostral to the anterior commissure. These areas receive inputs from the dorsolateral prefrontal, lateral orbitofrontal, posterior parietal, and temporal association cortices. Finally, the limbic loop, which involves the ventral striatum, including the nucleus accumbens and the rostroventral caudate nucleus and putamen, transmits inputs from the anterior cingulate and medial orbital frontal cortices, as well as the amygdala and the hippocampus. This segregation of cortical information is maintained at all levels of other basal ganglia nuclei and in the basal ganglia-receiving regions of the thalamus. Functional interactions between these loops likely occur through corticocortical connections.

Because of its role in the pathophysiology of movement disorders, the sensorimotor circuit has been most extensively studied. Channels of information flow from motor and somatosensory cortices related to specific body

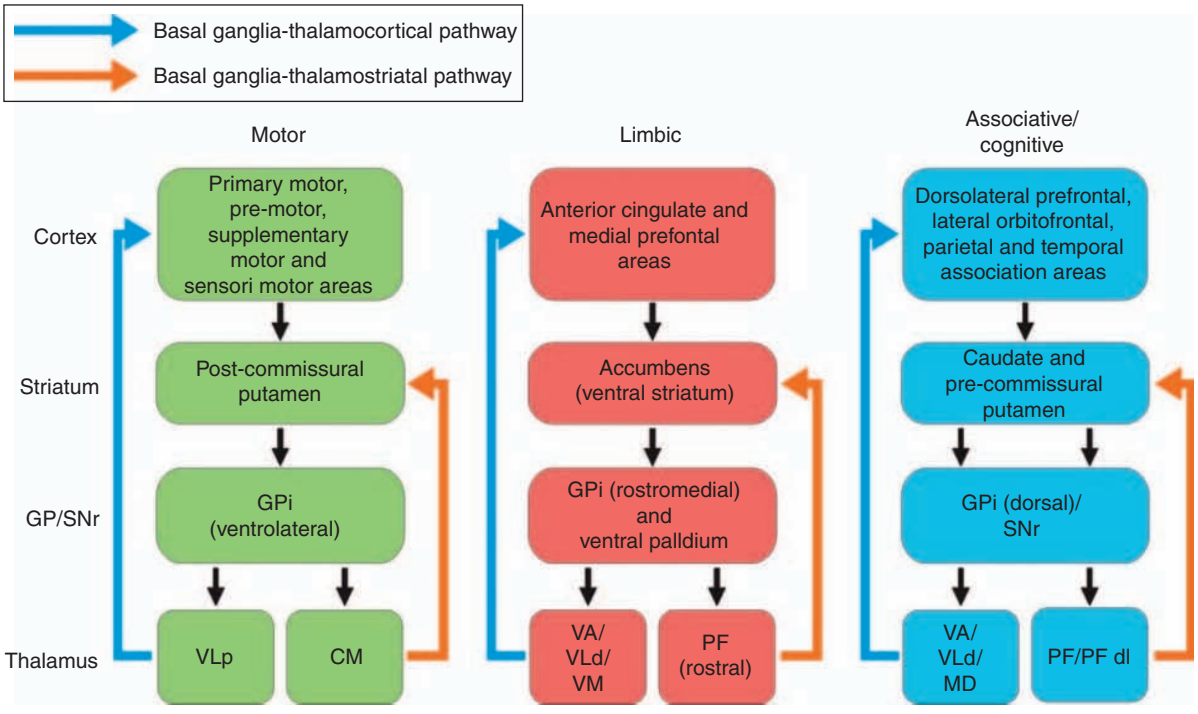

Figure 1 Segregated basal ganglia–corticothalamic and basal ganglia–thalamostriatal loops. For simplicity, some pathways have been omitted. CM, centromedian nucleus of thalamus; GPi, globus pallidus internal segment; PF, parafascicular nucleus of thalamus; PF dl, dorsolateral part of PF; SNr, substantia nigra reticulata; VA, ventral anterior nucleus of thalamus; VLp, posterior part of the ventrolateral nucleus of thalamus; VLd, dorsal part of ventrolateral nucleus of thalamus; VM, ventromedial nucleus of thalamus.

parts converge onto common regions of the postcommissural putamen, which then transmits the information to specific areas of the ventrolateral GPi. In turn, the motor basal ganglia outflow is conveyed to segregated areas of the ventral motor thalamic nuclei and the brainstem pedunculopontine nuclei (PPN) to influence motor behaviors through ascending thalamocortical projections or descending projections from the PPN to the reticular formation and spinal cord.

Cellular and Hodological Organization of the Basal Ganglia

Cell Types in the Basal Ganglia

The main input nucleus of the basal ganglia, the striatum, is composed of spiny and aspiny neurons, characterized by the presence or scarcity of spines on their distal dendrites, respectively. The medium-sized spiny neurons (MSNs), which account for as much as 90–95% of the total striatal neuronal population, are the projection neurons of the striatum, and they use γ-aminobutyric acid (GABA) as neurotransmitter.

The aspiny cells are interneurons that use GABA or acetylcholine as neurotransmitters. The cholinergic interneurons are the largest neurons in the neostriatum, and they likely correspond to the so-called tonically active neurons (TANs) characterized by their tonic firing rate. The cholinergic interneurons are important intrinsic regulators of MSNs and play a key role in learning.

Three major subtypes of GABAergic interneurons have been identified based on their chemical content and physiological activity: (1) the parvalbumin cells, also referred to as 'fast spiking interneurons' based on their high frequency of firing; (2) the nitric oxide synthase/neuropeptide Y/somatostatin interneurons, also known as 'persistent and low-threshold spike neurons,' due to their characteristic low-threshold calcium spikes and prolonged calcium dependent plateau potential; and (3) the calretinin interneurons, which seems to be functionally similar to the 'persistent and low-threshold spike neurons.' These GABAergic interneurons, especially the parvalbumin cells, exert powerful monosynaptic inhibition onto MSNs, thereby playing an important role in regulating striatal outflow.

In contrast to the striatum, the other basal ganglia nuclei have a more homogeneous cellular organization, being largely made up of projection neurons and only a few (if any) interneurons. The GPe, GPi, and SNr comprise GABAergic projection neurons with significant intrinsic axon collaterals arborization, whereas the STN projection cells are glutamatergic with limited intranuclear connectivity. The SNc is made up almost exclusively of dopaminergic neurons, but receives local GABAergic influences from axon collaterals of SNr projection neurons.

Extrinsic Connectivity of the Basal Ganglia

The striatum receives glutamatergic afferents from the cerebral cortex and thalamus. Inputs from the cortex originate from most cortical areas. In rodents, pyramidal corticostriatal neurons can be divided into two major subtypes; the intratelencephalic (IT) neurons of which axonal projections remain within the confines of the telencephalon, and the pyramidal tract (PT) neurons that send their main axon into the PT and have collateral projections to striatum. However, the functional role of PT corticostriatal neurons in rodents and the existence of such neurons in primates remain controversial.

The thalamostriatal projections use glutamate as their transmitter and originate mainly from the caudal intralaminar thalamic nuclei, specifically the centromedian and parafascicular nuclei (CM/PF). Nonetheless, these projections have significant contributions from the rostral intralaminar, midline, associative, and motor-related nuclei. Until recently, the thalamostriatal system was largely neglected or considered to play a minor role in the basal ganglia circuitry. However, it has now been demonstrated that this projection is massive, highly specific, and physiologically relevant. The CM/PF complex is also considered as a new therapeutic target for deep brain stimulation in movement disorders.

The intrastriatal arborization and synaptic connectivity of afferents from the CM/PF complex are characteristically different from corticostriatal inputs and other thalamic afferents. Thus, while cortical innervation to the striatum is widely distributed, and provides only few axonal varicosities to individual striatal cells, single axons from CM/PF neurons form dense clusters of terminals concentrated in small portions of the striatum. At the synaptic level, most cortical and a significant subset of thalamic inputs terminate almost exclusively on dendritic spines of MSNs. In contrast, most CM/PF afferents target preferentially dendritic shafts. Besides these anatomical features, recent evidence indicates differences in glutamate release probability and long-term plasticity between thalamostriatal and corticostriatal synapses.

Along with the striatum, the STN is considered an input nucleus of the basal ganglia. In primates, the corticosubthalamic projection arises mostly from motor cortices, including primary, supplementary, presupplementary, premotor, and cingulate motor areas in the frontal lobe. Inputs from the primary motor cortex are somatotopically organized and confined to the dorsolateral part of the STN, whereas other motor inputs overlap in the dorsomedial sector of the nucleus. Primary motor cortex and supplementary motor cortex inputs display a reverse somatotopic arrangement in the monkey STN. Through the corticosubthalamic route, the cerebral cortex provides strong excitation to the GPi and SNr, with faster conduction velocity than information flowing through striatofugal

pathways. Because of its fast conduction and direct access to basal ganglia output nuclei, this connection is known as the 'hyperdirect pathway.' It has been suggested that the hyperdirect pathway plays an important role in a center-surround model of action selectivity in the GPi, by inhibiting irrelevant motor programs. However, the anatomical and physiological basis for such model remains to be further studied. Besides the cortex, the STN receives glutamatergic inputs from the thalamus and the PPN.

Other extrinsic inputs to the basal ganglia originate from the amygdala and hippocampus, which target mainly limbic striatal regions, and brainstem afferents from serotonergic, cholinergic, and noradrenergic cell groups in the raphe, PPN, and locus coeruleus, respectively.

Intrinsic Connectivity of Basal Ganglia

The main targets of extrinsic inputs to the striatum are GABAergic MSNs, which are divided into two groups based on their dopamine receptor expression, peptide content and main basal ganglia projection targets. The so-called 'direct pathway' neurons project directly to the basal ganglia output nuclei, GPi and SNr, and express preferentially D1 dopamine receptors, whereas the 'indirect pathway' neurons project mainly to the GPe and express D2 dopamine receptor. As discussed in detail elsewhere, the degree of segregation of these two pathways has been challenged over time and remains controversial.

The striatum receives a prominent dopaminergic input from SNc and VTA, which plays a critical regulatory role over cortical glutamatergic influences through pre- and postsynaptic mechanisms at the level of spines on MSNs. Dopamine neurons are the sources of complex information related to movement, reward-related stimuli and aversive events to the striatum. Although the exact sources of such information to midbrain dopamine neurons remain unknown, specific subcortical nuclei including the lateral habenula (LHb), the superior colliculus (SC), and the PPN likely contribute significantly to the regulation of nigral dopaminergic outflow (see **Figure 2**).

Even though the striatum is the main basal ganglia target of midbrain dopaminergic neurons, the GP and the STN also receive modest nigral dopaminergic input. Furthermore, the local dendritic release of dopamine from SNc neurons may play an important role in regulating the activity of SNr GABAergic neurons. Therefore, the characteristic loss of SNc dopaminergic neurons that occurs in Parkinson's disease can have widespread influences throughout the basal ganglia circuitry, not only in the striatum, but also in extrastriatal targets.

Basal Ganglia Outflow

The GPi and the SNr are the output nuclei of the basal ganglia. Both nuclei receive functionally segregated inputs from the striatum (through direct and indirect routes), and in turn send GABAergic projections to their thalamic and brainstem target structures. Furthermore, some of the pallidal and nigral targets project back to the basal ganglia, creating feedback circuits (**Figure 1**).

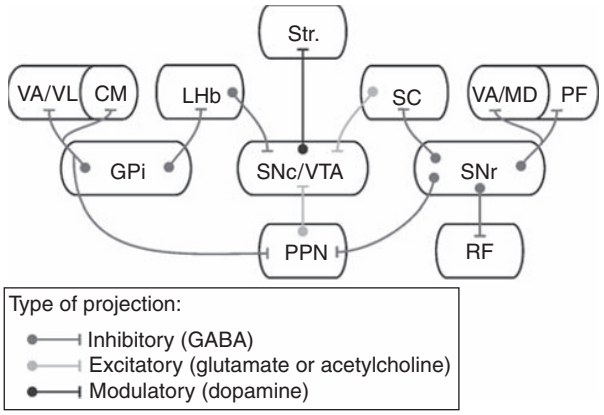

Figure 2 Output pathways of the GPi and SNr, and subcortical inputs to the SNc. In the GPi, a population of neurons project to the thalamus and the PPN, while a different cell group projects to the LHb. In contrast, the degree of collateralization in the SNr is more heterogenous. For simplicity, only major projections are represented. CM, centromedian nucleus of thalamus; GPi, globus pallidus internal segment; LHb, lateral habenula; PF, parafascicular nucleus of thalamus; PPN, pedunculo pontine nucleus; RF, reticular formation; SNc, substantia nigra compacta; SNr, substantia nigra reticulata; Str, striatum; VA/VL, ventral anterior and ventrolateral nuclei of thalamus; VA/MD, ventral anterior and mediodorsal nuclei of thalamus; VTA, ventral tegmental area.

Efferent projections of GPi

The GPi sends a topographic projection to the ventrolateral (VL) and ventral anterior (VA) nuclei of the thalamus. Efferent projections from the sensorimotor GPi (ventrolateral two thirds) are segregated from associative (dorsal third) and limbic (rostromedial pole) GPi inputs in the thalamus. Sensorimotor pallidothalamic projections are somatotopically organized and further segregated into different channels based on their main sources of motor-related cortical influences. The VA/VL nuclear complex is the main thalamic recipient of GPi outflow, but these projections are highly collateralized and also provide significant inputs to the caudal intralaminar nucleus CM and to the PPN in the brainstem (**Figure 2**). Through these projections, cortical information can be sent back to frontal cortical regions via segregated basal ganglia–thalamocortical loops or specific striatal regions via basal ganglia–thalamostriatal projections (**Figure 1**). Alternatively, basal ganglia outflow can gain direct access to descending motor systems via the PPN that sends back glutamatergic and cholinergic projections to most basal ganglia nuclei, but also gives rise to significant

descending influences on motor-related neurons in the lower pons, medulla, and spinal cord.

Another segregated population of neurons located along the borders of GPi sends projections to the LHb (**Figure 2**), a small circumscribed component of the so-called epithalamus located in the dorsal part of the caudal diencephalon. Similar to other pallidofugal pathways, the pallidohabenular projection is topographically organized and made up of different functional channels of information that terminate in specific sectors of the LHb. In turn, the LHb sends inhibitory projections to ventral midbrain dopaminergic neurons in the SNc and VTA. Through this system, the pallidohabenular projection may initiate reward-related signals in midbrain dopaminergic neurons (see above). Based on recent findings showing that the LHb has the potential to control both reward-seeking and punishment-avoidance behaviors through its projections to the ventral midbrain, the extrinsic regulation of LHb neurons by GPi can have widespread influences over motor, cognitive, and limbic-related behaviors.

Efferent projections of SNr

The thalamic targets of the SNr include the medial magnocellular divisions of the VA (VAmc) and the mediodorsal nucleus (MDmc). These thalamic regions, different from those that receive GPi inputs, project to anterior regions of the frontal lobe including the principal sulcus, orbital cortex, frontal eye fields, and areas of premotor cortex. A subset of SNr neurons also gain access to thalamocortical neurons that project to the area TE in the inferotemporal cortex, suggesting a possible role of SNr in high order processing of visual perceptions. Many nigrothalamic neurons send axon collaterals to thalamostriatal neurons in PF.

The SNr also sends a massive and topographically arranged projection to the intermediate layers of the SC. These nigral fibers terminate mainly on tectospinal neurons, and are critically important in the control of saccadic eye movements. In turn, a recently described tectonigral projection is considered as a potential source of unpredicted, biological salient, sensory events to midbrain dopaminergic neurons in the SNc, thereby providing a substrate for midbrain dopaminergic responses to sensory prediction errors. Other targets of the SNr are the orofacial motor nuclei in the medullary reticular formation and the noncholinergic neurons in the PPN (**Figure 2**).

Models of Basal Ganglia Function and Dysfunction

The most influential model of the sensorimotor basal ganglia circuit was proposed in the late 1980s to explain how basal ganglia dysfunction could result in hypokinetic movement disorders such as Parkinson's disease, and hyperkinetic movement disorders such as Huntington's disease. This functional 'direct and indirect pathway' model of the basal ganglia circuitry has been instrumental in our understanding of the pathophysiology of basal ganglia disorders and the development of surgical therapy for Parkinson's disease. The readers are referred to other chapters in the Encyclopedia for a more detailed account of the functional anatomy and physiological organization of this model.

Motor and Nonmotor Functions of the Basal Ganglia

Although the basal ganglia have long been recognized as critical components of the extrapyramidal motor system, there is strong anatomical and functional evidence that they also play major role in cognitive and limbic-related behaviors. First, as outlined in this chapter and illustrated in **Figure 1**, each basal ganglia structure and its thalamic targets comprise segregated functional territories that process sensorimotor, associative, and limbic information. Since the original introduction of the concept of segregated basal ganglia–thalamocortical loops by Alexander, DeLong, and colleagues in the mid-1980s, this model of organization has generated significant interest and has been further supported using more sophisticated anatomical tracing methods and physiological approaches. However, two major issues remain unclear about this model of basal ganglia information processing. The exact substrate of cross-communication between the various channels of information must be further characterized. Although suggestions have been made that such cross talk most likely occurs through the complex corticocortical circuitry, others have argued that subsets of basal ganglia neurons may also contribute to these functional interactions. Another important issue to unravel is the mechanism by which segregated basal ganglia output neurons lose their functional specificity in Parkinson's disease. Whether this reflects a lack of dopamine modulatory influences at the cortical or subcortical levels must be determined.

Additional strong evidence for the role of basal ganglia in nonmotor functions comes from clinical and postmortem human studies, showing that patients who suffer of traditionally known 'motor' basal ganglia disorders such as Parkinson's and Huntington's diseases, also present clear cognitive and emotional disturbances in attention, working memory, set shifting, set formation, and actions planning, even at early stages of the disease process. Furthermore, pathologies characterized by emotional, cognitive, and psychiatric deficits, including OCD, Tourette's syndrome, attention deficit disorders, and depression, involve neurochemical disruption of basal ganglia networks and/or pathology of specific basal ganglia nuclei. Some of the psychiatric and nonmotor side-effects that result from

ablative surgery or deep brain stimulation of the GPi or STN also indicate that the basal ganglia function extends far beyond mere motor control. In fact, our limited understanding of the exact role of basal ganglia in motor control is another evidence of the complex mechanisms by which these brain nuclei integrate and process sensorimotor information. Functional data obtained so far suggest that the basal ganglia are involved in both the preparation and execution of movements as well as learning of motor sequences and habits.

Basal Ganglia, Functional Organization

T Wichmann and M R DeLong, Emory University, Atlanta, GA, USA

Glossary

Basal ganglia – A group of subcortical brain nuclei that are connected to thalamus and the cortex. The basal ganglia consist of the striatum, the globus pallidus with its external and internal segment, the substantia nigra with its pars compacta and pars reticulata, and the subthalamic nucleus.

Dendritic spines – Extensions of dendrites that can be detected at the light- and electron microscopic level. In terms of basal ganglia anatomy, dendritic spines are a distinct feature of medium spiny neurons in the striatum. Dendritic spines are an important termination point of cortical and thalamic inputs to the striatum. It is thought that the information transfer via dendritic spines is strongly regulated through the presence or absence of the neurotransmitter dopamine.

Direct and indirect pathways – A common anatomical scheme used to classify the intrinsic connections between the basal ganglia nuclei that receive extrinsic inputs (the striatum), and the basal ganglia that provide output to other structures (the internal pallidal segment and the substantia nigra pars reticulata). The direct pathway is monosynaptic, while the indirect pathway is polysynaptic.

(Hemi-)Ballism – A rare movement disorder characterized by the development of involuntary movements of the limbs on one side of the body, which are often proximal large-amplitude movements. The disorder is typically caused by strokes or other lesions of the subthalamic nucleus on one side of the brain, and is therefore usually unilateral (hemiballism).

Huntington's disease – Huntington's disease is an autosomal dominant trinucleotide repeat disorder. This genetic condition leads to progressive degeneration of neurons in the cortex, striatum, and other brain regions. Clinically, the disease manifests itself with a combination of neuropsychiatric symptoms (such as mood disturbances, behavioral

abnormalities, and cognitive impairments) and the appearance of involuntary movements (chorea).
Movement disorders – A group of diseases dominated by disturbances of movement in the absence of weakness. Movement disorders are usually associated with an impairment of the ability to carry out coordinated movements. These disorders are generally grouped into disorders in which the overall amount of movement is reduced (hypokinetic disorders such as Parkinson's disease), and disorders with an excess of movements, which are typically involuntary (hyperkinetic disorders, such as ballism or Huntington's disease).
Parkinson's disease – A complex neurodegenerative disease, characterized clinically by the appearance of poor movement (akinesia), slowness of movement (bradykinesia), tremor at rest, and muscular rigidity These symptoms are caused by dopamine loss in the basal ganglia and can be treated with dopaminergic replacement therapy. Other parkinsonian features include gait instability, autonomic symptoms such as constipation or blood pressure fluctuations, and cognitive impairment. These symptoms probably arise from pathology outside of the basal ganglia and are not effectively treated with dopamine.

Functional Anatomy of the Basal Ganglia

Basal Ganglia Structures

The basal ganglia are a group of anatomically interconnected subcortical nuclei, including the striatum, which is divided into a ventral and dorsal portion (consisting of the caudate nucleus (CN) and the putamen), the external and internal segments of the globus pallidus (GPe, GPi, respectively), the pars compacta and the pars reticulata of the substantia nigra (SNc, SNr, respectively), and the subthalamic nucleus (STN).

Striatum

The striatum is the major input structure of the basal ganglia. It receives projections from large portions of the cerebral cortex, brain stem, and from several thalamic nuclei. The most common striatal cell type is the GABAergic 'medium spiny' neuron (MSN), named so because of the abundance of dendritic spines. In rodents, these neurons constitute more than 90% of all striatal neurons; in primates, this percentage is likely to be smaller (70–75%). MSNs are the primary striatal recipients of extrinsic inputs and is the only striatal neuron type with extrinsic projections. Output from these cells is directed to GPe and GPi, as well as the ventral pallidum and the SNc. These GABAergic projections can be distinguished by the cotransmitters they express and by other biochemical specifics. GPe-projecting MSNs express enkephalin and D2-type dopamine receptors, while GPi/SNr-projecting MSNs express substance P and D1-family dopamine receptors.

Several classes of local interneurons regulate MSN activity. The most abundant interneuron type is the large aspiny cholinergic interneuron. These neurons receive glutamatergic inputs from the thalamic centromedian and parafascicular nuclei (CM/PF), and GABAergic inputs from neighboring interneurons and local MSN axon collaterals. Together with dopaminergic inputs from the midbrain (see below), these cells may play a role in procedural learning by providing MSNs with information regarding the behavioral saliency of external stimuli. All of the other identified interneurons are GABAergic. These interneurons can be further subclassified, based on their electrical activities, and on anatomic features, such as the fact that they express specific proteins (including parvalbumin, calretinine, and nitric oxide synthetase). The functions of most of these interneuron types are not known. However, parvalbumin-containing interneurons have been shown to receive cortical inputs, and may alter the activities of neighboring MSNs as part of a feed-forward inhibitory process.

Other basal ganglia structures

GPe, GPi, and SNr consist of GABAergic projection neurons. While there is substantial collateral interaction among GPe cells, there is less local interaction among GPi and SNr cells. GPe cells are part of the intrinsic basal ganglia circuitry, while GPi and SNr are the major output nuclei of the basal ganglia, with projections to specific thalamic nuclei (ventral anterior and ventrolateral nuclei VA/VL, and CM/PF). Additional projections reach nuclei in the brainstem, such as the pedunculopontine nucleus (PPN), and the lateral habenula.

The STN is a dense cellular structure, situated between the thalamus and SNr. It receives inhibitory projections from GPe, and excitatory connections from the cerebral cortex, thalamus, and brain stem. STN neurons are glutamatergic (excitatory), and their axons reach GPe, GPi, and SNr, as well as midbrain and brainstem nuclei (such as PPN and SNc). This nucleus is seen as a major driving force of pallidal and nigral activity. It has gained prominence in recent models of basal ganglia function, specifically because abnormalities in this nucleus have been described to occur in movement disorders such as Parkinson's disease (PD). The fact that portions of all basal ganglia–thalamocortical circuits (see below) pass through this small nucleus has made it a primary target for surgical interventions in patients

with movement disorders and other disorders of basal ganglia origin.

The SNc, along with portions of the ventral tegmental area (VTA), is comprised of dopaminergic cells that project heavily to the striatum and, to a lesser degree, to the other nuclei of the basal ganglia. Dopaminergic fibers terminate preferentially on dendritic spines of striatal MSN, and may modulate cortical and thalamic inputs that also end on the spines. The dopaminergic control over corticostriatal transmission is seen as central to striatal functioning, specifically to the role of the basal ganglia in procedural learning.

Other neuromodulators, such as serotonin (released from projections of the raphe nuclei in the brainstem) and norepinephrine (released from terminals of projections of the nucleus coeruleus) may also play a significant role in the striatal and extrastriatal basal ganglia functions. However, the functions of these systems are not well understood till date.

Basal Ganglia Circuits

Topography, segregation of activity

Like most other brain regions, the basal ganglia do not function in isolation but are strongly related to other brain regions. They are components of cortico-subcortical reentrant pathways, which include thalamus and the cerebral cortex. Interestingly, these circuits appear to remain largely segregated throughout their subcortical course, although interactions between them may take place at the cortical levels.

Several major circuits have been identified and are named after the functions of the cortical areas from which they originate (**Figure 1**). The 'motor' circuit is centered on the precentral cortical motor fields, the 'oculomotor' circuit, originates from the frontal and supplementary eye fields, prefrontal circuits involve the dorsolateral prefrontal and lateral orbitofrontal cortex (LOFC), and a 'limbic' circuit is centered on the anterior cingulate and medial orbitofrontal cortex (MOFC) (**Figure 2**). Each of these circuits is comprised of several subcircuits. The anatomic building blocks of these circuits are similar, and it seems fair to assume that the different basal ganglia–thalamocortical circuits function as modules that perform the same type of processing on different functional types of input (determined by the respective functional roles of the cortical areas that provide input). The specific operations performed by the basal ganglia have not been determined.

A similar modular arrangement may also exist for circuits formed by the cerebellum, thalamus, and cortex which function largely in parallel to the basal ganglia-traversing circuitry. In terms of behavioral control, cerebellar circuits may be more involved in the online adjustment of movement, while the basal ganglia circuitry may influence functions such as adaptation, reward processing, or procedural learning.

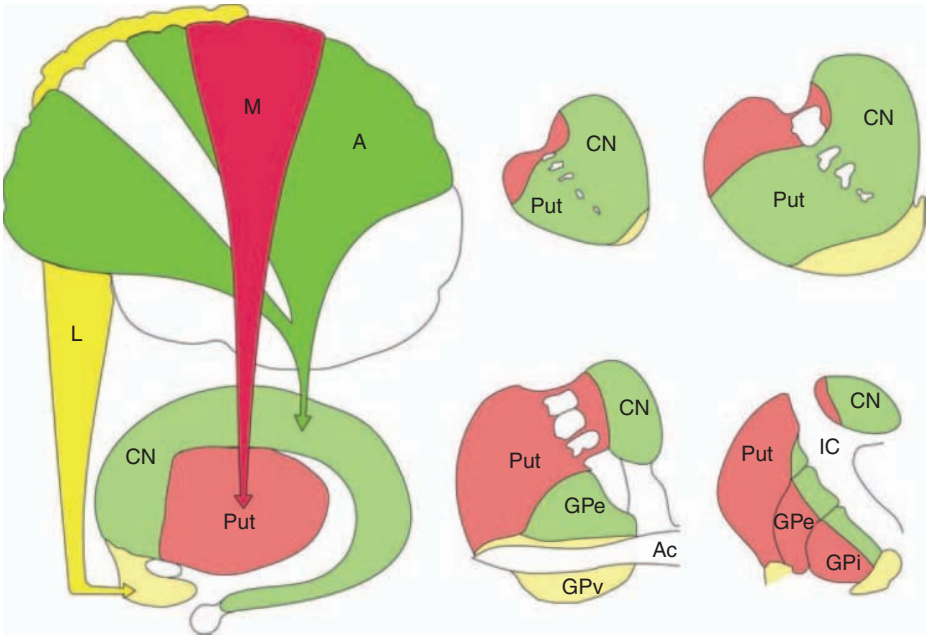

Figure 1 Organization of cortico-basal ganglia interactions. The basal ganglia topographically receive inputs from the cerebral cortex which serve to divide the basal ganglia into distinct functional territories. This simplified diagram shows cortical and corresponding basal ganglia areas that belong to the motor circuit (red, labeled 'M'), the limbic circuit (yellow, labeled 'L'), and the associative circuit (green, labeled 'A'). As is shown in **Figure 1**, each of the basal ganglia-thalamocortical circuits utilizes portions of striatum, GPe, GPi, SNr, STN, and parts of the VL, VA, and mediodorsal thalamus (MD), respectively. Of the different circuits passing through the basal ganglia, the motor circuit has been the most intensely investigated, because abnormalities in this circuit play a major role in the development of the motor abnormalities in PD and other movement disorders. This circuit arises from the precentral motor fields, and engages the putamen, 'motor' portions of GPe, STN, and GPi/SNr, as well as parts of the VL thalamus. The circuit contains groups of neurons which discharge in conjunction with either the preparation for, or the execution of, limb movements.

The basal ganglia projections to the VL thalamus appear to modulate the activity of cortico-thalamocortical circuits. The basal ganglia also send projections to the intralaminar nuclei of the thalamus (CM/PF). The interaction of these nuclei with the cerebral cortex is limited. Instead, CM/PF send topographically organized projections to the striatum. These thalamostriatal projections close a feedback loop by which basal ganglia output influences activity at the major input stage of the basal ganglia.

Through descending projections to the PPN and other brainstem nuclei, the basal ganglia may directly influence brainstem and spinal motor mechanisms. The PPN is also a part of several feedback circuits through its projections to the basal ganglia and the thalamus.

Direct, indirect, and hyperdirect pathways

GPi and SNr receive most of their inputs via pathways that originate in the striatum. The connections that link the striatum and GPi/SNr can be split into several pathways with possibly opposing functions (**Figure 3**). These input and output structures of the basal ganglia are connected via a *direct*, monosynaptic connection, and via an *indirect* pathway that passes first to GPe and from there to GPi/SNr, either monosynaptically or via the intercalated STN. In addition, the output nuclei receive inputs from the STN that reflect cortico-subthalamic inputs, the so-called *hyperdirect* pathway. As mentioned earlier, these pathways can be distinguished histochemically. The degree of separation between direct and indirect pathway, and the interactions between these pathways and the hyperdirect pathway are not fully defined, but are obviously of great importance in terms of the function of the basal ganglia circuitry as a whole.

The striatal neurons that give rise to the direct and indirect pathways appear to receive inputs from different populations of cortical neurons. Thus far, this has been demonstrated only in rodents. There is also limited evidence that direct pathway neurons may receive stronger inputs from CM/PF than the indirect pathway neurons, although there is a rich network of interneurons and axon collaterals in the striatum which would be capable of transferring information between the two pathways. CM/PF inputs to the striatum appear to be more concentrated and focal than the cortical inputs. These two

types of glutamatergic inputs can be distinguished anatomically by their expression of different types of the vesicular glutamate transporter (vGluT); the corticostriatal inputs express vGluT1, while the thalamic inputs express vGluT2. The use of these markers has demonstrated different termination patterns of the two glutamatergic inputs. While cortical inputs tend to end on striatal spines, a large proportion of the thalamic inputs from CM/PF are found along shafts of MSN dendrites.

Basal Ganglia Function

Ever since the demonstration that movement disorders such as PD, Huntington's disease (HD), or dystonia are associated with basal ganglia pathology, these nuclei have been seen primarily as playing a role in the control of movement. However, the realization that nearly all disorders of the basal ganglia are associated not only with movement abnormalities but also with disturbances in cognition and mood has led to the current view that the basal ganglia have broad functions in the control of behavior, and that the anatomical organization of these structures may provide the framework for understanding these findings.

The diverse functions of the basal ganglia are reflected in the segregated circuit anatomy that is outlined above. The motor circuit is thought to play roles in several behavioral functions, ranging from the control of individual movement parameters, such as the amplitude or velocity of movement, to the initiation or execution of internally triggered movements, sequencing of movements, switching between movements or motor programs, or a role in procedural learning. The oculomotor circuit is concerned with the control of saccadic eye movements, and with head and neck movements during orienting behaviors. The associative prefrontal circuits are implicated in executive functions. Finally, the limbic circuit participates in mood regulation, motivation, and responses to reward.

Hypotheses regarding the role of the direct and indirect pathway topography have been specifically developed with regard to the motor circuit. Similar functional interactions may also be true for the other circuits. One function of the motor circuit may be to regulate the overall amount of movement or to facilitate cortically initiated movements. Activation of the direct pathway by cortical inputs (for instance, in relation to planned or ongoing movements) would inhibit the activity of the output nuclei (GPi/SNr), and thereby disinhibiting thalamocortical projection neurons. This would result in greater activity of thalamocortical and cortical neurons, and presumably facilitation of movement. In contrast, activation of striatal neurons that give rise to the indirect pathway would have a net excitatory effect on GPi/SNr activity and would act to inhibit thalamocortical neurons, and to inhibit or stabilize the activity in the thalamus and brainstem, thereby suppressing potential competing movements or terminate ongoing movements or postures.

Dopamine is thought to exert opposing effects on the direct and indirect pathways. Increased release of dopamine may activate the direct pathway (via D1-receptors) and inactivate the indirect pathway (via D2 receptors). Together these changes would act to reduce basal ganglia output to the thalamus. Conversely, a reduction of the release of dopamine would result in disinhibition of the indirect pathway, and reduced facilitation of the direct pathway, leading to increased basal ganglia output. Dopamine is also released at extrastriatal sites within the basal ganglia. For instance, dopamine released from local dendrites of SNc neurons may activate D1-receptors on terminals of the striatonigral projection. This may then result in increased local GABA release in the SNr, and subsequent inhibition of the activity of SNr neurons. Basal ganglia output may also be shaped by nonlinear effects that go beyond straight excitation or inhibition. These effects may be similarly influenced by dopamine and other neuromodulators. While phenomena such as rebound bursting

or changes in oscillatory basal ganglia activity are well-documented to occur during normal basal ganglia function, their behavioral significance is not known.

Among the most actively discussed functions of the basal ganglia is their role in the regulation of habit formation and procedural learning. Procedural learning is a form of memory formation in which implicit rules of behavior are learned, often without the subject's knowledge. The basal ganglia may help to generate responses to recurrent behavioral situations, and to provide preformed procedures (or 'chunks of behavior') to the cerebral cortex that can then be executed at reduced computational cost when specific behavioral conditions are met. Central to the formation and storage of such procedures appears to be the modulation of the strength of specific corticostriatal synapses through adaptive processes such as long-term potentiation or long-term depression. Procedural learning and habit formation is not dependent on a single basal ganglia circuit but may involve transfer of information between circuits over time: in the process of learning motor procedures, limbic and associative areas of the basal ganglia may be involved first, followed by a gradual shift of activity patterns away from the initial areas and toward the motor circuit.

Role of Abnormal Basal Ganglia Function in Human Disease

Circuit Disorders

The fact that basal ganglia function is best understood in terms of their interaction with cortex, thalamus, and brainstem has given rise to the view that 'basal ganglia' disorders are in reality 'circuit' disorders, which affect not just basal ganglia function, but also has profound effects on related brain areas. A wide spectrum of motor and nonmotor disorders has been described as the consequence of dysfunction of these circuits. Pathophysiological details have been elaborated specifically for PD, while much less is known about other movement disorders and neuropsychiatric conditions.

Parkinsonism

The cardinal motor features of PD, that is, akinesia/bradykinesia, tremor at rest, and muscular rigidity, result from decreased dopaminergic transmission in the motor portions of the basal ganglia, in particular in the putamen, due to progressive loss of dopaminergic neurons in the SNc which project to this portion of the striatum. Dopamine loss in the putamen has recently been shown to also affect the morphology of nondopaminergic neural elements in the striatum. The most salient change secondary to dopamine loss is the reduction in the number of dendritic spines on MSNs. The reason(s) for this change are not clear, but it is likely that the spine loss may strongly affect cortico- and thalamostriatal transmission onto striatal neurons.

Other features of the disease such as depression, autonomic dysfunction, sleep disorders, cognitive impairment, and gait/balance problems may result in part from decreased dopamine levels within the nonmotor portions of the basal ganglia, but there is strong evidence that widespread pathological changes outside of the dopaminergic system (such as in brainstem, thalamus, and cerebral cortex) play a major role in the development of these symptoms. Due to the lack of suitable animal models, these extra-dopaminergic aspects of the diseases are poorly understood. We will focus on the aspects of the disease that result from dopamine deficiency and that can be studied in animal models of the disease and, to some extent, in patients.

Numerous studies of single cell activity in the basal ganglia of Parkinsonian primates have found increased levels of neuronal discharge in the STN and GPi with decreased discharge in GPe, indicating an increased level of inhibition of the thalamus and other targets of pallidal outflow and, thus, reduced and slowed movements. Such studies have suggested that parkinsonism is associated with substantial changes of corticostriatal transmission at corticostriatal synapses which then acts to strongly influence the activity of striatal efferents. At a very simplistic level, it is proposed that the activity along the striato-GPe pathway is increased because of dopamine loss at the inhibitory postsynaptic D2-type dopamine receptors in the striatum, resulting in over-inhibition of the GPe, disinhibition of STN cells, and excessive stimulation of GPi/SNr. In addition, a reduction of activity over the direct (striato-GPi/SNr) pathway is proposed, as a result of the reduced activation of the (stimulatory) D1-type dopamine receptors in the striatum. Dopamine loss at other sites within the basal ganglia (in STN, GPi, and SNr) may also play a role in these changes.

Parkinsonism is associated with changes in firing patterns in the basal ganglia which are likely the result of striatal dopamine loss. Single neuron and local field potential recording studies have demonstrated that pathologic oscillations in the 10–25 Hz range of frequencies throughout the basal ganglia and cortex are associated with parkinsonism. These oscillations are speculated to disturb normal patterns of oscillatory (and presumably other) activities at the cortical level. In addition, the proportion of cells in STN, GPi, and SNr which discharge in bursts is greatly increased in parkinsonism, and cells are known to show an abnormally high level of synchrony in their firing.

Functional imaging of the cerebral cortex in parkinsonian patients has demonstrated that the altered subcortical activity has indeed strong effects on cortical activity patterns. It is not known how such abnormalities are then translated into the movement abnormalities in parkinsonian subjects. Although far less explored, altered basal ganglia output to brainstem areas such as the PPN, or to the intralaminar thalamic nuclei may also contribute to parkinsonism.

Hyperkinetic Disorders

Hyperkinetic disorders are a heterogeneous group of diseases characterized by the presence of excessive involuntary movements. Prominent examples for diseases in which these occur include Huntington's chorea and hemiballism. Hemiballism is the most clear cut example of a hyperkinetic disorder resulting from discrete basal ganglia damage: discrete lesions of the motor region of the STN are responsible for the development of involuntary movements of the contralateral limbs. Reduction of the excitatory (glutamatergic) STN output has been shown to lead to a reduction of GPi/SNr activity which would then act to disinhibit thalamocortical projection cells, leading to involuntary movements. The hyperkinetic aspects of the movement disorder in HD are thought to be due to the degeneration of striatal neurons (potentially through excitotoxic processes triggered by abnormal glutamatergic transmission in the striatum) that belong to the indirect pathway. This may secondarily lead to release of GPe neurons from GABAergic inhibition, resulting, in turn, in excessive inhibition of STN neurons.

While the reduction in overall GPi activity appears to be critical for the production of excessive movement, the specific type of movement seen in hyperkinetic diseases (such as chorea, ballismus, or dystonia) may be determined by differences in the neuronal discharge of single neurons or networks of neurons in GPi/SNr. The specific features of these different disorders have not been determined.

Disturbances of Cognitive Functions or Mood

Obsessive compulsive disorder (OCD) may, at least in part, be due to dysfunction of the basal ganglia–thalamocortical circuits originating from the orbitofrontal and cingulate cortices. These abnormalities are far less defined than they are in movement disorders. However, functional imaging studies in human patients have shown prominent activity changes in OCD in the ventral striatum (VS) and in the midbrain. Tourette's syndrome (TS), that is, the combination of OCD-like symptoms with vocal or motor tics, is also associated with abnormalities in the limbic circuit, in addition to the changes in the areas of the motor circuit.

Functional Neurosurgery

The knowledge that the aforementioned 'circuit disorders' are associated with dysfunction in circumscribed regions of the basal ganglia has resulted in renewed interest among neurosurgeons and neurologists in the treatment of advanced forms of these conditions with highly targeted surgical interventions, such as lesioning or deep brain stimulation. In PD patients, lesions or high frequency stimulation of GPi or STN were found to be highly effective in reducing off-time and producing longer on-times without medication side effects. Similarly, impressive results were also obtained in patients with tremor and dystonia. The utility of neurosurgical interventions is also now being explored in neuropsychiatric conditions such as OCD or TS. While the specific brain target site of the intervention is crucial for the therapeutic success of these procedures in these diseases, the exact mode of intervention (ablation or stimulation) may be less critical. This suggests that the primary effect of the interventions may be nonspecific, perhaps acting simply to remove (with ablation) or to override (with stimulation), abnormal basal ganglia output, and freeing up thalamic and cortical mechanisms.

Concluding Remarks

The basal ganglia together with the cerebral cortex and thalamus are components of parallel cortico-subcortical circuits that play a role in both motor and nonmotor behaviors. The traditional view that the basal ganglia are primarily involved with movement and play a role in the control of specific aspects of movement is largely based on the fact that basal ganglia pathology often results in prominently disordered movement and/or in involuntary movements. It is now becoming clear that these structures may have important functions in the control of higher-order aspects of behavior, linking emotion, cognition, behavior, and movement, and that they may have specific relevance for adaptive shaping of behaviors.

The circuit models of basal ganglia function and dysfunction continue to evolve. The traditional view that the basal ganglia simply relays cortical activity back to cortex is being replaced by more general organizational schemes in which large-scale oscillatory and nonoscillatory activities of local or spatially distributed ensembles of neurons play a major role and in which surgical intervention not only activates or inactivates basal ganglia activity, but also modulates firing patterns and other features of basal ganglia activity.

The current circuit models of basal ganglia function and dysfunction have had a major impact on the treatment of diseases such as PD, tremor, and dystonia, and in the renaissance of neurosurgical approaches to the treatment of neuropsychiatric disorders such as TS or OCD.

Beam Walking Test

R Drucker-Colín, Universidad Nacional Autónoma de México, México DF, Mexico

Glossary

Methylphenyltetrahydropyridine (MPTP) – Substance used to induce specific destruction of dopamine producing cells of the subtantia nigra.

The evaluation of motor deficits in small animals is faced with problems of specificity, that is, tests should be measuring true motor capabilities uncontaminated by tests which rely on reflexive or memory aspects of behavior; or depend on subjective criteria; or on complex motor functions such as stride length; or on fine motor function, as does the pole test, which tests bradykinesia. The beam walking test described here is an inexpensive and simple test of motor function which has the additional advantage of not being subject to practice effects and is specifically designed to detect motor deficits in aged rats and in animals with pharmacologically altered dopaminergic striatal functions.

The apparatus consists of 2-m wooden strips supported by two pedestals at each end. The pedestals are of different heights (42.5 and 100 cm) in order to allow for an inclination of 15°. This inclination is enough to stop animals from crawling over the beam. The width of the strips varies and 3, 6, 12, 18, and 24 mm strips are available. Variably strip widths are achieved by merely clamping strips together in order to obtain desired widths. At the end of the inclined strip, a cage is placed, so that the animals could step into the home cage. **Figure 1** illustrates the apparatus and gives a picture of rats traversing the beam.

It is important to make sure that the entire apparatus be placed at a height of at least 1 m above the ground, so as to make sure that the animal fears the height and really attempts to reach the goal box.

All rats must be trained to walk over a beam for 5 days before testing. The test procedure is identical for all rats tested and performed in the same environment preferably in the morning. The rat is placed on the lower end of the beam and the time needed to reach the home cage is recorded. A ceiling of 120 s is employed at the end of which the rat is removed and placed in the cage by hand and receives, if it is the case, a score of 120 s. The beam width sequence used in each testing session is determined with a table of random numbers. Pilot studies show that this manipulation almost completely eliminates practice effects. The measure utilized for each rat is 'total time' to reach the cage. However, during testing, rats frequently have episodes of immobility. Accordingly, a second measure is taken designated as 'no movement time'. This measure reflects the amount of time that animals merely stood immobile with what appeared as olfactory and visual exploration of surroundings.

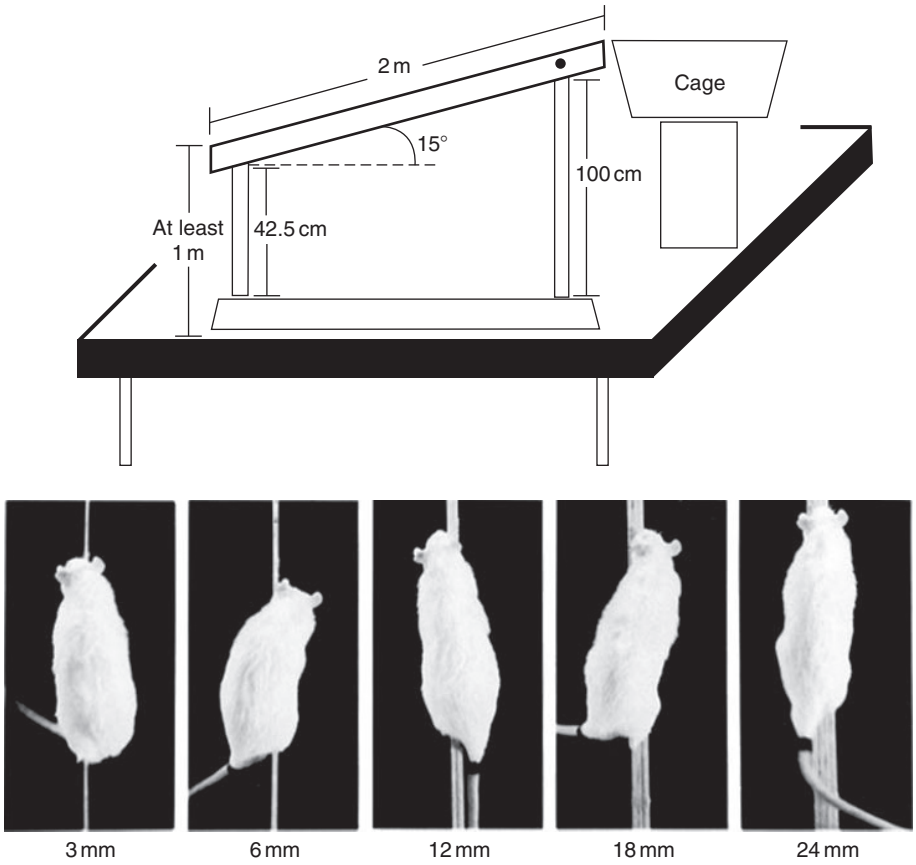

Figure 1 The upper part of the Figure is a diagram of the set up, the lower part is a top view photograph showing the relation between beam widths and size of rats.

It is important to use young rats as controls, but since young rats are usually about half the weight of older rats, a lead belt weighing 100 g is placed around the chest of young rats, in order to determine whether weight is an important factor in the capacity to traverse the beam. The 100 g weight represents an increase of about 40% of the total body weight of the young rats.

This test has been shown to be very effective in detecting pure motor capabilities in rats which have a tendency to show deterioration because of aging processes, but also in those whose striatal dopaminergic function is pharmacologically altered. Anyone who uses this equipment can measure with a great degree of precision, the displacement capacity of the animals. In fact, in this test, very old rats show a similar hesitant motor displacement when placed in very narrow strips, which reminds us of the hesitant march of either advanced Parkinson patients or very aged persons.

Recently a beam walking apparatus was designed and reported to detect behavioral impairments in methylphenyltetrahydropyridine (MPTP) treated mice. Deprenyl was reported to improve the mice's capabilities for traversing the beam. This beam walking test and the one described here seem to be the two best tests detecting pure motor functions. Anyone of the two are highly recommended for detecting pharmacological compounds capable of improving motor capabilities or testing striatal motor function or dysfunction.

Belly Dancer's Dyskinesia

A Aggarwal and P D Thompson, Royal Adelaide Hospital and University Department of Medicine, University of Adelaide, Adelaide, Australia

Glossary

Dyskinesias – Generic term used to describe involuntary movements.
Dystonia – Twisting, repetitive involuntary movements superimposed on abnormal postures produced by sustained muscle contraction.
Electromyography – Study of the electrical characteristics of muscle activity. In the context of movement disorders, this may include recording the patterns of muscle recruitment and investigation of reflex activity and stimulus sensitivity.
Myoclonus – Sudden, brief, shock like involuntary movements.
Tardive movement disorders – Involuntary movements (dyskinesias) developing after long-term exposure to dopamine antagonists (e.g., neuroleptics).

Definition and History

The term 'belly dancer's dyskinesia' was introduced by Iliceto et al. to describe the unusual slow rhythmic writhing contortions of the abdominal wall and multidirectional displacements of the umbilicus produced by involuntary contractions of the abdominal wall and respiratory muscles. A range of movement disorders has been recognized as producing belly dancer's dyskinesia.

The original report of the 'belly dancer's dyskinesia' included five patients who developed a complex motion of the umbilicus and writhing abdominal movements produced by variable contraction of the rectus abdominus, oblique muscles, and the diaphragm. Spread of muscle activity to paraspinal and perineal muscles was observed in some patients. The movements were discomforting and often associated with pain. In three patients, the movements developed after abdominal surgery. In further two cases, the movements followed childbirth by apparently uncomplicated vaginal delivery. The clinical pattern of sustained muscle contraction and long duration bursts (400–1000 ms) of electromyographic (EMG) activity with superimposed jerky component were considered to reflect a dystonic origin of the involuntary movement. Similar belly dancer's dyskinesia with associated pain developing after abdominal surgery (colonic resection) was later described as segmental myoclonus. In this case, the abdominal muscle activity consisted of long duration bursts of EMG activity lasting for 200–600 ms, and unlike other reports, spread of muscle activity to quadriceps muscles was noted. These examples of belly dancer's dyskinesias, in common with other focal dyskinesias, illustrate the recognized association of pain and involuntary movements at the site of previous trauma.

A further case report described dystonic movements of the abdominal wall developing 5 months after pontine and extrapontine myelinolysis complicated correction of severe hyponatremia. The movements were slow and had a superimposed jerky element, consistent with a delayed onset dystonia reported previously in osmotic dysequilibrium syndromes.

An undulating motion of the abdominal wall was described in a young girl who was later discovered to have an intramedullary thoracic cord tumor. The movements persisted during sleep and were unaffected by voluntary movement or breathing, suggesting an autonomous generator located in segments of the spinal cord isolated from normal descending motor pathways.

Spontaneous arrhythmic abdominal movements similar to a belly dancer's dyskinesia have been recorded as a manifestation of paroxetine (selective serotonin reuptake inhibitor) induced spinal myoclonus, spreading from the abdominal wall to thoracic and lumbar paraspinal muscles. This patient also had evidence of a compressive thoracic radiculopathy, which the authors postulated may have contributed to the movement disorder. The EMG bursts accompanying the abdominal movements in this case were characterized by brief duration (100–500 ms), 3 Hz motor unit discharges with occasional high frequency discharges, suggesting a peripheral contribution to the movement disorder. Spinal myoclonus was also considered the cause of asymmetric, predominantly right sided, abdominal movements in a 63-year-old man. Detailed electrophysiology demonstrated stimulus sensitivity and spread of muscle activity to thoracic and lumbar paraspinal muscles, suggesting that a spinal reflex was driving the abdominal movements.

Abdominal movements as a manifestation of tardive dyskinesia have been described as 'rocking belly movement.' Similar tardive movements comprising continuous sinuous abdominal movements superimposed on episodic tightening of the axial musculature, breathing difficulties, and anxiety were reported following the exposure to clebopride (a substituted benzamide related to metoclopramide).

Slow undulating protrusion and retraction motion of the abdominal wall representing a peak dose levodopa induced dyskinesia were observed in a patient with presumed multiple system atrophy.

Diaphragmatic flutter can also lead to abdominal wall movement and belly dancer's dyskinesia. It is characterized by contraction of one or both domes of the diaphragm at frequencies of 1–8 Hz superimposed on normal tidal breathing. The diaphragmatic movements depress the abdominal contents during each descent, leading to repetitive protrusion and retraction of the anterior abdominal wall, creating a jerky or pulsatile motion. Additional muscles including the intercostals, scalenes, epiglottis, paraspinal, and abdominal muscles may be recruited and may contribute to the observed abdominal movements. The fluttering diaphragm movements are best observed on video fluoroscopy. The movements are intermittent and fluctuate during the breathing cycle. Deep inspiration and breath holding may suppress the movements.

Abdominal movements are the most frequent manifestation of diaphragmatic flutter. The intensity of the movements may be forceful enough to produce an audible sniffs, succession splash, and gurgling noises. Respiratory (tachypnoea, hyperventilation) and gastrointestinal (belching, hiccups, retching) presentations are also described.

Belly dancer's dyskinesias are of cosmetic concern and most are difficult to treat, despite numerous trials of pharmacological agents.

Benign Paroxysmal Torticollis of Infancy

M Scavina, DuPont Hospital for Children, Wilmington, DE, USA

Glossary

Ataxia – Lack of coordination.
Benign – Not malignant or life threatening.
Cervical dystonia – Involuntary contraction of muscles of the neck causing awkward posture and abnormal movements of the head and neck.
Hypotonia – Decreased muscle tone.
Paroxysmal – Intermittent, recurring.
Torticollis – From Latin, meaning 'twisted neck.'

Definition and History

Benign paroxysmal torticollis (BPT) of infancy was first described by Snyder in 1969. The condition is characterized by recurrent episodes of torticollis that begin in infancy and resolve by 2–5 years of age. The torticollis may alternate from side to side, may last for minutes to days, and may cycle by several weeks to months until it resolves. Associated features include hypotonia, pallor, vomiting, ataxia, irritability, and drowsiness. Infants with this condition may develop benign paroxysmal vertigo (BPV) in childhood and migraine later in life.

The etiology continues to unfold. When first described, BPT was felt to be due to a peripheral vestibular disturbance. Since then, others have pointed to the cerebellum and vestibulocerebellar connections as sources of the condition. More recently, it is felt that BPT is a precursor of migraine in children.

Pathogenesis and Physiology

When first described by Snyder in 1969, the etiology of BPT was felt to be a disturbance of the peripheral vestibular system, such as a labyrinthitis. This was based on the

fact that a number of the first cases reported lacked vestibular responses to caloric testing and some had decreased hearing. Later, cases of BPT were reported in which testing of the vestibular response and hearing were normal. Possible etiologies proposed were vascular abnormalities affecting the cerebellum or vestibulocerebellar connections, or a migraine equivalent. More recently, several cases of BPT were described in which there were family members with familial hemiplegic migraine and mutations in the calcium channel gene CACNA1A. The authors propose that BPT may be a childhood migraine equivalent and possibly associated with a calcium channelopathy. They postulate that the channelopathy may have different manifestations at different stages of development. The torticollis seen during an episode of BPT has been studied by surface EMG recordings placed on the sternocleidomastoid muscle. Continuous electrical discharge has been recorded and felt to be consistent with a dystonia of the muscle. Some have proposed that the dystonia may in fact be an atypical motor aura which is mediated by calcium channel abnormalities affecting the cerebellum. The International Headache Society-International Classification of Headache Disorders 2nd edition (IHS-ICHD II) classifies BPT under migraine and subcategory of childhood periodic syndromes that are commonly precursors of migraine. Further studies need to be carried out to enhance our understanding of this condition.

Epidemiology/Risk Factors

BPT is an under-recognized entity. There does not appear to be a gender or ethnic predominance. To date, a single gene defect has not been linked to the disorder. However, there have been cases in which there is a positive family history of torticollis in infancy as well as in family members with migraine or familial hemiplegic migraine. Recently, there were two cases described from families with known mutations in the CACNA1A gene and familial hemiplegic migraine.

Clinical Features

Frequently, the torticollis will appear in the morning upon awakening. An infant will awake with head tilted to one side or the other, and eyes facing the opposite direction. There is usually not a precipitating illness or event. The head can usually be brought to the neutral position. Episodes can last from several minutes to days and resolve completely. There may be associated features which accompany the torticollis and include decreased tone, pallor, vomiting, lethargy, and irritability. Often the child will be unsteady or ataxic. The neurologic exam is generally normal except for the torticollis and ataxia during an episode and normal in between attacks. As the infant grows older, the frequency of the attacks decreases and ultimately they resolve. These episodes may then be replaced with episodes of vertigo, or BPV of childhood. Individuals may then go on to develop migraine in adulthood.

Differential Diagnosis

Torticollis can be seen in a number of entities in childhood. The presentation of early onset, recurring torticollis, with previously described associated features and no other focal neurological deficits, should lead to a diagnosis of BPT. However, when evaluating a child for new onset torticollis, several processes should be included in the differential after a thorough history and physical examination have been completed. Drug-induced dystonia should be excluded by a thorough drug history and specifically asking for the use of medications such as phenothiazines and metoclopramide. Posterior fossa tumors and atlantooccipital subluxation leading to spinal instability should be ruled out. Other cervical lesions would include Chiari malformation, cervical abscess, or trauma. Upper respiratory tract infections, superior oblique palsy, retropharyngeal abscess, seizures, and Sandifer syndrome are also included in the differential. Sandifer syndrome is a condition which includes spasmodic torsion dystonia with arching of the back and opisthotonic posturing of the neck, back, and upper extremities, and is associated with gastroesophageal reflux or hiatal hernia.

Diagnostic Work Up/Tests

A proper history and physical examination are essential in making the diagnosis of BPT. Neuroimaging, included MRI of the brain and cervical spine should be carried out to rule out structural lesions. Electroencephalograms (EEGs) are often ordered to rule out the possibility of a seizure given the associated features which can accompany the torticollis. In the case of BPT, however, both neuroimaging studies and EEG are normal. Referral to a Gastroenterologist may be worthwhile if other associated features of gastroesophageal reflux are noted.

Management

Once the diagnosis is made, no specific therapy is indicated as the episodes are self-limiting. Children should be monitored for the development of BPV or migraine later in life.

Prognosis

Episodes of recurring torticollis usually resolve by 2–5 years of age. As stated, infants can go on to develop vertigo

in childhood or migraines as adults and should be monitored and treated accordingly. Prognosis overall is good.

Benzodiazepines and Movement Disorders

S Gancher, Oregon Health Sciences University, Staff Neurologist, Kaiser Permanente, Portland, OR, USA

Glossary

CBD – Cortical basal degeneration.
Dystonia – A movement disorder causing abnormal postures.
GABA – γ-Aminobutyric acid, an inhibitory neurotransmitter in the brain and spinal cord.
MSA – Multiple system atrophy.
Myoclonus – A movement disorder causing muscle jerks.
PSP – Progressive supranuclear palsy.

Introduction and Pharmacology

Benzodiazepines are members of a class of medications that have anxiolytic, hypnotic, amnestic, anticonvulsant, and skeletal muscle relaxant effects. Although there are over 30 drugs in this class and many have overlapping effects, they can roughly be divided by their clinical use into hypnotic sedatives and anxiolytics.

Members of the latter group include alprazolam, diazepam, lorazepam, and clonazepam which are the ones that are chiefly used in the treatment of movement disorders and will be discussed in this chapter.

Pharmacokinetics

Benzodiazepines are well absorbed by following oral administration. Lorazepam is well absorbed after sublingual administration as well. Absorption of lorazepam is also rapid and complete following intramuscular administration, whereas the absorption of diazepam after intramuscular injection is slow and erratic.

The distribution, clearance, and metabolism of benzodiazepines are somewhat complex. They are highly bound to plasma proteins but are also lipophilic and rapidly penetrate the CNS. This initial redistribution phase is followed by a slower phase in which the drugs and their active metabolites accumulate into less vascular tissues such as fat, and then more slowly diffuse back into plasma and prolong the clearance and some of the clinical effects. This is especially prominent with diazepam.

Benzodiazepines are metabolized into both active and inactive metabolites depending on the drug. Diazepam is converted to nordiazepam, an active metabolite with a far longer duration of action, as well as to oxazepam, before being converted to inactive compounds. Alprazolam is also converted to active metabolites, whose duration of action is roughly similar to the parent drug. Clonazepam and lorazepam, in contrast, have no active metabolites. The metabolism of benzodiazepines occurs in the liver

and the duration of action may be quite prolonged in patients with hepatic insufficiency.

CNS Pharmacology

Benzodiazepines largely act by binding to a portion of the γ-aminobutyric acid ($GABA_A$) receptor, referred to as benzodiazepine receptors (BzR). Occupancy of the BzR receptor by a benzodiazepine produces a conformational change in the GABA receptor which increases the binding of GABA. This in turn, increases the permeability of an associated chloride channel and hyperpolarizes the associated neuron. There are effects on other ion channels; the hypnotic effects of benzodiazepines may be mediated by alterations in calcium permeability, and anticonvulsant effects may partially depend on effects on sodium channels.

The actions of benzodiazepines vary throughout the CNS. BzRs are found in high density in the cerebral cortex, cerebellum, substantia nigra, and inferior colliculus, with somewhat lower densities found in the striatum and spinal cord. In addition, there are multiple subtypes of $GABA_A$ receptors. These receptors are a pentameric structure, including α, β, and γ subunits. Sedation and anticonvulsant properties appear to be mediated through binding onto the $GABA_A$ receptors which are made up of α_1 subunits, whereas anxiolysis and muscle relation are mediated by $GABA_A$ receptors that have the α_2 subunit.

Tolerance: A common property of all benzodiazepines is that tolerance develops with chronic administration, reflecting downregulation of the BzR density in target tissues. The degree of tolerance varies between patients and to different clinical effects. Tolerance may develop more rapidly and completely to sedation, for example, than to motor effects. However, a declining effect to benzodiapezepines occurs in most patients and limits the effectiveness of therapy. Strategies to avoid tolerance should include using the medications for intermittent, rather than constant use if possible, choosing short acting drugs if appropriate, and limiting the dose and duration of treatment.

Dependence: both psychological and physical dependence occur with long term administration of benzodiazepines. Sudden withdrawal or a rapid reduction in the dose may produce a state of heightened anxiety, tremulousness, tachycardia, and can produce seizures.

Hypokinetic Movement Disorders

Parkinson's Disease

A number of different symptoms commonly experienced in patients with Parkinson's disease may be improved by adjunctive use of a benzodiazepine. In addition to control of anxiety and insomnia, which are very common in Parkinson's disease, several motor symptoms and sleep associated disorders may be improved with the use of a benzodiazepine.

Motor symptoms

Although levodopa, dopamine agonists, anticholinergics, amantadine, and MAO B inhibitors are effective for most motor symptoms in Parkinson's disease, not all motor symptoms can be adequately treated.

Tremors that occur despite the standard antiparkinsonian drug treatments may improve with a benzodiazepine, particularly if the tremors worsen with fatigue, excitement, or social anxiety (such as dining in a restaurant or public speaking). If these exacerbations are predictable, intermittent use of alprazolam or lorazepam, taken an hour beforehand, may reduce the severity of tremor and improve functioning. As tolerance tends to develop over time, frequent or scheduled use of these agents may be less effective. One exception, though, is in patients with a generalized anxiety disorder. In these patients, treatment with a longer acting anxiolytic such as diazepam or clonazepam may improve both the anxiety and tremor.

Dystonia is another motor symptom which generally improves following the administration of a benzodiazepine. Dystonia can occur in a number of different settings. A number of different benzodiazepines can be used to treat dystonia. A longer acting drug, such as clonazepam or diazepam taken before sleep, can be helpful in reducing early morning dystonia. Some patients experience unpredictable 'off' episodes during the day, and painful dystonic spasms can be especially prominent. In these episodes, an agent with a quick onset of action, such as alprazolam, may be helpful in reducing both the pain and the severity of dystonia.

In addressing both tremor and dystonia in the context of Parkinson's disease, adjustment of antiparkinsonian medications is first line approach, making benzodiazepines secondary medications, unless there are concomitant issues with anxiety or insomnia that would make them appealing choices.

Sensory and psychological symptoms

Anxiety is quite common in Parkinson's disease, affecting over half of the patients. In addition to antidepressants that have anxiolytic effects, benzodiazepines have an important role in treatment. In the chronically anxious patient, clonazepam, lorazepam, or diazepam may be helpful. However, these medications can also worsen depression if taken long term, and other medications should be tried first.

Anxiety and dysphoria are extremely common symptoms during 'off' episodes as well. Some patients have mood fluctuations that are more bothersome than motor fluctuations; moods may swing widely between euphoria

and depression, anxiety, dysphoria, or panic like attacks. In these patients, alprazolam or lorazepam, taken on an as needed basis, can be helpful. If severe and frequent, longer acting benzodiazepines may be needed.

Sensory symptoms, including coldness, tingling, aching, and stiffness also can occur, either as a constant or intermittent symptom; similar to anxiety, these symptoms may be worse or only occur during 'off' periods and may also respond to benzodiazepines.

Parasomnias

REM behavior disorder (RBD) is characterized by the acting out of dreams that are vivid, intense, and violent. These movements occur due to a loss of normal atonia that occurs during REM sleep that is produced by actions of pontine nuclei on descending motor pathways in the lower brainstem and spinal cord. In patients with RBD, a loss of inhibition of these pontine nuclei seem to be the anatomical basis for the disorder, due to loss of dopaminergic, noradrenergic, and cholinergic inputs into these structures. Clonazepam is the drug of choice for this condition, both in patients with Parkinson's disease as well as in other patients. It is effective in up to 90% of patients, relieving symptoms at doses of 0.5–1 mg at night. In contrast to other conditions, tolerance generally does not develop. With long term treatment, some associated behaviors such as sleep talking or limb movements may reemerge, but the more violent, potentially injurious behaviors usually remain controlled.

Restless leg syndrome (RLS) and periodic limb movement disorder (PLMD) are also very common symptoms in patients with Parkinson's disease. As with RBD, these conditions are not specific to Parkinson's disease but affect most patients when studied by polysomnography. These conditions cause an urge to move the limbs when awake (RLS) and periodic, semiregular limb movements during sleep (PLMD). These conditions are generally controlled with dopaminergic medications, but benzodiazepines are useful adjuncts in some patients with these conditions. As with dystonia, a longer acting benzodiazepine such as diazepam or clonazepam may be a good choice if used nightly.

Secondary parkinsonism (PSP, MSA, CBGD)

In addition to rigidity and bradykinesia, dystonias commonly occur in patients with these illnesses. Unlike Parkinson's disease in which dystonias more commonly waxes and wanes with other motor symptoms, the dystonias that occur with these conditions are relatively constant. Limb dystonia that occurs in CBGD can become extremely marked and may evolve into fixed contractures. As discussed in the preceding section, both intermediate and long acting benzodiazepines may be useful adjuncts in the control of dystonia.

Myoclonus is also a common accompaniment to CBGD and, as discussed below, typically responds well to lorazepam or clonazepam.

Hyperkinetic Movement Disorders

Dystonias

In addition to botulinum toxin injections, oral medications, including anticholinergics and benzodiazepines, are useful adjunctive drugs in many patients with focal or generalized dystonia. This may include patients with primary dystonia, such as cervical dystonia or Meige syndrome, as well as in secondary dystonias such as tardive dystonia, stroke, or in patients with a degenerative disorder in which dystonia is present. Benzodiazepines are a mainstay in the treatment of cerebral palsy in which dystonia or athetosis is a major feature. They can be effective in reducing all aspects of dystonia, such as pain, dystonic tremor, and posturing, although the effects may be somewhat modest.

Acute dystonic reactions are episodes of severe dystonia that typically follow administration of an antiemetic or a dopamine antagonist. It is generally reversed with parenteral doses of antihistamines or anticholinergics, but is also effectively treated with parental doses of lorazepam or diazepam.

In most patients with constant symptoms, clonazepam is the best tolerated, but in other patients with intermittent symptoms, alprazolam or lorazepam may be the better choices. A common setting in which benzodiazepines may be especially useful is in patients receiving botulinum toxin injections; as the effects of the injections wear off, treatment with clonazepam or lorazepam, with or without other oral medications, may be helpful.

One challenge in some patients is that moderate or high doses of a benzodiazepine may be needed to improve dystonia and sedation, ataxia, depression, and confusion, generally limit treatment in most patients over time. Sudden withdrawal of any benzodiazepine may cause sudden worsening of dystonia and should be avoided.

Tolerance to this class of drugs may also limit treatment in some patients, and intermittent or short term treatment may be indicated in some patients.

Tic Disorders

In some patients with Tourette's syndrome or other tic disorders, benzodiazepines may be effective, particularly when treating tics with a fast, clonic appearance or tics driven by anxiety, although no study has ever shown a direct effect of benzodiazepines on tic counts. Clonazepam is the preferred drug as it is less sedating, but if intended for intermittent use (such as treating tics that occur in social situations), a shorter acting benzodiazepine such as

alprazolam or lorazepam may be more appropriate. Although less effective than dopamine antagonists, the use of a benzodiazepine does not carry the risks of tardive dyskinesia or cardiac arrhythmias and may be more appropriate in patients with a mild tic disorder. The anxiolytic effects of a benzodiazepine may also be beneficial and may be a necessary part of a treatment regimen in patients with both severe tics and psychiatric disease.

Although helpful, there are significant limitations in the treatment of tic disorders with benzodiazepines. Patients with severe motor tics or with disruptive phonic tics generally do not respond adequately to benzodiazepines. This class of drugs is largely ineffective in the treatment of obsessive compulsive disorder. In adolescents and young adults especially, benzodiazepines carry a real risk of drug misuse and dependency, of impairing school performance and driving, and can be dangerous when combined with alcohol. Tolerance also develops with long term use of benzodiazepines in the treatment of tic disorders.

Myoclonus and Hemifacial Spasm

Myoclonus can occur as a primary disorder as well as a secondary symptom in a large number of other neurological and systemic medical disorders and can originate from many regions in the central and even peripheral nervous system.

One pattern of myoclonus, in which random jerks can occur in multiple body parts, is the common manifestation of metabolic encephalopathy, particularly hepatic and renal failure.

Unlike other movement disorders in which benzodiazepines have a more minor effect or adjunctive role, several myoclonic disorders generally respond well to clonazepam. Epileptic myoclonus, palatal myoclonus, and myoclonus of spinal origin seem to respond well to clonazepam. Myoclonic dystonia, a condition in which patients experience a mixture of dystonia and superimposed myoclonic jerking, also responds well. Other benzodiazepines may be beneficial but their effectiveness is somewhat less well established.

In contrast to other conditions, tolerance does not seem to develop as readily in the treatment of myoclonus with benzodiazepines.

Hemifacial spasm, a condition in which the periorbital and perioral muscles exhibit synchronous contraction, is usually due to vascular compression of the facial nerve and may cause fast, clonic contractions as well as slower movements of the affected region.

Essential Tremor

In addition to beta blockers and primidone, benzodiazepines may also reduce the severity of essential tremor in some patients. Both shorter acting drugs such as alprazolam and lorazepam, and longer acting drugs, such as diazepam and clonazepam, may be used.

Some variants of tremor may respond particularly well to benzodiazepines. Clonazepam is effective in some patients with orthostatic tremor, a rapid, tremor like movement that affects the legs and trunk when standing. Cerebellar action tremor may also improve partially with large doses of clonazepam.

Because of the tendency to develop tolerance with continued use, intermittent or short term use of shorter acting benzodiazepines may be more effective over time.

Stiff Person Syndrome

This condition (formerly termed stiff man syndrome) is an autoimmune disease, producing fluctuating stiffness of trunkal and proximal limb muscles.

In most patients, plasma and CSF antibodies directed against glutamic acid decarboxylase (GAD) are found. This enzyme synthesizes GABA, and anti GAD antibodies have been shown to block GABAergic neurotransmission.

Benzodiazepines have a central role in treatment. Along with other medications such as baclofen, tizanidine, and immunosuppression or IVIG, high doses of diazepam or other long acting benzodiazepines are needed.

Tetanus

Tetanus is a neuromuscular disease which results from an intoxication resulting from an infection by an anaerobic bacteria, *Clostridium tetani*, most commonly following puncture wounds and lacerations. This bacteria secretes a potent neurotoxin, tetanospasmin, which prevents release of neurotransmitters from neurons. Inhibitory GABAergic and glycinergic intereurons in the spinal cord and brainstem are particularly susceptible. This leads to failure of inhibition of motor reflex responses to sensory stimulation. Although there are several clinical forms, the most common form is generalized tetanus. After a 4–21 day incubation period after infection, symptoms generally begin in the cranial musculature and include trismus, facial grimacing, dysphagia, neck stiffness, and spasms, and then spread distally, affecting the extensor muscles of the trunk and extremities and can cause generalized severe spasms (opisthotonus). Dysautonomia and laryngeal spasm can occur and can be life threatening.

In addition to a number of other supportive treatments, diazepam is a mainstay of treatment. High doses, including an infusion of up to 40 mg h^{-1}, may be needed in severely affected individuals.

Beta-blockers and Movement Disorders

R J Elble, Southern Illinois University School of Medicine, Springfield, IL, USA

Glossary

Beta blocker – A competitive antagonist of one or more of the three beta adrenergic receptor subtypes (1, 2, and 3).
Long-loop sensorimotor reflex – A long-latency stretch reflex loop that includes the cerebral cortex.
Mechanical-reflex tremor – A tremor that is produced by the inherent tendency of a body part to oscillate, caused by the mechanical properties of the limb. Segmental and long-loop sensorimotor reflexes become involved when the tremor is enhanced by fatigue, hyperthyroidism, drugs, anxiety, or other states of increased adrenergic stimulation (enhanced mechanical-reflex tremor).

Definition

Beta blockers are competitive antagonists of one or more of the three beta adrenergic receptor subtypes (1, 2, and 3). All three beta receptors are coupled to stimulation of adenyl cyclase. The systemic effects of beta receptor stimulation and inhibition are well known, but the effects on the peripheral and central nervous system are not clearly defined, particularly as they pertain to movement disorders. Selective β-3 antagonists are not available for clinical use, and their relevance to the field of movement disorders is unknown. Consequently, only β-1 and β-2 antagonists are considered in this review.

Pharmacology

Propranolol is the prototypic beta blocker. It is nonselective, meaning that it blocks β-1 and -2 receptor subtypes. It also has high lipid solubility, so it is believed to enter the central nervous system more readily than beta blockers with low lipid solubility. However, little is known about the penetration and binding of these drugs in the central nervous system.

Beta blockers have been used extensively in the treatment of tremor, and lipid solubility and receptor sensitivity have not been reliable predictors of clinical efficacy (**Table 1**). Lipid solubility and receptor sensitivity are of relative importance. Plasma concentration and receptor affinity are also important.

Pathophysiology

All voluntary and involuntary limb movements are mediated through peripheral sensorimotor loops and the associated musculoskeletal system. This mechanical-reflex system can be the source of involuntary movement (e.g., clonus, physiologic tremor) and can facilitate the transmission of involuntary movements that emerge from central motor pathways. Pathologic tremors (e.g., Parkinson, essential and cerebellar), in particular, are enhanced by increased reflex sensitivity and by faster muscle twitch times. The effect of mechanical-reflex dynamics on other dyskinesias has not been studied.

Stretch reflex sensitivity is increased by peripheral infusion of catecholamines. This effect is due possibly to peripheral enhancement of muscle spindle sensitivity. Peripheral infusion of epinephrine or isoproterenol also reduces the relaxation time of muscle contractions, resulting in less tetanic attenuation of high-frequency fluctuations in muscle force (**Figure 1**). Such peripheral mechanical-reflex modifications could affect the amplitude of involuntary movements, regardless of any additional role played by central nervous system pathways. Peripheral beta blockade will reduce involuntary movements to the extent that they are enhanced

Table 1 Pharmacologic properties of common beta blockers

Drug	*Receptor sensitivity*	*Lipid solubility*	*Plasma half-life (h)*	*Efficacy for ET*[a]
Propranolol	β-1 ≈ β-2	High	4	Level A
Sotalol	β-1 ≈ β-2	Low	12	Level B
Nadolol	β-1 ≈ β-2	Low	22	Level C
Atenolol	β-1 > β-2	Low	6	Level B
Metoprolol	β-1 > β-2	Moderate	5	Level U

[a]Based on the American Academy of Neurology Practice Parameter for essential tremor by Zesiewicz et al.

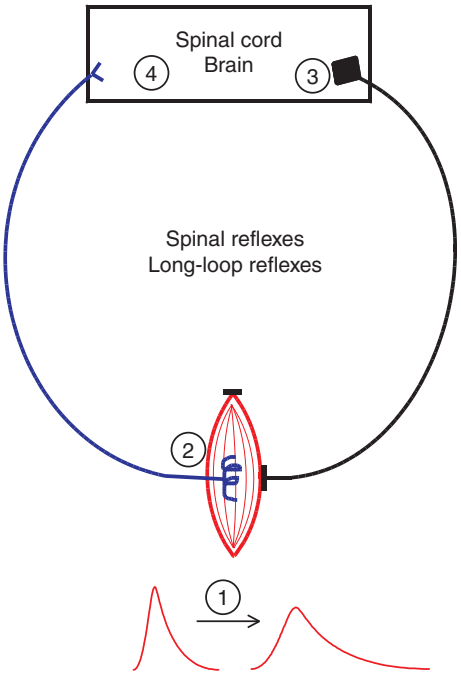

Figure 1 A schematic diagram of the putative sites of action of beta blockers in the suppression of tremor. (a) Slower muscle contraction and relaxation, resulting in greater attenuation of high-frequency fluctuations in motor drive, (b) reduced sensitivity of muscle spindles, (c) reduced sensitivity of alpha and gamma motoneurons, and (d) suppression of abnormal central neuronal network firing or unstable long-loop sensorimotor reflex pathways, which may produce oscillation, other dyskinesias, and systemic release of catecholamines.

by adrenergic stimulation of peripheral mechanical-reflex components (e.g., spindles and skeletal muscle).

Stretch reflex sensitivity is also influenced centrally by catecholamines. Beta adrenergic receptors are found in the spinal cord and brain, particularly the hippocampus, cerebellum, and cortico-basal ganglia-thalamocortical loop. Thus, central beta blockade might suppress tremor and other abnormal involuntary movements directly through lower motoneuron sensitivity and through a disruption of abnormal neuronal network behavior. Central beta blockade might also work indirectly through an attenuation of centrally-mediated conditions (e.g., stress, anxiety) that result in increased blood levels of catecholamines (**Figure 1**).

Management

Abnormal tremor produced by fatigue or increased endogenous release of catecholamines is called enhanced physiologic tremor. Marsden and colleagues demonstrated that catecholamine induced tremor is mediated at least in part by peripheral β-adrenergic receptors. Whether the effect is β-1, β-2, or both is unclear. Beta blockers are understandably effective for enhanced physiologic tremor caused by fatigue, anxiety, and other conditions in which there is heightened central or peripheral adrenergic stimulation of mechanical-reflex pathways.

Beta blockers have been shown to reduce essential tremor through peripheral β-blockade. The mechanisms are unclear, although reduced spindle (stretch reflex) sensitivity and reduced contractile speed of skeletal muscle are two possibilities. Central mechanisms are also at play in essential tremor because peripheral intraarterial infusion of propranolol has less effect on essential tremor than chronic oral therapy.

No beta blocker has been found to be superior to the nonselective β-blocker propranolol, which also has high lipid solubility and, therefore, presumably enters the CNS better than drugs with low lipid solubility. However, atenolol has been shown to have an effect on essential tremor, and it is predominantly a β-1 blocker with low lipid solubility. The failure of some essential tremor patients to respond to beta blocker suggests that other pharmacologic and innate personal susceptibility factors are at play.

Beta blockers have also been shown to reduce Parkinson tremor through peripheral β-blockade. A central mode of action is also likely. The benefit of beta blockade is often disappointingly small in patients with Parkinson disease, suggesting that β-adrenergic mechanisms may play less of a role in this disease, compared with essential tremor. The effect of beta blockers on other pathologic tremors (e.g., dystonic, cerebellar, orthostatic, and rubral) has not been studied extensively but is anecdotally small or nil in most patients.

Beta blockers have been found to reduce lithium-induced tremor, thyrotoxic tremor, and other tremors that are produced by stimulation of segmental and long-loop sensorimotor reflex pathways (enhanced mechanical-reflex tremor). Similar results have been reported for akathisia.

Precautions

Beta blockers are generally well tolerated, and serious side effects are rare. They should be avoided in patients with asthma, uncompensated heart failure, heart block, and sick sinus syndrome. Fatigue, lightheadedness, and bradycardia are the most common side effects. Erectile dysfunction and depression are often feared but are less frequent than commonly believed. Abrupt cessation of beta blockers can cause severe exacerbations of coronary artery disease and migraine.

Propranolol is rapidly and completely absorbed through the gastrointestinal tract, but most of the absorbed drug is metabolized during its first passage through the liver. This first-pass effect varies greatly among healthy people and is, of course, affected by liver disease and other drugs metabolized in the liver. Consequently, there is a 20-fold variation in plasma levels for a given dosage in healthy people. In general, the beta blockers with greater lipophilicity are metabolized mostly by the liver, while the more hydrophilic drugs are mainly excreted by the kidneys. It is best to begin with a low dosage of these drugs and titrate the dosage slowly, as tolerated and as needed.

Binswanger's Subcortical Arteriosclerotic Encephalopathy

I Sibon, Université Victor Segalen Bordeaux 2, Bordeaux, France

Definition and History

In 1894, Otto Binswanger reported eight patients with slowly progressive mental deterioration and pronounced white matter changes on a macroscopic examination of the brain performed in one of them. In a communication to the German psychiatrists in Munich, Alzheimer subsequently reported the microscopic features, including severe gliosis of the white matter and hyalination, intimal fibrosis, and onion-skinning of the long medullary arteries, and firstly used the terms 'Binswanger form' or 'encephalitis subcorticalis chronica Binswanger's.'

Subsequently, several other synonyms, such as 'subcortical arteriosclerotic encephalopathy of Binswanger's type' or 'chronic microvascular leukoencephalopathy' were proposed. Today, Binswanger disease (BD) is considered as a form of vascular dementia characterized by diffused white matter lesions and a varying degree of lacunar infarction in the basal ganglia and white matter. However, more than one century after its initial

description, intense controversy still surrounds the clinical manifestations, pathophysiology, and prevalence of BD.

Pathogenesis/Pathophysiology

BD is characterized by ischemic brain damage in the distal watershed periventricular areas and of the deep central white matter. The pathological spectrum can show significant differences in severity and intensity of the lesions. Some brains may reveal milder forms of ischemic change with absence of lacunes but loss of myelin and nerve fibers sparing the arcuate U fibers, whereas others show multiple small deep infarcts and severe loss of myelin and axons.

These parenchymal brain lesions are associated with alterations in the walls of the small penetrating medullary arteries arising from the leptomeningeal border zone and supplying the periventricular white matter. They may be affected by tortuosity that exacerbates the pressure drop related to their long course, hyalinization, concentric thickening of the media, interruption or destruction of the inner elastic membrane with proliferation, and fibrosis of the intima transforming these arteries to rigid 'earthen pipes' and progressively resulting in luminal narrowing and vessel occlusion. These arterioscelerotic changes mainly result from high blood pressure and atherosclerosis but are sometimes related to rare disorders such as pseudoxanthoma elasticum, antiphospholipid antibodies syndrome, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), and amyloid angiopathy. Morphological changes deprive the blood vessels of their function of regulating the blood flow, increasing the susceptibility to injury from hypoperfusion, and ischemic damage. The causal pathway between vascular changes and leukoaraiosis is not well understood. Misery perfusion, hypotensive and hypertensive spells, blood–brain barrier disorders, edema, acidosis, endothelial dysfunction, and coagulation activation seem to be involved. The main clinical symptoms observed in BD (dementia, parkinsonism) could result from a disruption of frontal–subcortical circuits by lacunar infarcts or deep white matter changes.

Epidemiology and Risk Factors

BD was for years considered a relatively rare disorder diagnosed only at necropsy. The sensitivity of magnetic resonance imaging (MRI) to subcortical white matter pathology has rekindled interest in the disorder and raised the possibility of its antemortem diagnosis. The exact prevalence of the disease still remains a matter of debate and strongly depends on the clinical, radiological, and pathological criteria used to make the diagnosis. However, BD seems to be one of the most common forms of vascular dementia in the elderly.

Based on the pathological studies, it has been suggested that there may be two types of small vessel disease that can be differentiated on brain imaging. The first involves atheroma at the origins or proximal portions of the larger (200–800 μm diameter) perforating arteries and is associated with single or a few larger lacunar infarcts without leukoaraiosis. The second involves a diffuse arteriopathy of the smaller perforating arteries, 40–200 μm in diameter, resulting in multiple smaller lacunar infarcts with leukoaraiosis such as observed in BD. While the first group is mainly associated with hypercholesterolaemia, diabetes, and myocardial infarction, BD seems to be mostly related to age and hypertension.

Clinical Features and Diagnostic Criteria

The onset, between 54 and 66 years, sometimes even at 75 years, is often marked by an insidious appearance of the focal cerebral signs. However, a sudden stroke is the opening event in one-third of the cases. The main clinical symptom of BD is progressive mental deterioration. Subcortical lesions are often considered to be associated with abnormalities of information processing speed, executive function, and emotional lability. The neurobehavioral features of Binswanger's syndrome include apathy, lack of drive, mild depression, and alterations of mood. Binswanger's syndrome also includes neurological deficits with pyramidal and language disorders, pseudobulbar disturbances (e.g., dysarthria, dysphagia, forced laughing and crying, small stepped gait), cerebellar (limb ataxia) and extrapyramidal signs (e.g., deterioration of gait, slowness and decrease of associated movements, impairment of posture when standing, trunk and limb rigidity), and lateral homonymous hemianopias. Associated vascular abnormalities, in particular arterial hypertension, are found in the majority of patients. The subsequent course is a chronic one over a period of 5–10 years, punctuated by frequent falls, epileptic attacks, syncopes, urinary incontinence, and sometimes acute stroke. Thus, impairment may develop either gradually or stepwise. In a minority of the subjects, the clinical spectrum may be characterized by the absence of hypertension, neurological signs, and dementia or any clinical sign (asymptomatic cases diagnosed on pathological studies). This clinical picture, as well as the pathological one, somewhat weakens the usefulness of the standardized clinical criteria proposed for the diagnosis of BD in vivo.

Differential Diagnosis

The slowly progressive dementia may lead to an erroneous diagnosis of Alzheimer's disease. The presence of gait disturbance, urinary incontinence, and ventriculomegaly may be mistaken for normal pressure hydrocephalus.

A familial form of BD presenting in younger patients in the absence of vascular risk factors should raise the possibility of CADASIL and other rare hereditary small vessel diseases.

Diagnostic Work-up/Tests

The advent of neuroimaging shifted the focus of attention on BD from pathological to clinical findings. The major findings revealed by morphological neuroimaging are (see **Figure 1**) (1) irregular hypodensity on computed tomography (CT) or hyperintensity on T2-wieghted MRI of the periventricular white matter, extending into the adjacent white matter, (2) moderate or severe symmetrical confluent hypodense/hyperintense lesions in central white matter, not continuous with the periventricular ones, (3) multiple lacunes or infarctions in the central white matter, corona radiata, internal capsule, centrum semiovale, thalamus, basal ganglia, or pons with absence of either large or multiple cortical lesions, (4) enlargement of the third and the lateral ventricles, and (5) microbleeds. Cerebral blood flow (CBF) studies performed with MRI, positron emission tomography (PET), and single photon emission computed tomography (SPECT) have found hypoperfusion in the pathological and normal-appearing white matter sometimes associated to cortical hypoperfusion, mainly in frontal areas. Moreover, evaluation of acetazolamide reactivity has demonstrated alteration of the perfusion reserve in BD. The place of other functional imaging studies investigating neurochemical changes (PET and SPECT) or structural modification (MRI spectroscopy) in the investigation of BD remains to be evaluated in prospective studies.

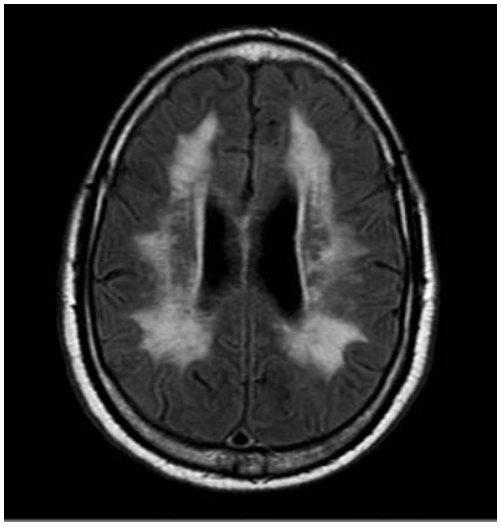

Figure 1 Brain MR: FLAIR sequence demonstrating diffuse hyperintensities of the periventricular white matter.

Prognosis and Management

Leukoaraiosis associated to BD has been associated with an increased risk of small deep infarcts, intracerebral bleeding after thrombolysis or under anticoagulation, dementia, poststroke disability, poorer prognosis following infratentorial stroke or after carotid endarteriectomy, and vascular mortality.

Appropriate control of arterial hypertension and elimination of other vascular risk factors should be the mainstay of therapy in patients with BD. Antiplatelet agents, such as aspirin, dipyridamole, or clopidogrel are indicated to lower the levels of platelet activation. Finally, medications such as pentoxifylline or propentofylline have been proposed to lower fibrinogen levels, but their benefit remains to be investigated in future trials.

Blepharospasm

D M Swope, Loma Linda University, Loma Linda, CA, USA

Glossary

Basal ganglia – Deep region of the brain involved in initiating and maintaining movement.
Blepharospasm – A form of focal dystonia that affects muscles of eye closure.
Botulinum toxin – Toxin produced by clostridium botulinum that can cause muscle weakness and botulism.
Dystonia – A neurologic disorder that causes abnormal involuntary contraction of muscles.
Idiopathic – A condition for which no known cause can be determined.
Meige syndrome – Segmental cranial dystonia that includes a combination of blepharospasm and lower facial dystonia.

Definition and History

Blepharospasm is a form of focal dystonia characterized by involuntary eye closure. This chronic neurologic disorder may be progressive and is sometimes disabling. Involuntary muscle spasms of the orbicularis oculi muscles may be clonic or tonic causing excessive eye blinking, palpebral fissure narrowing, or complete eye closure. The majority of cases are idiopathic but blepharospasm may also be secondary. It may be focal or a component of segmental or generalized dystonia. Treatment options include oral medications, botulinum toxin injections, and surgical management.

Pathogenesis and Pathophysiology

Like other focal dystonias, blepharospasm is thought to arise from basal ganglia dysfunction. Postmortem studies of brains of patients with adult-onset dystonia usually do not show any specific pathology. Both positron emission tomography (PET) and magnetic resonance imaging spectroscopy have shown evidence of hypometabolism in the lentiform nuclei and other regions of the basal ganglia. Neurophysiologic studies in patients with blepharospasm have demonstrated an increase in the duration of the corneal reflex supporting the hypothesis of increased excitatory drive from the basal ganglia to brainstem nuclei. Reciprocal inhibition, which refers to the inhibition of activity in antagonistic muscles during contraction of the agonist, has also been shown to be reduced in dystonia. These findings support the concept of abnormal circuitry involving abnormal basal ganglia input on brainstem and spinal interneurons.

Genetic factors may also be important in the etiology of blepharospasm and other adult-onset focal dystonias. Although the genetics of adult-onset dystonia are poorly understood, dystonia may be transmitted by an autosomal dominant gene with reduced penetrance. However, no specific gene mutation has been identified in adult-onset dystonia. Childhood-onset dystonia due to the DYT1 mutation typically begins in a limb and is more likely to become generalized than adult-onset dystonia.

Epidemiology and Risk Factors

The incidence of blepharospasm has been estimated to range from 16 to 133 per million. An epidemiologic study in Olmstead Co., Minnesota, found a calculated incidence of 1.2 persons per a population of 100 000 per year. Onset typically occurs in the fifth and sixth decades and it is more common in women than men by a ratio of 3:1.

A history of previous head trauma, family history of dystonia, and the existence of other eye diseases may be risk factors for developing blepharospasm. Age and female gender are also risk factors for the development of blepharospasm and spread of muscle involvement. Ocular trauma may precede the onset of symptoms, but it remains uncertain what role trauma plays in the development of blepharospasm. Trauma may be a trigger for symptom onset in susceptible individuals.

Clinical Features and Diagnostic Criteria

Symptoms may begin in one eye but may inevitably become bilateral. Early symptoms may be mild and nonspecific such as eye irritation, burning, and photophobia. Symptoms of eye irritation and strain may be attributed to other ophthalmologic conditions such as 'dry eyes.' Excessive eye blinking may persist or progress to episodes of sustained eye closure. Patients often have a combination of these symptoms.

Involuntary muscle spasms occur in orbicularis oculi muscles, resulting in increased blinking, brief eye closure, and sustained forceful eye closure. Episodes of eye closure may persist for seconds or even minutes. Contraction of the pretarsal portion of the orbicularis oculi results in eye

closure with an inability to open the eyes or to maintain eye opening. This is often associated with contraction of the frontalis muscle in an attempt to open the eyelids and results in brow elevation. The dystonic spasms of blepharospasm may also spread to muscles of the lower face and jaw. Meige syndrome, or segmental cranial dystonia, involves both upper and lower facial muscles.

Symptoms may be triggered initially by bright lights, blowing wind, movement, and stress. As symptoms progress, daily routine activities such as reading, driving, and watching television may be impaired. Up to 15% of patients may become legally blind.

Various sensory 'tricks' have been used by patients to relieve symptoms. Simple activities such as touching the face, pulling on eyelids, and talking or singing have been found to temporarily improve symptoms in some patients. The presence of a sensory trick supports the diagnosis of idiopathic dystonia and implies that the peripheral nervous system may play a role in the pathophysiology of dystonia.

Adult-onset focal dystonia may remain localized or it may spread to contiguous regions but rarely becomes generalized. There appears to be a greater risk of spread of disease in patients with blepharospasm compared with other focal dystonias with up to one-third of patients with blepharospasm experiencing spread, primarily to the lower face and jaw. Blepharospasm has also been associated with a more rapid rate of spread than other focal dystonias, with most spread occurring within 1–2 years of onset.

Secondary blepharospasm may be a symptom of many neurologic disorders although the most common cause of secondary blepharospasm is tardive dystonia due to chronic exposure to neuroleptic agents. Blepharospasm can be seen in Parkinson's disease and other parkinsonian syndromes. It may be an early symptom in patients with progressive supranuclear palsy. Other neurologic disorders that may be associated with blepharospasm include Tourette's syndrome, Huntington's disease, and Wilson's disease. Patients with stroke, multiple sclerosis, and severe head trauma may also develop focal dystonia although blepharospasm is not usually associated with focal lesions. A psychogenic etiology can be difficult to confirm but should be considered in cases of sudden onset or in the presence of other nonorganic findings. Secondary blepharospasm may be clinically identical to idiopathic blepharospasm.

No specific diagnostic study is available to confirm the diagnosis or determine the underlying cause of idiopathic blepharospasm. In the workup of blepharospasm, laboratory studies are performed to rule out treatable secondary causes of blepharospasm or to better understand the prognosis in patients with a secondary cause. Imaging studies may be done to rule out structural lesions but are usually not necessary in a patient with a typical history and otherwise normal neurologic exam. Laboratory studies are usually performed to screen for metabolic, inflammatory, and other potentially treatable disorders.

The diagnosis of blepharospasm is made on clinical grounds. A detailed history as well as careful neurologic examination can usually distinguish idiopathic from secondary dystonia. Neurologic signs apart from dystonic movements are not present in idiopathic dystonia and other signs support the diagnosis of secondary dystonia.

The history of subtle eye abnormalities and gradual progression of symptoms of involuntary eye closure should strongly suggest the diagnosis. Since blepharospasm is often part of a more wide-spread segmental or generalized dystonia, a complete examination is necessary to document the extent of involvement for prognostic and treatment considerations. A history of exposure to dopamine blocking agents (i.e., neuroleptic agents, antiemetics) suggests the possibility of tardive dyskinesia or dystonia.

Differential Diagnosis

Conjunctival and corneal lesions associated with blepharitis, due to inflammatory or infectious processes, may cause eye irritation and excessive blinking. Ophthalmologic examination may be necessary and patients often present to an ophthalmologist initially because of eye related complaints. Ptosis due to any neuromuscular disorder may resemble blepharospasm, although this should be easily differentiated by clinical examination. Hemifacial spasm resembles blepharospasm but is usually unilateral. Upper and lower facial muscles are often involved and facial weakness may be present, especially in long-standing cases. Hemifacial spasm is most often caused by vascular compression of the facial nerve and is considered to be a peripherally induced form of myoclonus.

Management

The approach to the management of blepharospasm is similar to the treatment of all focal dystonias. Treatment options in the management of blepharospasm include oral medications, intramuscular injections of botulinum toxin, and surgical intervention. A combination of these approaches may be necessary for severe cases or in patients with more wide-spread involvement. The treatment of underlying disorders may improve symptoms in patients with secondary dystonia, although symptomatic treatment is the same regardless of the etiology.

Mild cases may be managed effectively with benzodiazepines, including clonazepam and lorazepam. Anticholinergic medications have been shown to be the most effective pharmacologic agents in the treatment of moderate to severe dystonia. Trihexyphenidyl is the most commonly used anticholinergic drug but dose-limiting side effects often preclude its effectiveness. Baclofen and

tetrabenazine may also be considered but pharmacologic treatments are only modestly effective in most patients.

Injection of botulinum toxin into dystonic muscles has become the treatment of choice for focal dystonias, including blepharospasm. The treatment of blepharospasm was among the first FDA indications for botulinum toxin type A when it was approved in 1989 and it continues to be the most effective treatment available. Botulinum toxin blocks the release of acetylcholine presynaptically and results in chemical denervation of treated muscles. Relaxation of overactive muscles provides significant clinical benefit in about 90% of blepharospasm patients. The average duration of response is 12–14 weeks and treatment can be given on a routine basis. Multiple clinical trials have demonstrated the safety and efficacy of botulinum toxin in the treatment of focal dystonia. The most common side effect associated with this treatment is ptosis caused by the diffusion of toxin into the levator palpebrae.

Patients who do not respond adequately to pharmacologic therapy or botulinum toxin injections may be candidates for surgical treatment. Partial myectomy, or resection of the orbicularis muscle, can reduce the severity of spasm in medically refractory patients. Patients who undergo myectomy may continue treatment with botulinum toxin, often with improved response and longer duration of benefit. Experience with deep brain stimulation for the treatment of blepharospasm is limited but may be considered in patients with segmental or generalized dystonia who do not respond to less invasive measures.

Prognosis

Idiopathic blepharospasm is a chronic neurologic disorder. Spontaneous remission rarely occurs and is more likely in younger patients and in patients with a short duration of symptoms. Progression of symptoms and spread of muscle involvement occur relatively early in blepharospasm and little change is expected after 5 years of disease. Disease spread is more likely in idiopathic blepharospasm relative to other adult-onset focal dystonias.

Symptomatic treatments are effective in the majority of patients. However, no treatment has been shown to alter the natural course of the disorder or cure the underlying disease. Treatment can have a significant impact on the quality of life in patients with idiopathic and secondary blepharospasm.

Blood Oxygenation Level Dependent (BOLD)

D E Vaillancourt, University of Illinois at Chicago, Chicago, IL, USA

Glossary

Deoxyhemoglobin – Hemoglobin without oxygen attached, leaving it paramagnetic.

Diamagnetic – Having the property of a weak repulsion from a magnetic field.

Hemodynamic response – Change in the magnetic resonance signal on T2* images following local neuronal activity. A decrease in the amount of deoxygenated hemoglobin causes the hemodynamic response to increase.

Magnetic resonance – Absorption of energy from a magnetic field that oscillates at a particular frequency.
Oxyhemoglobin – Hemoglobin that has oxygen attached leaving it diamagnetic.
Paramagnetic – Having the property of being attracted to a magnetic field.

Blood oxygenation level dependent (BOLD) functional magnetic resonance imaging (fMRI) has emerged as one of the most widely used techniques to study brain function in vivo in humans. Like any such technique, BOLD fMRI has evolved due to developments in engineering, physics, applied mathematics, biology, and neuroscience. The changes in blood flow and blood oxygenation in the brain are closely linked to neural activity. When nerve cells are active, they consume oxygen carried by hemoglobin in red blood cells from local capillaries. The local response to this oxygen utilization is an increase in blood flow to regions of increased neural activity, occurring after a delay of approximately 1–5 s. This hemodynamic response rises to a peak over 4–5 s, before falling back to baseline. This leads to local changes in the relative concentration of oxyhemoglobin and deoxyhemoglobin and changes in local cerebral blood volume in addition to this change in local cerebral blood flow. BOLD fMRI is based on this neurovascular response.

The discovery of the BOLD response occurred due to several fundamental developments. In 1936, an American chemist and Nobel laureate Linus Pauling and his student Charles Coryell conducted systematic investigations into the hemoglobin molecule. They discovered that hemoglobin has magnetic properties. Oxygenated hemoglobin is diamagnetic (zero magnetic moment) and deoxygenated hemoglobin is paramagnetic (significant magnetic moment). Completely deoxygenated blood has a magnetic susceptibility 20% greater than fully oxygenated blood. Magnetic resonance (MR) pulse sequences configured to be sensitive to T2* show more signal when blood is highly oxygenated and less signal when blood is deoxygenated. This prediction was verified in a paper by Thulborn and colleagues. They found that the decay of transverse magnetization depended on the proportion of oxygenated hemoglobin within a test tube of blood. They also noted that the effect varied with the field strength of the magnet.

The theoretical development of nuclear magnetic resonance, MRI technology, and commercially available scanners has also allowed BOLD fMRI to develop at a rapid pace. In the late 1940s, two physicists named Felix Bloch and Edward Purcell published seminal papers which characterized the measurement of MR in bulk matter. These two individuals shared the Nobel Prize in 1952, for their work in physics. The basic setup used by Bloch's group provided the backdrop to most MR scanners today. They had a strong static magnetic field, a transmitter coil that sends electromagnetic energy to the sample, and a detector coil that measured energy emitted back from the sample. It is the relaxation back to the static field which most MR applications rely upon today. About two decades later, Damadian demonstrated that cancerous cells from a rat had a different relaxation time than noncancerous cells, and thereby provided one of the first biological applications of nuclear magnetic resonance. In 1973, a paper by Paul Lauterbur tested the idea that if the strength of the magnetic field varied over space, the resonant frequency of protons of different locations could also vary accordingly. He showed that measuring energy emitted to the detector coil at different frequencies could identify how much of that object was present at each location. This provided the first MR image. In 1976, Peter Mansfield improved upon the work of Lauterbur by developing the basis of echo-planar imaging, which provided the ability to acquire one image slice at a time, rather than the one-dimensional approach used in the past. In the 1980s and 1990s, MRI scanners became more and more prevalent for both research and clinical medicine. In 2003, Paul Lauterbur and Peter Mansfield shared the Nobel Prize in Medicine.

In the early 1990s, there were several important papers that led to the development of BOLD fMRI. Ogawa and colleagues hypothesized that manipulating the proportion of blood oxygen would affect the visibility of blood vessels on T2*-weighted images. They confirmed this hypothesis in anesthetized rodents using 7 Tesla MRI. The rats breathed in different proportions of oxygen. When the rats breathed 100% oxygen or 100% carbon monoxide, their brains showed very few blood vessels, yet the structural differences were evident. When the rats breathed normal air, which contains about 21% oxygen, the images contained thin dark lines throughout the cerebral cortex. When the oxygen content was reduced to 0%, the lines became more prominent. Ogawa and colleagues concluded that these thin lines represented magnetic susceptibility effects caused by the presence of paramagnetic deoxygenated hemoglobin in blood vessels. This effect observed by Ogawa and colleagues became known as BOLD contrast fMRI. In another study, this same group manipulated the gases inhaled by anesthetized rats and found similar effects for high field BOLD contrast and electroencephalography (EEG).

In 1992, the first fMRI studies using behavioral tasks to elicit the BOLD response were published by three different groups. Kwong and colleagues used gradient-echo-planar imaging at 1.5 Tesla to show BOLD contrast changes in the visual cortex following light stimulation. Ogawa and colleagues reported a similar finding in the

visual cortex. In the first demonstration related to the motor system, Bandettini and colleagues showed that when subjects repeatedly touch their fingers with their thumb reliable BOLD contrast changes could be observed in the motor cortex.

The neurovascular contributions to neuroimaging have received considerable focus over several decades. It is now widely recognized that several changes in neurovascular coupling affect the BOLD signal. The usual signal increases reported in BOLD fMRI studies are due to the fact that neural activation causes an increase in cerebral blood flow. It also increases glucose utilization that is larger than the oxygen consumption rate. The result from an increase in neural excitation is a reduction in deoxyhemoglobin, which in turn increases signal strength. It has also been shown that the BOLD response depends on cerebral blood volume.

Despite the cascade of biological changes that occur between a measurable neural recording and the BOLD fMRI signal, there are strong correlations between neural recordings and the BOLD response. Logothetis and colleagues have inserted microelectrodes into the extracellular space during BOLD fMRI studies in animals. They recorded broad band frequency content of these signals detecting single unit activity, multiple unit spiking activity, and local field potentials. The findings obtained thus far indicate that the low-frequency content of the local field potential provides the best correlation with the fMRI BOLD response. The studies of Logothetis and colleagues suggest that regions where BOLD fMRI responses are found may not have single unit activity in the specific region. The BOLD fMRI response, instead, reflects large population activity from many neurons that had an influence on the low-frequency content measured at the microelectrode.

Analysis of BOLD fMRI studies has evolved since the initial three studies in 1992. It is estimated that since the seminal papers in 1992, over 1000 fMRI papers are published each year and eight were published each day in the year 2007. The analyses used in the BOLD fMRI studies rely upon the general linear model which is implemented in software packages such as statistical parametric mapping (SPM) and analysis of functional neuroimages (AFNI). Another widely used analysis approach is a region of interest analysis that is focused on a specific set of regions which are defined anatomically. A region of interest analysis is particularly useful in parametric fMRI studies and pharmacological fMRI studies. In addition, recent studies have developed analyses which characterize the connectivity between anatomical regions using different approaches.

Botulinum Toxin

J Jankovic, Department of Neurology, Houston, TX, USA

Glossary

Blepharospasm – Involuntary eye closure due to contractions of orbicularis oculi, procerus, and corrugator muscles.
Botox – Botulinum toxin type A generic name assigned by the FDA: onabotulinumtoxin A.
Botulinum toxin (BoNT) – Botulinum otulinum neurotoxin.
Cervical dystonia (also known as torticollis) – This focal dystonia involving the neck muscles causes abnormal turning, flexion, extension and other movements and postures of the neck and head.
Dysport – Botulinum toxin type A generic name assigned by the FDA: abobotulinumtoxin A.
Dystonia – Neurological disorder manifested by sustained, repetitive, patterned contractions of muscles causing abnormal movements and postures.
Hemifacial spasm – Abnormal twitching involving one side of the face.
Immunoresistance – Loss or responsiveness to BoNT treatment due to the development of blocking antibodies.
Myobloc/Neurobloc – Botulinum toxin type B.
Sialorrhea – Drooling due to overproduction or impaired clearance of saliva.
Spasmodic dysphonia – Laryngeal dystonia resulting in involuntary approximation (adductor dysphonia) or separation (abduction dysphonia) of the vocal cords.
Writer's cramp – Focal hand dystonia interfering with writing and other specific tasks.
Xeomin – Botulinum toxin type A.

Definition and History

The history of botulinum toxin (BoNT) dates to 1817, when Christian Andreas Justinus Kerner first recognized that food-borne botulism was due to a toxin that paralyzed skeletal muscles and parasympathetic function. He proposed the term botulinum toxin and suggested that it could be used to treat involuntary spasms and movements. In 1895, Emile Van Ermengem first isolated the bacterium clostridium botulinum after an outbreak following a funeral ceremony in the Belgian village Ellezelles. Edward Schantz first cultured Clostridium botulinum and isolated the toxin in 1944, and in 1949, Burgen and his colleagues found that BoNT blocked neuromuscular transmission by blocking the release of acetylcholine. It had not been until 1973 that the therapeutic value of BoNT was recognized by Alan Scott, who demonstrated that strabismus in monkeys could be corrected by BoNT injections into the extraocular muscles. The first report of clinical application of BoNT was published in 1984, when it was demonstrated to be safe and effective in the treatment of blepharospasm. Subsequent double-blind, placebo-controlled, and open-label studies provided evidence that BoNT was a powerful therapeutic tool in a variety of neurologic and other disorders. Although its widest application is still in the treatment of disorders manifested by abnormal, excessive, or inappropriate muscle contractions, its use is rapidly expanding to include the treatment of a variety of ophthalmologic, gastrointestinal, urologic, orthopedic, dermatologic, secretory, painful, and cosmetic disorders (**Table 1**).

Pharmacology and Physiology of Botulinum Toxin

The therapeutic value of BoNT is due to its ability to cause chemodenervation and to produce local paralysis when injected into a muscle. There are seven immunologically distinct toxins (A–G); type A has been studied most intensely and used most widely. Synthesized as single-chain polypetides (molecular weight of 150 kD), these toxin molecules have relatively little potency until they are cleaved by trypsin or bacterial enzymes into a heavy chain (100 kD) and light chain (50 kD). The three-dimensional structure of the BoNT complex is known. When linked by a disulfide bond, these dichains exert their paralytic action by preventing the release of acetylcholine (Ach). While the

Table 1 Botulinum neurotoxins

Neurotoxin	*Substrate*	*Localization*
BoNT – A, E	SNAP-25	Presynaptic plasma membrane
BoNT – B, D, F	VAMP/synaptobrevin	Synaptic vesicle membrane
BoNT – C	SNAP-25, Syntaxin	Presynaptic plasma membrane

heavy chain of the toxin binds to the presynaptic cholinergic terminal, the light chain acts as a zinc-dependent protease that selectively cleaves proteins that are critical to fusion of the presynaptic vesicle with the presynaptic membrane. This is accomplished via a three-step process that involves binding to the acceptors on presynaptic membrane (heavy chain), internalization (endocytosis), and an enzymatic action (light chain). BoNT/A enters neurons by binding to the synaptic vesicle protein SV2, which acts as the BoNT receptor. The light chains of BoNTs act by cleaving the SNARE (soluble *N*-ethlymaleimide sensitive factor attachment protein receptor or soluble *N* ethylmaleimide sensitive factor attachment protein receptor (SNAP) receptor or neuronal synaptosome-associated proteins) proteins that are involved in the docking of presynaptic Ach vesicle before releasing Ach into the neuromuscular junction. The light chains of both BoNT/A and BoNT/E cleave SNAP-25, but at different sites. The light chains of BoNT B, D, and F prevent the quantal release of Ach by proteolytically cleaving synaptobrevin-2, also known as VAMP (vesicle-associated membrane protein), an integral protein of the synaptic vesicle membrane. BoNT/C cleaves both SNAP-25 and syntaxin, another plasma membrane-associated protein. Although BoNT may enter the central nervous system, it is unlikely that this results in any clinically meaningful effects.

The original commercial preparation of BoNT was the type A BoNT, marketed as BOTOX® (Allergan, Inc., Irvine, CA, USA). This purified neurotoxin complex is supplied as 100-mouse unit vials of freeze-dried BoNT/A. Another clinically available form of BoNT/A is Dysport® (Beaufour-IPSEN, France-UK). Other BoNT/A preparations used clinically include Xeomin® (Merz Pharmaceuticals GmbH, Frankfurt, Germany), a purified, freeze-dried BoNT/A, which is free from complexing proteins. Besides BOTOX®, Dysport®, and Xeomin®, the other type of BoNT/A currently in clinical trials is PureTox® (Johnson & Johnson, USA). In addition, there is a Chinese form of BoNT/A (Prosigne or CBTX-A, Lanzhou Biological Products Institute, China). Currently, only one preparation of BoNT/B is marketed worldwide and is known by the brand name Myobloc® (US) or Neurobloc® (Europe) (Solstice Neurosciences Inc, Malvern, PA, USA).

It is important to note that the biologic activity, measured in units, is different for the different products. When administered intravenously or intramuscularly to monkeys, the LD50 for the BOTOX was estimated to be 40 U kg^{-1}, and about 3000 U when extrapolated to a 75 kg man. In addition to the biologically active toxin, many products include various amounts of nontoxin proteins include hemagglutinins and other proteins that presumably stabilize the three-dimensional structure of the toxin. The toxins dissociate in basic conditions (pH $>$ 7), but remain relatively stable under neutral (pH = 7; BOTOX®, Dysport®) or acidic (pH = 5.6, Myobloc®/Neurobloc®) conditions. Xeomin® and PureTox® are free of complexing proteins. Although each preparation should be considered unique in its potency and properties, various studies have suggested that the potency ratio between Dysport® and BOTOX® is about 3 to 1 and between Myobloc/Neurobloc® and BOTOX® as 50 or 60 U to 1, whereas Xeomin® and BOTOX® seem to be equivalent in their potency. In this review, we use BOTOX® units unless specified otherwise.

While side effects occasionally result form local diffusion of BoNT, remote or systemic adverse effects are quite rare. Patients with postpolio syndrome and Eaton–Lambert syndrome, however, have been reported to have generalized weakness after local BoNT. Other contraindications to the use of BoNT include myasthenia gravis, motor neuron disease, concurrent use of aminoglycoside antibiotics, and pregnancy, although women, inadvertently injected during pregnancy, reported no untoward side effects to the fetus.

The optimal treatment benefits depend on a large number of factors, including the selection of the appropriate target, dosage, and dilution, as well as the technique used and experience of the clinician. One of the major controversies related to injection techniques is the use of electromyography (EMG) in selecting the abnormally active muscles and in guiding the injection needle to the appropriate target muscle. While some clinicians favor this approach, there is little evidence to indicate that EMG significantly improves the outcome.

Immunogenicity of Botulinum Toxins

Although the various neurotoxins are antigenically different, they contain a common subunit structure and cross-reactive epitopes may cause cross-neutralization of antibodies. This has been demonstrated particularly between BoNT/A and BoNT/B. The original preparation of Botox contained 25 ng of neurotoxin complex protein per 100 U, but in 1997, the Food and Drug Administration (FDA) approved a new preparation that contains only 5 ng per 100 U, which has been associated with lower antigenicity. Methods used to detect blocking antibodies include the mouse protection assay, the mouse phrenic nerve hemidiaphragm test, and many other research and commercial tests. A unilateral brow injection (UBI) is a useful clinical test as inability to frown on the injected side confirms the absence of clinically meaningful immunoresistance. Depending on the technique used to detect blocking antibodies, the risk of antibodies to Botox has markedly decreased and is now estimated to be about 1–2% of patients receiving the product repeatedly for up to 4 years. While low antigenicity has been predicted with formulations of BoNT without complexing proteins (e.g., Xeomin® and PureTox®), no long-term data are available to support this notion. The presence of blocking

antibodies, directed to the heavy chain of the BoNT molecule, usually indicates that the patient has developed immunoresistance and will not respond to the next injection. Delaying the subsequent injection by at least 18 months, considered as the minimum time for the antibodies to vanish from the patient's immune system, may be associated with a positive response. Most patients who develop blocking antibodies, however, have an increased risk of developing antibodies again and these patients seem to also have an increased risk of developing blocking antibodies to a different type of BoNT. Thus patients who have developed blocking antibodies to BoNT/A may initially respond to BoNT/B but are likely to soon develop immunoresistance to the alternate type of BoNT.

Clinical Applications of Botulinum Toxins

Blepharospasm

In 1987, we reported the results of a double-blind, placebo-controlled trial of BoNT in 28 patients with cranial-cervical dystonia, including blepharospasm, oromandibular dystonia, and cervical dystonia (CD), the results of which were in part used by the FDA to approve BoNT in 1989 as a therapeutic agent in patients with strabismus, blepharospasm, and other facial nerve disorders, including hemifacial spasm. Subsequently there have been many open-label studies confirming the safety and efficacy of BoNT in the treatment of blepharospasm, but because of paucity of double-blind, placebo-controlled trials, the Therapeutics and Technology Assessment Committee of the American Academy of Neurology (TTAC-AAC) concluded that there is only level B (probably effective) evidence for the efficacy of BoNT/A for the treatment of blepharospasm. Most studies have concluded that the average latency from the time of the injection to the onset of improvement was about 3–5 days and the average duration of benefit was about 12–14 weeks. While about a third of all treatment sessions are followed by some side effects (ptosis, blurring of vision or diplopia, tearing, and local hematoma), only 1–2% affect patient's functioning, and complications usually improve spontaneously in <3 weeks. The relationship between blepharospasm, BoNT, and occurrence of dry eyes in some patients is not well understood. The efficacy of BoNT in the treatment of blepharospasm is largely dependent on the skills and experience of the physician. Several studies have suggested that in addition to injecting the medial eyebrows (corrugator and procerus muscles) an injection into the pretarsal rather than preseptal portion of the orbicularis oculi is associated with a significantly lower frequency of ptosis. Furthermore, ptosis and other complications, such as tearing, can be prevented by injecting initially only 5 U in the lateral portion of the upper lid and 5 U medially and by injecting 5 U only into the lateral portion of the lower lid.

In a double-blind, parallel-group, multicenter study, 304 patients with blepharospasm received either Xeomin or Botox, both the treatments produced statistically significant improvements from baseline in the Jankovic Rating Scale (JRS) at week 3 (primary efficacy variable; Xeomin: −2.90; Botox: −2.67; $p < 0.0001$ from baseline for both), with no difference between treatments, indicating that Xeomin were clinically noninferior to Botox. The most common adverse event was ptosis (6.1% Xeomin and 4.5% Botox). The efficacy and safety of Xeomin in the treatment of blepharospasm was also confirmed by a prospective, double-blind, placebo-controlled, randomized, multicenter study involving 109 patients (mean total dose of Xeomin per treatment visit was 64.8 U), the JRS severity subscore was significantly reduced compared with placebo ($p < 0.001$). The most commonly reported adverse effects related to Xeomin versus placebo were eyelid ptosis (18.9 vs. 8.8%), dry eye (16.2 vs.11.8%), and dry mouth (16.2 vs. 2.9%).

Oromandibular Dystonia

Oromandibular dystonia is among the most challenging forms of focal dystonia to treat; it rarely improves with medications; there are no surgical treatments; and BoNT therapy can be complicated by swallowing problems. Clenching, trismus, and bruxism are frequent manifestations of primary (idiopathic) as well as secondary oromandibular dystonia. Patients with dystonic jaw closure, treated with injections into the masseter and temporalis muscles, generally respond better than those with jaw-opening dystonia. Although most patients with jaw opening dystonia benefit from injections into the submental muscle complex, some may also require injections into the lateral pterygoid muscles. As with blepharospasm, the improvement is usually noted within the first 5 days and persists for about 3–4 months. Early treatment of oromandibular dystonia with BoNT may prevent dental and other complications, including the temporomandibular joint syndrome.

Laryngeal Dystonia (Spasmodic Dysphonia)

Until the introduction of BoNT, the therapy of spasmodic dysphonia has been disappointing. Several studies have established the efficacy and safety of BoNT in the treatment of laryngeal dystonia and this approach is now considered by most to be the treatment of choice for spasmodic dysphonia. This approach usually requires a multidisciplinary team, consisting of an otolaryngologist experienced in laryngeal injections and a neurologist knowledgeable about motor disorders of speech and voice. There are three approaches currently used in the BoNT treatment of spasmodic dysphonia: (1) unilateral

EMG-guided injection of 5–30 U; (2) bilateral approach, injecting with EMG-guidance 1.25–4 U in each vocal fold; and (3) an injection via indirect laryngoscopy without EMG. Irrespective of the technique, most investigators report about 75–95% improvement in voice symptoms. Patients with the adductor form of spasmodic dysphonia produced by involuntary contraction of the thyroarytenoid muscle, usually report more robust improvements than those with the abductor spasmodic dysphonia, the less frequent type of dysphonia. Although more complicated, BoNT injections into the posterior cricoarytenoid muscle with the EMG needle placed posterior to the thyroid lamina may be used quite effectively in the treatment of the abductor form of spasmodic dysphonia. Adverse experiences include transient breathy hypophonia, hoarseness and rare dysphagia with aspiration. BoNT produces less consistent benefits when spasmodic dysphonia is accompanied by voice tremor.

Cervical Dystonia (CD)

The introduction of BoNT in the treatment of CD has not only improved the quality of life of patients with this most common adult-onset focal dystonia, but has also changed the natural history in that cervical contractures are now much less frequent than they were prior to BoNT. A variety of instruments has been used to assess the response in patients with CD, but the Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS) is used most commonly. The efficacy and safety of BoNT in the treatment of CD have been demonstrated in several controlled and open trials and the (TTAC-AAC) report concluded that BoNT should be offered as a treatment option for the treatment of CD (Level A evidence). In a first US multicenter, double-blind, randomized, controlled trial assessing the safety and efficacy of Dysport® in CD, 80 patients were randomly assigned to receive one treatment with Dysport (500 U) or placebo. Dysport® was significantly more efficacious than placebo at weeks 4, 8, and 12 as assessed by the TWSTRS. The median duration of response was 18.5 weeks. Side effects were generally similar in the two treatment groups; only blurred vision and weakness occurred significantly more often with Dysport®. These results were confirmed by another pivotal study of Dysport® in CD involving 116 patients. The most common treatment-related adverse events in other studies of BoNT in CD were mild to moderate weakness, dysphagia, neck pain, and injection-site pain. In a prospective, open-label, multicenter study of 333 patients with CD, never previously exposed to BoNT, after a median of 9 of BOTOX® treatments, with mean doses per session ranging from 148.4 to 213.0 over a mean of 2.5 years (range: 3.2 months to 4.2 years), only 1.2% tested positive for blocking antibodies (**Table 2**).

Table 2 Recommended doses of BoNT in patients with CD

Muscle	*BoNT/A (Botox/ Xeomin)*	*BoNT/B (Myobloc/ Neurobloc)*
Trapezius	35–100	1500–5000
Sternocleidomastoid	40–70	2000–3000
Splenius capitis	60–100	2500–5000
Levator scapulae	25–60	1250–2500
Scalene complex	25–60	1250–2500

The most important determinants of a favorable response to BoNT treatments are a proper selection of the involved muscles and an appropriate dosage. Although the treatment must be individualized, the average optimal dose for patients with CD is 200 U of BOTOX® or Xeomin®, 500 U of Dysport®, and 10 000 of Mybloc/Neurobloc®. BOTOX® and Myobloc were directly compared, at 1:40 dose ratio, in 139 patients with CD, the so-called 'ABCD Study,' using a randomized, double-blind parallel arm study design. While the improvement in TWSTRS score at 4 weeks following injection did not differ between the two serotypes, dysphagia and dry mouth were more frequent with Mybloc®. A post hoc comparison of these two groups with respect to EMG use found that the only difference between the two groups was in number of muscles injected and toxin dosage, both being statistically higher in the EMG-guided group. In another study, designed as a noninferiority trial, 111 patients with CD were randomized to receive either Botox (150 U) or Myobloc/Neurobloc® (10 000 U) at a dosing ratio of 66.7. There were no significant differences in the efficacy or occurrence of injection-site pain and dysphagia. Dry mouth has been consistently found to be more frequent with Myobloc/Neurobloc® than with BOTOX®. Also, the risk of immunoresistance seems to be higher with Myobloc/Neurobloc® than with BOTOX®. In one study of 100 patients with CD followed for 42 months over a mean of 5 (up to 12) visits, a third of the patients who were negative for BoNT/B antibodies at baseline became positive for such antibodies at the last visit. Thus although BoNT/B offers a useful alternative to patients with immunoresistance to BoNT/A long-term efficacy is limited by the development of blocking antibodies, probably as a result of the cross-reactivity between the two serotypes.

Writer's Cramps and Other Limb Dystonias

The treatment of hand dystonia with BoNT is more challenging than the other dystonias, because there are more muscles involved in finely coordinated motor function required in the act of writing, dressing, other activities of daily living and in various demanding tasks such as playing musical instruments and sport activities. Using

the Burke–Fahn–Marsden scale, a marked improvement in the severity and disability was achieved with EMG-guided injection of BoNT in 47 patients with writer's cramp, whereas primary writing tremor was little improved. In one study, 69% of 84 musicians reported improvement with EMG-guided BoNT (Dysport) injections, but only 36% reported long-term benefit. Appropriate recognition of overflow and mirror dystonia induced by volitional movement in the unaffected hand may provide clues to the muscles involved in the hand that are primarily affected by the focal hand dystonia.

Several open and double-blind controlled trials have concluded that BoNT injections into selected hand and forearm muscles probably provide the most effective relief in patients with various task-specific and occupational dystonias. Although EMG guidance may be appropriate for BoNT treatment of limb dystonia, supported by the finding that only about a third of needle placement attempts reached the proper hand muscles in the absence of EMG guidance, this does not mean that placement with EMG guidance correlates with better results since the selection of the muscle involved in the hand dystonia is based on clinical examination and not on EMG. Ultrasound-guided EMG techniques are increasingly applied in the treatment of hand and other focal dystonias.

Hemifacial spasm

Hemifacial spasm is defined as a neurologic disorder manifested by involuntary, recurrent twitches of the eyelids, perinasal, perioral, zygomaticus, platysma, and other muscles of only one side of the face. It is an example of a peripherally induced movement disorder (segmental myoclonus) in which the muscular contractions result from an irritative lesion of the ipsilateral facial nerve. While microvascular decompression of the facial nerve has a high success rate, this surgical treatment is associated with certain risks, such as permanent facial paralysis, deafness, stroke, and death. Therefore, local injections of BoNT into involved facial muscles offer a useful alternative to surgical therapy. Nearly all patients improve; the complications are minimal and transient; and the approach can be individualized by injecting only those muscles the contractions of which are most disturbing to the patient. Along with blepharospasm, the FDA approved BoNT injections for hemifacial spasm in 1989.

In our experience with BoNT injections in 110 patients with hemifacial spasm, 84 (76%) of whom had adequate follow-up, the amount of Botox used in each injection varied from 5 to 100 U, with an average of 32.7±12.9 U. The latency from injection to the onset of benefit was 5.4±7.8 days (range: 0–45 days) and the total duration of benefit averaged 18.4±6.1 weeks (range: 0–37). Sixty seven (80%) of the 84 patients had a peak effect of 4 (marked improvement in severity and function) and 13 (15%) had a score of 3 (moderate improvement in severity and function). The side effects included facial weakness ($N = 25$), lid weakness ($N = 22$), ptosis ($N = 17$), teary or dry eyes ($N = 10$), diplopia ($N = 7$), hematoma ($N = 6$), and diverse other side effects ($N = 5$). The average duration of improvement in hemifacial spasm, 5 months, was longer than in any of the dystonic disorders and rare patients have achieved long-lasting remissions. Facial myoclonus associated with Rasmussen encephalitis, similar to hemifacial spasm, but pathophysiologically related to focal cortical seizure, has been also reported to improve with BoNT.

Tremor

Tremor accompanies dystonia in about half of all dystonic patients, and in some patients treated for focal dystonia with BoNT, their dystonic tremor improved. Chemodenervation with BoNT may ameliorate not only dystonic tremor, but also essential tremor involving hands, as demonstrated by at least two double-blind, placebo-controlled studies. Although BoNT is clearly a useful treatment in patients with hand tremor, it has been found particularly effective in patients with head tremor and may even improve primary writing and other task-specific tremors, jaw tremor and voice tremor.

Tics

Motor and phonic tics associated with Tourette's syndrome typically improve with antidopaminergic drugs, but when these drugs do not adequately control the tics or are associated with troublesome side effects, BoNT injections into the affected body parts not only may provide satisfactory control of the tics but also may eliminate the premonitory urge. BoNT treatment is particularly useful in the treatment of focal motor tics and phonic tics, including coprolalia. In a placebo-controlled study of 18 patients with simple motor tics, BoNT treatment was associated with a 39% reduction in the number of tics per minute within 2 weeks after injection as as against a 6% increase in the placebo group ($p = 0.004$). In addition, there was a 0.46 reduction in 'urge scores' with BoNT as against a 0.49 increase in the placebo group ($p = 0.02$). This preliminary study, however, lacked the power to show significant differences in other measured variables, such as severity score, tic suppression, pain, and patient global impression. Other limitations of the study include the following: (1) the full effect of BTX may not have been appreciated at only 2 weeks, (2) a single treatment protocol does not reflect the clinical practice which involves several adjustments in doses and sites of injections over several treatment visits, and (3) the patients were relatively mild as suggested by the statement that they 'did not rate themselves as significantly compromised by their treated tics' at baseline.

Spasticity and other Hypertonic Disorders

In addition to involuntary movement disorders, BoNT has been used effectively to treat disorders of muscle tone, including spasticity associated with cerebral palsy, multiple sclerosis, or following stroke. One double-blind, placebo-controlled study showed that Botox (200–240 U) reduced wrist and finger spasticity in patients following stroke. In another one controlled study, 125 patients with cerebral palsy and dynamic equinus spasticity during walking were randomized to receive 10, 20, or 30 mg kg^{-1} of Dysport®, or placebo to the gastrocnemius of both the legs. There was a statistically significant improvement in all the three dose groups, particularly the 20 mg kg^{-1} group, compared with placebo in the dynamic component of the gastrocnemius muscle. Experienced injectors have recommended the following doses of BoNT/A (BOTOX®) in the treatment of spasticity: for the lower limb 3–6 U kg^{-1} per muscle, for the upper limb above the elbow 2–3 U kg^{-1} per muscle, for the upper limb below the elbow and posterior tibialis 0.5–2 U kg^{-1} per muscle. In children with cerebral palsy, BoNT (2–8, up to 16 U per kg body weight per muscle) is often found effective when injected in calf muscles to correct equinus deformity and toe walking, in the hamstring muscles to correct crouch and scissor gait, to improve sitting and hygiene care, and to reduce pain. In a double-blind, controlled study patients with cerebral palsy receiving 40–80 U of BOTOX® per muscle experienced a significantly greater improvement in Ashworth score and gait measures than the 'low-dose' group (20–40 U per muscle). The results of many of the studies are difficult to interpret and compare, because patients with various forms and etiologies of spasticity were enrolled and different methodologies were used to inject and rate the patients. Although some double-blind trials have demonstrated meaningful functional improvement in patients with spasticity, other controlled studies have failed to demonstrate improvement. Many of the published studies suffer methodological problems, particularly in selecting the appropriate outcome measures that may or may not capture the functional goals of the patients.

Table 3 Clinical applications of botulinum toxin

Dystonia
Blepharospasm (lid 'apraxia')
Oromandibular-facial-lingual dystonia
Cervical dystonia (torticollis)
Laryngeal dystonia (spasmodic dysphonia)
Limb dystonia
Task-specific dystonia (e.g., writer's or other occupational cramps)
Other focal/segmental dystonias (primary, secondary)
Other involuntary movements
Hemifacial spasm
Limb, head, voice, chin tremor
Palatal myoclonus
Motor and phonic tics, including coprolalia
Nystagmus and oscillopsia
Myokymia
Inappropriate contractions
Spasticity (stroke, cerebral palsy, head injury, multiple sclerosis)
Painful rigidity
Strabismus
Bruxism and temporo-mandibular joint syndrome
Stuttering
Muscle contraction headaches
Lumbosacral strain and back spasms
Radiculopathy with secondary muscle spasm
Myofascial pain syndromes
Achalasia (lower esophageal sphincter spasm)
Spasm of the inferior constrictor of the pharynx (cricopharyngeal muscle)
Spasm of the sphincter of Oddi
Spastic bladder, detrusor-sphincter dyssenergia
Anismus
Vaginismus
Other applications
Protective ptosis
Hyperlacrimation
Drooling (sialorrhea)
Hyperhidrosis
Gustatory sweating
Anal fissure
Constipation
Overactive bladder
Prostatic hypertrophy
Obesity (distal stomach)
Diabetic foot ulcers
Cosmetic (wrinkles, brow furrows, frown lines, 'crow's feet,' platysma lines, facial asymmetry)
Tennis elbow and other sports injuries
Debarking dogs

Other Indications

The use of BoNT is continuously expanding as clinicians are becoming more familiar with its therapeutic potential. In addition to treating focal dystonias, such as blepharospasm, oromandibular, cervical, laryngeal, and limb dystonia dystonia, and other movement disorders, such as hemifacial spasm, tics, tremors, palatal myoclonus, and even restless legs syndrome, BoNT is increasingly used in a variety of cosmetic, painful, gastrointenstinal, urological, and autonomic disorders (**Table 3**).

Braak Classification

K Del Tredici and H Braak, University of Ulm, Ulm, Germany

Introduction

In the clinically recognizable phase of sporadic (idiopathic) Parkinson's disease (PD), patients present with a combination of motor dysfunction signs, such as bradykinesia or hypokinesia, cogwheel rigidity, resting tremor, and postural instability. However, the same clinical phenotype can appear as 'parkinsonism' in other disorders associated with dopamine depletion of the nigrostriatal system. Familial forms of parkinsonism also exist, and the syndrome may result following head trauma, infection, or intoxication. In addition, it may develop as a result of metabolic disease, normal pressure hydrocephalus, or cerebrovascular disease. Finally, parkinsonism accompanies neurodegenerative protein misfolding-related disorders known as 'tauopathies' and 'synucleinopathies.'

For this reason, and because there are currently no biomarkers for the synucleinopathy sporadic PD, an accurate differential diagnosis is difficult and autopsy-based neuropathological assessment is necessary not only to confirm the clinical diagnosis but also to detect the potentially presymptomatic individuals in the broader population at large. To date, the intraneuronal aggregated filamentous inclusion bodies that are the morphological hallmarks of sporadic PD, α-synuclein-immunopositive Lewy neurites (LNs) in axons, and Lewy bodies (LBs) in the somata of host nerve cells are not known to affect the nervous systems of nonhuman vertebrates or to involve organ systems apart from the nervous system.

Vulnerable nerve cell types cannot be distinguished from those that resist the pathological process with respect to neurotransmitter type and functional systems (see **Figure 1**), but all of the neurons that become involved belong to the class of projection neurons. Additionally, the presence of the presynaptic neuronal protein α-synuclein of the somal lipofuscin pigment or neuromelanin granules (see next section below), and a disproportionately long and thin-caliber axon that is sparingly myelinated or unmyelinated appear to be among the prerequisites for the formation of the misfolded and abnormally aggregated α-synuclein (Lewy pathology). All the intrinsic and extrinsic factors that contribute to the induction and maintenance of α-synuclein misfolding and aggregation are presently unknown.

Axons and neurons that contain aggregated α-synuclein can survive for years. For this as well as other reasons, it is hotly debated whether LNs and LBs cause premature neuronal death, and whether they contribute to nerve cell dysfunction or loss at all. Some argue or postulate that LBs are neuroprotective. Neuronal survival, however, is *not* synonymous with *functional integrity*, and there are indications that inclusion-bearing neurons do forfeit some of their functional capacities (e.g., reduced synthesis of tyrosine hydroxylase, loss of dendritic spines) long before cell death occurs. It is also reasonable to surmise that beyond a certain threshold the intraneuronal inclusions ultimately become detrimental to the host neuron's and organism's health.

Sensory centers	Olfactory: early and severe involvement Nociceptive: early involvement Somatosensory: mostly intact Viscerosensory: mostly intact Auditory and visual: mostly intact
Motor centers	Visceromotor: early and severe involvement Somatomotor: partial involvement Limbic: severe involvement
Stage 1	Anterior olfactory nucleus Olfactory bulb, olfactory tract Dorsal motor nucleus of the vagal nerve Intermediate reticular zone
Stage 2	[plexuses of Meissner and Auerbach] Lower raphe nuclei Magnocellular reticular nuclei Coeruleus–subcoeruleus complex
Stage 3	[spinal cord lamina I] Central subnucleus of the amygdala Olfactory tubercle, piriform cortex (olfactory system) Periamygdalear cortex (olfactory system) Medial entorhinal region (olfactory system) Substantia nigra, pars compacta Edinger Westphal nucleus Upper raphe nuclei Tuberomamillary nucleus of the hypothalamus Magnocellular basal forebrain nuclei Tegmental pedunculopontine nucleus
Stage 4	Interstitial nucleus of the terminal stria Cortical and basolateral amygdala Thalamic intralaminar nuclei Thalamic midline nuclei Anteromedial temporal mesocortex Ammon's horn, second sector (CA2) Insular and subgenual cortex Anterior cingulate cortex Claustrum
Stage 5	High-order sensory association neocortex Prefrontal neocortex Entorhinal region, CA1 and CA3 sectors
Stage 6	First-order sensory association neocortex Premotor neocortex Primary sensory areas Primary motor field

Figure 1 A distinctive topographic or temporospatial distribution pattern of Lewy pathology as well as nonrandom neuronal dysfunction and, at some sites, neuronal loss characterize sporadic Parkinson's disease (PD). Sensory components of the human nervous system remain uninvolved or, for the most part, intact, with the exception of olfactory structures and portions of the pain system. The most disease-related damage revolves around motor areas: particularly around superordinate centers of the limbic and visceromotor systems as well as portions of the somatomotor system. Terms in brackets [ ] indicate extracerebral structures where Lewy pathology occurs and the earliest Braak stages *to date* at which the lesions are seen in relation to brain stages. CA, cornu ammonis (hippocampal formation).

The presence of lesions associated with other proteinopathies does not appear to diminish the pathological influence of LNs and LBs in sporadic PD. In fact, there is some evidence for a facilitatory or synergistic effect between Alzheimer-related lesions of the neurofibrillary type and abnormal α-synuclein fibrillization.

Neuropathological Staging

Neuropathological staging is based on the topographic extent of the Lewy pathology, neuroanatomical connectivities between involved sites, and neuronal loss in specific nuclei.

Lewy pathology in immunoreactions against α-synuclein appears as spindle-shaped or thread-like LNs within neuronal processes and, in the somata of vulnerable projection neurons, as punctate (particulate) aggregations, faintly contoured pale bodies, and globular LBs. Voluminous LNs/LBs can be visualized in 6–30 μm paraffin sections stained for general overview with hematoxilin-eosin or in unconventionally thick (≥100 μm) polyethylene glycol-embedded sections with an advanced silver technique. Prior to the era of α-synuclein immunocytochemistry, the punctate aggregations, very thin LNs and smaller LBs could be most effectively visualized using immunoreactions against the heat shock protein ubiquitin.

Deposits of lipofuscin pigment occur in the somata of most nerve cell types in the human adult and are more difficult for macrophages or astrocytes to degrade than LBs and LNs. Structurally, lipofuscin and neuromelanin are so stable that they survive delayed or suboptimal fixation unchanged. It is precisely this asset that can be exploited to assess neuronal loss. Special histochemical techniques stain deposits of neuronal lipofuscin pigment more prominently than granules of the same type in glial or nonneuroectodermal cells. Such aldehyde fuchsin-Darrow red staining enables the viewer to visualize the breakdown of nerve cells in the form of extraneuronal lipofuscin pigment remnants, a phenomenon sometimes termed 'pigment incontinence.' In the adult human brain, neuromelanin is an oxidative byproduct of the biosynthesis of catecholamines and, thus, we utilize it as a marker for catecholamine-synthesizing nerve cells (**Figure 2**). Because neuromelanin can be specifically labeled and its natural brown color is recognizable even in unstained tissue sections, it is easy to diagnose the degradation of all the melanized nerve cell types. Phagocytosing cells take up the neuromelanin granules and stay in place for long periods of time, thereby, marking the sites of lost melanized neurons (**Figure 2(e)**).

In the brain, the distinctive temporospatial distribution pattern of the lesions is despite exceptions, more or less symmetrical and remarkably consistent across cases, thereby permitting the recognition of six neuropathological stages. Staging systems are imperfect because they are artificial constructs requiring validation and revision – ideally within the context of findings from large prospective (longitudinal) autopsy-controlled studies, which include cohorts of 'healthy normals' (controls). The staging systems by Braak et al. and Saito et al. are based on retrospective cross-sectional studies performed on series of nonselected autopsy cases using immunocytochemical and semiquantitative methods. The earlier of the two staging systems proposes assigning symptomatic cases (i.e., individuals with clinically diagnosed PD) to one of four subgroups that differs with respect to the temporospatial distribution of Lewy pathology in the brain. In other words, each subgroup displays additionally involved brain regions together with the lesions at previously involved sites.

Sporadic PD does not develop overnight and, as such, the presymptomatic phase continues to occupy a focal position with respect to the pathogenesis of the disorder. At autopsy, ~5–20% of nonsymptomatic individuals above the age of 60 display mild (incidental) lesions in portions of the nervous system known to be susceptible to PD. In the Braak staging system, such cases were also subdivided into three subgroups using temporospatial criteria. An essentially caudorostral trajectory of the pathological process was observed in the brain (i.e., it probably begins in the lower brainstem and ascends until it reaches the cerebral cortex). Taken together, it was proposed that all six subgroups may reproduce the progressive nature of the disorder. Both sets of subgroups combined may reflect the spectrum of the larger pathological process (presymptomatic or preclinical versus symptomatic or clinical phase) that underlies sporadic PD.

The term 'presymptomatic phase' implies that incidental Lewy pathology in persons without classical motor symptoms is, neuropathologically speaking, equivalent to the incipient PD and the forerunner of the symptomatic phase. The pathological process underlying both the presymptomatic and symptomatic (motor) phases is marked by the presence of the same types of α-synuclein-immunoreactive inclusion bodies in the same susceptible neuronal types in specific regions of not only the brain but also of the peripheral and enteric nervous systems.

It is the topographic distribution and extent of the Lewy pathology *via interconnected anatomical fiber tracts* as well as neuronal dysfunction/loss at specific sites that provide the basis for the Braak classification (staging system). No remarkable nerve cell loss takes place in the earliest stages, but whether mild neuronal loss is negligible or proves functionally deleterious may well depend on comorbidities, neuronal reserve, and the nerve cell types involved. A nonrandom loss of nerve cells probably impairs function, whereas comparable but random neuronal loss may be less likely to do so.

Stage 1: Medullary Autonomic Region and Anterior Olfactory Structures

LNs in the brain are seen in preganglionic cholinergic projection neurons of the dorsal motor nucleus of the vagal nerve, sometimes together with Lewy pathology in the intermediate reticulate zone of the lower medulla, olfactory bulb, anterior olfactory nucleus, and olfactory tract. Cases with incidental Lewy pathology confined to the olfactory bulb and/or anterior olfactory nucleus ('olfactory only' cases) in the absence of medullary and/or nigral Lewy pathology also exist (unpublished findings). From stage 3 onwards, additional olfactory structures (piriform cortex, periamygdalar cortex, medial entorhinal region) become involved. Lewy pathology has not been found in the olfactory epithelium; however,

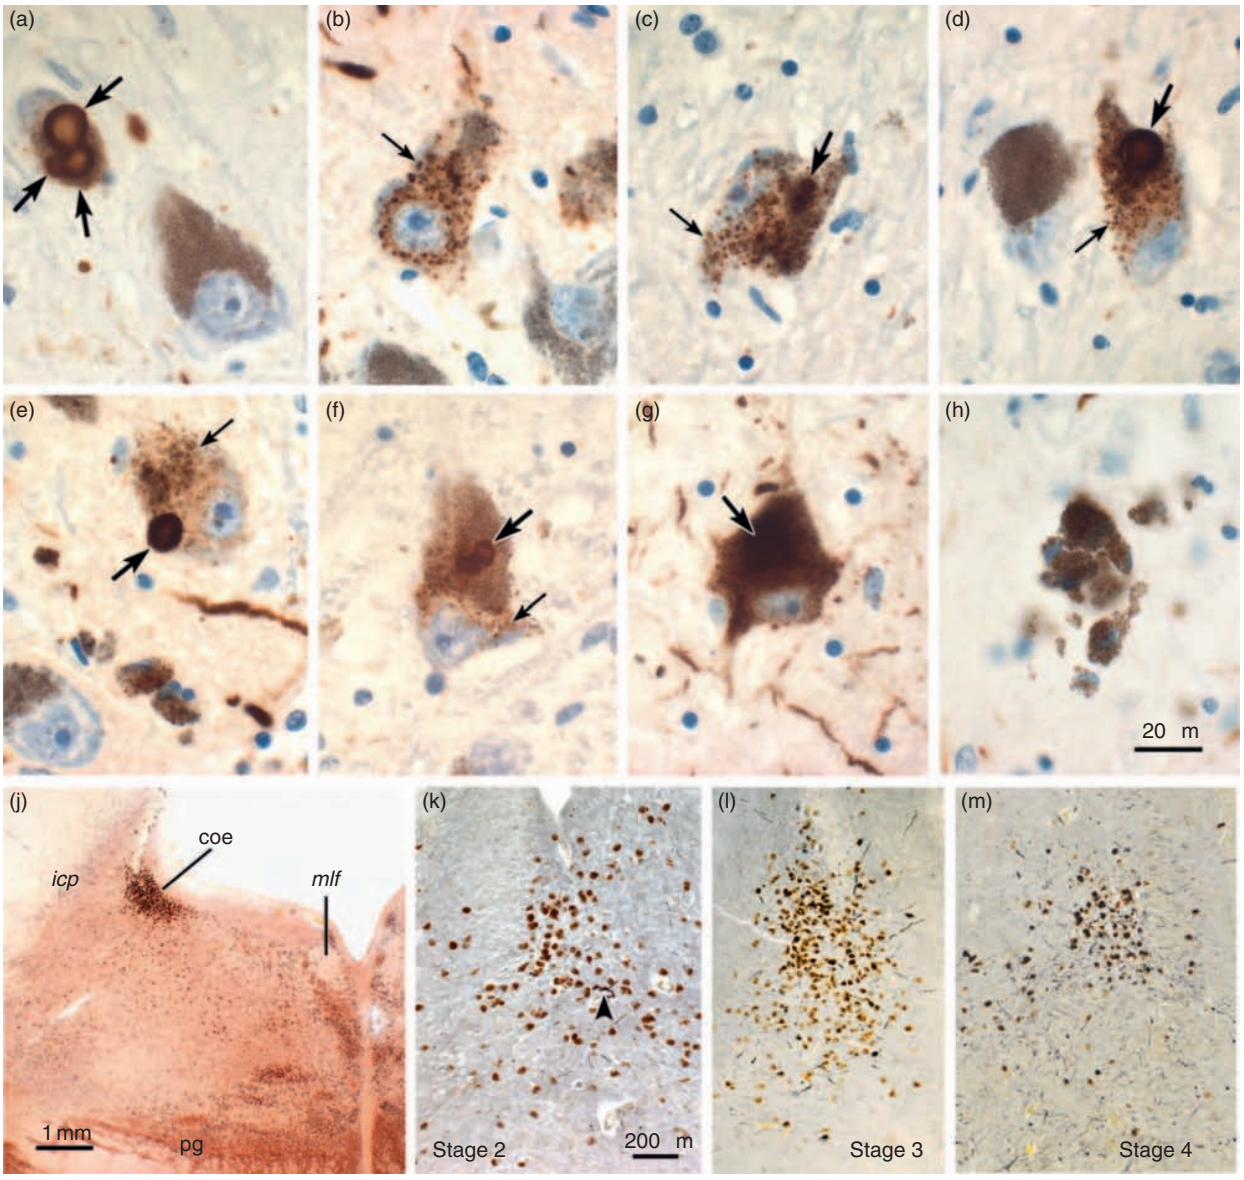

Figure 2 Lewy bodies (LBs) in especially vulnerable melanized (noradrenergic, dopaminergic) projection neurons of the pontine and midbrain tegmentum in sporadic PD. (a)–(h) Micrographs showing dopaminergic nerve cells in the substantia nigra and pars compacta. (a) Multiple mature LBs (arrows) fill a large proportion of the cell body. The adjacent melanized nerve cell is healthy. (b)–(f) Aggregated punctate, that is, particulate, α-synuclein (small arrows) appears to organize into LBs (large arrows). (d) Compare the normal melanized neuron, without α-synuclein particles, with the melanized nerve cell at the right. (e). Two smaller astrocytes (below, directly in the middle) have ingested α-synuclein immunoreactive abnormal material together with neuromelanin. The terms 'extraneuronal' neuromelanin or 'pigment incontinence' apply to such material. (g) In this micrograph, it is difficult to distinguish the LB (arrow) from the immediately surrounding and densely packed particulate α-synuclein. (h) Following cell death, a group of macrophages containing neuromelanin granules and immunoreactive LB remnants mark the shape and site of the former nerve cell. Such 'extraneuronal' LBs are no longer surrounded by a neuronal cell body with a nucleus. They remain visible in the tissue (neuropil), similar to ghost tangles in Alzheimer's disease, but they are more rapidly degraded by macrophages than extraneuronal neurofibrillary tangles. α-Synuclein immunoreactions (Syn-1, BD Bioscience Laboratories, Mountain View, CA, USA) in conventional 6 μm paraffin sections. Scale bar in (h) is valid for (a)–(g). (j) Overview of transverse section through the pontine tegmentum, including the coeruleus–subcoeruleus complex of the level setting system, from a control case. Staining for topographic orientation, lipofuscin pigment, and Nissl material (aldehyde fuchsin-Darrow red) in unconventionally thick 100 μm polyethylene glycol-embedded sections. (k–m) Lewy pathology (arrowhead in (k) indicates a Lewy neurite) without neuronal loss develops in the locus coeruleus during stage 2. The lesions there subsequently worsen (l) accompanied by clear signs of loss of melanized (catecholeminergic) neurons (l, m). α-Synuclein immunoreactions (Syn-1, BD Bioscience Laboratories, Mountain View, CA, USA) in unconventionally thick 100 μm polyethylene glycol-embedded sections. Scale bar in (k) also applies to (l, m). Abbreviations: Coe, coeruleus–subcoerules complex; *icp*, inferior cerebellar peduncle; *mlf*, medial longitudinal fascicle; pg, pontine gray.

the gradient of the olfactory pathology appears to be from more peripherally placed structures (bulbopetal) in the olfactory bulb to the anterior olfactory nucleus and cortical olfactory structures rather than vice versa. The discussion regarding the olfactory vector hypothesis of sporadic PD is still unresolved.

Other components of the medullary autonomic dorsal vagal area (area postrema, gelatinosus nucleus, nuclei of the solitary tract, myelinated motor neurons of the ambiguus nucleus) remain uninvolved. Notably, the catecholaminergic melanized nerve cells (A2 group) in the dorsal vagal area and intermediate reticulate zone (A1 group) are not drawn into the disease process until stage 3.

Stage 2: Level Setting Nuclei of the Lower Brainstem and Pontine Tegmentum

The term 'level setting' (or 'gain setting') system is not widely known in Anglo-American anatomical usage. It encompasses three groups of nuclei: the serotonergic lower raphe nuclei, the magnocellular portions of the adjoining reticular formation, and the noradrenergic coeruleus/subcoeruleus complex (A6, A7 catecholaminergic groups). All three groups are driven by supramedullary centers of the limbic (central subnucleus of the amygdala) and somatomotor (tegmental pedunculopontine nucleus (PPN)) systems. An intact level setting system temporarily inhibits relay nuclei for the conduction of incoming pain signals (somatosensory and viscerosensory) and places the organism's voluntary motor neurons in a heightened state of preparedness in fight-or-flight situations. Normally, the target neurons of these limbic system-moderated level setting nuclei are capable of switching back and forth from a lower to a higher level of activity, and the individual's emotional status determines the appropriate level in any given situation. An intact limbic system is necessary for the maintenance of this adaptive behavior. In the course of PD, patients can experience a dissociation between the voluntary and emotional motor systems.

Stage 2 cases are marked by the presence of Lewy pathology within the cell somata and thinly myelinated axons of the level setting nuclei (**Figure 2(k)–2(m)**). The observation that all of these nuclei, and only these, become involved at stage 2 is consistent with the concept that retrograde axonal and transneuronal transport via anatomical pathways may play an important role in the pathogenesis of sporadic PD.

During the first two neuropathological stages, Lewy pathology routinely occurs in olfactory areas, portions of the lower brainstem, and in lamina I of the spinal cord. Also involved at these early stages are the Auerbach and Meissner plexuses of the enteric (gut) nervous system as well as sympathetic portions of the peripheral nervous system (cardiac nerves, vesicoprostatic plexus). Thus, the pathological process in sporadic PD does not appear to have the substantia nigra as its point of departure. On the contrary, nigral involvement presupposes the existence of Lewy pathology in the lower brainstem and, possibly, in the spinal cord and peripheral nervous system (**Figure 1**).

Stage 3: Nuclear Complex of the Amygdala, Midbrain Tegmentum, Nonthalamic Diffusely Projecting Nuclei, Basal Forebrain, and Cortical Olfactory Structures

Stage 3 cases are characterized by the presence of Lewy pathology in the central subnucleus of the amygdala followed by involvement of the pedunculopontine tegmental nucleus, the pars compacta (A9 catecholaminergic group) of the substantia nigra, and nonthalamic nuclei that project extensively to the cerebellum, subcortical sites, and cerebral cortex. Among the diffusely projecting nonthalamic nuclei that become involved during this stage are the upper raphe (serotonergic) nuclei, the magnocellular (cholinergic) nuclei of the basal forebrain (medial septal nucleus, interstitial nucleus of the diagonal band, basal nucleus of Meynert), the hypothalamic tuberomamillary nucleus with its GABAergic and histaminergic neurons as well as the paranigral and parabrachial pigmented nuclei with their dopaminergic neurons (A10 group) (**Figure 1**). In stage 3, Lewy pathology also appears in the catecholaminergic melanized neurons of the dorsal vagal area (A2 group), intermediate reticulate zone (A1 group), and in nerve cells (A4 group) close to the roof of the fourth ventricle that form the cerebellar portion of the coeruleus nucleus.

The central subnucleus of the amygdala regulates all nonthalamic nuclei with diffuse cortical and subcortical projections. It also exercises limbic influence on subcortical nuclei that regulate autonomic and endocrine functions. From the central subnucleus, the pathological process progresses into the basolateral (mainly basal and accessory) subnuclei of the amygdala in stage 4. The central subnucleus sends thinly myelinated descending projections not only to the level setting nuclei but also to the dorsal motor nucleus of the vagal nerve, and it receives afferents from the substantia nigra and basolateral complex of the amygdala. The latter group has reciprocal connectivities with the hippocampal formation and is fed by afferent projections arriving from the magnocellular nuclei of the basal forebrain and from the temporal mesocortex.

The PPN consists of cholinergic and GABAergic as well as glutamatergic neurons. LNs occur within the nucleus followed by LBs in the somata of its cholinergic projection neurons that connect the PPN with the substantia nigra, subthalamic nucleus, thalamic intralaminar nuclei, and the previously mentioned nonthalamic nuclei with diffuse cortical, cerebellar, and subcortical projections. The PPN probably channels the pathological process into the striatal circuit. Together with the level

setting nuclei, the PPN also belongs to a rhythmogenic complex that initiates and modulates oscillatory patterns of activity, including those of the sleep-waking cycle and states of consciousness (arousal, vigilance, attention).

Macroscopically, the pars compacta of the substantia nigra in stage 3 cases appears to be intact. Thinning and obliteration of melanized neurons set during stage 4 and then persist (**Figure 2(h)**). Stage 3 is marked by the appearance of LNs in the posterolateral subnucleus of the substantia nigra, pars compacta, and by LBs in the dopaminergic melanized neurons there (A9 group) (**Figure 2(a)–2(g)**). By contrast, the nonmelanized projection neurons in the pars reticulata do not become involved in the disease process. Approximately, 450 000 dopaminergic melanized neurons populate the pars compacta in each half of the midbrain and, apparently, a mild loss of these cells accompanies aging. Thus, once the pathological process enters the substantia nigra, a cascade of events presumably follows which accelerates the decline and loss of involved nigral cells. Among the possible factors contributing to portions of the nigra's increased susceptibility are neuromelanin, high iron content, proteasomal dysfunction, free radical formation, and inflammation. In addition, each individual is different. In some, the nigral destruction is fulminant and massive, in others prolonged and milder.

The paranigral nucleus and pigmented parabrachial nucleus display less pronounced pathology than the substantia nigra, whereas the perirubral subnucleus and other dopaminergic neurons of the mesencephalic central gray contain little or no Lewy pathology. To date, no truly plausible explanation exists for the resistance on the part of these dopaminergic neurons.

In addition to the lesions that develop during this stage in many of the nonthalamic nuclei (including those not described here in greater detail), the presence of Lewy pathology within the piriform cortex, periamygdalear cortex, and medial entorhinal region provides evidence that the disease process within the olfactory system is also progressive (**Figure 1**).

Stage 4: Thalamic Midline and Intralaminar Nuclei, Mesocortex, Allocortex

Retrospective study of available clinical records revealed that the clinical course of sporadic PD is subject to considerable interindividual variation with respect to symptoms and severity. Because PD-related motor symptoms were mentioned in the clinical records of some stage 3 individuals and in the majority of those with stage 4 brain pathology, we interpreted these remarks as an indication that the presymptomatic phase may yield to the clinically recognizable phase of the disorder at approximately this time.

From stage 4 onwards, Lewy pathology appears in vulnerable regions of the thalamus, including the glutamatergic neurons of the midline and intralaminar nuclei (**Figure 1**). Notably, the intralaminar nuclei send poorly myelinated diffuse projections to layers I and VI of the neocortex.

The pathological process also progresses during this stage into the cerebral cortex, and its point of entry is the anteromedial temporal mesocortex. The mesocortex creates an interface between the sensory neocortex and centers of the limbic system, including the entorhinal region, hippocampal formation, and amygdala. All vital information passing from neocortical high-order sensory association areas to the prefrontal cortex does so via the temporal mesocortex. LNs can be seen there in cortical layers II and III, whereas LBs occur predominantly in layers V and VI. In the adjacent allocortex, LBs appear in the entorhinal region and LNs in the second sector of the Ammon's horn (CA2 of the hippocampal formation).

Stages 5 and 6: Neocortex

During these last two neuropathological stages, the disease process reaches its widest topographic extent. In the locus coeruleus and in susceptible subnuclei of the substantia nigra, the loss of melanized neurons is recognizable upon macroscopic inspection. Lewy pathology within the Ammon's horn expands into the adjoining CA1 and CA3 sectors. The temporal mesocortex and CA2 sector are among the most severely involved regions in the cerebral cortex.

In stage 5, the temporal mesocortex is the point of departure from which the pathological process goes on to occupy portions of the adjoining mature neocortex, beginning with expansive high-order sensory association and prefrontal areas. At this point, the primary sensory and motor fields as well as the first-order sensory association fields of the neocortex are intact. During stage 6, the lesions progress from the high-order sensory association and prefrontal areas into the neocortical first-order sensory association areas and premotor fields. Mild Lewy pathology is also observable in the primary sensory and motor fields.

Summary Remarks

The pathological process associated with sporadic PD is progressive, does not go into remission, and can last for decades. The definition of sporadic PD as a monosystemic disorder with preferential obliteration of dopaminergic neurons in the nigrostriatal system has been recognized as inadequate because it is too narrow. The pathology is widely distributed throughout parts of the entire nervous system, including the spinal cord, peripheral, and enteric nervous systems as early as stage 2.

It is still unclear why the formation of LNs precedes, as a general rule, the appearance of LBs. Since, in its native state, α-synuclein is localized mainly in presynaptic terminals, one would expect to see the earliest aggregations

there. Nevertheless, the earliest light microscopically detectable accumulations begin proximal to the synaptic terminals, that is, in the axon (**Figure 3**). The aggregations fill extensive portions of the axon, leaving only the presynaptic terminals and the initial axon segment free. Terminal axons of corticostriatal and corticothalamic projections appearing as α-synuclein-immunoreactive 'dots' may be exceptions. It remains to be seen whether the abnormal intraaxonal aggregations are transported retrogradely to the cell soma and, there, contribute to the formation of LBs.

The assumption that the pathological process underlying sporadic PD may not begin (or progress) simultaneously in all susceptible regions of the nervous system (olfactory, peripheral autonomic, sympathetic, or parasympathetic nervous systems) but advances in a uniform sequence from predisposed initiation sites still has to be proved, as does the assumption that Lewy pathology in sporadic PD is pathogenic. Nevertheless, in the brain, the process follows an essentially caudorostral trajectory along the neuraxis and progresses from the lower brainstem through

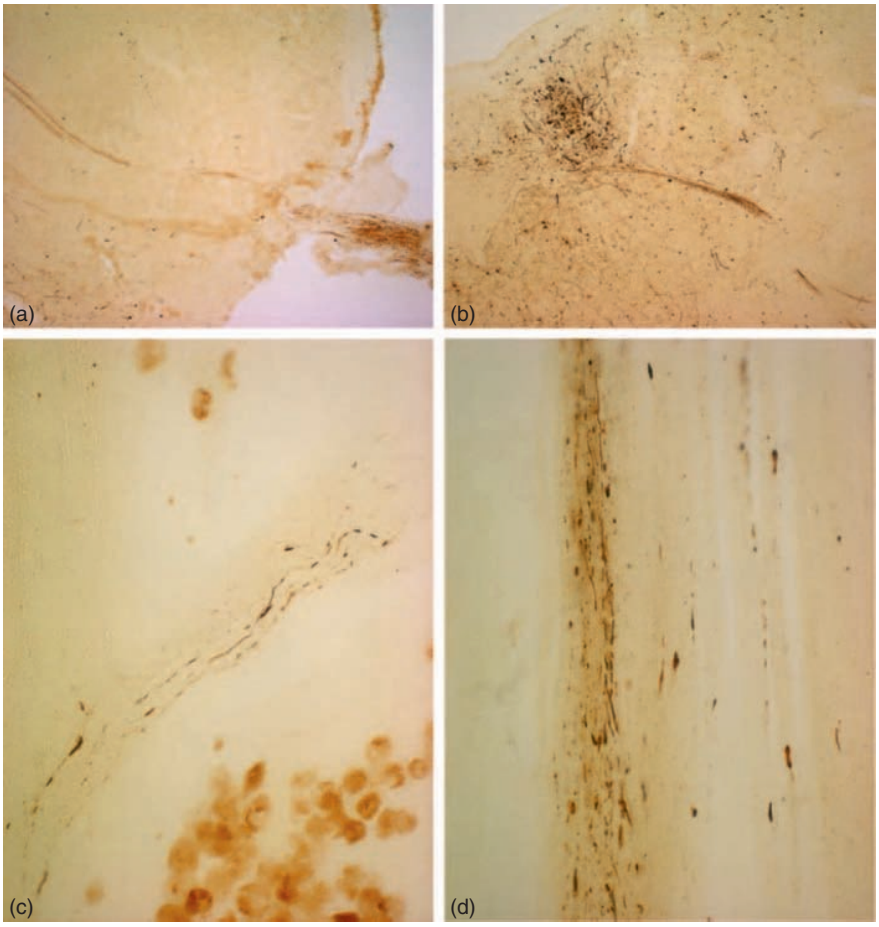

Figure 3 Lewy pathology in the medulla oblongata and peripheral vagus nerve in sporadic PD visualized with α-synuclein immunoreactions (Syn-1, BD Bioscience Laboratories, Mountain View, CA, USA) in unconventionally thick 100 μm polyethylene glycol-embedded sections. (a) Overview of transverse section through the medulla oblongata (intermediate reticular zone) from a 61-year-old male (Hoehn and Yahr stage V, neuropathological stage 5). Note the immunopositive axons (upper left) of the intramedullary vagal nerve and also at the point where they exit the brainstem (lower right). (b, c) Micrographs of a 71-year-old female (Hoehn and Yahr stage V, neuropathological stage 6). (b) Overview of transverse section showing Lewy neurites and LBs in the dorsal motor vagal nucleus (upper left) and in axons of the vagal nerve (lower right). (c) Detail of LNs (intraaxonal Lewy pathology) from a segment of the left peripheral vagus nerve in the mediastinum at the level of the first thoracic vertebra. Fatty tissue appears at the lower right. α-Synuclein aggregations and the extent to which they occur in the peripheral vagus nerve in sporadic PD have not been studied until now because full-body autopsy is not part of the standard routine in neuropathology departments. (d) Detail at higher magnification from another part of the same peripheral nerve. In all probability, such LNs, which in this case were seen in vagal axonal fibers extending from the larynx to the aortic arch, eventually disrupt somatopetal/somatofugal transport and, in doing so, impair the functional capacities of involved nerve cells. Impairment of axonal transport also may induce abnormally high concentrations of α-synuclein within the soma and possibly trigger LB formation within the host neuron.

basal portions of the mid and forebrain until the cerebral cortex becomes involved (**Figure 1**). More caudally located structures are involved early. This trajectory has been confirmed in its essential correctness by independent laboratories. Whereas the Braak staging results originally achieved 88% convergence, other groups have convergence rates between 60% and 94% and include at least one very large prospective study (Honolulu Asia Aging Study). A variable number of cases are not stageable using the systems proposed by Braak et al. or Saito et al. Such individuals often have more than one neurodegenerative disease, for example, Alzheimer-related lesions plus amygdala-predominant Lewy pathology.

The existence of cases with brainstem Lewy pathology in the locus coeruleus but not in the cholinergic neurons of the medullary dorsal motor nucleus of the vagal nerve or in the pigmented neurons of the dorsal vagal area is not incompatible with the proposed caudorostral trajectory, namely, that selectively vulnerable lower brainstem pigmented nerve cells, as well as olfactory structures may become involved prior to the substantia nigra. The caudorostral progression in the lower brainstem does not achieve machine-like precision, but there is also no evidence to indicate that the pathological process begins in all susceptible brain regions at once or that it progresses according to a hit-or-miss principle. It is still open, however, whether the beginnings of the pathological process are mono or multicentric (i.e., brain and spinal cord, brain, and peripheral nervous system), and very large autopsy-controlled prospective studies including healthy 'normals' are required to answer this question.

Presently, much attention is being focused on reversing the impaired somatomotor functions that result from the destruction of nigral dopaminergic nerve cells. However, transplantation of fetal midbrain cells into the putamen of levodopa-refractory patients is fraught with the risk of developing new lesions and does not alleviate nerve cell dysfunction, neuronal loss, or dysfunctional motor neuron responsiveness in other parts of the nervous system as a whole (e.g., limbic system-moderated level setting nuclei, gastrointestinal tract). In addition to the continuing search for biomarkers that can identify individuals who are in the presymptomatic phase of sporadic PD, strategies are needed that can prevent the protein α-synuclein from misfolding or hindering the pathological process from reaching the substantia nigra.

Bradykinesia

R Simões and I Litvan, Hospital Fernando Fonseca, Amadora, Portugal; University of Louisville School of Medicine, Louisville, KY, USA

Glossary

Basal ganglia (BG) – Group of nuclei encompassing the striatum (which includes the caudate, putamen, and accumbens nuclei), globus pallidus, substantia nigra, and subthalamic nucleus that control motor and nonmotor functions through the thalamocortical projections.
Festination – Sudden shortening of stride and quickening of gait usually observed in Parkinson's disease.
Freezing – Sudden loss of mobility usually in initiation of gait or triggered by turning, obstacles and multitasking.
Hypomimia – Reduced facial expression.
Hypophonia – Reduced vocal loudness.
Micrographia – Smaller handwriting, usually characterized by decremental size and speed.
Sialorrhea – Decreased ability to control oral secretion, leading to pooling of saliva and eventually drooling.
UPDRS – Unified Parkinson's disease rating scale, scale used to evaluate the severity of motor symptoms and signs in this disease.

Summary

Bradykinesia is usually used as a broad term to include three different phenomena: slowness (bradykinesia), low amplitude (hypokinesia), and difficulty in initiating movements (akinesia). Although clinical dissociation exists, their differentiation is at present of uncertain value. The common underlying mechanism is basal ganglia (BG) hypofunction interfering with selection and performance of motor programs. The most common and paradigmatic etiology is parkinsonism. Automatic and voluntary movements, including facial expression, handwriting, speech, and gait, are affected. Repetitive and rapid maneuvers of isolated limbs, rising from a chair and gait characteristics, are helpful in clinical practice. Differential diagnosis includes paralysis, fatigue, depression, apraxia, ageing, abulia, and catatonia. Treatment is dependent on the physiopathology and topography of the dysfunction and includes sensory rehabilitation strategies and dopaminergic stimulation when there is an underlying dopaminergic deficit.

Introduction

Bradykinesia is defined as slowness of movements, as stressed by its two Greek roots (*brady* = low; *kinesis* = movement). Frequently the terms bradykinesia, hypokinesia, and akinesia are used interchangeably but their meaning differs. Bradykinesia refers to the decreased velocity with which a movement is performed, while hypokinesia refers to the decreased amplitude of the movement and akinesia means the inability or difficulty to initiate the movement. Although these phenomena are usually related and may coexist, at present there is not enough evidence to support that the differentiation is of value in clinical practice.

Etiology

There are multiple possible etiologies for bradykinesia. In fact, it can occur in both hypokinetic and hyperkinetic syndromes. Bradykinesia, in the broad sense, is a cardinal feature of parkinsonism, the hallmark of BG hypofunction. Parkinsonism is defined by the presence of two of the following features: bradykinesia, rigidity, rest tremor and postural instability, and the paradigm is Parkinson's disease (PD). Bradykinesia, in the strict sense, usually coexists with hypokinesia and akinesia in parkinsonian disorders. Akinesia and bradykinesia can be particularly significant in some of the parkinsonian disorders such as progressive supranuclear palsy and corticobasal degeneration. However, bradykinesia may occur dissociately from the other phenomena in hyperkinetic movement disorders such as Huntington's disease (HD) and dystonia. Also, pure akinetic syndromes, such as pure akinesia and freezing of gait, exist. Other disorders presenting with akinesia include frontal lobe disorders and schizophrenia.

Physiopathology

Physiopathological mechanisms leading to bradykinesia, hypokinesia, and akinesia are not yet clearly defined. The common underlying mechanism is the disruption of the BG circuits. The BG is a complex functional-anatomic unit that has two main output pathways (direct and indirect pathways). Along with the thalamus and cortex, the BG forms multiple segregated, parallel, and reentrant circuits controlling motor and nonmotor behaviors. The motor circuit has an important role in selecting and reinforcing appropriate patterns of cortical activity during the

preparation and execution of motor programs. This role is critically modulated by striatonigral dopaminergic projections. Deficiency of striatal dopaminergic transmission leads to hypoactivity of the direct pathway with increase in the inhibitory output of the thalamus and consequent decreased activation of motor cortex. This inhibition is responsible for underscaled recruitment and later modulation of motor units in the spinal cord, leading to undershooting and slowness of movements. However, the clinical dissociation between bradykinesia and hypokinesia in different clinical disorders suggests that these two phenomena have different underlying pathological mechanisms involving different subcircuits. For example, in early HD, which is characterized by preferential involvement of GABAergic neurons in the indirect pathway with intact dopaminergic projections, presents with chorea and bradykinesia, but not hypokinesia. In contrast, in PD, the characteristic striatonigral dopaminergic dysfunction that affects different thalamocortical pathways leads to bradykinesia, hypokinesia, and akinesia, and other additional cardinal features of parkinsonism. An alternative hypothesis is that hypokinesia may be a direct consequence of rigidity, and this concept would explain why it is not dissociated from other parkinsonian cardinal features. Akinesia on the other hand, might result from impairment of the motor subcircuits that connect with preparatory areas such as the supplementary and mesial cortical motor areas. These subcircuits provide an internally generated cue that triggers a previously learned motor task, allowing the switch between different movements. When impaired, akinesia ensues, as motor function becomes more dependent on external cueing to be triggered. Besides the contribution of BG dysfunction to akinesia, involvement of other structures such as the pedunculopontine nuclei may also probably play a role.

Clinical Manifestations

Individual description of the different clinical expressions of bradykinesia, hypokinesia, and akinesia, although of uncertain clinical value, is an interesting exercise and might prove helpful in future research assessing this theme. **Table 1** shows a simplistic approach of the possible manifestations of these three phenomena in different motor settings.

A frequent complaint suggesting bradykinesia in parkinsonian patients is the progressive slowness in performing the activities of daily living, such as feeding, dressing, bathing or turning in bed, and in other motor activities such as writing, talking, walking, arising from a car seat or chair or houseworking. On the other hand, hypokinesia manifests as decreased arm swing while walking, lagging one shoulder behind when both shoulders are shrugged and frank reduction in amplitude of limb movements. The decreased arm swinging may be one of the first signs of early PD and consequent shoulder pain, due to secondary joint chances, is in fact one of the most common presentations of this disease. Asymmetric bradykinesia and hypokinesia are typical of PD. Akinesia contributes to the loss of automatic movements. All spontaneous movements and gestures are decreased as evident by patients not moving their hands when speaking, not moving in the chair to relief discomfort, nor crossing or uncrossing their legs.

In parkinsonian patients, the face is expressionless with attenuated wrinkling, also known as hypomimia. This is an expression of hypokinesia. In early stages, it may be referred as 'poker face' as it simulates an apparent lack of emotions, occasionally misinterpreted as depression. In severe stages, might be named 'masked face,' as it becomes completely fixed with the lips apart. Akinesia, shown by decreased automatic movements such as blinking, also contributes to the hypomimic face. Decreased swallowing, another impaired automatic movement, in addition to the hypomimia, leads to pooling of saliva (sialorrhea) and drooling.

Changes in handwriting may be the first reported symptom with parkinsonism starting in the dominant upper extremity. Patients usually report that their handwriting becomes smaller and sometimes unintelligible. This hypokinetic hallmark is named micrographia, and is not only characterized by a smaller letter size, but also

Table 1 Clinical expression of bradykinesia, hypokinesia, and akinesia (simplistic approach)

Feature	*Bradykinesia*	*Hypokinesia*	*Akinesia*
Facial expression		Hypomimia	Decreased blinking
Phonation	↓ verbal debit	Soft, breathy monopitch voice	Eyelid apraxia
Articulation		Imprecise consonants	
Swallowing			Drooling
Associated movements		↓ arm swing	Loss of associated movements
Writing	Slow writing	Micrographia	
Voluntary movements	Slow	↓ amplitude	↑ latency to initiate
Gait	↓ cadence (steps/min)	Small steps (↓ stride)	Hesitation Freezing
Repetitive Movements	↑ cycle duration	↓ amplitude	Difficulty initiating the movement and changing patterns

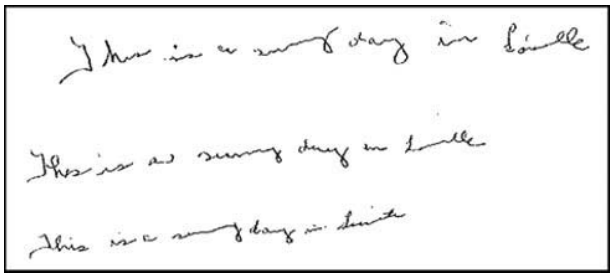

Figure 1 Micrographia. The letters are small and progressively decrease in size, translating the progressive decrease in the amplitude of the movement with repetitive tasks. It is written 'This is a sunny day in Louisville.'

by a progressively decreasing size of the letters as the writing task continues (**Figure 1**). Micrographia is usually associated with slowness and effort in performing this task, which could be phenomenologically described by the neologism 'bradygraphia.' However, the opposite is not always true.

Hypokinesia, contrasting with bradykinesia, has major repercussions in speech. The speech disturbance results from the interaction of multiple factors that include respiratory effort, phonation, and articulation. The decreased amplitude of respiratory movements is at least partially responsible for a soft voice (hypophonia). Phonation may also be impaired by the decreased amplitude of the movements of the vocal cords that leads to glottal incompetence (incomplete adduction) and clinically manifests as breathiness, and decreased variability and low vibration frequencies that explain the monopitch speech. Hypokinesia of the lips, cheek, mandible, and tongue is responsible for the slurred dysarthria with imprecise consonants. The reduction in language flow is a consequence of both bradykinesia and akinesia. Speech disturbances are usually a late feature in PD but can be an early feature of other parkinsonian disorders.

Gait is differently affected by bradykinesia, hypokinesia, and akinesia. Bradykinesia manifests as decreased stride cadence (reduced number of steps per minute), independent of the width or length of the stride. Hypokinesia translates as a decreased stride length (small steps) that is not necessarily slow and in fact can have a normal or compensatory increased cadence. Festination, the increasing speed with progressively shorter steps, is a consequence of hypokinesia that is typical of PD and is not found in other hypokinetic-rigid disorders. The hypokinetic gait can be found in hypokinetic-rigid BG syndromes, usually with coexisting bradykinetic features, and in frontal disorders. The accompanying signs, such as posture and balance, and the distribution of hypokinesia, help to define the etiology. The presence of asymmetric hypokinesia and bradykinesia, a stooped posture and small, slow, narrow-based steps usually suggest PD. In contrast, small slow steps, wider or normal width base, normal or even increased arm swing and less stooped posture, particularly if balance is affected, might indicate atypical parkinsonism, vascular parkinsonism, or normal pressure hydrocephalus.

Freezing or motor blocks are a hallmark of akinesia. Freezing can occur in any motor task, but its major expression is in gait, usually occurring when initiating the gait (start hesitation), turning or approaching an obstacle, or trying to undertake multiple tasks simultaneously. Freezing is a major cause of falls in parkinsonian syndromes.

To assess bradykinesia, hypokinesia, and akinesia, patients are asked to perform rapid and repetitive movements such as finger tapping, fist opening and closing, alternate supination–pronation of the hands and forearms and heel or toe tapping. With these manoeuvers, bradykinesia and hypokinesia can be dissociated. In bradykinesia is evident, with very slow movements of normal amplitude. In the movements are of short amplitude but fast, reflecting hypokinesia without bradykinesia. Decremental amplitude and arrest in ongoing movement characterizes the hypokinesia and akinesia of BG disorders. The unified Parkinson's disease rating scale (UPDRS) is the most common rating scale used to assess these three phenomena in this disorder and includes performance of repetitive tasks with each limb, getting up from a chair and walking. These tasks should be performed individually by each limb, as identical manual tasks facilitate the movement of the most affected side and deteriorates the least affected one. In this scale, bradykinesia, hypokinesia, and akinesia are not rated separately and the score in each individual task does not allow evaluating individualized contributions to the disability.

Differential Diagnosis

Bradykinesia, hypokinesia, and akinesia in movement disorders are specifically related to impairment of the BG and related frontal circuits. Muscle strength is preserved and access to motor programs can be delayed but is possible, making these phenomena distinct from paralysis/weakness or apraxia. The term motor arrest, that in this context is a manifestation of akinesia when intending to initiate or when performing a motor task, should not be confounded with some forms of frontal epilepsy in that the motor arrest is paroxysmal, generalized, independent of a motor task, and usually associated to unconsciousness. Special forms of akinesia, such as catatonia and abulia, should also be distinguished. Although slowness and lack of initiative can be features of depression, hypothyroidism and aging, the underlying physiopathological mechanism is different, and the differentiation must be understood from a complete clinical history and examination.

Treatment

Treatment of bradykinesia, hypokinesia, and akinesia depends on the specific etiology and topography of the disorder.

Nonpharmacological strategies include sensory cues that can significantly improve performance and help to overcome and prevent freezing, when the dysfunction relies in the BG. Cues can be visual, such as striped lines on the walkways, and acoustic, such as the regularly paced beats of a metronome. These external cues substitute for the internally generated cues that are deficiently triggered in BG disorders, and theorically mainly affect akinesia. Their effect in hypokinesia and bradykinesia is different, with visual cues preferentially contributing to the enlargement of the stride, and acoustic cues mostly improving speed and step cadence. They are of no help in hypokinetic frontal gait disorders.

Pharmacological and surgical treatments of bradykinesia, hypokinesia, and akinesia are only available for parkinsonism with a predominant dopaminergic dysfunction of the BG, as in PD. The three phenomena are improved by dopaminergic stimulation, including treatment with levodopa or dopamine agonists. Also in PD, bilateral deep brain stimulation of the subthalamic nucleus has been shown to increase motor UPDRS scores. The differential effect of these therapeutic strategies in the different clinical phenomena is difficult to assess as most studies rely on UPDRS motor subscales that do not differentiate between them.

Bradyphrenia

A K Howard, University of British Columbia Hospital, Vancouver, BC, Canada
M Zurowski, University of Toronto, Toronto, ON, Canada

Glossary

Diffusion tensor imaging – MRI-based imaging that assesses the structural integrity of white matter by measuring the rate and directionality of the displacement distribution of water molecules between tissues.

Information processing speed – The amount of time required to complete a cognitive task that also requires the manipulation of acquired knowledge.
Inspection time – The duration of exposure to a stimulus necessary for an individual to make a simple visual discrimination, for example, determine which of the two lines are longer, with near certain accuracy.

Processing speed – The length of time required to complete a cognitive task or the degree of cognitive output completed in a fixed period of time.
Psychomotor retardation – A visible deceleration of thought and movement.
Reaction time – A measure of duration from stimulus to response that can be classified as either simple (press a button when stimulus appears), recognition (press a button when certain stimuli appear, while ignoring others), or choice (press corresponding button when specific stimulus appears).
Response latency – The amount of time taken to respond after a stimulus, such as a question, is presented.
Subcortical dementia – A syndrome often accompanying movement disorders, consisting of but not limited to mental slowing, retrieval memory difficulties, working memory impairment, personality changes such as loss of motivation, affective changes such as depression and apathy, and marked frontal dysfunction such as loss of ability to initiate and sequence tasks.
Thought blocking – A sudden disruption in an individual's stream of thought interfering with its completion.
Working memory – The ability to sustain attention while manipulating acquired knowledge.

Definition

Bradyphrenia represents a pathological slowing in cognition. Synonymous with the historical term's 'psychic akinesia,' it is a highly sensitive although nonspecific indicator of cerebral dysfunction. Operational definitions depend on the measure used and include impairments in processing speed, information processing speed, complex attention, mental speed, reaction time, and inspection time.

Clinically the patient or caregiver endorses the patient's decreased productivity on timed tasks or the need to take longer time periods to complete mental process. Clinicians may observe increased response latency. Processing speed is a multifactorial construct, comprising speed of perception, processing, and response, the exact definition and objective measurement of which are challenging. The most elementary tasks tap multiple domains and are confounded by sensory and motor dysfunction. Consequently, bradyphrenia is best reported in the presence of cognitive slowing out of proportion to that expected from other contributing impairments.

Historical Context

Empirical measurements of processing speed emerged from the interest in individual intellectual differences suggested by evolutionary theory in the mid-nineteenth century. Sir Francis Galton, with subsequent contributions from Wundt, Cattell, Donders, and Burt, studied individuals' reaction times. They accurately hypothesized but failed to demonstrate intelligence correlating with processing speed. When their data were unable to predict students' grades, enthusiasm for the field waned.

In 1882, Ball first noted slowing of perception, movement, and ideas in parkinsonism. Following the encephalitis lethargica pandemic in the 1920s, Naville coined the term 'bradyphrenia,' known as 'bradypsyche' to German authors, to describe slowed intellectual processing in 40% of the patients. A lack of will and other psychological explanations for the psychiatric sequelae of parkinsonism dominated theories for the next 30 years.

The 1960s represented a renewed effort by experimental psychologists to uncover the heritability and neurophysiological underpinnings of the cerebral basis of 'psychic akinesia' as Hassler termed bradyphrenia. In 1964, Steele reported cognitive deficits in a series of patients with progressive supranuclear palsy. Albert later confirmed bradyphrenia in this population. Significant efforts ensued to characterize slowing in other disorders. In 1981, a processing speed index appeared in the Wechsler Adult Intelligence Scale demonstrating the importance of this measure to overall cognitive–intellectual functioning. However, working models of speed and intelligence as well as bedside and lab measures of bradyphrenia remain elusive.

Pathogenesis

Lesions of the medial neuraxis from frontal pole to pons, specifically the mesocortical pathway and reticular formation, were postulated as the injury site for psychic akinesia in the 1960s. However, no single brain lesion causes bradyphrenia. Its manifestation in subcortical dementias implicates a subcortical focus. However, it also occurs in cortical disease. Potential neurobiological correlates are suggested below.

White Matter Integrity

In multiple sclerosis, total lesion volume directly and independently predicts bradyphrenia. Patients with temporal lobe epilepsy with white matter volume reduction, survivors of severe traumatic brain injuries with quantitative corpus callosum deficiencies, and elderly subjects with more numerous white matter hyperintensities detected on MRI demonstrate clinically significant reductions in

processing speed. Recent diffusion tensor imaging data relate disruption of white matter pathways carrying efferent thalamocortical fibers to age-related cognitive slowing.

Frontal–Subcortical Dysfunction

Both hypokinetic and hyperkinetic basal ganglia disorders are associated with bradyphrenia. Frontally impaired individuals with Parkinson's disease (PD), nondemented subjects with caudate and thalamic lesions, and elderly patients with loss of the D_2 (dopamine)-receptor binding sites in the caudate and putamen manifest disproportionate processing speed deficiencies.

Neurotransmitter Changes

Reduced processing speed in various conditions has been linked to cholinergic deficits, hypodopaminergic states, and altered glutamate activity.

Clinical Assessment

Epidemiology

Factors such as age, baseline intelligence, cerebrovascular risk factors, and genetics modestly predispose individuals to cognitive slowing.

Presentation

The course of bradyphrenia may fluctuate or progress insidiously depending on the associated condition. Sudden arrests of movement in patients with parkinsonism may coincide with thought blocking. Clinical reports consistently associate thought blocking and response latency with reduced motivation, hypophonia, fatigue, apathy, poverty of speech and content, distractibility, perseveration, lack of awareness, and memory disturbance. Cognitive slowing impacts mobility, gait, balance, transitions from sitting to standing, driving competency, and functional reach. Processing speed correlates with functional and quality of life measures.

Bradyphrenia amplifies deficits in other cognitive functions including working memory, episodic memory, executive functioning, reasoning, verbal abilities, problem-solving, reading, arithmetic, and visuospatial skills. Inaccuracies from impairments in these domains in turn contribute to slowing. Despite these interactions, bradyphrenia independently affects performance even in patients with preserved overall intellectual functioning.

Associated Disorders

Table 1 lists some of the many clinical conditions in which bradyphrenia is present. The majority of research

Table 1 Conditions listed by etiology reporting bradyphrenia as a clinical characteristic

Congenital/genetic
Adrenoleukodystrophy
Choreoacanthocytosis
Fragile X tremor–ataxia syndrome
Metachromatic leukodystrophy
Myotonic dystrophy
Pediatric myelomeningocele with shunted hydrocephalus
Williams syndrome
Degenerative
Alzheimer's disease
Corticobasal degeneration
Guamanian parkinsonism–dementia complex
Hallervorden–Spatz disease
Huntington's disease
Mild cognitive impairment

Vascular dementia

studies focus on psychiatric syndromes, movement disorders, multiple sclerosis, and traumatic brain injury.

Conflicting evidence exists over the presence of generalized bradyphrenia in PD patients without dementia. Those with little or no dementia manifest disproportionately slower complex reaction times compared to Alzheimer's patients and elderly controls. The presence of dementia and increased task complexity predict processing speed impairments in the Parkinson's population. Disease duration and severity are not associated. Age, depression, and motor infirmity amplify bradyphrenia. Cognitive slowing contributes to disruptions in speech, mobility, sentence comprehension, executive function, and working memory.

Confounding Conditions

When assessing illnesses characterized by bradyphrenia in the elderly, age-related declines in processing speed require consideration. Cognitive slowing with age also mediates changes in memory, spatial ability, and executive function.

The overlap between psychomotor retardation in depression and bradyphrenia has long been appreciated. A common pathophysiological substrate appears likely. However, slowing in depression reflects more of an abulic or amotivational state, varying less as a function of task complexity compared to bradyphrenia. Phenomenological differences including tearfulness, guilt, suicidal thoughts, and hypochondriasis point to an affective etiology. Bradyphrenia is less likely to improve with antidepressant treatment when the conditions coexist.

Attempts to dissociate bradykinesia and bradyphrenia are long-standing, but have yielded conflictual results. Electrophysiological markers uncontaminated by patients' motor responses show slowing in mid and long-latency auditory evoked potentials delaying further with task complexity. Findings of motor but not cognitive speed improvements after dopamine replacement, and changes in processing speed on tasks requiring similar motor output but more complex decision-making also demonstrate that bradykinesia and bradyphrenia are dissociable phenomena.

Other variables masquerading as reduced processing speed include working memory impairments, apathetic frontal lobe symptomatology with delays in initiating self-generated responses, pathological indecisiveness in obsessive–compulsive disorder, and medication effects, especially due to anticholinergics.

Testing

No gold standard exists for the assessment of processing speed. Principles to guide accurate approximation include use of data from a wide variety of tests, interpretation of findings of processing speed in conjunction with performance on other measures, and minimizing confounding variables such as impairments in sensorimotor functioning, anxiety, impaired arousal, language, education or cultural biases, and practice effects. **Table 2** lists various techniques of eliciting bradyphrenia.

Table 2 Tests for assessing processing speed

Bedside examination
Alphabet backwards
Alphanumeric sequencing: alternate counting with letters of alphabet
Letter fluency: name words beginning with certain letter in given time limit
Serial 7s: consecutively subtract seven from 100
Trail making test: draw line from numbers one through 25 (A) then alternate letters and numbers (B)
Psychomotor and psychophysical speed measures
Simple reaction time: press button in response to stimulus, for example, light
Recognition reaction time: respond to certain stimuli, for example, symbols by pressing button; ignore others
Choice reaction time: respond to identified stimuli, for example, letter on corresponding side
Inspection time: briefest target stimulation duration to score near-perfect recognition of stimulus, for example, which leg of Greek letter π (pi) is longer
Neuropsychological measures[a]
Adult memory and information processing battery: cross out second highest number in each row, timed
Paced auditory serial addition test: single digits presented serially must be summed to previous digit, interstimulus interval varied
Stroop: name color written in incongruous ink
Symbol digit modalities test (SDMT): write target number that matches one of nine geometric figures
Wechsler Adult Intelligence Scale-III digit symbol coding: SDMT but with symbols not figures
Wechsler Adult Intelligence Scale-III symbol search: scan search group of five symbols for presence of target group of two symbols
Computerized measures[b]
Auditory or visual threshold serial addition test: PASAT but report sum aloud while computer determines rate of stimulus presentation producing 50% success rate
Sternberg memory scanning test: memory set of one, two, or four digits, press one of two keys if digits on screen match digits in set
Electrophysiological measures[c]
P300 latency: oddball task – parietally distributed peak on EEG when low probability target stimulus easily discriminated from frequent nontarget stimuli
Alpha peak EEG frequency: fourier transformation performed on EEG time series may demonstrate slowing of alpha peak frequency

[a]When administered together a factor/index of processing speed may be formed.
[b]Most specific measures of processing speed.
[c]Experimental.

Management

Additional time to complete tasks and a greater focus on existing abilities such as verbal skills help compensate for

cognitive slowing. Processing speed training with computer-based target identification, detection, discrimination, and localization improves test measures, driving performance, and timed activities of daily living.

Confounding conditions including apathy and depression require treatment. Elimination of offending medications, minimization of cerebrovascular risk factors, and normalization of blood sugar and cobalamin levels are recommended. The underlying disorder demands optimum management. Empirical trials of psychostimulants and cholinomimetics may attenuate the profound functional impact of bradyphrenia.

Brainstem Reticular Myoclonus

R P Gandhy, Georgetown University Hospital, Washington DC, USA
E A Shamim, Georgetown University Hospital, Washington DC, USA; National Institutes of Health, Bethesda, MD, USA

Clinical Syndromes and Definitions

Myoclonus is defined as 'quick movement of muscle.' The resulting brief jerks are shock-like involuntary movements due to either a muscle contraction (positive myoclonus) or a brief interruption of contraction of active muscles (negative myoclonus). The term myoclonus initially included a variety of involuntary movements including tics. In 1903, Lundborg proposed the first classification to help specify this entity. Today, myoclonus can be classified based on clinical features, pathophysiology, or cause. On the basis of the clinical characteristics and electrodiagnostic studies, a relatively accurate site of origin in the nervous system can be predicted. Myoclonus can arise from the cortex, brainstem, spinal cord, and rarely from peripheral nerves. Those arising from the brainstem include exaggerated startle, reticular reflex myoclonus, and palatal myoclonus/tremor.

Exaggerated startle diseases or hyperekplexias (Greek for 'to startle excessively') refer to the brief, explosive, and overblown response to unexpected, mainly auditory stimuli but less frequently to visual or somesthetic stimuli. They were first described in 1958 by Kirstein and Silfverskiold; the definitive description in a large Dutch family occurred in 1966. Clinically, the hyperekplexias are characterized by three major features. A generalized

stiffness in response to handling occurs after birth and disappears by 1 year of age. With time, an exaggerated response to sound stimulation becomes evident especially when the patient is anxious, tired, or frightened. An inconsistent generalized stiffness lasting a few seconds follows the startle and frequently leads to falls and injury. Periodic limb movements during sleep, hypnagogic myoclonus, hernias (umbilical, inguinal, and epigastric), epilepsy, swallowing, and respiratory problems in children, and sudden infant death syndrome may also be concomitantly present. Intelligence is usually normal, but mild mental retardation may be observed. On examination, affected infants may exhibit head retraction reflex, increased muscle tone, and hypokinesia. Adults have wide-based gait without ataxia with an exaggerated head retraction reflex.

The hyperekplexias are largely thought to be familial, but sporadic forms are known to occur. The major autosomal dominant forms are mapped to chromosome 5q33–35; a variety of missense mutations have also been identified in the glycine receptor (GLRA1) gene. Glycine is the most common inhibitory neurotransmitter in the nervous system and its receptor consists of five subunits (3α and 2β); mutations located on the $\alpha 1$ subunit are associated with these diseases. Normally glycine receptors are linked to chloride channels and oppose depolarization. Abnormalities in the receptor lead to decreased inhibition of neuronal activity. Genetic associations are not known to occur with sporadic hyperekplexias, which can result from brainstem infarct, hemorrhage, and encephalitis. Although clonazepam is considered the drug of choice, other benzodiazepines, phenobarbital, vigabatrin, phenytoin, carbamazepine, chlorodiazepoxide, propofol, fluoxetine, 5-hydroxytryptophan, and piracetam can be tried.

Reticular reflex myoclonus was first described in 1977 by Hallet et al. and is thought by some to be a fragment of a generalized form of epilepsy originating in the brainstem. Rat models with urea-induced myoclonus have been well studied, and extensive electrodiagnostic studies including intracellular recordings implicate the nucleus reticularis gigantocellularis of the brainstem. Paroxysmal depolarization shifts (PDS), the most elemental component of a seizure discharge, are found in these regions. Reticular reflex myoclonus appears to be the human version of the brainstem myoclonus in rats. Some experts assert that seizures are a cortical phenomenon, and reticular reflex myoclonus should be considered nonepileptic.

Clinically, these patients have generalized jerks affecting mainly the proximal and flexor regions but are found all over the body. They can be elicited by voluntary movements or by sensory stimulation. Reticular reflex myoclonus was initially described in a patient with post-hypoxic myoclonus (Lance–Adams syndrome) and has been described with renal insufficiency. Single cases were reported in a patient with parkinsonism plus myoclonus, Lyme disease, procarbazine therapy, and neck trauma.

Diagnosis

Reticular reflex myoclonus can be differentiated from the hyperekplexias by several features. Although both appear to need a sensory stimulus to evoke the myoclonus, auditory stimulation is paramount in the startle syndromes. Hyperekplexia patients have the greatest sensitivity to taps in the mantle regions (head, upper chest, and back), while the reticular reflex myoclonus patients greatest sensitivity to taps is in the distal limbs. Presence of spontaneous and action-induced jerks characterize the reticular reflex myoclonus, which have an electromyographic (EMG) burst duration of 10–30 ms. EMG burst duration of more than 75 ms is characteristic of the startle syndromes. When cranial nerves are involved in the reticular reflex myoclonus, the sternocleidomastoid muscle is activated first. Thyrotropin-releasing hormone is thought to have stimulatory effect on the reticular neurons in the medulla and may exaggerate this type of myoclonus. This may be helpful diagnostically in patients with reticular reflex myoclonus. Like exaggerated startle, reticular reflex myoclonus is usually treated with clonazepam. 5-Hydroxytryptophan can be beneficial in patients with reticular reflex myoclonus as well.

Other forms of startle syndromes have been described worldwide for more than 100 years. The startle syndromes, including reticular reflex myoclonus, share a characteristic rostrocaudal progression of muscle contraction and lack of habituation. These syndromes exhibit some variability in excessive startle. The jumping Frenchmen of Maine was first described in the family of French–Canadian lumberjacks in Moosehead, Maine in 1878. In Indonesia and Yemen, the afflicted are referred to as 'latah' and are usually women. In Siberia, these individuals are referred to as Myriachit and in Louisiana, as 'ragin Cajun.' There is some debate that these disorders may be psychogenic or functional in nature but should be distinguished from startle epilepsy.

Palatal tremor is the currently accepted term for what used to be called palatal myoclonus. In the past, this condition was referred to as rhythmic palatal myoclonus, oculopalatal myoclonus, palatal nystagmus, brainstem myorhythmia, and palatal myorhythmia. It is a rhythmic involuntary tremor of the soft palate and can be unilateral or bilateral. It is classified into symptomatic or essential palatal tremor (SPT or EPT, respectively). SPT results from the rhythmic contraction of the levator veli palatini muscle and EPT from tensor veli palatini. Nucleus ambiguus may be the site of origin for SPT and the trigeminal

nucleus for EPT. While other brainstem findings may be evident in patients with SPT, EPT patients have rhythmic clicking in the ear with no other brainstem findings. Pathologic evaluation consistently reveals contralateral hypertrophic degeneration of the inferior olive in SPT patients but not in EPT patients. Magnetic resonance imaging reveals a similar enlargement of the inferior olive and a T2 hyperintensity in the same region. The initial assumption that the lesion had to be within the triangle of Guillain–Mollaret is no longer considered to be completely accurate. Disruptions in other connections may lead to this type of clinical phenomenon also.

Treatment

Surgical and medical treatments for palatal tremor are frustrating. Antiepileptics and sedatives like benzodiazepines can provide some benefit. Botulinum toxin injections can be tried, but administration is difficult and the results are not reliable. Frequent injections are needed with unpredictable results.

Bruxism

P Blanchet, Universite de Montreal, Montreal, QC , Canada

Glossary

Bruxism – From the Greek word *brychein*, 'gnashing of teeth.' The condition distinguishes wakeful from sleep bruxism.
Cyclic alternating pattern – Periodic, synchronous, widely diffuse EEG activity of nonrapid eye movement (REM) sleep characterized by stereotyped phasic patterns lasting <60 s and separated by time-equivalent intervals of background activity. It is an EEG marker of arousal instability during non-REM sleep and is associated with changes in vigilance, muscle tone, and autonomic activity.
Occlusal device (splint) – Any removable artificial intraoral occlusal surface used for diagnosis or therapy affecting the relationship of the mandible to the maxillae. It may be used for occlusal stabilization, for treatment of temporomandibular disorders, or to prevent wear of the dentition. Its mechanism of action has not been fully elucidated.
Occlusion – The static relationship between the incising or masticating surfaces of the maxillary or mandibular teeth or tooth analogs.
Oculomasticatory myorhythmia – Concurrence of pendular vergence oscillations of the eyes along with contractions of the masticatory muscles, suggested as a unique involuntary movement disorder in Whipple's disease, a rare multisystem infectious disease caused by the soil-borne Gram-positive bacillus *Tropheryma whipplei* (Actinomyces family).
Rhythmic masticatory muscle activity (RMMA) – Cocontraction of opening and closing jaw muscles, either in a phasic pattern with single bursts lasting up to 2 s, or in a tonic pattern lasting 3 s and more, or both (mixed episode), occurring mainly in light sleep about once per hour in normal subjects, and up to 2–12 times per hour in those with sleep bruxism. It is the most characteristic electromyographic event associated with tooth-grinding noise during sleep. It is preceded by autonomic and cortical activation.

Definition

First described by Marie and Pietkiewicz, in 1907, this condition consists of an involuntary oral activity characterized by frequent, stereotyped teeth clenching or grinding. If moderate to severe in intensity, the disorder often causes some degree of physical or social discomfort. The condition distinguishes wakeful from sleep bruxism.

Diagnosis

In normal individuals, wakeful bruxism consists of repetitive, aimless, and more or less conscious teeth clenching. In pathological cases, teeth clenching and grinding occur in a variety of psychological, neurological, and orodental conditions. It is often more severe than its sleep counterpart. The clinical diagnosis of sleep bruxism is based on the criteria of the American Academy of Sleep Medicine (**Table 1**). Polygraphic and audio–video recording in the sleep laboratory is the gold standard tool for diagnosis, with moderate-to-severe cases characterized by the presence of more than four (two in mild cases) episodes or 'events' of sleep bruxism or 25 bursts of rhythmic masticatory muscle activity (RMMA) per hour of sleep, and at least two episodes associated with tooth-grinding noise during sleep. The episodes can occur during all stages of sleep but are most common during stages 1 and 2 of light sleep. This method allows the distinction from physiological sources and other types of masticatory muscle activity, such as facio-mandibular myoclonus, tooth tapping, and epilepsy. It can also best document the co-occurrence of a parasomnia (sleep talking, in particular) or a sleep breathing disorder (snoring, apnea).

Epidemiology

Most prevalence studies rely on self account or on a reporting housemate. Wakeful bruxism is a common disorder, particularly in women, with prevalence estimates ranging between 5% and 96% in the adult population (20% on average), reflecting the inaccuracy of self reporting and wide discrepancies in the study design and diagnostic criteria used. The prevalence of bruxism during normal sleep decreases with age based on self report, from 14% to 17% in childhood to 8% in the general adult population, and down to 3% in the elderly, without clear gender predominance.

Table 1 Clinical diagnosis of sleep bruxism (American Academy of Sleep Medicine, 2005)

Criteria
1. Report or awareness of tooth-grinding sounds or clenching during sleep
2. At least one of the following associated feature: (1) abnormal tooth wear; (2) jaw muscle discomfort, fatigue, or pain and jaw lock upon awakening; (3) masseter muscle hypertrophy upon voluntary forceful clenching
3. No other explanation for the disorder (another sleep disorder, medical or neurological condition, medication use, substance use)

Complications

Bruxism activity exerts extremely powerful forces on teeth, periodontal structures, temporomandibular joint, and masticatory muscles. It is often associated with tooth wear and destruction, stress on periodontal tissues, fractures/failures of restorations or dental implants, cheek biting, jaw lock, and tender masticatory muscles hypertrophy causing a characteristic 'square jaw' appearance. Pathological wakeful bruxism may also interfere with normal activities, such as food intake, chewing, swallowing, retention of dental prostheses and bridges, and cause speech impairment.

In sleep bruxism, chronic temporomandibular joint and muscle pain as well as tension-type headache may occur in adolescents as well as in adults, but the pain intensity does not correlate with the intensity of bruxism. Although the sleeper is unaware of the jaw activity, the grinding noise, most conspicuous in severe cases, can disrupt the sleep of the bedroom partner and cause social embarrassment.

Pathophysiology

Pathological wakeful bruxism is a heterogeneous condition (**Table 2**). It has been ascribed to psychological disturbances in individuals with clenching habits. Neurological disorders associated with wakeful bruxism are extremely varied, including mental retardation, dementia, certain neurodegenerative conditions (Rett syndrome, in particular), and subcortical infarcts, supporting the existence of a cerebral origin. Wakeful bruxism has been argued to represent a focal form of dystonia in some cases. It can arise alone or with other dyskinetic manifestations during exposure to medications and amphetamines that directly or indirectly alter the brain dopamine levels, perhaps linking dopamine neurotransmission and abnormal basal ganglia neural processing in the development of some forms of wakeful bruxism. Peripheral factors such as edentulism, denture condition, occlusal disturbances, and overbite, may also contribute to clenching and other parafunctional orofacial activities during wakefulness in otherwise normal individuals, and these factors should not be neglected even in those suffering from a neurological condition that readily provides an obvious 'central' explanation for the disorder. A distinct form of persistent

Table 2 Causes of bruxism

Subtype	*Cause*
Wakeful bruxism	Anxious habit
	Drug-induced
	Antipsychotics
	Antidepressants
	Levodopa
	Anticholinergics
	Acute toxic exposure (ecstasy, amphetamines)
	Mental retardation (Down syndrome)
	Form of focal dystonia, regardless of etiology
	Gilles-de-La-Tourette syndrome
	Neurodegenerative disorders
	Alzheimer disease
	Amyotrophic lateral sclerosis
	Huntington disease
	Neuroacanthocytosis (with 'eating dystonia')
	Wilson disease
	Rett syndrome
	Head trauma
	Subcortical infarcts
	Anoxic encephalopathy
	Cerebellar hemorrhage
	Coma
	Infections
	Whipple disease
	Syphilis
	Temporal lobe epilepsy (rare)
	Peripherally induced
	Malocclusion
	Edentulism
	Ill-fitting dental prosthesis
Sleep bruxism	Idiopathic
	Psychological disturbance
	Emotional stress
	Occlusal factors (limited evidence)
	Drug-induced (antidepressants)
	Oculomasticatory myorhythmia (Whipple's disease)
	Temporal lobe epilepsy (rare)

bruxism can also arise in Whipple's disease as part of a picture of 'oculomasticatory myorhythmia.'

The prime generator of sleep bruxism is still debated. A yet undefined genetic predisposition may contribute. Peripheral biomechanical factors, such as changes in dental occlusion or craniomandibular dysmorphology, proposed for decades as key mechanisms, are now thought to play a minor role, if any. As in other movement disorders, psychological factors, emotional or work-related stress, and personality traits may enhance the expression of sleep bruxism. A basal ganglia contribution has been suggested on the basis of the bruxogenic effect of certain drugs, and the results of a neuroimaging study, which showed an asymmetric distribution of iodobenzamide-labeled dopamine D2 receptors in the striatum in subjects with sleep bruxism relative to controls, a finding of unknown significance awaiting replication. Recent evidence suggests that bruxism episodes are associated with the so-called cyclic alternating pattern (CAP) and are generated in the brainstem as part of a cerebral and autonomic microarousal reactivation state, increasing trigeminal neuron activity. A few minutes prior to bruxism, an increase in central sympathetic drive is apparent, followed by acceleration in brain wave activity and a change in some physiological parameters (rise in suprahyoid muscle tone, faster heart rate, deep breath), which occur ~4 s and 1 s, respectively, prior to the actual occurrence of tooth grinding. A strong swallowing ensues in over one-half of the episodes. This central mechanism better explains the enhancing influence of various factors such as anxiety, smoking, alcohol, caffeine, illicit drugs, and medications.

Management

There is a paucity of consistent evidence-based recommendations regarding the management of unremitting, moderate-to-severe bruxism. The enhancing factors described should be systematically inquired and stopped if possible before any treatment plan is proposed. The orodental condition of bruxers should be monitored periodically and treatment provided accordingly. In general, dental treatments are restricted to oral hygiene maintenance, preservation of chewing function, replacement of ill-fitting dentures, and acute pain management. Children with sleep bruxism are usually managed conservatively with observation and reassurance. The traditional treatment for sleep bruxism, offered whenever the damage is deemed significant, has included occlusal (intraoral devices in many versions), psychological (stress reduction therapy), and behavioral feedback (sound alarms) approaches. Occlusal splints (nightguards) made of hard acrylic are the oral appliances primarily used, designed not to correct the causative mechanisms but to prevent and treat the consequences of bruxism and protect the teeth, with variable and transient results on bruxism activity itself. A different protrusive mandibular splint designed to clear the upper airways has also shown benefit on bruxism. There is no evidence to support the use of irreversible restructuring approaches such as occlusal equilibration, and extensive orthodontic treatment is best avoided. A wide variety of behavioral approaches of questionable value have been tried, including biofeedback, psychoanalysis, autosuggestion, progressive relaxation, hypnosis, meditation, lifestyle improvement, sleep hygiene, self-monitoring, or habit awareness.

Finally, several medications have been reported to be efficacious mainly in open pilot studies, including GABA-enhancing drugs such as gabapentin, tiagabine, and clonazepam. Unlike propranolol, the α_2 adrenergic agonist clonidine was found to reduce RMMA in an acute single-dose study, supporting the view of a sympathetic

drive contributing to sleep bruxism. The practicability of this approach as a long-term treatment has not been addressed. In contrast, dopaminergic drugs have produced only modest or insignificant effects. Magnesium supplements have provided symptomatic relief, but controlled large-scale studies are needed to confirm the benefit and the optimal dosage. Intramuscular botulinum toxin is an increasingly popular option in severe bruxism, but its efficacy has not been tested in a controlled trial.

C

Caenorhabditis Elegans

S Vartiainen, University of Tampere, Tampere, Finland

Glossary

Hermaphrodite – An organism that is able to produce self-fertilized progeny by having both male and female reproductive organs.
High-throughput screening – Possibility to perform scientific experiments quickly and in a large scale in order to test, for example, pharmacological compounds, automated data handling, and robotics are often used in high-throughput screens.
Molting – The shedding of the cuticle in order to allow growth.
Nematode – A roundworm, an unsegmented worm from the phylum nematoda, mostly free-living but parasitic forms exist.
RNA interference (RNAi) – Silencing of an endogenous gene by administrating double-stranded RNA, the microRNA controlled gene expression is not discussed.

Definition and History

The free-living soil nematode *Caenorhabditis elegans*, also referred to as the worm, has gained increasing amounts of attention during the last decades. At the moment the worm is the simplest multicellular model organism still able to produce a variety of behavioral patterns. Its other qualities, such as transparency, ease of genetic manipulations and rapid generation time, make the *C. elegans* an ideal tool for various research purposes. The research on *C. elegans* was originated in 1960s and it was first focused on studying the cell divisions in the developing worm. The following mutagenesis screens revealed genes which induced abnormal movement, but to study the human diseases in a worm model the evidence for the genomic similarity between man and a worm was needed. The genome sequencing projects in 1990s provided us with the information that 65% of human disease genes have a counterpart in *C. elegans* and ever since the worm has been utilized to study a variety of human disorders.

Basic Worm Biology

Adult *C. elegans* hermaphrodite is 1 mm in length and its body consists of 959 cells, 302 of these being neurons. A newly laid egg develops into an adult worm in 3 days. *C. elegans* has four larval stages and the worm transits from one stage to another through molting. The normal lifespan of a worm is ~3 weeks, but the lifespan as well as the developmental time depends greatly on ambient temperature. There are two sexes in *C. elegans*; hermaphrodite and male. The hermaphrodites are self-fertile organisms usually populating most of the worm cultures. Occurrence of males in self-fertilized progeny is a rare result of spontaneous nondisjunction of the X chromosome. This gives the male a genotype of five autosomes and only one X chromosome while the hermaphrodites have two X chromosomes. By self-fertilization hermaphrodites produce 300 eggs during their lifespan and approximately one out of thousand in this progeny will be a male. With the appearance of the male worm the population dynamics change rapidly. The hermaphrodites fertilized by males not only produce over 3 times more eggs but also the portion of males in the offspring rises to 50%. Most of the research results discussed below comes from hermaphrodites. The male behavior is somewhat comparable to the hermaphrodites', but males have also many specific additional behavioral patterns.

Different Movement Behaviors in *C. elegans*

The worm feeds on bacteria both in nature and in the laboratory. In the laboratory the most common habitat for

a worm is a petri dish with agar and bacterial lawn. There the *C. elegans* moves by alternating the contraction and relaxation of its bilateral body wall muscles thus resulting into a movement which is composed of ventral and dorsal turns of the body. The muscles are innervated with excitatory motor neurons that use acetylcholine as a neurotransmitter and with inhibitory γ-butyric acid (GABA) utilizing neurons. The firing of these neurons with opposite activities is coordinated by neuronal interactions. The result of this neuron–muscle interplay is seen in the typical worm tracks, that is, balanced sine waves on a bacterial lawn (**Figure 1**).

In normal conditions the worms are more or less in constant movement. The movement slows down when the worms are foraging on the bacterial lawn and speeds up when they are on areas with no food available. This behavior originates from mechanosensory stimulus and it is mediated by the neurotransmitter dopamine. Other stimuli that result into change in movement in *C. elegans* include touch, odorants, and temperature. When a normal *C. elegans* is touched on the nose it moves quickly backwards to avoid collision. Touch to the posterior part of the body induces faster forward movement. Harsh touches to other parts of the body are followed by movement to avoid the source of sensation. The movement responses to different stimuli are modified by the worm's earlier experiences. An example of this is habituation, the decreased response after repeated stimulation such as touch.

Worm phenotypes that commonly arise from genetic manipulations have been organized into several classes in Wormbase, an online database for worm genetics. The phenotype class *movement abnormal* is a subgroup of *organism behavioral abnormalities* which also include abnormalities in body posture and/or mechanosensation. *Uncoordinated* (*unc*) is a short version of class *locomotion abnormal*. There are hundreds of gene mutants with different uncoordinated phenotypes. Some of the *unc* phenotypes are self-explanatory, such as *shrinker* or *twitcher*, whereas others, such as *rollers* which rotate around their longitudinal body axis as they move forward, are less clear. There are various methods for analyzing worm locomotive behavior; the preferred method depending on which kind of abnormality is being studied. Many of the movement impairments can simply be seen as changes in the worm trail on bacterial lawn. The worm tracks may be irregular in shape, have marks of worm stopping frequently or have only very small waves. The basic test for *C. elegans*' motor performance is the thrashing assay. In the thrashing assay a worm is placed in an isotonic liquid droplet and as it tries to reach solid ground it makes fast sinusoidal movements that can be counted. One thrash is determined as the movement of the head from dorsal to ventral side. Test times up to 2 min have been used but usually thrashes are counted for 30 s and during that time a normal worm can perform ∼90–100 thrashes. The method for analyzing velocity of the movement and/or coordination of the worm is called radial locomotion assay. In the assay a few worms are placed in the middle of the petri dish and the distance they have moved from the centre is measured at certain time points.

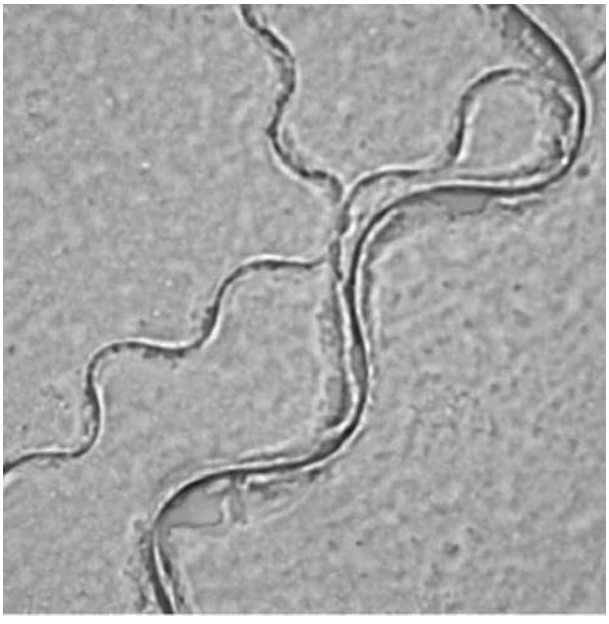

Figure 1 Normal *C. elegans* tracks on bacterial lawn.

Tests assessing functions other than locomotion are also available and they may be applicable when analyzing the effects of gene manipulations. The pharyngeal pumping rate is used to quantify the amount of food taken in by the animal. The pumping rate is analyzed from rhythmic forward–backward movement of the pharyngeal pump as the animal forages. A low pumping rate in *eat-2* mutants is linked to caloric restriction and thus extended life span. Egg-laying and defecation are worm behaviors controlled by neurons and muscles and assays for analyzing them are available. Similarly, tests for monitoring learning have been developed. Worms can be taught to avoid odorants or temperatures by starving them and a failure in avoiding these circumstances refers to a problem either in learning or in perception.

Usage of *C. elegans* in Modeling Human Disorders

The ease of genetic manipulations in *C. elegans* is one of its greatest advantages. Expressions of certain human disease genes, such as β-amyloid peptide, huntingtin, tau, and α-synuclein, have provided both behavioral and morphological phenotypes (**Table 1**). These transgenic worms have thereafter been available for further genetic manipulations or high-throughput drug screens. Different high-throughput analyses in order to break down the pathway

Genetic mutant	Mutation in gene *cle-1*	76%	*Journal of Neuroscience* 2003;23(9):3577–3587
RNAi treatment	Down-regulation of ceGAT-1	124%	*Journal of Biological Chemistry* 2005;280 (3):2065–2077
Transgenic	Pan neuronal expression of human MAPT gene	60–95%	*Proceedings of the National Academy of Sciences USA* 2003;100(17):9980–985
Transgenic	Pan neuronal expression of human α-synuclein	50–60%	*Journal of Neurochemistry* 2003;86(1):165–172

of disease pathogenesis are the forte of *C. elegans* research. With *C. elegans* it is possible to study effects of various treatments on whole animal in 96- or 384-well format with computerized analysis systems. However, it must be kept in mind that the more subtle changes in *C. elegans* behavior still require the expertise of a skilled worm behaviorist.

The discovery of RNA interference (RNAi) has provided a grand tool for *C. elegans* researchers. With no other multicellular animal administration of double-stranded RNA (dsRNA) is as simple as it is in *C. elegans*. Feeding the worms with dsRNA-producing bacteria, injecting the worms with dsRNA or soaking the worms in dsRNA media generates a similar gene silencing phenotype. Full genome RNAi screens have been performed and the data are available. The screens have revealed many uncoordinated and other behavioral phenotypes which can be used to model movement disorders. Especially when the etiology of the disease is known, the simple worm model can significantly help in resolving the cause and effect chain of a gene mutation.

Camptocormia

N J Diederich, Centre Hospitalier de Luxembourg, Luxembourg, Luxembourg

Glossary

Dystonia – A neurologic syndrome characterized by sustained muscle contractions, producing twisting and repetitive movements or abnormal postures or positions.
Myopathy – A muscular disorder in which the primary symptom is muscle weakness due to dysfunction of muscle fibers. Other symptoms of myopathy can include muscle cramps, stiffness, and spasms. Myopathies can be inherited or acquired.
Myositis – The general term for an inflammation of the skeletal muscles. The most common causes are injuries, infections, or autoimmune diseases.

Definition and History

The term camptocormia (CC) was coined in 1914 by Souques and Rosanoff-Saloff. Derived from the greek 'kampto' or to bend and 'kormos' or trunk, it means a pathological bending over of the trunk. During World War I and II, CC was used to describe psychogenic conversion reactions of the soldiers. Later on, French rheumatologists, best represented by the works of Laroche and colleagues and Delcey and colleagues, have linked CC with various, mostly axial myopathies. Recently, there has been a renewed interest for CC as a levodopa-refractory and late-stage parkinsonian syndrome.

Pathophysiology

There is no unitarian pathophysiological concept of CC. As proposed by Djaldetti and Melamed, two schools of thought can be distinguished. The first connects CC to peripheral mechanisms, in particular to myopathy of the antigravity muscles. The latter considers CC as a central disorder, in particular an extreme form of rigidity, or an action dystonia of the spine. The two mechanisms are not mutually exclusive but may add up in the individual patient, leading to a cascade of CC mechanisms (see **Table 1**).

Peripheral Causes

Axial and, more rarely, generalized myopathy have been reported in well-documented case reports and a few small case series. Mostly, the myopathic changes have been unspecific. In some patients, myositic changes were predominant. Two objections against a myopathic cause have been advanced. First, the association of a rare myopathic condition with the even rarer syndrome of CC raises the question of whether there is causal link or just coincidental appearance. Second, most myopathies, with the exception of inclusion body myositis, cause pelvic girdle weakness and thus lumbar kyphosis. However, CC is associated with lumbar kyphosis. The contributive roles of spondylarthrosis and other arthrogenic changes have been questioned because CC is not immutable and disappears in the recumbent position. Cumulative age-dependent factors such as loss of muscle tone, tissue elasticity, chronic stretch, and partial denervation of the paraspinal muscles from degenerative spinal disease have been proposed as contributive peripheral causes.

Central Causes

Three possibilities have been discussed: first, a focal action dystonia of the spine; second, an extreme form of rigidity primarily due to dysfunction of nondopaminergic pathways in the basal ganglia and the brainstem (i.e., the reticulospinal pathway); and third, an imbalance between excessive central motor drive to the abdominal wall muscles and reduced motor drive to the paraspinal muscles. In one series of 16 CC patients reported by movement disorder specialists, two thirds of the subjects were suffering from PD, while four patients had dystonia and one patient had Tourette syndrome. According to Lepoutre, only a quarter of PD patients show some mild improvement of CC after levodopa. CC has also been described in Parkin-gene mutation PD and multiple system atrophy (MSA). Finally, the acute onset of CC has been described in a few patients with vascular lacunar lesions of the putamen or the caudate nucleus.

Cascade from Central to Peripheral Causes

It is possible that in Parkinsonian patients, dystonia of the trunk, possibly triggered by initial high dosage of levodopa, causes continuous straining of the erector trunci, resulting in secondary myositis. Such a pathophysiological cascade could explain the localized delineation of the myositic changes, and the only focal muscle atrophy and replacement by fat tissue. In analogy, excessive load on the paraspinal musculature has been proposed as the cause of myopathy seen in the dropped head syndrome. Theoretically, a

Table 1 Etiology of camptocormia

Parkinsonism
Idiopathic Parkinson's disease
Often end-stage disease
Predominant axial symptoms
Poor or no levodopa response
Possibly myopathic or myositic changes in muscle biopsy
Parkin-related Parkinsonism
Multiple system atrophy
Possibly myositic changes in muscle biopsy
Dystonia
Primary axial dystonia
Secondary
Medication-induced
Tourette syndrome
Neuromuscular
Amyotrphic lateral sclerosis
Unspecific myopathy of the erector trunci
Inclusion body myositis

Caudate nucleus
Psychogenic
Conversion reaction secondary to wounding during war
Malingering

spreading of a mitochondriopathy or a synucleinopathy from the central nervous system to muscle neurons or paravertebral muscles is also conceivable, but has not been demonstrated so far.

Epidemiology and Risk Factors

CC is a rare condition. Prevalence studies have not been published. Most series have been published by specialized movement disorder or neuromuscular clinics. Thus, the distribution in the general population is unknown. Mild CC, expressed by an anteroflexion angle of less than 45° may be overlooked. Old age, male gender, and in patients with Parkinsonism, long disease duration and predominant axial involvement have been proposed as risk factors for CC. Indeed in the study by Lepoutre and colleagues, most PD patients had severe other axial symptoms such as dysarthria, freezing, and postural instability. A genetic predisposition has been discussed because in the study by Laroche and colleagues, 20 out of 27 patients with myopathy-linked CC had a positive family history for CC.

Clinical Features

CC is characterized by hyperflexion of the thoracolumbar spine that manifests while standing and walking and that, typically, vanishes in both the sitting and the supine position. The angle of the hyperflexion has been differently defined by various authors, ranging from 15° to 90°. Mostly, an inclination of at least 45° is required to establish the diagnosis. CC may worsen during ambulation, throughout the diurnal cycle, or due to stress and fatigue. 'Sensory tricks', as used in dystonia, can rarely help to overcome the flexion posture. CC is associated with back pain in some patients, while it is painless in others. In PD patients, rapid appearance of CC (in $<$1 year) is not unusual. According to three larger case series (Laroche et al., 1995; Azher and Jankovic, 2005; and Lepoutre et al., 2006), the mean age of patients with CC is 65–69 years. In PD patients, the mean duration from onset of the neurologic symptoms to manifestation of CC is 6–7 years.

Allied Conditions

The drop head or anterocollis syndrome, the Pisa syndrome (see the corresponding chapter), and CC represent all axial involvement and may thus represent a continuum of the same underlying condition. Focal myopathy has most convincingly been demonstrated in the drop head syndrome. CC and Pisa syndrome can be concomitant features of an axial dystonia. Anterocollis is considered to be a 'red flag' for the possibility of MSA, while CC has only rarely been described in MSA. Other late manifestations of end-stage PD such as bent-knee posture or tiptoeing have been linked to CC as well, and, similarly, are apparent during ambulation but not in the recumbent position.

Diagnostic Work-Up

CC is a clinical diagnosis. In PD patients, the abatement of the marked anteroflexion of the trunk in the recumbent position and the lack of response to levodopa are pathognomonic signs (see **Figure 1**).

Laboratory investigations include inflammation markers and muscle enzymes. *Electromyography* is often not interpretable, because patients cannot sufficiently relax and extend their trunk in a sitting position. In contrast, two other diagnostic procedures involving the thoracolumbar spine can be very helpful. *MRI of the erector trunci* can demonstrate fatty involution and focal patchy hyperintensities with gadolinium enhancement of the paraspinal muscles. The high signal intensity lesions are best visualized on the T2-weighted, fat-suppressive, short inversion time inversion recovery (STIR) sequence (see **Figure 2**). *Paraspinal muscle biopsy* can evidence an increase of fibrous tissue, focal myopathy, or myositis. Interestingly (see **Figure 3**), such changes have also been found in patients with PD or MSA, thus suggesting that the muscle

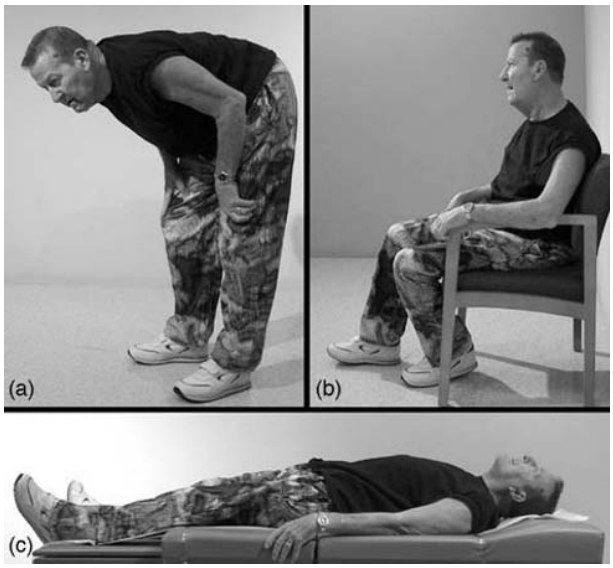

Figure 1 Patient with CC in different positions: (a) While standing, (b) markedly improved on sitting, and (c) markedly improved in the supine position. Reproduced from Azher SN and Jankovic J (2005) Camptocormia: Pathogenesis, classification, and response to treatment. *Neurology* 65: 355–359, with permission from ● ● ●.

pathology may be either the primary cause of CC, a focal reaction to the CC posture, or a coincident syndrome of old age. In PD patients with CC, conventional MRI of the brain and single-photon emission computed tomography with dopamine transporters have not evidenced significant differences between PD patients with or without CC, although in one study, a negative correlation between the severity of CC and the normalized brain volume and sagittal pons area has been demonstrated.

Management

Treatment of CC is mostly unsatisfactory. The treatment responsiveness probably depends on the underlying pathophysiological mechanism. However, as shown above, this mechanism remains mostly elusive. Furthermore, secondary and irreversible mechanical damage to overstretched muscle fibers may preclude substantial effect of any causal treatment strategies. Symptomatic or palliative treatment regimens, however, deserve a 'trial and error approach' in patients with the most disabling syndromes.

Dopaminergic Drugs

CC is mostly insensitive to adjustment of the dopaminergic medication in both directions (increasing dosages and complete withdrawal). Similarly, in PD patients, the severity of CC remains mostly unchanged during 'on' or 'off' phases, although a minority of patients show a temporary deterioration during the 'off' periods.

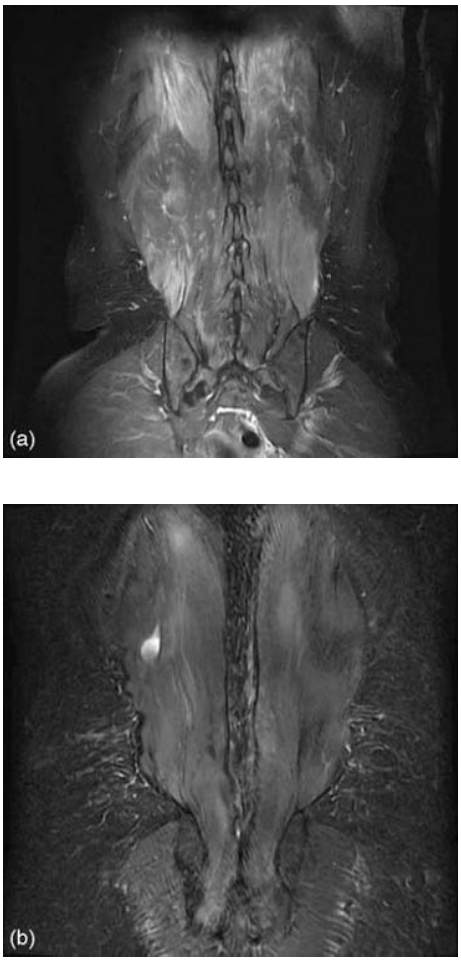

Figure 2 MRI of the erector trunci. (a) Fast T1 spin echo coronal section with fat suppression and after contrast medium injection. Heterogeneous gadolinium enhancement and patchy hyperintensities of the posterior bilateral paraspinal muscles, (b) Fast T2 spin echo coronal section with fat suppression. (2006) Camptocormia associated with focal myositis in multiple-system atrophy. *Movement Disorders* 21: 390–394, with permission from ● ● ●.

Deep Brain Stimulation

In the presence of axial dystonia, bilateral stimulation of the globus pallidum internum or the nucleus subthalamicus has been reported to produce persistent alleviation of CC in a few patients. However, there has been no systematic study, and publication bias is possible.

Botulinum Toxin (BT)

In one study, four out of nine patients receiving BT injections in the rectus abdominus showed notable improvement of the CC, while in another study with BT injections in the iliopsoas muscle, performed under ultrasound guidance, there was no beneficial effect

Immunomodulation

Corticosteroids, applied in patients with myositic changes, occasionally and temporarily relieve the forward flexion and produce some pain relief. In rare cases, immunoglobulins and cyclosporine have produced the same effect.

Physical Therapy

Pardessus and coworkers have published a retrospective study on the use of flexible leather corsets (LC) in patients with CC of various origins. Prescribed in 27 patients, LC was used by 20 patients, and 19 answered a questionnaire after a mean treatment time of 33 months. Three quarters of these patients responded positively to five of the seven functional areas assessed and two-thirds wore the LC at least 9 h a day.

Prognosis

The prognosis is poor, with CC being mostly progressive and patients ending up in a crippling condition and wheelchair-bound. In some patients, a plateau phase can be maintained with constant physiotherapy.

Cannabinoids

S H Fox, University of Toronto, Toronto, ON, Canada

Glossary

Cannabinoid – A compound that is structurally related to compounds derived from the *Cannabis sativa* plant.
Inverse agonist – A compound that binds to a receptor but reverses the constituent activity of the receptor.
Long term depression – Synaptic plasticity resulting in the release of endocannabinoids and long-lasting inhibition of neurotransmitter release.
Psychoactive – Having properties that induce psychotic symptoms such as altered perceptions, hallucinations, and delusions.

Definitions

Cannabinoids are C_{21}compounds that are present in *Cannabis sativa* as well as structurally related to the main psychoactive component, delta-9-tetrahydrocannabinol (Δ^9-THC).

History

Medicinal properties of the exogenous cannabinoid *C. sativa* (marijuana) have been known for millennia. The proposed uses included antinausea, pain control, muscle spasms, and epileptic seizures. Until recently, however, most uses were generally unsubstantiated, and there was a lack of scientific rationale or clinical trial evidence to support these claims. In addition, concerns regarding cognitive and psychotropic effects of cannabinoids have generally limited clinical development of these drugs. *C. sativa* is made up of over 60 naturally occurring cannabinoids. The main psychoactive component is Δ^9-THC. Several other components have been identified, and they include cannabidiol and cannabinol. Following the discovery of these components, several closely related cannabinoid drugs were synthesized (**Table 1**).

Cannabinomimetic Effects

Acute effects of cannabinoids in human may include euphoria, relaxation, perceptual alterations, time distortion, and intensive sensory experiences, as well as impaired short-term memory, motor skills, and reaction times. In animal studies, cannabinoids produce four classical cannabinomimetic effects including antinociception (analgesia) without respiratory suppression: reduced spontaneous activity, catalepsy, and hypothermia. The effect on motor activity depends on the dose of agent; thus low doses will induce hyperactivity but higher doses, catalepsy. These behavioral properties have now been confirmed using cannabinoid receptor knockout mice models.

Cannabinoid Receptors

The biological effects of cannabinoids are now known to be mediated by two cannabinoid receptors, CB_1 (cloned in 1990) and CB_2 (cloned in 1993) (**Table 2**). Cannabinoid receptors are members of the G-protein-coupled receptor superfamily and inhibit Gi/o resulting in inhibition of adenylyl cyclase. In addition, CB_1 receptors activate potassium and N-type and P/Q-type calcium channels. The cannabinoid system is unusual in that despite the wide distribution of cannabinoid receptors, to date; only two types of receptors are present. Thus, all actions of cannabinoids are mediated through these two receptors, mainly the CB_1 receptor, and as such, therapeutic potential for cannabinoid agonists is potentially limited by unwanted actions and side effects.

Table 1 Clinically available cannabinoid drugs

Name of drug	*Type of cannabinoid*	*Licensed indication*
Nabilone (Cesamet ®)	Mixture of Δ^9-THC, cannabinol, cannabidiol, and other cannabinoids	Treatment of chemotherapy-induced nausea and vomiting that has not responded to conventional antiemetics. Treatment of anorexia and weight loss in patients with AIDS
Dronabinol (Marinol®)	Δ^9-THC	Treatment of severe nausea and vomiting with chemotherapy that has not responded to conventional antiemetics and AIDS-related anorexia
Sativex®	Buccal spray of *cannabis sativa* extract containing Δ^9-THC (2.7 mg) and cannabidiol (2.5 mg)	Symptomatic relief of neuropathic pain and adjunctive analgesic treatment in advanced cancer for pain control despite opioid therapy Approved in Canada as adjunctive treatment for the symptomatic relief of neuropathic pain in multiple sclerosis
Cannador®	Oral cannabis extract of *cannabis sativa* containing Δ^9 THC (2.5 mg) and cannabidiol (1.25 mg)	
Rimonabant	CB_1 receptor antagonist	Treatment of obesity (licensed in European union)

Table 2 Relative affinity of exogenous and endogenous cannabinoids at cannabinoid CB_1 and cannabinoid CB_2 receptors

Cannabinoid	*Name*	*CB_1*	*CB_2*
Exogenous cannabinoids	Δ^9-THC	++	+
	Δ^8-THC	++	+
	Cannabinol	(+)	(+)
	Cannabidiol	0	0
Synthetic cannabinoids	11-hydroxy-Δ^8-THC (HU 210)	+++	+++
	CP55,940	+++	+++
	WIN55,212-2	+++	+++
	Arachindonyl-2-chloroethylamide (ACEA)	+++	0

Cannabinoid CB1 Receptors

CB_1 receptors are widely distributed in both the peripheral and central nervous system. Cannabinomimetic effects are related to CB_1 receptors within particular brain regions.

Memory

CB_1 receptors are located in the hippocampus, particularly in CA3 field of Ammon's horn and the molecular layer of the dendate gyrus.

Analgesia

CB_1 receptors are located on the peripheral terminals of primary sensory neurons and in the dorsal horn of the spinal cord, in addition to the central sites that may mediate pain including amygdala, thalamus, superior colliculus, and rostral ventromedial medulla.

Thermoregulation

CB_1 receptors are located within the hypothalamus.

Antiemetic

CB_1 receptors are located in the dorsal vagal complex, consisting of the area postrema (the chemoreceptor trigger zone for emetic reflexes), nucleus of the solitary tract, and the dorsal motor nucleus of the vagus in the brainstem.

Motor functions

The basal ganglia have one of the highest concentrations of CB_1 receptors in brain. CB_1 receptors are located on the presynaptic terminals of the GABAergic striatopallidal pathways in the globus pallidus (GP) (both internal (GPi) and external (GPe) segments) and the substantia nigra pars reticulata (SNpr). In addition, CB_1 receptors are found on the corticostriatal glutamatergic projection neurons as well as paravalbumin positive interneurons of the striatum. In the cerebellum, CB_1 receptors are located in the molecular layer, which contains the fibers and dendritic processes from Purkinje cells.

Other locations

CB_1 receptors are also found in the periphery in vasculature, heart, bladder, and small intestine and vas deferens.

Several synthetic cannabinoids are now available (**Table 1** and **Table 2**).

Cannabinoid CB_2 Receptor

The CB_2 receptor is principally located in the immune system both in the brain and periphery. The receptor was initially derived from a human promyelolocytic leukaemia (HL60) cell line and is found in high amounts in B-cells and natural killer cells. In addition, CB_2 receptors are located in microglia and blood vessels. Until recently, CB_2 receptors were not thought to be located in neuronal tissue, but they have been demonstrated in the brainstem as well as in the hippocampus and cerebellum. The function of CB_2 receptors in the brain is currently unknown, but a role in neuroprotective mechanisms has been implied. The CB_2 receptor shares 68% homology with the CB_1 receptor.

Non-CB Receptors that Mediate Cannabinomimetic Effects

Several actions of cannabinoids appear to be mediated by non-CB_1 or CB_2 receptors. Thus, vasodilatory and some analgesic properties of cannabinoids appear to be due to an action at capsaicin (vanilloid VR-1 or TRPV1) receptors. Other targets of cannabinoids include N-type and T-type calcium channels, sodium channels, voltage gated potassium channels, nicotinic receptors, glycine receptors, and 5-HT_2 and 5-HT_3 receptors.

Endocannabinoid System

The discovery of the cannabinoid receptors led to the discovery of the endogenous ligands called endocannabinoids for these receptors. Several endocannabinoids have now been described, but arachydonoyl ethanolamide (anandamide) and 2-arachidonylglycerol (2-AG) are the best characterized. These are ecosanoid phospholipids produced on receptor-mediated demand in response to elevated intracellular calcium and immediately released. This is in contrast to the classical neurotransmitters that are synthesized and stored in vesicles in presynaptic terminals. Anandamide is produced from hydrolysis of membrane phosphatidylethanolamine, and is released and removed by active reuptake, via an anandamide transporter and hydrolyzed by fatty acid aminohydrolase (FAAH). 2-AG is produced from sequential hydrolysis of phosphatidylinositol (4,5)-biphosphate, and the effects are terminated by active uptake into cells and hydrolysis.

Function of Endocannabinoids

The function of the endocannabinoids system is to modulate neurotransmission. Thus, depolarization of the postsynaptic membrane results in release of the endocannabinoids that diffuse to the presynaptic membrane and inhibit GABA and glutamate activity. In addition, endocannabinoids function as retrograde messengers and are implicated in synaptic plasticity in the hippocampus, thus potentially having a role in memory and learning. Within the striatum, endocannabinoids also act as retrograde messengers and mediate long term depression by interacting with dopamine D_2 receptors in the indirect striatopallidal pathway.

Cannabinoid Receptor Antagonists

All cannabinoid receptor antagonists currently available are competitive antagonists at CB_1 or CB_2 receptors of endogenously released endocannabinoids. However, these compounds also have inverse agonist properties by negative, possibly allosteric, modulation of the constitutive activity of CB receptors and by shifting the receptor from a constitutively active to an inactive state. In addition, these compounds may also block non-CB-mediated effects, for example antagonism of endogenously released adenosine at A_1 receptors.

Cannabinoids in Movement Disorders

The potential role of the endocannabinoid system in movement disorders stems from the high concentration of CB_1 receptors found within the basal ganglia as well as elevated levels of endocannabinoids. To date, there is no consensus on changes in CB_1 receptors in Parkinson's disease (PD). Investigating the localization of cannabinoid receptors has been difficult due to the highly lipophilic nature of their ligands and has been restricted to in vitro studies with inconsistent results. A recent cannabinoid ligand [^{18}F]MK-9470 has been developed for in vivo use in PET imaging that will potentially enhance the understanding of these receptors in disease states.

Endocannabinoid System in Parkinson Disease

FAAH inhibitors

Increased endocannabinoids are found in untreated PD patients (in CSF) and in the striatum of animal models of untreated PD. This may be a compensatory effect for the loss of dopamine. Stimulation of CB_1 receptors decreases corticostriatal glutamatergic transmission, and enhanced

endocannabinoids may thus be an attempt to decrease the enhanced glutamate input in PD. Further enhancing endocannabinoids may therefore result in the alleviation of the PD motor symptoms. Inhibition of FAAH, prevents breakdown of endocannabinoids and reduces excitatory striatal glutamate activity in 6-OHDA lesioned rats. In addition, in PD, overactivity of the indirect striatopallidal pathway may be in part due to loss of long-term depression (LTD), an effect mediated by both dopamine D_2 receptors and endocannabinoids. Thus, combined treatment of 6-OHDA-lesioned rat or reserpine-lesioned rat models of PD with a dopamine D_2 agonist and a selective FAAH inhibitor URB597 reversed parkinsonism. To date, no studies using FAAH inhibitors have been reported in primate models of PD and none are clinically available.

CB_1 Cannabinoid receptor antagonists

Alternatively, enhanced endocannabinoids within other regions of the basal ganglia may be mediating parkinsonian symptoms. Thus, in reserpine treated rats and untreated MPTP-lesioned primates, increased levels of endocannabinoids in the GPe are found. These endocannabinoids, by stimulating CB_1 receptors within the GPe, and reducing GABA reuptake may lead to reduced activity of the GPe, a key abnormality in PD. Thus, CB_1 antagonists may have an antiparkinsonian action. The CB_1 selective antagonist, rimonabant, had a mild effect on reversal of motor symptoms in the 6-OHDA-lesioned rat and MPTP-lesioned primate, while another CB_1 antagonist carboxylic acid amide benzenesulfonate (CE) had no antiparkinsonian action alone but enhanced the antiparkinsonian actions of levodopa in the MPTP-lesioned primate. In clinical studies, in four advanced PD patients, there was no effect on PD motor symptoms using rimonabant (20 mg d^{-1}) compared to placebo as add-on therapy, but no adverse effects were noticed. To date, no further clinical studies have been performed.

Endocannabinoid System in Levodopa-Induced Dyskinesia (LID)

CB1 receptor agonists

In PD patients following long term treatment with levodopa, involuntary movements (dyskinesia) may develop. The neural mechanism underlying levodopa-induced dyskinesia (LID) involves overactive corticostriatal glutamate activity; CB_1 receptor stimulation reduces glutamate release from corticostriatal inputs in the striatum, and thus, CB_1 receptor agonists may be useful in reducing LID. An alternative site of action may be via stimulation of CB_1 receptors on the striatopallidal terminals of the indirect GABAergic pathway which reduces GABA reuptake and thus reduces the firing of the GPe. In preclinical studies, the CB_1 agonist WIN55,212 reduced LID in the reserpine and 6-OHDA-lesioned rat. An alternative action of cannabinoids may be on TRPV1 (vanilloid) receptors and the TRPV1 agonist, capsaicin, reduces levodopa-induced hyperkinesia in the reserpine treated rat. In the MPTP-lesioned marmoset model of LID, nabilone reduced dyskinesia without affecting the antiparkinsonian action of levodopa. In clinical studies, nabilone was shown to have a mild effect on reducing dyskinesia in a Phase IIa trial using a cross-over acute challenge study design in seven PD patients. There was no effect on parkinsonian disability, and all patients had a nonsignificant fall in systolic blood pressure and experienced side effects of mild sedation and dizziness. Another Phase II randomized controlled trial (RCT) study using Cannador®, showed no significant effect on LID or any significant adverse effects in 19 PD patients when treated over 4 weeks. The variable effects may relate to the different cannabinoid agents used as well as to the differences in trial design. To date, no further studies have been performed in PD patients to assess the effects of cannabinoids on LID.

CB_1 receptor antagonists

Cannabinoid antagonists have also been proposed to reduce dyskinesia as increased levels of anandamide are found in the striatum in MPTP-primates after long term levodopa. CB_1 receptor stimulation on corticostriatal inputs may reduce overactive glutamate transmission, a key abnormality underlying dyskinesia. Preclinical studies in rodents and MPTP-lesioned primates have suggested that the CB_1 cannabinoid receptor antagonist rimonabant and another CB_1 receptor antagonist AVE1625 may reduce dyskinesia, without affecting parkinsonian disability and PD activity. As discussed, rimonabant has been assessed in a single study and also had no significant effect on dyskinesia.

Endocannabinoids in Dystonia

The neural mechanism underlying idiopathic dystonia is less well-defined but probably involves reduced output from the GPi and SNpr, an effect that may be driven by increased activity of the GPe. Animal models of the phenomenology of idiopathic dystonia are limited, but a genetic model of paroxysmal dystonia has been used for pharmacological investigation into potential therapies for dystonia. In this model, the CB_1 agonist WIN55,212 reduced dystonia, an effect blocked by the CB_1 antagonist rimonanbant. Several case reports have suggested potential for cannabinoids in focal dystonia. An RCT of acute treatment with nabilone in idiopathic generalized dystonia failed to show benefit (Fox et al., 2002). Further investigation of cannabinoids in dystonia is ongoing.

CAPIT, CAPSIT

H Widner, Lund University Hospital, Lund, Sweden

Introduction

The core evaluation program for intracerebral transplantation, the CAPIT, was created in response to the plethora of evaluation tests various groups within the neural tissue transplantation field presented at a Conference in Sweden in 1990. When trying to deduce any communality of the effects of the procedures, it became clear to all the participants at the meeting that a common evaluation program was essential, and a committee was appointed with members from various ongoing and planned transplantation programs. The CAPIT aimed at defining a minimal set of criteria for how a patient should be evaluated in an experimental transplantation study and defined diagnostic criteria, inclusions, exclusions, and the many issues around when and how to observe and evaluate patients. The CAPIT quickly became a standard for how to perform neurosurgical studies for Parkinson's disease in general, but it also soon became clear that what was sought to be a minimal common program was regarded as too cumbersome to manage larger patients groups. As some of the recommendations were clearly limited to the transplantation field and objections to some items were raised in the scientific literature, a new version was worked on by a working group within a EU-sponsored scientific project. The aim of the new version was to be applicable also to other neurosurgical techniques such as deep brain stimulation, DBS, and hence the new acronym CAPSIT, Core Assessment for Surgical Interventions and Transplantation. It was also added a tail – PD for Parkinson's disease, as a parallel EU-sponsored project, that worked toward the same end for transplantations and interventions in Huntington's Disease, resulting in a CAPSIT-HD. The original members of the CAPIT committee, along with the critics, were consulted prior to the completion of the CAPSIT-PD, and all have endorsed the newer version along with the EU-project participants. The CAPSIT should be regarded as the 2nd generation generic evaluation program.

The Core Evaluation and Suggested Protocol

The CAPIT/CAPSIT protocols aim at defining a minimal common evaluation program, allowing for comparisons between studies. It sets the criteria for how and when patients are to be assessed and is meant to be "inclusive," that is, allowing for the exchange of various items tested, bearing in mind that evaluation protocols also evolve

but that investigators should keep in mind the ability to compare back in time keeping also the "old versions" around for this purpose. The protocol is meant to be open in order to allow for specific study designs as needed (see **Figures 1** and **2**). There is a list of suggested terms and definitions that is very helpful and also a time chart.

Core Inclusion Criteria

Clinical Diagnostic Criteria

To secure as much as possible the diagnosis of idiopathic PD for the patients selected for surgery, a disease duration of a minimum of 5 years should be considered. The use of

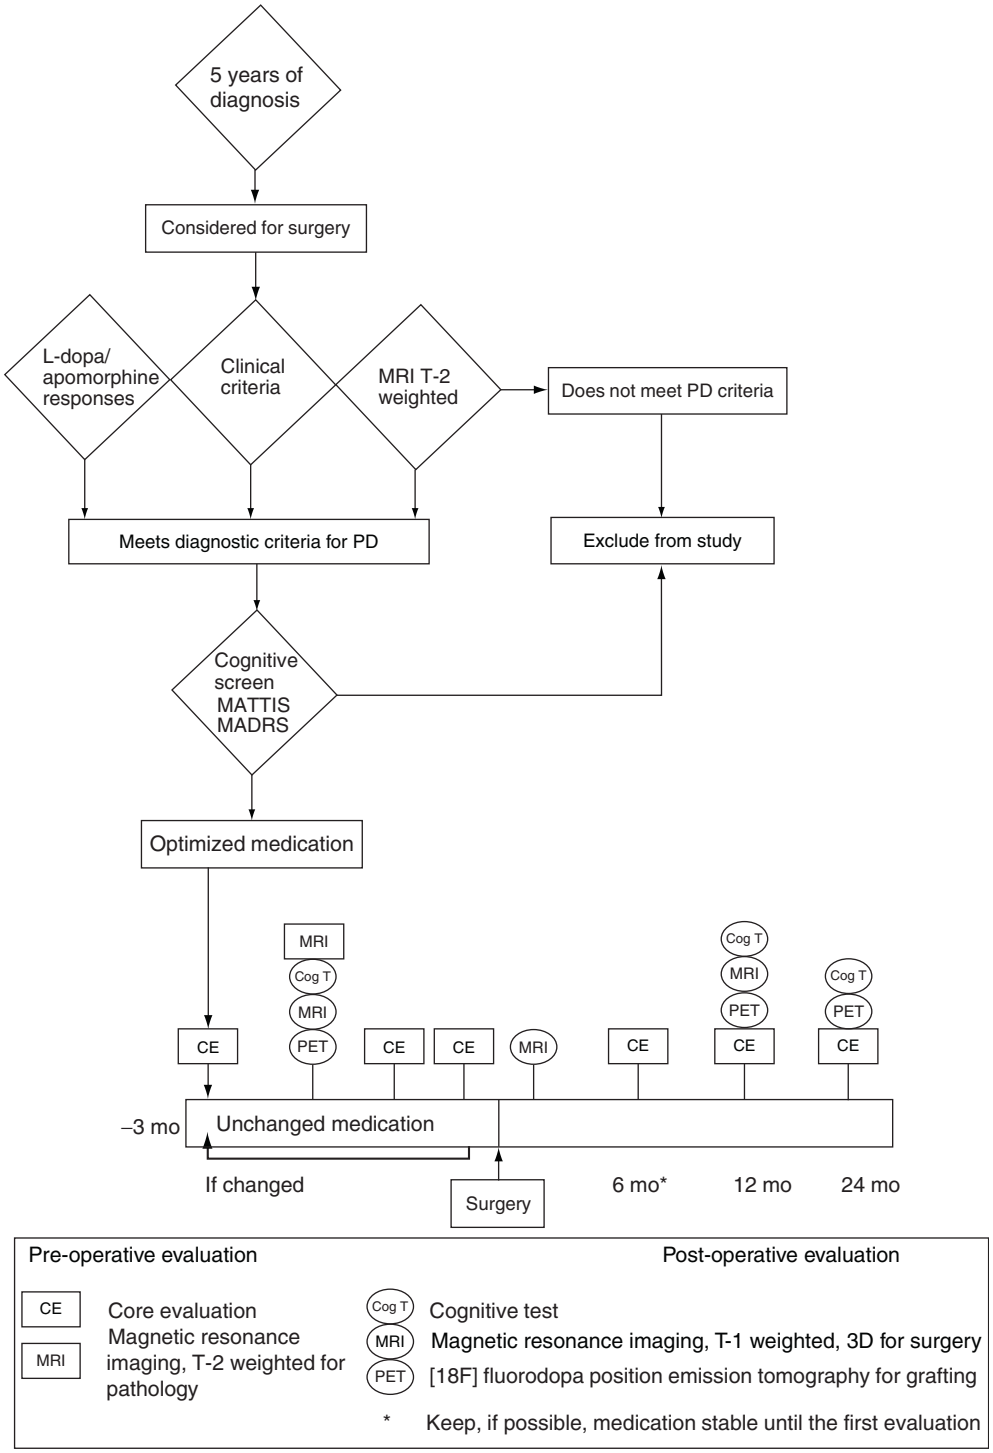

Figure 1 Schematic outline and proposed flow chart of the Core Assessment Program for Surgical Interventional Therapies. The time points for the different items in the program are indicated by symbols.

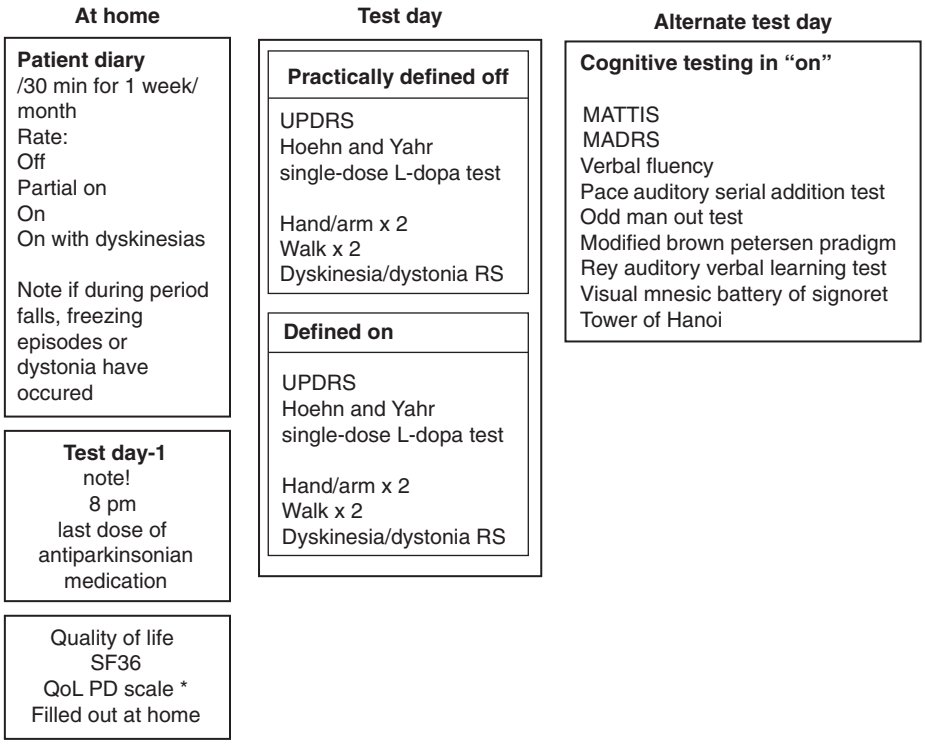

Figure 2 Outline of the contents of the Core Evaluation and a suggestion of the cognitive evaluation.

published consensus guidelines for PD with dementia, Multiple System Atrophy (MSA), dementia with Lewy bodies, and Progresive Supranuclear Palsy (PSP) is recommended to exclude patients with atypical parkinsonism.

Dopaminergic Responsiveness

The term dopaminergic responsiveness was intentionally chosen in place of L-dopa responsiveness in order to allow selection of patients treated and evaluated with dopamine agonists only. The dopaminergic responsiveness should be confirmed by a pharmacological test using L-dopa, or apomorphine for patients who cannot take, tolerate, or be correctly evaluated using L-dopa at the time of the selection for surgery. The test should induce at least a 33% decrease of the UPDRS part III score.

Cognitive and Behavioral Criteria

Two levels of evaluation are defined: the first level consists of a screening process in order to exclude patients with cognitive deterioration and/or having severe depression, with predetermined cutoff-scores defined and/or having major behavioral disorder.

The second level consists of standardized cognitive assessments in order to evaluate the impact of surgery on cognitive functions.

Definitions

Defined-off=the off condition observed after a patient has received no antiparkinsonian medication for 12 h.

Defined-on=the condition during the pharmacological test; the patient and the investigator both agree that the functional benefits are the most beneficial.

Core Methodology

Clinical Rating Scales

Unified Parkinson's Disease Rating Scale version (3.0) as a primary scale for the motor score (Part III) for evaluating dopaminergic responsiveness evaluation, and Hoehn and Yahr Staging are recommend.

Quality of Life Scale

The use of the SF 36 scale is highly recommended to assess the patient's quality of life. In addition, a PD-specific QoL scale is strongly encouraged. The patient should complete the scale forms before starting the preoperative evaluation, and thereafter, at the time of subsequent assessments, that is, 6 months, 1 and 2 years, and then once a year if the evaluation is continued.

Dyskinesia/Dystonia Rating Scale

There are different patterns of hyperkinesias, and the amount of dyskinesias varies over the day. There is no simple way of quantifying dyskinesias. Ratings are performed at least once in conjunction with the Core Evaluation with the patient in "defined-Off" and in "defined-On" conditions, as defined previously. For quantification, the patient is made to sit in a chair and observed at rest. The patient is then asked to perform the tests in the UPDRS motor part (III), that is, speaking, hand grips, finger taps, hand pronation/supination, leg ability test, raising from chair, and the timed tests, the hand–arm and the walking test as defined in the following section. The highest score of the dyskinesias observed during these tasks is recorded.

Self-Reporting

The use of a diary (over the day, waking hours, 30 min fractions) divided into four conditions is recommended: complete Off, partial Off, complete On, On with dyskinesias. The committee recommends that the patient perform the self-reporting as regular as possible at 1 week per month during the 3 preoperative months and then for 12 or, if possible, 24 months after surgery. Additional but optional items during each week of self-reporting are number of falls, number of freezing episodes, number of off episodes with dystonia.

Timed-Tests

Two timed tests are recommended for the motor evaluation:

- A hand–arm movement between two points 30 cm apart, for example, using a simple device for a defined fixed time (20 s). Each hand is tested twice and the mean time is reported.
- A walking-test, with the patient walking as fast as possible 7 m back and forth, including turning. The time and the number of steps are recorded. As an option, if freezing episodes occur, these can be noted.

These tests should be performed during the drug challenge in the defined-Off and defined-On conditions. In the case of a test failure, an a priori defined maximal value should be given.

Pharmacological Testing

A drug challenge using the patient's regular morning dose of L-dopa or apomorphine should be performed after a 12 h washout of antiparkinsonian drugs. If a patient fails to tolerate the washout, one should determine the longest tolerable washout and to keep this period for all subsequent assessments. The evaluations should include UPDRS and HY staging, timed-tests, and dyskinesia/dystonia rating. The dose (and the drug) used for the pharmacological test should be kept unchanged before and after surgery and should be the dose used to define the dopaminergic responsiveness. Other parameters of the test should be consistent, that is, patient fasted from midnight, gastrointestinal protection prior to apomorphine test, test started at the same time in the day.

Dopaminergic response parameters should be obtained for the defined-Off and the defined-On conditions respectively. Principally, DBS might be assessed in different conditions depending on the activity of the device (on or off) and the administration of the drug (with or without). It is recommended to perform the test in the following two conditions:

- device on, off medication;
- device on, on medication

In all cases, the stimulator should be maintained on during the washout period.

Timing and Numbers of Evaluations

The preoperative period should be at least 3 months and include three core evaluations.
The postoperative period should have three major end-points: 6 months, 1 year, and 2 years.
The assessment must be repeated on a yearly-basis if the evaluation is continued.

Medication Adjustment

The relatively short preoperative run-in period should not constitute any hindrance for a stable medication during this period. It is stressed that if the medication is changed at any time during the preoperative period, the latter should be restarted. It was further suggested that an assessment of the degree of medication changes at the last end-point of the evaluation (2 years) should be made.

Preoperative Period

During the 3 month preoperative period, medication should be kept unchanged. If not, a new evaluation period of 3 months should be started again.

Postoperative Period

For the postoperative period, the committee recommends to keep medication unchanged until the first end-point (6 months), provided there are no alteration of the clinical state and no negative interaction with the surgical procedure. The evaluation of a therapeutic end-point at 2 years (i.e., the % decrease of L-dopa and of other antiparkinsonian drugs) is recommended.

Imaging Criteria

Morphological Imaging

Preoperative period

MRI imaging (0–3 months prior to surgery) using T2-weighted coronal slices centered on the basal ganglia, and T1-weighted 3D images are strongly recommended. T2-weighted abnormalities should lead to exclusion of the patient from the study.

Postoperative period

MRI should be performed before stimulator implantation in deep brain stimulation surgery. For lesioning surgery, MRI might be performed in the first postoperative week, but an additional MRI 1 year after surgery is also recommended. The use of T1-weighted 3D images is again recommended.

In addition, the coordinates of the lesion/electrode position should be calculated. The use of Talairach's atlas for calculation of coordinates is recommended.

Functional Imaging

The use of PET in the evaluation of grafting procedure of parkinsonian patients has proved useful for the evaluation of survival and function of the grafted neuronal cells. If available, PET studies are recommended for neuronal graft procedures. [18F] Fluorodopa PET-scanning should be performed before and 1 and 2 years after surgery. The patients should be scanned ~10–12 hours after drug withdrawal (defined off). Carbidopa (100–150 mg) or benserazide (50 mg) should be given one hour before injection of the tracer. Measures of brain metabolism with [18F] Fluoro-deoxyglucose, or motor activation studies using H2[15O]-cerebral blood flow measurements, have evidenced functional changes.

Cognitive and Behavioral Assessment

The goal of the CAPSIT evaluation was to add neuropsychological inclusion/exclusion criteria as well as a test battery for pre- and postoperative assessments. Pre- and postoperative cognitive evaluations should incorporate tests sensitive to frontal lobe function in order to detect possible alterations by the surgical manipulations and should be selected according to the following considerations:

(a) the tests need to be especially sensitive for executive tasks, including working memory, episodic memory tasks, and procedural memory tasks;
(b) retest effect should be minimal or parallel forms must be available;
(c) the tests have to be sensitive enough in order to assess the preoperative patient status and to detect changes induced by the surgical procedure (positive or negative effect);
(d) completion of the test battery should not require more than 90 min.

To reduce psychiatric abnormalities that could interfere with the neurological assessment, patients with major behavioral disorders or severe psychiatric illness should be excluded. A psychiatric evaluation including the Minnesota Multiphasic Personality Inventory (MMPI) and the Montgomery and Åsberg depression rating scale (MADRS) in order to exclude patients with a high risk of psychiatric complications after surgery.

Exclusion–Inclusion Criteria

Mattis Dementia rating scale (MDRS) with a suggested cutoff score=130 or 120. Montgomery and Åsberg depression rating scale (MADRS); suggested cutoff score: 7–19. Minnesota Multiphasic Personality Inventory (MMPI).

Preoperative Evaluations and Follow-up

General and behavioral evaluation: Mattis Dementia rating scale and the Montgomery and Åsberg depression rating scale (MADRS).

Executive functions: Verbal fluency: letters F, A, and S (set maintenance with external cue). Paced Auditory Serial Addition Test (shifting ability). Odd-Man-Out Test (set maintenance with internal cue). Modified Brown Peterson Paradigm (MBPP: working memory).

Explicit memory: Rey auditory verbal learning test (RAVLT) and Visual mnesic battery of Signoret (BEM 144, only learning phase of graphic signs).

Procedural memory: Short Version of Tower of Hanoi.

Carbon Monoxide Poisoning

Y H Sohn, Yonsei University College of Medicine, Seoul, South Korea

Glossary

Carbon monoxide – A colorless, odorless, tasteless yet highly toxic gas, primarily produced by a partial combustion of carbon-containing compounds. Its molecule consists of one carbon atom covalently bonded to one oxygen atom.

Carbon monoxide poisoning – A leading cause of fatal poisoning worldwide, primarily caused by the inhalation of carbon monoxide gas. It mainly affects the brain and the heart.

Hemoglobin – The iron-containing, oxygen-transport metalloprotein in the red blood cells of vertebrates.

Hyperbaric oxygen therapy – The medical use of oxygen at a higher than atmospheric pressure.

Hypoxia – A pathological condition in which the body as a whole or region of the body is deprived of adequate oxygen supply.

Definition and History

Carbon monoxide (CO) is a colorless, tasteless, odorless, nonirritating but highly toxic gas, primarily produced by an incomplete combustion of hydrocarbons. CO was first described by the Spanish doctor Amaldus de Villa Nova in the eleventh century, and its toxic properties were first investigated by the French physiologist Claude Bernard around 1846.

Epidemiology/Pathophysiology

CO poisoning is a leading cause of poisoning mortality in the world and may account for more than half of all fatal poisonings. CO binds rapidly to hemoglobin with an affinity more than 200 times that of oxygen, leading to the formation of carboxyhemoglobin (COHb) that significantly decreases the oxygen-carrying capacity of the blood, causing tissue hypoxia. Reperfusion injury can be caused by CO-induced tissue hypoxia. Hyperoxygenation promotes the production of partially reduced oxygen species, which in turn can oxidize essential proteins and nucleic acids, resulting in typical reperfusion injury to the central nervous system (CNS). CO exposure also causes lipid peroxygenation producing demyelination of CNS lipids.

Diagnosis

The clinical symptoms and signs of CO poisoning are often nonspecific and may mimic various common disorders. Mild poisoning may cause flu-like symptoms, while severe poisoning can cause coma or even death. Thus, CO poisoning is often difficult to detect unless the attending physician has a high level of suspicion. CO poisoning can be suspected when more than one person or pet is affected, particularly if there are combustion appliances or a fireplace, or an environment with occupational exposure. Diagnosis of CO poisoning usually depends on a patient's serum COHb level. A nonsmoker would be expected to have a baseline level of less than 3% from the endogenous production of CO and background environmental exposure, whereas smokers may have levels of up to 10%, particularly immediately after smoking. Thus,

CO poisoning should be suspected if someone shows serum COHb higher than these levels. Relatively low COHb levels, between 10 and 20%, usually produce mild symptoms of CO poisoning such as nausea and headache, while levels greater than 60–70% are highly fatal. The half-life of serum COHb is about 4–5 h; the measurement of serum COHb level should be performed as soon as possible, and the interval between CO exposure and serum testing should be taken into account for the diagnosis of CO poisoning based on serum COHb levels.

Acute Intoxication

The brain and the heart, because of their high metabolic rates, are the organs most susceptible to CO toxicity. The clinical symptoms and signs associated with acute CO poisoning are listed in **Table 1**. Early neurologic manifestations include headache, dizziness, and nausea. More exposure may cause altered mental status, confusion, seizure, and coma. Early cardiovascular effects of CO poisoning present as tachycardia and tachypnea in response to hypoxia. Increasing exposure may result in hypotension, dysrhythmia, ischemia, infarction, and rarely cardiac arrest. CO poisoning also exacerbates the underlying cardiovascular diseases; even low-level exposure may produce dysrhythmia in patients with coronary artery disease. CO poisoning may also cause rhabdomyolysis as a direct toxic effect of CO on skeletal muscles and results in acute renal failure.

Table 1 Clinical signs and symptoms of CO poisoning

Acute poisoning	*Delayed sequele*
Mild	*Neurological deficits*
Headache	Parkinsonism/other motor disturbances
Dizziness	Ataxia/gait disturbance
Nausea/vomiting	Urinary and fecal incontinence
	Cortical blindness
	Seizure
	Mutism
Moderate	*Psychiatric deficits*
Confusion/memory loss	Memory loss
Irritability/disorientation	Emotional lability
Incoordination/weakness	Confusion/disorientation
Dyspnea/tachypnea	Psychosis/hallucinations
Chest pain/tachycardia	
Severe	
Hypotension/syncope	
Convulsions/seizures	
Myocardial ischemia/ cardiac arrest	
Coma	
Death	

Delayed Sequelae

The effects of CO poisoning are not confined to the acute period after exposure. There are two types of chronic sequelae of CO poisoning: the persistently progressive type and the delayed relapsing type. The persistently progressive type is diagnosed when the patient's neuropsychiatric deficits are progressively deteriorating without any sign of recovery from acute intoxication, while the delayed relapsing type, often referred to as 'delayed neurological sequelae (DNS),' is diagnosed when the patient apparently recovers from acute intoxication and then develops behavioral and neurological deterioration after a latency period of 2–40 days, the so-called 'lucid interval.' DNS may manifest itself as memory loss, confusion, ataxia, seizures, urinary and fecal incontinence, disorientation, hallucinations, parkinsonism, mutism, psychosis, and gait or other motor disturbances (**Table 1**). DNS occurs in about 10% of hospitalized patients with acute CO poisoning. The risk of developing DNS is particularly high in patients with more severe initial deficits such as loss of consciousness and/or older age. Once DNS develops, about 70% of the patients may recover within 1 year, while the others relentlessly deteriorate to become bedridden or even die. The mechanisms underlying DNS remain to be elucidated, but recent reports suggest that diffuse white matter changes, either demyelination or axonal damage, are mainly responsible for DNS.

Pathology

Pathological findings in the brains of CO-poisoned patients include white matter changes such as demyelination and axonal damage and necrosis of the globus pallidus. Accordingly, brain MRI often shows diffuse white matter hyperintensities and hemorrhagic necroses of the pallidum (**Figure 1**). Although the patients with DNS often have accompanying symptoms of severe parkinsonism, pathological studies rarely show substantia nigra damage. Dopamine transporter imaging of DNS patients has demonstrated a significant dopamine neuronal loss, but the degree of loss is much less than that observed in patients with Parkinson's disease. Recent reports suggest that white matter changes are more likely related to DNS than either pallidal necrosis or dopamine neuronal loss. Reversible DNS cases are usually thought to be associated with pure demyelination, while those with progressive deterioration presumably have additional axon damage. Routine brain MRI cannot distinguish pure demyelination from axonal damage, but MR spectroscopy may help to determine the severity of white matter damage and decide the prognosis of DNS patients.

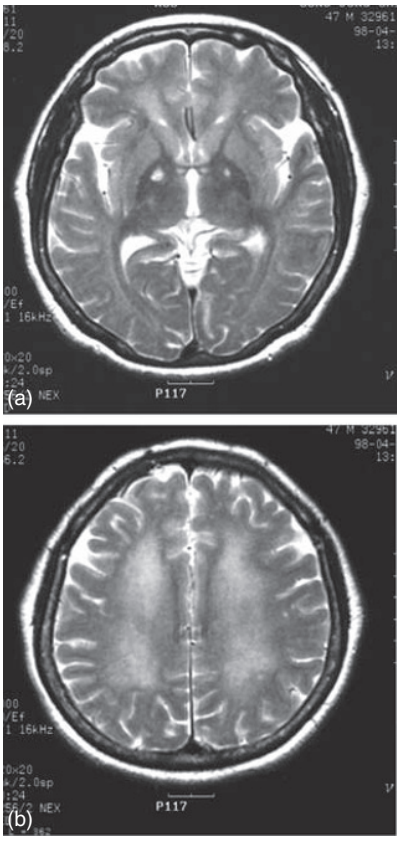

Figure 1 T2-weighted MRI obtained one month after CO poisoning in a patient shows (a) necroses of the bilateral globus pallidus and (b) diffuse high signal lesions in the white matter.

Management

Treatment of acute CO poisoning should begin with supplemental oxygen and aggressive supportive care that includes airway maintenance, blood pressure support, and cardiovascular stabilization. High-flow oxygen therapy helps in reducing damage from CO-induced hypoxia, as well as in promoting the elimination of CO from the body. Since the clinical signs and symptoms of CO poisoning are nonspecific, patients under suspicion of CO poisoning should be treated with oxygen inhalation immediately after blood is drawn for COHb measurements. Increasing the partial pressure of oxygen decreases the half-life of COHb: approximately 40–80 min with 100% oxygen under ambient pressure, and approximately 20 min with 100% oxygen at 2.5–3.0 atm absolute (ATA), also known as 'hyperbaric oxygen therapy' (HBOT). HBOT accelerates the dissociation of CO from hemoglobin and other heme-containing proteins such as cytochromes. However, animal experiments have demonstrated that HBOT does not prevent neuronal injury following CO poisoning and has the potential to increase oxidative damage because of increased production of free radicals. Randomized controlled trials, although they have failed to show consistent results, demonstrate that HBOT can promote recovery from acute CO poisoning and reduce the development of DNS better than oxygen under ambient pressure. Thus, HBOT may be indicated for patients of older age who present with severe CO poisoning.

Caspases and Neuronal Cell Death

B A Citron, Bay Pines VA Healthcare System, Bay Pines, FL, USA

Glossary

Amyotrophic lateral sclerosis (ALS) – Lou Gehrig's disease is caused by the death of motor neurons in the spinal cord resulting in progressive paralysis.
Apoptosis – A form of programmed cell death that is useful during development, to remove excess cells, but harmful when irreplaceable motor neurons are lost. It is characterized by DNA fragmentation, chromatin condensation, and membrane blebbing.
Caspase – Cysteine aspartic acid proteases digest and cleave other proteins, including other caspases, frequently inducing apoptosis.
Motor neuron – Large nerve cells predominantly populating the ventral horns of the spinal cord that communicate impulses to muscles.
Necrosis – Accidental cell death involving rapid cell lysis.
Parkinson's disease – A relatively common neurodegenerative condition leading to muscular rigidity and tremor.
Programmed cell death – Genetically dictated, active cell death requiring transcription and protein synthesis.
Transcription factor – An intracellular molecule that, as an early step in gene regulation, recognizes specific DNA sites and controls whether, and how often, messenger RNA is synthesized from particular genes.

Definition and History of Caspases

Apoptotic programmed cell death is a normal process in the developing central nervous system (CNS); however, it may also be induced by a variety of stimuli including toxins, pharmacologic agents, viral infections, and other biochemical upsets in a variety of disorders resulting in the loss of neurons and motor function. More than 50 genes have been identified as promoting apoptosis with more than one-fourth of these being proteases. The key proteases involved are termed caspases, for cysteine aspartic acid proteases, originally defined as members of the nematode, *Caenorhabditis elegans* cell death (CED-3) family of proteases by the Nobel Prize winning work of Sydney Brenner, Robert Horvitz, and John Sulston. Caspase-1 was originally identified as interleukin converting enzyme (ICE), and caspase-3 has been termed Yama (after the Hindu God of death), CPP32β, and apopain. Caspase-3 cleaves poly(ADP-ribose) polymerase (PARP), an enzyme involved in DNA maintenance.

Apoptosis was first used in a modern, cell biology context by Kerr, Wylie, and Currie in 1972. The term apoptosis is, of Greek origin, referring to dropping off of petals and leaves, and Hippocrates used the term medically in ~400 BC, followed by Galen in ~175 AD. In the 1800s, the process was described by Carl Vogt studying tadpoles and later by Walter Flemming. Various alternative programmed cell death mechanisms have also been reported, for example paraptosis, identified in 2000, has been observed in some instances and does not involve the same protease activations or apoptotic bodies. The other common form of cell death is necrosis which involves rapid lysis. Discriminating characteristics of apoptosis versus necrosis are listed in **Table 1**. After the first three papers in 1972, publications addressing apoptosis reached 100 in 1990, and these have since increased exponentially to over 19 000 in 2008.

The primary caspase mediated cell death mode, apoptosis, is a positive process during development, when vestigial organs and excess neurons are removed. Later, apoptosis is involved in the removal of harmful cells and regulation of the immune system. Dysregulation of apoptosis is harmful in certain disorders of the immune system, cancer, and neurodegenerative diseases. Caspase triggered cell death can be induced through starvation, hypoxia, viral infection, or stress. Signaling through death receptors, involving tumor necrosis factor receptors (TNFR) and tumor necrosis factor associated death domain proteins (TRADD, FADD) can lead to conversion of procaspase-8 to activated caspase-8 which in turn activates caspase-3 by removal of its N-terminal prodomain. Caspase-3 cleaves cell survival (repair) proteins in an irreversible process resulting in apoptotic bodies and cell death. Positive regulators of caspases include bax, bak, bid, and bad and negative regulators include bcl-2, bcl-xl, and bcl-W. These factors generally involve response mechanisms for cellular damage.

Caspase Functions

When caspase-3 is knocked out in mice, they do not survive longer than about 2 weeks. In these mice, there are obvious brain abnormalities including disorganization, duplicate

structures, and overall brain size 2–3 times larger than normal.

There are probably several hundred caspase substrates, and these include regulatory proteins (e.g., DNA fragmentation factor (DFF/ICAD), PKCδ), cytoskeletal proteins (Actin, Fodrin), nuclear proteins (PARP, 70 kD U1 small nuclear ribonucleoprotein (SNRP)), and molecules for triplet repeat neuromuscular disorders (e.g., Huntingtin) (see **Table 2**).

Apoptosis is measured by directly counting changes in cell numbers, viability assays, staining with cell impermeant dyes, observing chromatin condensation with nucleic acid stains like Hoechst 33342, examining DNA fragmentation by TUNEL, ISEL, or electrophoresis on agarose gels, staining for external phosphatidyl serine with Annexin V, and electron microscopy which early on was considered the standard to define apoptotic cells.

Table 1 The major forms of neuronal cell death

Apoptosis	*Necrosis*
Mild insult	Major insult
Nuclear chromatin condensation and margination	Degradation
Cytoplasmic shrinking, endoplasmic reticulum dilation	Swelling
Membrane blebbing	Early membrane disruption
Intact mitochondria, some swelling	Swollen mitochondria
Apoptotic bodies	Lysis
Caspase activation	Not programmed

Table 2 Caspase categories

Category	*Caspases*	*Target*	*Known substrates*
Group I	1, 4, 5, 11, 12, 13	WEHD	Inflammatory processes, pro-IL-1β, procaspases-1,-3,-4
Group II	2, 3*, 7, CED-3	DEXD	Maintenance and repair proteins during apoptosis, CED-3 sterol regulatory binding proteins, PARP, procaspases-6,-9, DNA dependent protein kinase, kinase Cδ
Group III	6, 8, 9, 10	(L/V) EXD	Caspases-3 and-7, poly(ADP-ribose) polymerase, lamins
*Caspase-3, (CPP32, Yama, apopain)		DEVD	Poly(ADP-ribose) polymerase, huntingtin, sterol regulatory element binding proteins, D4G-protein dissociation inhibitor, 70 kDa subunit of U1 SNRP

Regulation of Caspases

Caspases are central to a variety of pathways important to the health of neurons and some of these are shown in **Figure 1**.

In the mid-1990s, apoptosis was identified in spinal cords and brains after traumatic injury. It was shown that caspase-3 was activated and that inhibition of caspase-3 could result in improved recovery in animal models. Importantly, the peak of apoptosis occurs in neurons, microglia, and astrocytes about 3 days after the impact injury providing a window of therapeutic opportunity.

Dysregulated genes fall into categories generally consistent with functional and morphological changes in the motor system. Certain proapoptotic genes, like death-associated protein kinase 1, are upregulated while some antiapoptotic genes, such as peroxiredoxin 2, are downregulated. In injured rat spinal cords, proapoptotic p53 mRNA was upregulated more than twofold. At 24 h after moderate injury, mRNA for the Bcl-2 antagonist of cell death, Bad, increased 60%. Bad inhibits the apoptosis repression activity of Bcl-x(L) and hence promotes apoptosis. This might counter the increased expression of the antiapoptotic factor, bcl-2, after cord injury. A similar increase was seen in a neuronal cell death related gene, DN-7, also known as the TATA box binding protein-associated factor 9 (TAF9) which interacts with p53 to induce transcription of target genes, such as bax. A moderate upregulation of the death effector domain containing protein, DEDD, was also seen. These observations of pathways involved in motor neuron loss in vitro and in vivo may help us understand how we may preserve neurons.

Transcription Factors

Sp1, p53, NF-κB, Atf3, Atf5, Atf6, c-Jun, CREB, HSF1, and C/EBP and several other transcription factors are involved to varying extents in cell death pathways. NF-κB is one transcription factor that plays a significant role in inflammatory responses. NF-κB is activated by a variety of intercellular signals that can both induce and prevent apoptosis. Controversy currently exists, as to whether NF-κB is primarily a pro- or antiapoptotic signal. Experiments testing NF-κB involvement have been aided by parthenolide, a sesquiterpene lactone, that can inhibit NF-κB activity either by alkylating the p65 subunit and/or by inhibiting the degradation of IκBs. The ability to directly and specifically inhibit transcription factors provides tests as to their

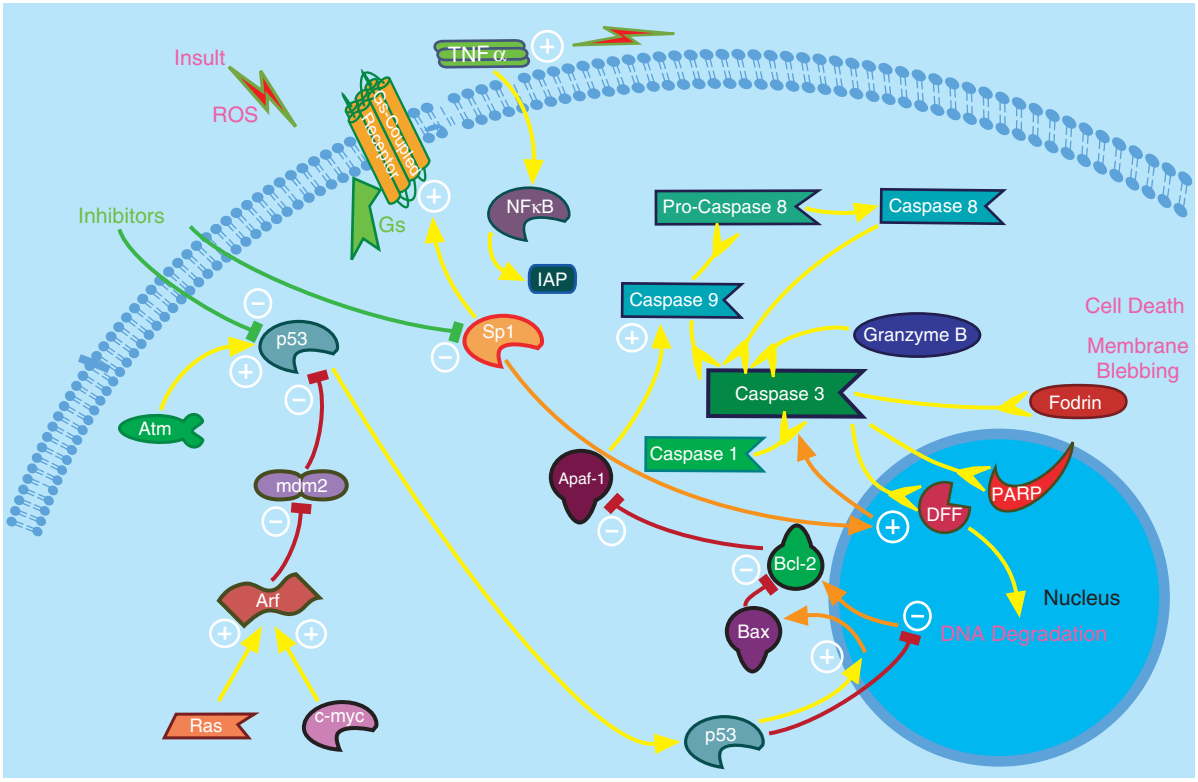

Figure 1 Caspases are among many factors involved in neuronal survival. Several pathways important to neuronal health have been drawn with BioCarta icons and symbology (www.biocarta.com). Insults can result in increased proteases which trigger protease activated receptors (PARs) coupled to G-proteins. Transcription factors such as NF-κB, Atf5, and Sp1 participate in regulatory choices important to survival although the extent of this regulation is not understood in motor neurons or in the degenerating spinal cord. Reactive oxygen species (ROS) also trigger cell death. Many other pathways are not shown. For example, tissue transglutaminase (tTG) is cleaved by proteases or its RNA is alternatively processed to produce a potentially hyperactive protein. tTG can crosslink proteins into aggregates and inclusions (e.g., Lewy bodies). Calcium influx (Ca^{2+}) affects enzymes requiring calcium for activity (e.g., transglutaminase). Also, the proteinase complex, regulated by Parkin and other factors, processes many proteins involved in neurodegeneration including Tau, neurofilament, β-amyloid, synuclein, huntingtin, and p53. Two mechanisms naturally regulating p53 are illustrated in the diagram. The oncogenes Ras and c-myc can induce Arf which promotes the degradation of the mouse double minute 2 homolog, mdm2. Mdm2 could otherwise complex p53 inhibiting its gene transactivation. The ataxia telangiectasia mutated protein (Atm) activates p53 by phophorylation, in response to damage. Examples of genes regulated by p53 include induction of proapoptotic Bax and downregulation of antiapoptotic B-cell lymphoma oncogene, Bcl-2. Bcl-2 would block Apaf-1 initiation of the caspase cascade through caspase-9, caspase-8, and Granzyme B activation of caspase-3 leading to cell death. Caspase substrates include DNA fragmentation factor (DFF), poly (ADP-ribose) polymerase (PARP), and Fodrin (nonerythroid spectin). Their cleavages are the terminal biochemical events leading to membrane blebbing and cell death.

roles in cellular responses and suggests a role in future treatments of disorders associated with transcription factor activation.

Motor neurons may also become susceptible to cell death by early upregulation of the transcription factor, p53. Supporting this, we have determined that p53 levels increase twofold in mouse spinal cords when motor neurons are programmed to die. In a major motor neuron loss disease, Lou Geherig's disease (also known as amyotrophic lateral sclerosis, ALS), p53 is prominently involved.

Although caspases are predominantly constitutively expressed and activated by proteolysis, the central apoptotic caspase-3 is also regulated at the level of gene expression. Differential mRNA display and other measures of mRNA levels demonstrated upregulation of caspase-3 during motor neuron loss in neurodegenerative mouse models and after traumatic CNS injury. Caspase-3 is regulated by the transcription factor Sp1, based on consensus sequences in the promoter and biochemical analysis of caspase-3 regulation in cultured cells and inhibition with the Sp1 inhibitor, mithramycin A.

Therapeutic Prospects

Many neurodegenerative disorders, including spinal cord injuries, have no cure. From a molecular standpoint, there is no reason to doubt that there can be an effective

Table 3 Drugs reducing apoptosis

Compound	*Target*	*Compound*	*Target*
Nerve growth factor (NGF)	Tumor necrosis factor (TNF) superfamily receptors	Glial cell-line derived neurotrophic factor	Neurotrophic factor receptors
Progesterone	Hormone receptors	E-64-d	Calpain
Fibroblast growth factor (FGF)	Tyrosine kinase receptors	Antiinflammatory agents	TNF-α
Indolcarbazole derivatives	c-Jun N-teminal kinase 1 (JNK1)	Fasudil HCl	Protein kinase (PK) inhibition
Dihydroxytestosterone	Androgen receptors	Deprenyl, diphenylpiperazines	Monoamine oxidase (MAO) inhibition
Minocycline, Boc-D-FMK	Caspases	MK-801, *N*-methyl-D-aspartate (NMDA) receptor antagonists, glutamate antagonists	Glutamate excitotoxicity
Pifithrin-α	p53	Granulocyte colony stimulating factor	Induces antiapoptotic pathways
Ac-DEVD-CHO	Caspase-3	Tirilazad mesylate, α-tocopherol	Reactive oxygen species (ROS)

treatment for spinal cord injury. Although regeneration or replacement via stem cells will likely prove fruitful, an earlier intervention aimed at preventing the initial loss of neurons should benefit many patients. There are early indications that portend well for the future. Several studies have provided evidence that tetrapeptide caspase inhibitors reduce cavitation and enhance functional recovery after spinal cord injury in rodent models.

It is likely that effective prevention of irrecoverable motor neuron loss will involve multiple pharmaceuticals targeting several processes. Since apoptosis is a major process in the death of neurons in the CNS, inhibition of different apoptotic pathways should prove to be beneficial and several inhibitors that have been tested are shown in **Table 3**.

Cayman Ataxia

R L Albin, University of Michigan, MI, USA

Glossary

Ataxia – Incoordination of movement.
Cerebellum – Major brain region mediating coordination.
Dystonia – Involuntary movements characterized by abnormal posture of the affected body part, often with a torsional component.

Epidemiology

Cayman ataxia (OMIM #601238) is a rare, autosomal recessive disorder found solely in the Cayman Islands. Founder effects and an isolated population with a high rate of consanguineous marriage resulted in a relatively high prevalence of Cayman ataxia and at least two other rare recessive disorders, Mucopolysaccharidosis III/A (Sanfilippo syndrome) and Usher syndrome. In 2006, there were an estimated living 24 individuals with Cayman ataxia, out of a total population of approximately 48,000 Cayman Islanders: an approximate prevalence of 50/100,000, greatly exceeding the prevalence of any ataxic disorder in the United States. The increasing diversity of the Cayman Islands' population and a drop in consanguineous marriages have caused a decline in the incidence and prevalence of Cayman ataxia.

Clinical Features

There is little published literature on the phenotype of Cayman ataxia. Available descriptions indicate the presence of hypotonia in early childhood, variable mental retardation, extraocular muscle paralysis, pes planus, and scoliosis. Cerebellar dysfunction, including limb dystaxia, dysarthria, nystagmus, dystaxic gait, and tremor, is prominent. There is no reported pathology of Cayman ataxia. One anecdotal report describes cerebellar hypoplasia on neuroimaging. Those with Cayman ataxia require special education. The overall impression is of a congenital static encephalopathy of variable severity. Cayman ataxia is compatible with a normal lifespan.

Genetics

In 2003, Bomar et al. established that Cayman ataxia was due to mutations in the *ATCAY* locus, which produces the caytaxin protein. Bomar et al. found two homozygous sequence variants in the DNA of Cayman ataxia subjects: a C-to-G change in exon 9, predicting a serine to arginine substitution at amino acid 301, and a G-to-T substitution in the third base of intron 9. The serine to arginine substitution is not predicted to alter caytaxin protein structure, but the intronic G-to-T substitution disrupts RNA splicing, producing a significantly truncated transcript and resulting in a marked but probably not complete deficit of mature caytaxin mRNA.

Rodent Homologs

The search for the ATCAY locus was paralleled and facilitated by the identification of 3 relevant, spontaneously occurring murine mutations. Jittery (*ji*), hesitant (ji^{hes}), and sidewinder (ji^{swd}) are allelic mutations of varying severity. Jittery and sidewinder mice have a severe phenotype with marked ataxia, dystonic limb postures, and death prior to 1 month of age. Hesitant mice have a milder phenotype with milder ataxia, dystonia, and normal lifespan and fertility. Bomar et al. discovered jittery, hesitant, and sidewinder result from different mutations in the murine homolog of *ATCAY*. Jittery has a B1 element insertion in exon 4 and hesitant has an IAP insertion in intron 1. Both mutations produce aberrant transcripts, but the hesitant mutation allows production of a small amount of normal message, accounting for the milder phenotype. The sidewinder mutation is a 2 base pair deletion in exon 5, resulting in a significantly truncated transcript.

Mutation of the rat homolog of *ATCAY* was identified subsequently as the defect underlying the phenotype of the recessive genetically dystonic rat. Homozygotes of this line exhibit marked generalized dystonia, which can be detected as early as postnatal day 12. Dystonia worsens and mice die by about postnatal day 40. The mutation is an IAP insertion in exon 1, resulting in abnormal transcripts. The phenotype can be largely ameliorated by cerebellectomy. Careful histologic analysis of genetically dystonic rats reveals only subtle changes. Cerebellar physiology, particularly the function of the olivocerebellar system, is markedly abnormal. Interestingly, routine histology of the jittery mouse is unrevealing as well.

The presence of apparent dystonia in these rats has led to the suggestion that cerebellar function abnormalities could underlie dystonia in humans.

Caytaxin Biology

Caytaxin is a 371 amino acid, 42 kD protein of unknown function. Caytaxin is suggested to have a CRAL-TRIO domain, which is responsible for binding small lipophilic molecules. Caytaxin has also been named BNIP-H (for BNIP-2 homology), because it has 69% amino acid sequence similarity to the BNIP-2 protein. BNIP-2 and related proteins may possess a novel protein–protein binding domain called BCH (BNIP-2 and Cdc42GAP homology). Caytaxin is expressed solely by neurons and is expressed widely in the CNS. Caytaxin expression is regulated in the course of development. Subcellular fractionation experiments indicate that caytaxin in localized to the presynaptic cytosol. In cerebellar cortex, caytaxin may be expressed by granule cell terminals synapsing on purkinje cells. Buschdorf et al. suggest that caytaxin binds to and regulates the glutaminase responsible for producing neurotransmitter glutamate. The phenotypes of Cayman ataxia and of rat and mouse *ATCAY* homolog mutants suggest that caytaxin plays an important role in cerebellar development and cerebellar function.

Central Nervous System Stimulants and Movement Disorders

S Gancher, Oregon Health Sciences University, Staff Neurologist, Kaiser Permanente, Portland, OR, USA

Glossary

Choreoathetosis – A movement disorder causing random movements with jerky, writhing qualities.
Dystonia – A movement disorder causing abnormal postures.
Stereotypy – A movement disorder in which similar movements are repeatedly exhibited. Tongue thrusting, chewing, lip licking, and lip protrusion are the most typical symptoms.
Substituted amphetamines – Drugs with an amphetamine structure in which additional molecules (usually a methyl group) have been added to the phenyl ring. They have mixed amphetamine and hallucinogenic properties.

Definition and History

Amphetamines are a class of compounds with a relatively simple chemical structure that is shared by catecholamine neurotransmitters (dopamine, epinephrine, norepinephrine) and some aromatic amino acids. They are old drugs; amphetamine was originally synthesized in the late 1800s and methamphetamine in 1919. First used as nasal decongestants and for asthma, amphetamines had become widely used as stimulants, for weight loss, to promote vigilance, and to improve concentration and memory before their abuse potential was recognized and their use restricted. Although both amphetamine and methamphetamine induce euphoria, methamphetamine is more potent, and when used parenterally, induces a strong 'rush' of euphoria that is very similar to cocaine but longer lasting.

Substituted amphetamines, most notably 3,4-methylenedioxymethamphetamine (MDMA) ('ecstasy'), have mixed stimulant and hallucinogenic properties; psychic effects include a feeling of increased energy as well as a sense of well being and empathy and visual hallucinations. More typical amphetamine effects such as increased body temperature, hypertension, tachycardia, and increased respirations also occur. Many of the substituted amphetamines have been poorly characterized and their toxicities are largely unknown.

Methylphenidate and pemoline (which has been withdrawn from use because of hepatotoxicity) are CNS stimulants that are structurally unrelated but have effects similar to amphetamine.

Cocaine, an alkaloid derived from the coca plant, has been used since antiquity as a stimulant and to suppress appetite. It became very popular in the 1800s and was widely available in tea and soft drinks, and was used medicinally for depression and as a patent medicine for nasal congestion and toothaches before being reclassified as a narcotic. A nonionized, basic form of cocaine ('free-base' or 'crack'), which is able to be vaporized by heat, has also become a widely abused form of the drug.

Pharmacology

Amphetamines are readily absorbed when administered orally; peak plasma concentrations occur in 2–3 h after immediate release and 4–7 h after sustained release formulations. Peak levels occur within minutes of parenteral administration.

Amphetamine and methylphenidate stimulate release of monoamine neurotransmitters from nerve terminals; in the peripheral nervous system, this results in sympathetic effects including tachycardia, hypertension, increased respiration, and temperature.

Substituted amphetamines have similar effects, but have a higher affinity for serotonergic nerve terminals.

Cocaine acts by a mechanism slightly different from that of amphetamines; rather than stimulating release of monoamine neurotransmitters, cocaine blocks their reuptake in presynaptic nerve terminals. The net effects are similar to amphetamine, though; the effects of an intravenous dose of cocaine are nearly indistinguishable from the effects of methamphetamine.

The increase in dopaminergic neurotransmission in the ventral striatum and nucleus accumbens is thought to account for most of the psychic effects and abuse potential of CNS stimulants. In addition, a major factor that likely leads to some of the movement disorders and psychosis induced by CNS stimulants is drug-induced sensitization.

With repeated administration of many drugs of abuse, an increase in their behavioral effects occurs. A simple example is locomotor activity induced by amphetamine or cocaine in rodents. With repeated administration of these drugs, a marked increase in the duration and peak behavioral effects is seen at doses lower than in previously untreated animals. In addition, more complex and novel behaviors develop with repeated drug administration; rodents may develop chewing behaviors that are not seen with initial drug exposure. This mechanism is probably the basis for the development of levodopa-induced dyskinesia in patients with Parkinson's disease.

The neuroanatomy and neurochemistry of sensitization is complex. Acetylcholine, adenosine, and serotonin are important in modulating the effects of amphetamine, MDMA, and cocaine in affecting firing rates and dopamine turnover in striatal or dopaminergic neurons, and each can be affected differently with repeated drug administration.

Tremor

The most common movement disorder induced by CNS stimulants is probably tremor, particularly at higher doses and with more potent drugs. Methamphetamine, cocaine, and MDMA are well recognized by the lay public, drug counselors, and emergency physicians to cause tremor, usually accompanied by other signs of adrenergic effects such as tachycardia and hypertension.

Similar to a number of other drug-induced tremors, the tremor is usually a postural and action tremor, chiefly affecting the upper extremities. Although it is similar to essential tremor, drug-induced action tremor rarely affects cranial muscles, the trunk, or lower extremities.

In individuals who already have essential tremor or another drug-induced tremor, CNS stimulants can significantly exacerbate tremor.

Tic Disorders

Tic disorders are also commonly seen with the use of amphetamines and cocaine, as well as other CNS stimulants used in attention deficit hyperactivity disorder (ADHD) such as methylphenidate (and formerly pemoline).

Although tics can occur de novo with stimulant use, it is more common for these drugs to produce tics in individuals with a current or previous history of a tic disorder. This is especially common in children treated with stimulants for ADHD. When stimulants became commonly used in children, a number of case reports were published that described either emergence or worsening of a tic disorder, and these drugs were then felt to be injurious if a child developed a tic during treatment. More recent studies, though, indicate that these risks were

overestimated. Although ~5–10% of children treated with CNS stimulants may either develop tics de novo or may experience exacerbation of tics, it has also been seen that tics may improve or remit with continued stimulant treatment, and these drugs are now viewed to be relatively safe in most patients.

The tics that occur with cocaine or methamphetamine use in adults are similar to those seen in Tourette syndrome; the most common tics are simple motor tics such as forceful blinking, nose wrinking, or head jerking, but a wide variety of simple and complex motor and phonic tics can occur. They are sometimes admixed with psychosis and other, complex stereotypic movements during acute drug intoxication. As in children, tics generally remit after drug discontinuation in most adults who exhibit tics during use of amphetamine or cocaine use. However, there have been some case reports of individuals who have developed long-lasting tic disorders after brief exposures to cocaine and methamphetamine, although it would be hard to prove that the tic disorder was caused rather than having been unmasked by the stimulants.

Stereotypies and Complex Repetitive Motor Behavior (Punding)

A third group of movement disorders that are seen with amphetamines are repetitive motor behaviors. Adventitious jaw movements are a particularly common motor effect of methamphetamine and MDMA; trismus (jaw clenching), bruxism (tooth grinding), and chewing movements may be prominent effects seen with acute and chronic use of these drugs.

Other, more complex repetitive behaviors, termed 'punding' are seen with chronic use of methamphetamine. This may include compulsive disassembling and reassembling or manipulating objects, playing cards, searching drawers, etc. and is known colloquially by drug users as 'tweaking.' With +chronic use, a delusion that insects are crawling under the skin (formication) develops and leads to repetitive, compulsive picking at the skin. This behavior has characteristics of both punding and a compulsion.

Although complex repetitive behaviors are best known with methamphetamine use, it is not uncommon with cocaine use; one series estimated that 10–40% of cocaine-addicted individuals may experience punding.

Chorea and Dystonia

Choreoathetotic and akathisia-like movements are seen with chronic cocaine abuse. Case reports have described patients in whom a number of movements are seen; these include facial grimacing, lip smacking, blinking, choreoathetoid movements of the extremities, slow athetoid writhing of the trunk and extremities, hand wringing and foot stomping, semipurposeful movements of the hands, and sustained jaw opening movements.

The prevalence is largely unknown, but it is notable that there are English ('crack dancing') and Spanish ('twisted mouth') colloquialisms for movements seen with cocaine addiction, and it is probable that these movements are relatively common.

The effects are generally transitory but have been described by some cocaine addicts as lasting a few days. On rare occasions, more persistent movements can occur; one case report described a young woman with choreiform dyskinesias that persisted over 20 months after abstention from cocaine.

Although quite uncommon, there have been case reports of oromandibular dyskinesias and generalized choreoathetosis induced by amphetamines and pemoline.

There is also evidence that cocaine use may increase the sensitivity of an individual to develop an acute dystonic reaction when receiving a neuroleptic. On very rare occasions, withdrawal from acute cocaine use may also trigger an acute dystonic reaction.

Differential Diagnosis

In most cases in which movement disorders present acutely and there is a known history of stimulant use, the diagnosis is clear. In young adults or children with an acute presentation of a hyperkinetic movement disorder, drug use should be strongly suspected until ruled out.

A number of other signs and symptoms of acute and chronic stimulant abuse may aid in the clinical suspicion. For most stimulants, common autonomic manifestations may include tachycardia, hypertension, increased respiratory rate, mydriasis, dry mouth, and urinary retention. Psychiatric symptoms and signs, especially seen with cocaine and amphetamine addiction, may include agitation, anxiety, restlessness, or paranoia or overt psychosis, and violent behavior; in contrast, MDMA-intoxicated individuals may appear calm or euphoric.

Even in the setting of known or proven stimulant use, a preexisting or concomitant neurological disorder should also be suspected. Although tremors, tic disorders, chorea, and other movement disorders may occur in previously healthy individuals, it is far more common for these conditions to be worsened by CNS stimulants. Mild essential tremor or a prior history of a transient tic disorder, for example, may become obvious only to a patient in the setting of acute or chronic stimulant use.

A medical cause of chorea or tremor, such as a recent streptococcal infection or thyrotoxicosis, should be considered in the setting of severe tremor, tics, or chorea.

Drug interactions may also be a major factor in the acute presentation of a movement disorder associated with stimulant use. Recent or concomitant cocaine use, for example, increases the sensitivity to developing an acute dystonic reaction following administration of a neuroleptic or antiemetic, and a drug screen to rule out recent use of cocaine or amphetamines should be considered in patients with an acute dystonic reaction.

One serious disease that can present similar to an acute dystonic reaction is tetanus. Approximately 50–75% of patients with generalized tetanus present with trismus secondary to masseter muscle spasm, which is commonly accompanied by nuchal rigidity and facial grimacing. Tonic contractions, triggered by noise or touch may cause opisthotonus and look very similar to an acute dystonic reaction. A history of a recent laceration or puncture wound, a recent sore throat accompanied by dysphagia, or a chronic wound may be present but up to 10% of patients have no antecedent, known cause.

Although generalized chorea would be an unusual presentation, structural lesions in the basal ganglia or nearby structures can present with acute hemichorea or hemiballismus, and cranial imaging should considered.

Diagnostic Workup

Depending on the clinical presentation, blood tests for recent streptococcal infection and screening tests for hyperthyroidism should be considered in most patients with an acute presentation of tremors, tic disorders, or chorea. An acute dystonic reaction to health care professionals who are not used to this condition can appear similar to a seizure. In contrast to seizures, though, the level of consciousness is maintained during an acute dystonic reaction. Extensor posturing due to brainstem disease can also appear somewhat similar but is accompanied by a number of other neurological signs that would not be expected in acute dystonia.

In most patients, the movement disorders associated with stimulant use should disappear over a few hours, and persistent movement disorders, lasting more than 48 h after known drug ingestion, should prompt a search for other etiologies.

Treatment and Prognosis

In most cases, no specific treatments are needed to eliminate or reduce hyperkinetic movements, although dopamine antagonists, such as haloperidol, can be used to antagonize severe choreoathetosis or parenteral benzodiazepines or antihistamines for acute dystonic reactions.

In most individuals, the hyperkinetic movements disappear within 24–28 h. In some patients, tic disorder may be more persistent and may require treatment with dopamine antagonists.

In severely affected individuals or in patients with cardiovascular or hemodynamic instability, admission to the hospital and supportive care may be needed. Patients with MDMA poisoning may need aggressive care for treatment of seizures, hyperthermia, and hypotension.

In the short term, there are no medical complications immediately following discontinuation of chronic use of methamphetamine or cocaine. However, patients addicted to these agents typically have protracted depression after abstinence and may require intensive counseling, antidepressants, and anxiolytics.

Cerebrotendinous Xanthomatosis

T Simon-Tov, University of Michigan, Ann Arbor, MI, USA
N Gadoth, Tel Aviv University, Tel Aviv, Israel; Mayanei Hayeshua Medical Center, Bnei-Brak, Israel

Glossary

Ataxia – From Greek, 'lack of order.' Incoordination of muscle contractions during voluntary movements or sustained postures. Ataxia might be sensory (secondary to posterior column or peripheral nerve damage) or motor (secondary to cerebellar, cerebral, thalamic, basal ganglia, or brain stem dysfunction). The condition may affect the limbs, trunk, eyes, pharynx, or larynx. Patients most commonly present with unsteady gait, postural imbalance, speech, and gaze disturbances.
Extrapyramidal signs – A group of neurological signs indicating disturbed function of the extrapyramidal motor system. The extrapyramidal system includes substructures of the basal ganglia and brain stem and interconnections with certain regions of the cerebellum, cerebrum, and other areas of the central nervous system. It has a major role in modulation and regulation of motor activity, and when damaged can cause postural and muscle tone abnormalities as well as involuntary movements such as tremor, dystonia, chorea, athetosis, and tics.
Pyramidal signs – A group of neurological signs indicating the presence of damage to the upper motor neuron (cell bodies or corticospinal tracts). These include: spastic paresis/paralysis, hyperreflexia, clonus, pathological reflexes (extensor plantar responses (e.g., Babinski sign), Tromner's and Hoffmann's signs), and loss of superficial skin reflexes (abdominal, cremasteric).
Xanthoma – A lesion characterized by abnormal accumulation of lipid-laden macrophages secondary to disturbed lipid metabolism or a local cell dysfunction. Xanthomas usually occur in the skin and subcutaneous tissues but may rarely involve deep soft tissues such as the gastrointestinal tract, lung, and brain.

Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis (CTX; MIM 213700) is a recessively inherited lipid-storage disease caused by a deficiency of the mitochondrial enzyme, sterol 27-hydroxylase (CYP27A1). The metabolic defect results in impaired bile acid synthesis and the accumulation of cholesterol and its 5α-dihydro derivative *cholestanol* in numerous tissues. Clinically, CTX is characterized by diarrhea, cataracts, tendon xanthomas, and progressive neurological dysfunction. The first patients were described by van Bogaert, Scherer, and Epstein in 1937. About 30 years later, it was suggested that CTX is caused by deposition of cholestanol in the affected tissues. *CYP27A1* gene was identified in 1991 and was mapped to the long arm of chromosome 2 where the first mutations were detected. CTX is considered to be rare, though its actual prevalence rate is not well-established. The disease is reported worldwide, but is more prevalent in Japan, the Netherlands, and among Moroccan Jews in Israel.

Pathogenesis

CYP27A1 is a key enzyme in bile acid synthesis; it catalyzes the first step in the normal oxidation of the steroid side chain, converting cholesterol as well as other 7α-hydroxylated cholesterol metabolites into 27-oxygenated steroids (**Figure 1**). In its absence, biosynthesis of bile acids (especially chenodeoxycholic acid (CDCA)) is reduced. The negative feedback of bile acids on 7α-hydroxylase, a rate-limiting enzyme in bile acid synthesis, is impaired, and bile precursors are overproduced. Consequently, alternative pathways are activated leading to increased formation of cholestanol and 25-hydroxylated bile alcohols. Deposition of cholestanol was reported in CTX in almost all tissues, particularly the Achilles tendons, brain, and lungs.

CYP27A1 gene was mapped to 2q35 between markers D2S1371 and D2S424. It consists of nine exons and eight introns and spans 18.6 kb of DNA. The transcript is 1966 bp in size, and it encodes a 531 amino acid protein. So far, 49 different mutations of the *CYP27A1* gene have been reported worldwide. About 50% of these mutations were found in the region of exons 6–8, which is known to encode an adrenodoxin-binding site and a heme-binding site. No correlation was found between specific *CYP27A1* mutations and particular CTX phenotypes.

Clinical Features

CTX typically presents as infantile-onset diarrhea, childhood-onset cataracts, and/or adolescent- to young adult-onset tendon xanthomas. Adult-onset progressive

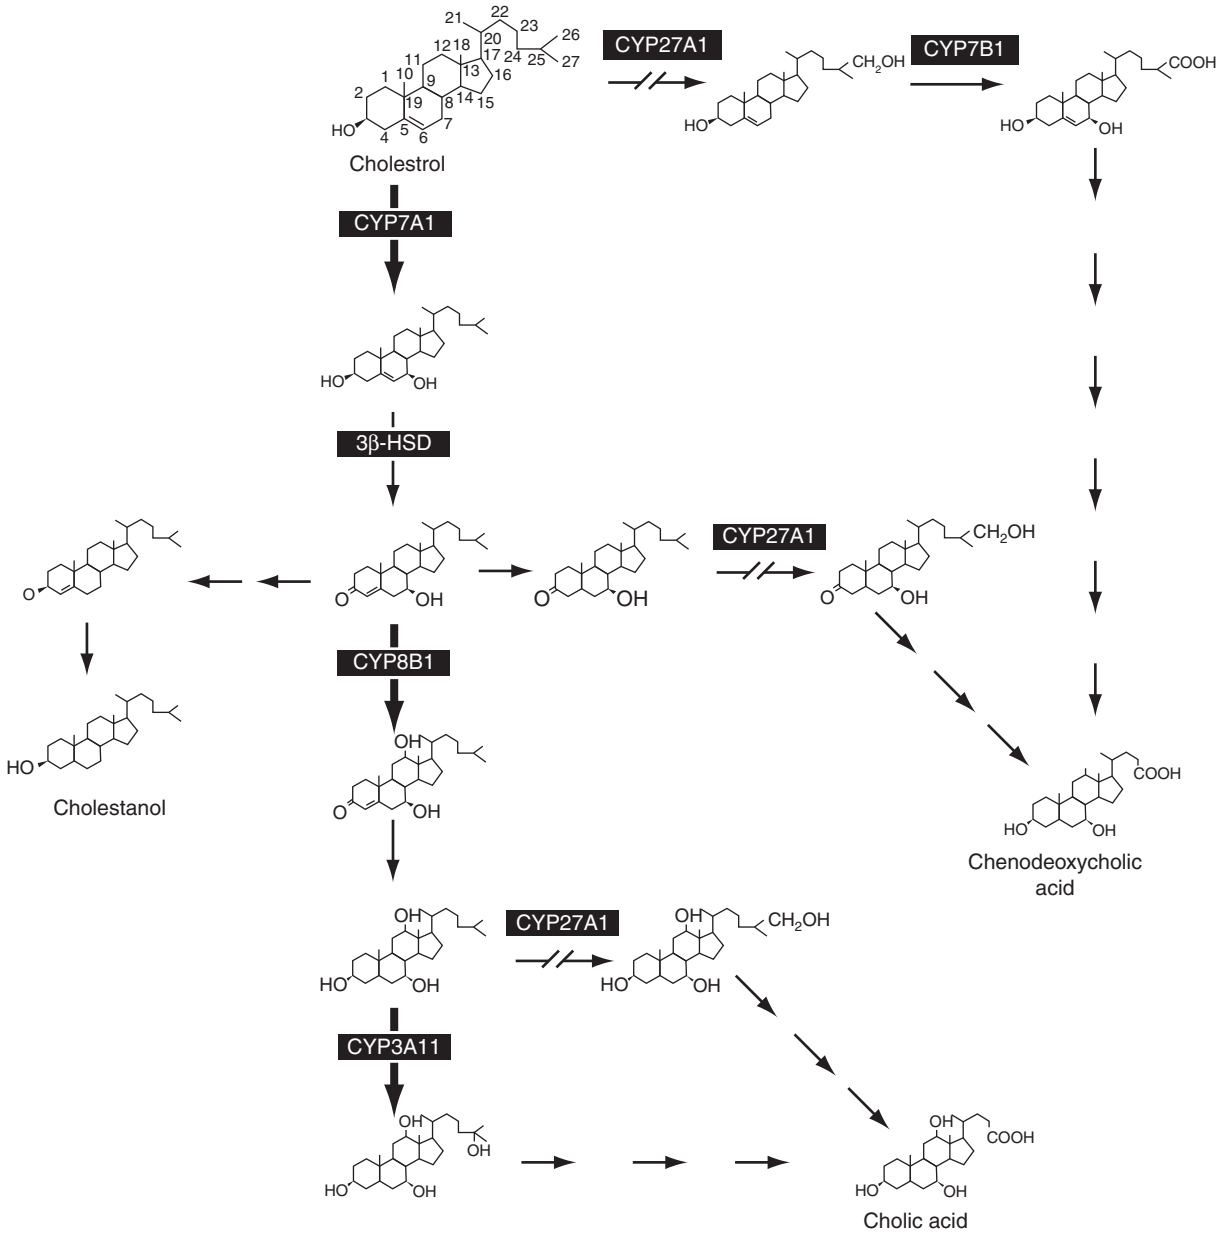

Figure 1 Bile acid synthesis pathways. 3β-HSD, 3β-hydroxysteroid oxidoreductase; CYP3A11, cytochrome P450 3A11; CYP7A1, cholesterol 7α-hydroxylase; CYP7B1, oxysterol 7α-hydroxylase; CYP8B1, sterol 12α-hydroxylase; CYP27A1, sterol 27-hydroxylase. neurological syndrome usually follows. The chronic diarrhea is thought to be secondary to the excessive amounts of bile alcohols in the gut. Cataracts can be visually significant or insignificant, and additional ocular findings such as optic disc paleness/atrophy, retinal vessel sclerosis, drusen, and pigment changes may also be present. Tendon xanthomas commonly involve the Achilles tendons (**Figures 2** and **3**), but may occur on the extensor tendons of the elbow and hand, the patellar tendon, and the neck tendons. Xanthomas have also been reported in the lung, bones, and the central nervous system (CNS). Other systemic manifestations include premature atherosclerosis and coronary artery disease, lipomatous hypertrophy of the atrial septum, pulmonary insufficiency, osteopenia with frequent bone fractures, hypothyroidism, cholelithiasis, nephrolithiasis, and palpebral xanthelasmas.

Accumulation of cholestanol in the nervous system leads to progressive and broad neurological dysfunction. Some individuals show mental impairment from early infancy, whereas the majority shows normal or slightly

subnormal intelligence during adolescence. Dementia with slow deterioration in intellectual abilities occurs in the twenties in over 50% of individuals. Neuropsychiatric symptoms such as behavioral changes, hallucinations, agitation, aggression, depression, and suicide attempts may be prominent. Pyramidal signs (spasticity, hyperreflexia, and extensor plantar responses) and/or cerebellar signs (ataxia, dysmetria, and dysarthria) are almost invariably present. A spinal form in which spastic paraparesis is the main clinical symptom was also described. Extrapyramidal manifestations may include atypical parkinsonism (resting tremor, rigidity, bradykinesia), dystonia, and palatal tremor. Epileptic seizures are reported in ~50% of patients. Peripheral neuropathy usually involves motor more than sensory fibers, and might lead to distal muscle atrophy and pes cavus. The combination of early onset cataract, premature atherosclerosis and ischemic heart disease, osteoporosis, dementia, and parkinsonism may mimic premature aging.

Diagnosis and Laboratory Work-up

CTX diagnosis is based on the typical clinical picture (especially the triad of cataract, tendon xanthomas, and progressive neurological disturbance) and typical laboratory findings as follows:

1. *Electrophysiological studies:* The electroencephalogram typically shows diffuse slow-wave activity with paroxysmal discharges. Evoked potentials studies may reveal delayed central conduction time. Electromyography (EMG) typically shows predominantly axonal sensorimotor neuropathy. Controversy still exists regarding the extent of the demyelinating component and the presence of myopathic EMG changes.
2. *Neuroimaging:* Magnetic resonance imaging shows cerebral and cerebellar atrophy, and usually includes regions of increased T2-signal intensity in the cerebellar and periventricular white matter, basal ganglia, brain stem, and more typically around the dentate nuclei. Magnetic resonance spectroscopy shows significant decrease in the *N*-acetylaspartate peak which may represent widespread axonal damage. In addition, an increased peak within the lactate region (0.9–1.3 ppm) is typically present and may represent cerebral mitochondrial dysfunction or increased lipid signal if the peak does not invert at an echo time of 135–144 ms.
3. *Neuropathology:* Classic CNS pathology findings include granulomatous and xanthomatous lesions in the cerebellar hemispheres, globus pallidus, and brain stem. Extensive demyelination and gliosis were reported in the cerebellar white matter and long tracts of the spinal cord, with multiple dispersed lipid crystal clefts. Accumulation of foamy cells and homogeneous myelin-like material was also described, especially around vessels. Nerve biopsy reveals primary axonal degeneration accompanied by a variable amount of demyelination. Muscle biopsy frequently shows neurogenic changes. Mild myopathic changes with some mitochondrial abnormalities were also reported.
4. *Biochemistry:* The biochemical hallmark and the key for laboratory diagnosis of CTX is high serum cholestanol in the presence of low to normal plasma cholesterol level. Large amounts of bile alcohols in serum, urine, feces, and bile can also contribute to the diagnosis as well as the demonstration of reduced CYP27A1 enzymatic activity in the liver, fibroblasts, or lymphocytes.

5. *Molecular genetic testing:* Sequence analysis of *CYP27A1* detects mutations in 90–100% of the affected individuals. Deletions and duplication mutations require special methods for detection.

Differential Diagnosis

The combination of a progressive neurological syndrome and typical systemic manifestations generates a unique phenotype with relatively restricted differential diagnosis. CTX shares some clinical manifestations such as xanthomas and accelerated atherosclerosis with other lipid storage disorders, including familial hypercholesterolemia and sitosterolemia. However, progressive neurological symptoms, diarrhea, cataract, and pulmonary insufficiency are not common features of these disorders. See **Table1** for neurogenetic syndromes associated with presenile cataract and **Table 2** for neurogenetic syndromes associated with peridentate region T2 hyperintensity (**Figure 4**).

Treatment and Prognosis

CTX diagnosis may be difficult because of its clinical heterogeneity and because the classic systemic symptoms, juvenile cataract, and tendon xanthomas, may be absent on presentation. However, early diagnosis of CTX is crucial as CTX is one of a few neurometabolic disorders with potential medical treatment. Long-term treatment with CDCA (250 mg t.i.d) was reported to arrest and possibly reverse the progression of the disease. Supplementing the bile acid pool with exogenous CDCA is thought to inhibit the abnormal endogenous bile acid synthesis. Under treatment, serum cholestanol levels are markedly reduced, urine excretion of bile acid metabolites is normalized, and neurophysiologic findings are improved. A few studies reported the prevention of neurological deterioration and even some improvement of existing deficits. Yet, the clinical efficiency of CDCA awaits further validation. The use of HMG–CoA

reductase inhibitors and low-density lipoprotein apheresis was also reported, but their effectiveness is still controversial.

If untreated, CTX is a debilitating and lethal disease. Early diagnosis and treatment with CDCA or the combination of CDCA and a HMG–CoA reductase inhibitor might prevent further deterioration.

Cervical Dystonia

K Dashtipour and D M Swope, Loma Linda University, Loma Linda, CA, USA

Glossary

Basal ganglia – Deep region of the brain involved in initiating and maintaining movement.
Botulinum toxin – Toxin produced by clostridium botulinum, which can cause muscle weakness and botulism.
Cervical dystonia – The most common form of idiopathic focal dystonia involving muscles of the neck.
Dystonia – Simultaneous cocontraction of agonist and antagonist muscles which usually causes an abnormal twisting posture.
Idiopathy – A condition for which no known cause can be determined.
Torticollis – A subclass of the cervical dystonia that causes head rotation.

Definition and History

Cervical dystonia (CD) is a simultaneous cocontraction of both agonist and antagonist muscles of the neck, resulting in abnormal postures and/or movements. Based on head posture, CD can be described as torticollis (neck rotation), anterocollis (head-forward flexion or pulled forward), retrocollis (head-posterior extension or pulled backward), or laterocollis (head tilt or lateral flexion). Most of the time, patients present with a combinations of these postures. In the sixteenth century, Rabelais applied the term 'torty colly' meaning wry-neck. Almost 200 years later in 1911, Oppenheim, used the term dystonia to describe the abnormalities in tone seen in patients with generalized dystonia.

Pathogenesis/Pathophysiology

The pathophysiology of idiopathic CD is not well understood. Recent studies have explained the pathogenesis of CD at the peripheral and central nervous system level.

Although any muscle in the neck may be involved, some muscles such as the splenius capitis are more commonly associated with abnormal head posture.

There are several physiologic variables that may contribute to the development of cervical dystonia. The first potential cause is loss of central inhibition as indicated by several studies. One hypothesis suggests that with a directed movement, a certain area of the motor cortex

activates for the desired movement and unwanted movements are inhibited by surround inhibition which has a concept similar to what has been described in the visual system. A few studies have shown that the basal ganglia affect cortical inhibition. SPECT studies have demonstrated that striatal D2 receptor binding decreases in focal dystonia. Assessing by SPECT, Naumann concluded that disturbances of the indirect pathway cause disinhibition of thalamocortical circuitry in cervical dystonia.

Another potential cause of dystonia is sensory deficit and sensorimotor mismatch. Trauma and other abnormal inputs could lead to focal dystonia. 'Geste antagonistique/sensory trick' is a sensory phenomenon used to improve abnormal postures in focal dystonia. These examples suggest that dystonia is, at least in part, a sensory-related disorder. Bara-Jimenez showed abnormal spatial discrimination in patients with writer's cramp, supporting the theory of sensory dysfunction in focal dystonia. Several studies suggest that improper sensory assistance in a motor activity may be the cause of the cocontraction of agonist and antagonist muscles seen in focal dystonia.

Aberrant neuroplasticity is another potential cause of dystonia. The nervous system is capable of neural adaptation and network reorganization, and brain injury or external stimuli can cause maladaptive reorganization. Recently, Bara-Jimenez showed an abnormal cortical somatosensory homunculus in patients with focal dystonia of the hand. Using TMS, the reversible reorganization of the motor cortex was shown for non-task-specific focal dystonias, such as torticollis. It suggested that aberrant neuroplasticity is correlated with both motor cortex and affected cervical muscles.

Abnormal basal ganglia discharges have also been suggested as another potential cause of dystonia. Sanghera compared the discharge rates and neuronal patterns in parkinsonian patients with those in patients with dystonia. He found that in both dystonia and Parkinson's disease (PD), the discharge rates in the putamen are very low, but discharge rates are much lower in the globus pallidus neurons in dystonia compared with PD. Recently, Zhuang analyzed neuronal discharges in the GPi, ventral thalamic nuclear group, ventral oral posterior/ventral intermediate (Vop/Vim), and subthalamic nucleus (STN) in patients with dystonia. Results were similar to Sanghera's, suggesting an association of dystonia with alteration in neuronal discharge in the basal ganglia and thalamus.

Epidemiology/Risk Factors

Cervical dystonia (CD) is the most common form of focal dystonia. Multiple studies have shown the prevalence of CD to be 9–30 per 100 000 in the United States. Currently, the number of cases of cervical dystonia in the United States is estimated to be greater than 90 000. Other studies show that prevalence differs among various ethnic groups. Claypool in 1995 reported an incidence of 1.2 per 100 000, while an incidence of 5.4 per 100 000 was published in a practice-based survey of dystonia in Munich.

Women are affected 1.3–2-fold more often than men. CD can occur at any time of life but most individuals experience their first symptoms in middle age. Chen reviewed the clinical details of cervical dystonia in 266 patients. In this study, the median age of onset was 41 years. A familial history of dystonia was found in 12% of cases and spontaneous remission occurred in 9.8% of patients.

Clinical Features and Diagnostic Criteria

Dystonia is usually classified according to the age of onset, etiology, or anatomic distribution. The age of onset is usually either in childhood or in adulthood (age >25 years). Primary dystonia may be hereditary or idiopathic. Anatomic classification includes focal (confined to one body part), segmental (affecting more than one contiguous region), multifocal (two or more nonadjacent areas), hemidystonia (one side of the body), or generalized. Cervical dystonia typically begins in adulthood and is idiopathic. It may remain focal but there is a risk of spread to nearby regions. Cervical dystonia may be part of more widespread involvement, especially in younger onset cases.

Idiopathic dystonia usually begins in adulthood, whereas childhood onset is often associated with the DYT-1 genetic mutation. Idiopathic, adult onset, focal dystonia usually involves the head and neck regions. Cervical dystonia is the most common form of focal dystonia. The onset is usually insidious with gradual worsening. Patients may notice only vague neck pain or discomfort or they may complain of neck tightness or a pulling sensation. Abnormal head postures may first be noticed by family or friends, especially if pain is not significant. The head can be pulled in any direction of movement. Although CD is often referred to as 'spasmodic torticollis,' this term is not always appropriate. The term torticollis refers to head rotation, laterocollis to head tilting, retrocollis to neck extension, and anterocollis to neck flexion. Patients commonly exhibit a combination of movements rather than movement in only one plane. The movements may be sustained or spasmodic. Dystonic head tremor may also occur and should be differentiated from other causes of head tremor by the presence of abnormal neck posturing. Neck pain may be present in up to 75% of patients, but the severity of pain does not necessarily correlate with the severity of neck movements. Shoulder elevation and anterior displacement are also common.

Symptoms of CD are usually progressive early in the course. It is thought that most of the progression occurs within the first 5 years after onset but this course has not

been well studied in large cohorts. Approximately 10–20% of patients will experience spread of dystonic symptoms to adjacent regions, including the jaw, eyes, lower face, vocal cords, trunk, and upper limbs.

Hand tremor is also more common in CD than in the general population. This tremor is usually present with action or posture holding and may or may not be associated with dystonic postures of the limb. The precise etiology of this tremor is unclear and debate exists as to whether it is of dystonic origin or whether there is a higher risk of developing essential tremor in patients with dystonia.

Some patients with torticollis find a sensory trick to alleviate their symptoms partially or completely. Sensory trick or 'geste antagoniste' is a unique feature of dystonia and is reported in more than 50% of patients with cervical dystonia. Typically, placing the hand on the chin, side of the face, or the back of the neck reduces muscle contraction. Interestingly, in some patients just thinking about a 'geste antagoniste' diminishes their symptoms. The exact mechanism of action of 'geste antagoniste' is still unknown. The presence of a sensory trick is very supportive of the diagnosis of idiopathic rather than secondary dystonia.

Patients with torticollis also show a high incidence of psychiatric comorbidities such as depression and anxiety. Psychiatric comorbidity is not just secondary to chronic disease or disfigurement and may have its own pathogenesis primarily related to dystonia. In some patients with cervical dystonia stress, emotion, self-consciousness, walking, carrying objects, writing, running, social situations, fatigue, and lack of sleep have been reported as detrimental factors. On the other hand, some patients reported sleep, lying on their back or side, relaxation and a 'geste antagoniste' as ameliorating factors.

Differential Diagnosis

Cervical dystonia can be the initial manifestation or presenting sign of diseases such as multiple sclerosis, spinocerebellar ataxia 17, and systemic onset juvenile rheumatoid arthritis. Rarely, cervical dystonia can be secondary and due to a variety of identifiable pathologies, including Wilson's disease, progressive supranuclear palsy, corticalbasal ganglionic degeneration, tardive dystonia, spinal cord ependymoma, posterior fossa tumor, pseudotumor cerebri, systemic lupus erythematosus, Huntington's disease, Langerhans cell histiocytosis, hemorrhagic and ischemic stroke, cerebello-pontine angle tumors, intramedullary glioma, cerebellar cavernous angioma, syrinx, retropharyngeal abscess, ocular pathology, electrical injury, arteriovenous malformation, multiple sclerosis, pantothenate kinase-associated neurodegeneration (PKAN), and ataxia-telangiectasia. As with all movement disorders, cervical dystonia may be psychogenic in origin. The diagnosis of psychogenic dystonia is difficult to make and should be done by someone with expertise in movement disorders.

Other diseases of the neck may be confused with dystonia. Cervical radiculopathy may cause neck pain with abnormal posturing or limited range of motion. Neurologic findings other than dystonia on examination (i.e. muscle weakness, reflex asymmetry) suggest a diagnosis other than idiopathic dystonia and require more diagnostic testing.

Diagnostic Workup/Tests

Cervical dystonia is a clinical diagnosis and there is no laboratory test or imaging study to confirm the diagnosis. Imaging studies of the brain and/or cervical spine may be indicated if secondary dystonia is suspected. Basic screening laboratory studies are also usually obtained during the initial workup to rule out metabolic disorders and Wilson's disease. However, in typical, long-standing cervical dystonia, imaging and laboratory studies are not diagnostic and usually not necessary. Patients may desire testing and this may be appropriate in some cases to relieve patient anxiety.

Management

Oral Medical Therapy

Many medications have been used to treat symptoms of cervical dystonia. However, medication trials have showed only a limited success rate in control of the symptoms. The medical treatment of CD is often limited by side effects and the benefit is usually modest. Medications that can be tried as medical therapy include anticholinergics, benzodiazepines, mexiletine, Baclofen, riluzole, tetrabenazine, valproate, olanzapine, and clozapine

Botulinum toxin

The treatment of cervical dystonia was revolutionized with the introduction of botulinum toxin type A in 1989. Botulinum toxin therapy is now considered as the treatment of choice for all forms of focal dystonia, including CD. Seven different serotypes of botulinum toxin have been identified. Their specific site of action is at the neuromuscular junction to block the presynaptic release of acetylcholine. This causes muscle weakness, resulting in a decrease in inappropriate cocontraction of agonist and antagonist muscles in dystonia. Over the last 15 years, intramuscular injection of botulinum toxin has become the treatment of choice for mild, moderate, and severe cervical dystonia. Botulinum toxin type A and B are used clinically for the treatment of cervical dystonia.

The mechanism of action of both serotypes is similar, although each has a specific site of action. All botulinum toxins initially bind to receptors on presynaptic

cholinergic nerve terminals, and then are incorporated into a vesicle and internalized. The active part of the toxin molecule is then released into the cytoplasm, where it then acts as an enzyme on its specific target protein. Type B toxin specifically cleaves synaptic vesicle associated membrane protein (VAMP), also known as synaptobrevin. Type A toxin cleaves another target protein, synaptosome-associated protein of 25 kDa (SNAP 25). Cleavage of these proteins blocks the docking and fusion of the synaptic vesicles with the nerve terminal membrane: a necessary step for neurotransmitter release.

A variety of injection techniques has been employed with success. Multiple controlled trials have shown between 60 and 90% improvement in abnormal head movements following intramuscular toxin injection. Pain is also significantly improved with treatment with botulinum toxin. Both type A and type B toxins have a similar clinical effect and duration of effect when used in comparable doses. Patients usually notice improvement of their symptoms in 5–10 days after injection with lasting benefit for 3–4 months.

Botulinum toxin type A

Botulinum toxin type A is effective and safe and has been shown to be more effective than medical therapy in controlling symptoms of cervical dystonia with a better side effect profile.

The efficacy and safety of botulinum toxin type A have been established in several clinical trials, with 70–90% of patients with cervical dystonia benefiting from this formulation. Botulinum toxin type A had been the most widely used and longest studied serotype. There is a risk of developing neutralizing antibodies with repeated therapy. The presence of neutralizing antibodies is associated with a loss of clinical efficacy, which is believed to be life-long. In general, avoidance of using high doses and extending the interdose interval to a minimum of 3 months duration is believed to lower this risk. In some early reports, neutralizing antibodies have been shown in up to 17% of patients but Jankovic, using the current formulation of botulinum toxin type A, did not detect the presence of blocking antibodies in a 3-year open-label observation. A large-scale, prospective study recently showed the risk of antibody production to be about 1% per year.

The effect of botulinum toxin may be potentiated by other drugs that interfere with neuromuscular transmission such as aminoglycoside antibiotics and other neuromuscular blockers. One study showed an antagonistic action of chloroquine with botulinium toxin by preventing internalization of the toxin. Adverse effects such as dysphagia, neck weakness, local pain, lethargy, dysphonia, and xerostomia are temporary but can last for weeks or months prior to waning. The most common side effects are local and related to excessive muscle weakness.

Botulinum toxin type B

Botulinum toxin type B was the first toxin approved by the FDA in December 2000 for the treatment of cervical dystonia. This serotype has also been shown to be effective in reducing the pain, severity, and disability associated with cervical dystonia in both botulinum toxin type A responsive and type A resistant. Dry mouth, dysphagia, and injection site pain are the most common reported side effects with botulinum toxin type B, and dry mouth is more common with this serotype than with type A.

Surgery

Surgical procedures for the treatment of cervical dystonia are considered in the uncommon case of botulinum toxin inefficacy or the development of resistance to both serotypes A and B, as well as failure of medical therapy. Both central and peripheral nervous system procedures have been used to treat cervical dystonia recalcitrant to medical intervention. To date, surgical therapy remains strictly an option when other treatments fail or become ineffective. Deep brain stimulation, usually of the globus pallidus, has been approved by the FDA for compassionate use in the treatment of dystonia.

Brain lesioning

Since the early 1940s, brain lesioning as a treatment for CD has been undertaken with variable results. Several targets have been explored in the basal ganglia and thalamus to treat movement disorders. Meyers reported a surgical procedure for postencephalitic tremor in 1941. Afterward, he reported his 10 years of surgical experience to treat movement disorders, including dystonia, by creating lesions in selected regions of the basal ganglia and thalamus. These results have been replicated by placing lesions in various regions of basal ganglia. Thalamotomy as a traditional stereotactic therapy for cervical dystonia shows controversial results. Bilateral thalamatomy can be modestly effective in treating symptoms of cervical dystonia but can cause serious side effects, including weakness and dysphagia. In contrast, unilateral thalamatomy shows less beneficial response but a more favorable safety profile. The lesioning of the globus pallidus was later reported as a treatment for cervical dystonia. The posteroventral medial pallidotomy targets the pallidothalamic pathway and is hypothesized to interrupt abnormal neurocircuitry involved in dystonia. Interestingly, most reports show gradual improvements over several months in dystonic patients following pallidotomy. Yoshor compared pallidotomy and thalamotomy to treat patients with different forms of intractable dystonia. The long-term outcome with pallidotomy was significantly better than thalamotomy for all patients with dystonia, including

cervical dystonia. Several reports show thalamotomy as a more effective procedure for secondary dystonia than primary dystonia.

Deep brain stimulation

Deep brain stimulation (DBS) is being used to treat several types of movement disorders. It has advantages over brain lesioning, because it is reversible and adjustable. DBS was used initially in the 1960s to control chronic pain, and decades later, it was used for various movement disorders such as Parkinson's disease, tremor, and dystonia. Several studies have shown DBS as a relatively safe procedure and a very useful therapeutic option for disabling cervical dystonia in patients who do not respond to medical therapy and botulinum toxin injection. The mechanism of action of DBS in dystonia is poorly understood. The target used for DBS in dystonia is located in the posteroventral lateral GPi, a target also used in Parkinson's disease. Several investigators are in favor of bilateral DBS over unilateral DBS because of the evidence showing bilateral basal ganglia dysfunction in patients with cervical dystonia. Postoperative improvement has been reported to be gradual, sometimes several weeks or months after surgery, but progressive and sustained in nature. Compared with DBS for other movement disorders like Parkinson's disease, initial settings require higher voltages and pulse widths, followed by gradual increment of intensity. Prospective studies have shown ongoing benefit in a gradual and exponential manner for up to 2 years.

Peripheral surgical intervention

Peripheral denervation is another surgical alternative to the treatment of patients with botulinum toxin resistant cervical dystonia. There are various types of peripheral surgical techniques, but selective peripheral denervation is the most commonly performed procedure. In 1987 and 1988, Bertrand et al. reported their observations and analysis with significant success rate in patients with cervical dystonia who underwent selective denervation. There are several well-established procedures for selective peripheral denervation such as denervation of the accessory nerve and the posterior rami of the cervical spinal nerves and more recently the levator scapulae muscle with a wide range of response rates. In an open-label study Ford et al. concluded that the best candidates for selective ramisectomy were those patients with secondary botulinum toxin failure. In contrast, Cohen et al. in a retrospective analysis concluded that outcome was not predicted by preoperative head position, severity and duration of symptoms, or response to botulinum toxin. The effects of surgical treatment are permanent and irreversible, and therefore, surgery should not be performed unless other noninvasive treatments have failed. A conservative approach with repeated procedures, if necessary, is considered to be safer and leads to fewer long-term complications.

Prognosis

Cervical dystonia can be sustained, may spread to other muscles, or may go into remission. Developing segmental or rarely generalized dystonia has been reported in some cases. Chen et al reported remission in 9.8% of their cases, but spontaneous remissions in up to 20% of patients also were observed in some reviews. In general, this is not a progressive disorder and most patients experience stabilization of symptoms within the first five years of toxin therapy.

Summary

Cervical dystonia is the most common form of focal dystonia. It is usually idiopathic and causes abnormal head movements and postures. Pain is also a common feature of CD. Once established, CD is a lifelong condition, which may occasionally spread to adjacent regions. Many symptomatic treatments are available but the safest and most effective treatment consists of local injections of botulinum toxin. Although not life-threatening, CD can have a significant impact on the quality of life.

Cholinesterase Inhibitors in Parkinson's Disease

D Aarsland, University of Bergen, Bergen, Norway
C Ballard, King's College London, London, UK

Glossary

ADAS-cog (Alzheimer's Disease Assessment Scale-cognitive subscale) – A cognitive screening test commonly used for patients with Alzheimer's disease.
Amyloid plaques – Protein fragments including β-amyloid, accumulated to form hard, insoluble plaques typically found in Alzheimer's disease.
Butyrylcholinesterase – Enzyme involved in the hydrolysis of brain acetylcholine. Among multiple variants of the gene for BuChE, the most common variant is *BCHE*-K, which is associated with a 30% reduction in serum BuChE activity.
Cholinesterase inhibitor – Class of drugs which inhibit the hydrolysis of brain acetylcholine.
Executive functions – Loosely defined collection of cognitive processes including planning, cognitive flexibility, and abstract thinking and information processing.
Homocysteine – Amino-acid, risk factor for vascular diseases and associated with deficiency of vitamin B12 or folate, and may be toxic for dopaminergic neurons. Elevation reported in PD.
Neurofibrillary tangles – Insoluble twisted fibers found inside the brain's cells typically found in Alzheimer's disease, consisting primarily of tau protein, which is abnormal in Alzheimer's disease.
Neuropsychiatric inventory – Standardized clinical interview which rates frequency and intensity of 12 psychiatric symptoms commonly found in people with brain disease.
Pedunculopontine nucleus – Located in the brainstem, caudal to the substantia nigra, including cholinergic, glutamatergic, and GABAergic cells, commonly affected in Parkinson's disease.

The Cholinergic System in Parkinson's Disease

The cholinergic system is one of the most important modulatory neurotransmitter systems in the brain and controls the activities that depend on selective attention and cognitive processing speed as well as other cognitive functions. In addition to the defining loss of dopaminergic neurons in substantia nigra, Parkinson's disease (PD) is associated with a profound disturbance of the cholinergic system, with involvement of the basal forebrain from stage III of the Braak staging for PD. The cholinergic deficits are particularly marked in patients with dementia (PDD), where the changes are even more pronounced than in Alzheimer's disease (AD). In addition to neuronal loss in cholinergic forebrain nuclei projecting to the hippocampus and neocortex, there is loss of cholinergic neurons in the striatum and the pedunculopontine pathways that project to the thalamus. As a consequence, there are extensive reductions of cholinergic markers in neocortical regions as well as in the thalamus. Furthermore, there are important changes in cholinergic receptor systems in PD, including upregulation of muscarinic receptors and reduced nicotinic binding both in the striatum and neocortex.

These cholinergic changes are related to clinical symptoms, highlighting the clinical relevance of cholinergic changes in PD. The most important clinical correlates of cholinergic deficits in PD probably include attention and executive function, hallucinations, and depression. Whether postural instability and gait symptoms are influenced by cholinergic changes in the pedunculopontine nucleus is not yet clear.

Cholinesterase Inhibitors in PD

Given the marked cholinergic deficit and their clinical correlates, drugs that stimulate the cholinergic system are attractive candidates to improve cognition and other symptoms in PD. However, since a cholinergic–dopaminergic balance in the striatum has been proposed as critical for normal motor symptoms, cholinergic agents may worsen motor symptoms.

The first report of cholinesterase inhibitors in PD was published as early as in 1996. Seven patients with PDD received open-label treatment with tacrine 40 mg day^{-1}. Remarkable and pronounced improvements of cognition, hallucinations, and even parkinsonism were reported. Although these findings have not been replicated by independent groups, this article spurred the interest in cholinesterase inhibitors and was followed by a number of studies. The available evidence was reviewed in 2004, including 12 studies, which included one parallel group and one cross-over, placebo-controlled randomized

trial (RCT) and 10 open-label case series, the majority including patients with PDD. The majority of studies used donepezil or rivastigmine, and one used galantamine, and treatment duration was usually <12 weeks. Overall, the results were positive, with a median improvement on the Mini-Mental State Examation (MMSE) score of 2.3 points over the treatment period, and improvement of hallucinations was reported in several studies. Most studies reported no or only mild worsening of parkinsonism. The two small RCTs were conducted with donepezil, and both studies reported statistically significant effects on cognition. Due to peripheral cholinergic side effects such as nausea, vomiting, and diarrhea, 57% withdrew due to adverse events in the donepezil group in one study, and 25% during donepezil compared with none during placebo treatment in the cross-over trial.

Rivastigmine

Subsequent to this review, several other studies have been published, including the first large RCT of a cholinesterase inhibitor in PDD. In this study, more than 500 patients with PDD were included, and two-thirds were treated with rivastigmine and one-third received placebo for 24 weeks. The primary outcome measures were a cognitive rating scale, the Alzheimer's Disease Assessment Scale-cognitive subscale (ADAS-cog), and clinical global impression of change, and both measures were significantly different between the two groups in favor of rivastigmine. A favorable response, defined a priori as any improvement on a global change scale, was noted in 41% of the rivastigmine group compared with 30% in the placebo group. Similarly, on all the secondary analyses, including neuropsychiatric symptoms, activities of daily living, and tests of executive function, rivastigmine compared significantly superior to placebo. Peripheral cholinergic side effects occurred in 29% of the rivastigmine group compared with 11% of the placebo group, but most events were mild or moderate. The proportion reporting serious adverse events were similar in both groups. Discontinuation due to adverse events occurred in 17% of the rivastigmine group compared with 8% in the placebo group. Although there were no differences in the motor subscale of the Unified Parkinson's Disease Rating Scale, suggesting no worsening of parkinsonism on rivastigmine, tremor was noted as an adverse event in 10% of the rivastigmine group compared with 4% in the placebo group (p=0.01), although tremor was severe enough to cause withdrawal of only 1.7% of patients in the rivastigmine group.

Donepezil

In addition to the two small RCT reported above, a third small placebo-controlled cross-over RCT with donepezil was reported in 2005. Donepezil was well tolerated and adverse events were usually mild. There was a nonsignificant trend towards improvement on the primary outcome measure (ADAS-cog), and significant differences in favor of donepezil were reported on global improvement and MMSE, a cognitive screening test, but not on daily functioning or psychosis.

A large, multicenter, parallel group RCT including 550 patients with PDD has been conducted, with three arms receiving placebo, donepezil 5 mg, and donepezil 10 mg, but the results have not yet been reported in full. Preliminary results were, however, reported as an abstract and poster presentation. One of the two primary outcome measures, a global impression of change scale, showed significant differences between the groups in favor of donepezil. However, the cognitive primary measure, ADAS-cog, showed only a nonsignificant, dose-dependent difference in favor of donepezil. Of the secondary analyses, MMSE, but not activities of daily living or neuropsychiatric symptoms, showed significant differences between the groups.

Which Symptoms Improve?

Improved cognition has been reported in most studies, including most of the RCTs, but little is known regarding the effect of the different cognitive domains. Executive functioning and attention improved on rivastigmine administration in the large RCT, and attention improved in an open-label study with donepezil. Improvement of activities of daily living was also reported in the large rivastigmine study. Similarly, improvement of neuropsychiatric symptoms has been reported in several studies. In the rivastigmine RCT, improvement was reported on the total Neuropsychiatric Inventory Score, but no information on specific symptoms was provided. Several of the open studies have reported improvement on visual hallucinations, including patients unresponsive to atypical antipsychotics. Psychotic symptoms are common in PD, and have important clinical implications such as caregiver burden, mortality, more rapid cognitive decline, and institutionalization. Currently, there is evidence of antipsychotic effect in PD only for clozapine. Given the potential of antipsychotic agents to worsen motor symptoms and cognition in PD, and in particular, PDD, the risk of severe neuroleptic sensitivity reactions, as well as increased risk for cerebrovcascular incidents and mortality, there is therefore a clear need for controlled studies to explore whether cholinesterase inhibitors, which have a better safety profile, can improve visual hallucinations and other psychotic symptoms in PD.

It is not known how long the treatment effect of cholinesterase inhibitors will continue in PD. The duration of the RCTs have been up to 24 weeks, and an extension study showed that the effect and safety profile of rivastigmine could be sustained for a further 24 weeks.

Sudden withdrawal seems to be detrimental, at least of donepezil, producing acute cognitive and behavioral decline. Although recommencement on donepezil appears to reverse this deterioration, abrupt discontinuation of cholinesterase inhibitors should probably not be made in this population.

Which Patients Improve?

The response to cholinesterase inhibitor treatment varies. Some patients have a marked response whereas others have no or only marginal response. However, since cognitive decline is progressive in PD, even stabilization of cognitive functioning should be considered an effect, although it is difficult to ascertain in individual patients due to the variation in rate of cognitive decline. Post hoc analyses of the large rivastigmine RCT have attempted to identify which patients would respond better to rivastigmine. In one study, exploring the response to rivastigmine and placebo in PDD patients with and without hallucinations, the effect was most pronounced in the group with hallucinations, and this group also had a more rapid cognitive decline on placebo. In another report, patients with hyperhomocysteinemia had a better response than those with normal or low homocysteine. In dementia with Lewy bodies (DLB), a syndrome with clinical and pathological similarities with PDD. There is preliminary evidence to suggest that patients with the butyrylcholinesterase wild-type genotype may have a preferable treatment response to rivastigmine than those with the K-variant, which is associated with reduced activity of the enzyme, but this has not yet been reported in PDD.

Mechanisms of Effect

Cholinesterase inhibitors, probably, exert their effect by amplifying the natural spatial and temporal pattern of acetylcholine release, leading to transient, symptomatic improvement but not affecting the underlying disease process. The physiologically relevant effect of cholinesterase inhibitors has been convincingly demonstrated in terms of increased perfusion in bilateral cingulate and frontal regions in both PD and AD. There are marked pharmacodynamic and pharmacokinetic differences between the three available cholinesterase inhibitors. Both the nicitonic agonist effect of galantamine and the additional inhibition of butyrylcholinesterase may have clinical implications in treating cognitive impairment in PD, although convincing comparative studies have not yet been reported.

However, there is evidence that cholinergic drugs may also influence the underlying disease mechanisms and improve neuronal survival. Patients with PD who had received chronic treatment with antimuscarinic drugs during life had more severe amyloid plaques and neurofibrillary tangles than those who had not been treated with such drugs, despite being comparable for age and disease duration. The resulting hypothesis that cholinesterase inhibitors might, therefore, reduce the severity of Alzheimer-type pathology was recently supported in a study of patients with DLB. In patients with DLB, treatment with cholinesterase inhibitors was associated with less severe amyloid deposition. Similarly, in AD, donepezil treatment has been found to be associated with slower progression of hippocampal atrophy. A potential neuroprotective effect of cholinesterase inhibitors is the stimulation of muscarinic receptors, which have been shown to influence the processing of amlyoid. In one study, this hypothesis was supported since (123)I-QNB uptake, a measure of postsynaptic M1-density, which has been linked with neuroprotection in AD is better preserved in AD patients on cholinergic treatment than on placebo. Finally, another potential mechanism for a disease modifying effect is the preliminary finding that cholinergic loss is associated with the loss of endogeneous stem cells, the brain's own capacity for neuroprotection and repair, and thus, it is possible that treatment with cholinesterase inhibitors may increase the number and activity of endogeneous stem cells.

Safety

Overall, the safety profile of cholinesterase inhibitors in PD seems to be acceptable. There is a relatively high proportion with troublesome peripheral cholinergic side effects, as in other patient groups receiving cholinergic drugs. In addition, there is a risk for disease-related adverse events. Although, overall, most studies report no worsening on rating scales of parkinsonism, there is a slightly increased risk for worsening of tremor during treatment with cholinesterase inhibitors. However, in a detailed analysis, it was found that the worsening is mild and transient in the titration period. In a 24-week extension observation study of the rivastigmine RCT, there was no evidence of adverse long-term motor outcomes. Similar findings of mildly increased tremor on rivastigmine in PD were also observed in a detailed assessment where tremor amplitude was also measured using accelerometers. No clinically significant drug–drug interactions between donepezil and levodopa/carbidopa were observed at steady state. Autonomic failure is common in PDD, and may be particularly sensitive to the cardiovascular effects of donepezil, such as reduction in heart-rate variability. An increase in falls and autonomic dysfunction amongst DLB patients treated with donepezil has been reported.

Summary and Discussion

There is convincing evidence that treatment with cholinesterase inhibitors can benefit some patients with PDD to a clinically meaningful degree. This is particularly true for rivastigmine, where a large RCT over 24 weeks showed significant effect on all primary and secondary outcome

measures, and which has been approved for the treatment of PDD in Europe and the United States. The novel patch treatment has been shown to have similar therapeutic effect but with improved tolerability compared with tablets in AD, but has not yet been tested in PD.

Several guidelines/recommendations on the use of cholinesterase inhibitors in PDD have been reported. A joint task force of the European Federation of Neurological Societies (EFNS) and the European section of the Movement Disorder Society (MDS) classified clinical evidence with rivastigmine as class I and donepezil as class II, although they acknowledged that improvement was modest. Similarly, a Cochrane review identified the rivastigmine trial as the sole study that met inclusion criteria, and concluded that rivastigmine appears to improve cognition and activities of daily living in patients with PDD, and that clinically meaningful benefit can be achieved in about 15% of cases. However, the need for more studies utilizing pragmatic measures such as time to residential care facility and both patient and carer quality of life assessments was underlined.

Chorea

R H Walker, James J. Peters Veterans Affairs Medical Center, Bronx, NY, USA; Mount Sinai School of Medicine, New York, NY, USA

Glossary

Acanthocytes – Contracted erythrocytes with thorny protrusions.
Chorea – A hyperkinetic movement disorder characterized by rapid, irregular movements of different body parts.
Neuroacanthocytosis – Neurological conditions in which there are abnormalities of red blood cell membranes, resulting in thorny protrusions.

Definition

Chorea, although technically derived from the Greek word for 'dance,' is used to describe an involuntary movement disorder characterized by irregular movements, which rapidly flit from region to region in an irregular pattern. The use of videography to document movement disorders has enabled a standardization of the use of such descriptive terms.

Pathogenesis

Chorea appears the same whether it is the result of a metabolic disturbance which disrupts neurotransmission in the putamen, neurodegeneration affecting the same structure, or a stroke affecting the subthalamic nucleus.

Despite its limitations, the model developed by Albin, Penny, and Young in 1989 can still be used to understand many of the pathophysiological aspects of movement disorders, and may be applied to chorea. In general, the direct pathway is responsible for the activation of a motor program following an input from the motor cortex, while the indirect pathway focuses and selects the

movements. This process most likely happens at several levels of the basal ganglia, including the caudate/putamen, subthalamic nucleus (STN), and the globus pallidus internal segment (GPi), and signal selection probably involves temporal coding in addition to anatomical interactions. Disruption of the pathway at several sites, for example, putamen and STN, may result in similar movements. According to the model, chorea arises when there is a decrease in the activity of the indirect pathway from the caudate/putamen to the external segment of the globus pallidus (GPe), resulting in overactivity of this nucleus. This inhibits its projection targets, the STN, the GPi, and the substantia nigra pars reticulata (SNr), which decrease their activity. This correlates with the fact that lesions of the STN are also well known to cause chorea (hemiballismus). According to this model, the excess involuntary movements are due to a decrease in the inputs from the STN to the GPi (the indirect pathway), causing the loss of specificity of motor signals which have arrived from the striatum via the direct pathway. Chorea may also be due to an increase in the activity of the direct pathway as may happen with L-DOPA-induced dyskinesias in Parkinson's disease, which are a form of chorea. Consequently, the inhibited GPi/SNr has decreased inhibition of the motor thalamus, and an increased signal is conveyed to the motor cortex. The model fits well with some disorders, for example, Huntington's disease (HD), in which the enkephalinergic neurons of the indirect pathway typically degenerate first, causing a decrease in the activity of this pathway, and with hemiballismus due to STN lesions. For other conditions, the model fits less well.

Clinical Features and Diagnostic Criteria

Chorea may be due to a very large number of neurological disorders, and it may often be part of a mixed movement disorder syndrome, coexisting in particular with dystonia. The term 'choreoathetosis' is not used as much at present as in previous years, but refers to a writhing movement with dystonia and choreiform components.

Etiologies of chorea include structural, metabolic, pharmacological, infectious, and inherited neurodegenerative causes. The phenomenology of chorea does not often give clues to the underlying diagnosis, as much as the features of the family and clinical history, and medical and neurological examination. Despite an extensive work-up, some patients may remain undiagnosed.

Differential Diagnosis

A number of features may provide diagnostic clues in the patient with chorea.

Family History

If positive, a family history may be extremely helpful, and should be taken carefully and in great detail, documenting all family members for whom the patient can provide any information. Any possible neurological or psychiatric disorder may be of significance. Autosomal dominant inheritance may be obscured by the unavailability of parental medical history due to various factors such as nonpaternity, or by parental death before disease onset. This is especially true for trinucleotide repeat diseases in which anticipation is found, characterized by younger age of onset for successive generations. Small family sizes may mean that an autosomal recessive pattern is not apparent. X-linked recessive disorders are suggested by the absence of male–male transmission, and when the unaffected mother of a male proband has affected male relatives. Mitochondrial disorders may be maternally inherited, but are often due to de novo mutations.

The absence of a family history does not rule out a genetic disorder. In addition to the points listed above, adoption may be an issue.

The ethnic background may be informative. Huntington's disease-like 2 (HDL2) has been reported to date almost exclusively in patients of African ancestry, although in some cases, the ancestry can be quite obscure and only revealed by haplotype analysis. One patient of Middle Eastern ancestry has been reported.

A couple of disorders appear to be more common in Japanese populations, likely due to a founder effect. Chorea-acanthocytosis (ChAc) appears to be of increased frequency in Japan, although it has been reported in most ethnic groups to date. Dentatorubropallidoluysian atrophy (DRPLA) has been found in only a very small number of families outside Japan.

Almost any movement disorder developing in a person of Filipino heritage raises the question of Lubag – X-linked parkinsonism-dystonia (DYT3) – which can present with a range of phenotypes, and can manifest in female carriers.

Time Course

The time course of the illness can be interpreted by an approach similar to the one used for other neurological conditions. A sudden onset indicates a vascular event, either ischemic stroke, or hemorrhage. A subacute onset, over weeks or months, may suggest a slowly growing mass lesion, particularly in the presence of localizing signs and asymmetry, a relationship to an underlying medical condition resulting in a metabolic condition such as hyperthyroidism or paraneoplastic syndrome, or prion disease.

A chronic and slowly progressive time course over years raises the likelihood of a neurodegenerative process. A chronic, nonprogressive course, following an acute or subacute onset, may suggest that the chorea is due to a medication, or alternatively, that it is benign hereditary chorea.

Episodic involuntary movements, especially starting in childhood, are characteristic of the paroxysmal dyskinesias, and the diagnosis is suggested by precipitating factors such as caffeine, alcohol, fatigue, movement, or stress.

Phenomenology

As mentioned earlier, the phenomenology of the chorea alone is rarely informative. One exception to this is when the chorea is purely unilateral, indicating either a structural lesion or that it is due to nonketotic hyperglycemia in noninsulin-dependent diabetes. The other situation is when the movements are more severe of the mouth, tongue, and lower face. These are often seen in tardive dyskinesia, due to neuroleptic use: in children with pantothenate kinase-associated neurodegeneration (PKAN); in boys with Lesch–Nyhan syndrome; and in the presence of self-mutilating tongue- and lip-biting, and specifically eating-induced dystonic tongue protrusion, in autosomal recessive ChAc.

Exacerbating/Relieving Factors

Episodic chorea following specific precipitants suggests one of the forms of paroxysmal dyskinesias. The precipitating factors, which may include movement, alcohol, caffeine, prolonged exertion, or fatigue, are informative in classification, as are the characteristics of the movements and any interictal features, such as spasticity or ataxia. As genetic linkage is performed in affected families and gene mutations are identified, it is becoming possible to distinguish these disorders on molecular grounds, and many appear to be due to mutations of ion channels.

Other Medical Conditions

It is important to note the presence of any other medical conditions, by history and by clinical examination, and medications which are taken for them.

The most common cause of chorea in childhood is Sydenham's chorea, which may follow pharyngitis due to a streptococcal infection. This diagnosis can be confirmed by the presence of antistreptolysin O antibodies, which may also interact with neuronal components of the putamen. This disorder is self-limiting, but the movements can be quite violent and bizarre and disabling, and require aggressive management.

Several endocrine disorders may be associated with chorea. One of the most common situations, in which typically unilateral chorea of relatively sudden onset is seen, is diabetic nonketotic hyperglycemia. It is not known why the chorea is asymmetric, but T2-weighted MRI shows oedema in the contralateral putamen, suggestive of inflammation and breakdown of the blood–brain barrier.

Hyperthyroidism may occasionally cause chorea. Hyperparathyroidism and other causes of disrupted calcium metabolism may result in the radiological finding of intracerebral calcium deposition (known by the nonspecific term of Fahr's disease). This is usually prominent in the basal ganglia and dentate nucleus of the cerebellum, and causes a variety of movement disorders.

Antibasal ganglia antibodies (whose target is not yet well defined) are likely to be the cause of chorea in several autoimmune disorders. These include antiphospholipid antibody syndrome, systemic lupus erythematosus, and systemic sclerosis.

A subacute time course, with onset over weeks, correlates with the diagnosis of a paraneoplastic syndrome. Chorea has been associated with renal, small-cell lung, and breast cancer, and with Hodgkin's and non-Hodgkin's lymphoma.

A history of gastrointestinal disturbance may indicate coeliac disease. The relationship of this disorder to several neurological findings has been postulated and debated, but there is evidence for chorea, ataxia, and peripheral neuropathy, which may in some cases respond to a gluten-free diet.

Chorea gravidarum should be considered in women in whom pregnancy is a possibility. The etiology may be related to the sensitization of basal ganglia dopamine receptors by estrogens, but antibasal ganglia antibodies have also been reported in this condition. The use of estrogens, either in the form of the contraceptive pill, or a hormone replacement therapy, has also been reported to cause chorea.

Medications

One of the commonest medication-related causes of chorea is L-DOPA in Parkinson's disease. Although the phenomenon is known as 'L-DOPA-induced dyskinesias,' the movements are typically choreiform. Dystonia can also occur, or a mixture of the two types of movements. These may be seen either at peak effect of the medication dose, or when the medication is taking effect or wearing off ('on-off' dyskinesias). These more often involve the legs rather than the arms or trunk. Orofacial chorea as an effect of L-DOPA is seen more often with the atypical parkinsonisms, such as multiple system atrophy or progressive supranuclear palsy.

Stimulant drugs of abuse which release dopamine or block its reuptake, specifically cocaine, especially 'crack' cocaine, and amphetamine, can cause chorea.

Chorea has also been reported with the use of various anticonvulsant medications, lithium, and other stimulants.

Estrogens, either in the form of oral contraceptives or hormone replacement therapy, have been reported to cause chorea, probably by a similar mechanism to that of *chorea gravidarum*, possibly involving an increased sensitivity of dopamine receptors.

Another very common form of chorea is tardive dyskinesia (TD). Again, the terminology is imprecise, but it is typically used to refer to choreiform movements. Tardive dystonia is not uncommon, and the fixed postures and action-induced overflow of movements seen in this condition are often more disabling than the fluid movements of tardive chorea. While a minimum total period of exposure to the causative agent of 3 months is usually accepted, occasionally cases may be seen where a briefer exposure appears responsible. The classically responsible agents are the typical neuroleptics, but there have been case reports of TD following the use of most of the newer atypical antipsychotics. As the temporal relationship is more poorly defined than one of a direct medication side-effect, causality can be harder to prove. Involuntary movements may appear or worsen on withdrawal of the offending medication, or following the use of a cocktail of possible agents. TD is reported to have developed following the use of anticonvulsants, lithium, selective serotonin reuptake inhibitors, and others.

The movements of TD typically involve the lower face and tongue, and are usually not distressing to patients. Similar movements have been reported in never-treated elderly schizophrenics and edentulous patients. If the upper face is involved, the movements are typically dystonic – blepharospasm; a variety of jaw, lingual, pharyngeal, and laryngeal tardive dystonias, including spasmodic dysphonia can also be seen.

The use of neuroleptics for the psychiatric symptoms seen in many of the basal ganglia neurodegenerative disorders may mask appreciation of movement disorder due to these etiologies (e.g., HD, HDL2, ChAc, McLeod syndrome); thus the development of new neurological features in a psychiatric patient should be carefully evaluated.

Other Neurological Features

Any asymmetry or localizing signs on neurological examination indicate a structural intracerebral lesion, or nonketotic hyperglycemia.

Psychiatric disease or personality change may be the first sign of a basal ganglia neurodegenerative disorder such as HD. Slowly progressive cognitive impairment, especially subcortical dementia, often with frontal signs, such as abulia or disinhibition, may also be due to the involvement of the basal ganglia.

Chorea may be seen as either a presenting or secondary feature in the inherited ataxias, both autosomal dominant and recessive. The presence of ataxia, hyper- or hyporeflexia, eye movement abnormalities, or sensory changes may be informative, particularly in the presence of a family history. Chorea has been reported in spinocerebellar ataxias 1, 2, 3, and 17; dentatorubropallidoluysian atrophy; Friedreich's ataxia, and the ataxias with oculomotor apraxia.

Decreased reflexes also suggest the neuroacanthocytosis (NA) syndromes of autosomal recessive ChAc, or X-linked McLeod syndrome.

The presence of seizures along with chorea may be seen in young-onset HD (although this is usually parkinsonian in phenotype), in paroxysmal kinesogenic dyskinesia, and in approximately 50% of patients with McLeod syndrome or ChAc.

Diagnostic Work-Up

Laboratory Work-Up

The diagnostic work-up (**Table 1**) will be guided by the clinical presentation, age of onset, time course, family history, etc., of the symptoms.

Routine blood chemistry may demonstrate electrolyte abnormalities, including calcium, which may cause chorea. Hyperglycemia in noninsulin-dependent diabetics with nonketotic hyperglycemia is a well-recognized cause, as mentioned earlier.

It is important to assay levels of liver enzymes, including γ-glutaryl transferase in addition to transaminases, total and direct bilirubin, and lactate dehydrogenase. The presence of liver disease may indicate Wilson's disease (WD), one of the few treatable neurodegenerative conditions, which should be considered and excluded in any unusual presentation of a movement disorder. Presentation of WD with chorea has not been reported, although it may be part of a mixed movement disorder phenotype, characterized by facial dystonia (risus sardonicus) and a flapping arm tremor.

If WD has been excluded as the cause of elevated liver enzymes, this finding strongly suggests one of the NA syndromes, ChAc or McLeod syndrome.

McLeod syndrome can be diagnosed by determining antigenicity of red blood cells to a panel of 23 antibodies to the Kell system, and to the XK antigen site known as Kx. This testing is usually performed in regional blood centers; most smaller blood centers will not have the full panel of antibodies. A request should be made to 'exclude McLeod phenotype' (which refers to the erythrocyte antigen profile) and not just to test for Kell, as this is nonspecific. Testing for mutations of the causative XK gene can be performed on a research basis, but is not required for diagnosis.

ChAc can at present be diagnosed only on a research basis by assaying levels of the affected protein, chorein,

Table 1 Laboratory evaluation of the patient with chorea

Test	*Possible diagnosis*
Blood chemistry	Hyper/hypoglycemia; hyper/hyponatremia; hypomagnesemia hyper/hypocalcemia; Lesch-Nyhan syndrome
CBC with smear	Neuroacanthocytosis syndrome (ChAc, MLS, HDL2, PKAN)
Liver function tests	Wilson's disease; ChAc; MLS
Thyroid function tests	Hypo-/hyper-thyroidism
Parathyroid levels	Hypo-/hyper-parathyroidism
Pregnancy test	Chorea gravidarum
Creatine phosphokinase	ChAc; MLS
Ceruloplasmin	Wilson's disease; aceruloplasminemia
Ferritin	Neuroferritinopathy
Sedimentation rate, antinuclear antibodies	Autoimmune disease
Lupus anticoagulant	Systemic lupus erythematosus
Antiphospholipid antibodies	Antiphospholipid syndrome
ASO titres	Sydenham's chorea
HIV test	HIV/AIDS-related infection
Anti-gliadin antibodies	Coeliac disease
Antineuronal antibodies (anti-CRMP-5, anti-Hu, anti-Yo)	Paraneoplastic syndromes
Erythrocyte Kx and Kell antigens	MLS
Genetic testing	As per test
MRI/CT + contrast	Structural lesions; iron deposition, calcification
EEG	Seizure-related syndrome; Creutzfeldt-Jakob disease
Lumbar puncture	Creutzfeldt-Jakob disease; chronic infection
Urinary and serum organic and amino acids	Organic/amino acidopathies

Abbreviations; ChAc = chorea-acanthocytosis; HDL2 = Huntington's disease-like 2; MLS = McLeod syndrome; PKAN = pantothenate kinase-associated neurodegeneration.

in peripheral blood. The responsible gene, *VPS13A,* consists of 73 exons with no particular hot-spot for mutations, thus screening for mutations is not practical, and is only performed on a research basis.

A peripheral blood smear should be examined for acanthocytes; however, their absence does not exclude the diagnosis of an NA syndrome, as their presence appears variable. If the clinical phenotype is suggestive of this diagnosis, and especially if there are elevated liver enzymes or creatine kinase, the appropriate protein-directed diagnostic tests should be pursued. CK elevation is very strongly suggestive of an NA syndrome, and is not attributable to chorea, as it is not seen in HD.

The sensitivity of the peripheral blood smear to acanthocytosis can be increased by incubating the fresh blood for 30–120 min on a shaker with normal saline containing 10 IU ml^{-1} heparin. At least five fields should be examined using phase-contrast microscopy, and over 6.3% acanthocytes is pathological. Care should be taken to distinguish acanthocytes, which should be contracted and irregular, with echinocytes, which have smaller and more regular protrusions. Electron microscopy of glutaraldehyde-fixed blood is confirmative. Acanthocytes are found in approximately 10% of patients with PKAN and with HDL2, which may confound the diagnosis.

Ceruloplasmin levels are reduced in WD, and often absent in aceruloplasminemia.

Low ferritin is suggestive of neuroferritinopathy, but can be elevated into the normal range in premenopausal women.

If the time course of the presentation is relatively acute or subacute, a paraneoplastic syndrome should be considered. Serum and cerebrospinal fluid (CSF) should be tested for anti-Hu, anti-Yo, and anti-CRMP-5 antibodies which have, to date, been associated with chorea. As paraneoplastic syndromes are often associated with occult malignancies, full-body imaging should be performed.

Lumbar puncture should be performed if there is a suspicion of an infectious encephalitis, or if the time course of progression over weeks or months suggests Creutzfeldt–Jakob disease (CJD). A positive test for 14-3-3 protein is highly suggestive of this diagnosis in the appropriate clinical context (although it may also be seen in more chronic neurodegenerative disorders).

Children with acute onset of chorea or a mixed hyperkinetic movement disorder should be tested for Sydenham's chorea by checking for antistreptolysin O antibodies.

Apart from this diagnosis, chorea in children and infants is most likely due to inherited metabolic disorders. Glutaric aciduria is a disorder which may present in infants with an acute deterioration and encephalopathy, along with hyperkinetic movements. The specific presentation and age will guide the testing, which should include serum and urinary organic and amino acid testing, assay of lysosomal enzymes and lactate and pyruvate levels, which if elevated, should lead to screening for mitochondrial mutations.

Genetic Testing

Genetic testing should always be preceded by thorough discussion of the possible ramifications of both positive and negative test results, ideally by a qualified genetic counselor. A positive result for an autosomal dominantly-inherited disease such as HD has potentially life-changing implications for the patient's parents, siblings, and children.

Genetic testing for HD is readily available, and is usually the first genetic test to be done once the other etiologies have been excluded. As mentioned earlier, a negative family history should not preclude such testing, although in young patients whose parents' medical

histories are fully known, the question of nonpaternity may be raised by a positive result.

Depending upon the clinical phenotype and other factors such as ethnic background, genetic testing may be considered for autosomal dominant and recessive ataxias, HDL2, and DRPLA. Information on the current availability of the tests for clinical and research purposes is available at http://www.geneclinics.org/.

Neuroimaging

All patients with chorea, with the exception of those whose symptoms are clearly medication-related, merit neuroimaging. The procedure of choice is an MRI scan with gadolinium contrast, to clearly identify any vascular or other lesions and whether there may be breakdown of the blood–brain barrier. If possible, a gradient echo sequence should be requested to increase sensitivity to iron deposition.

Atrophy of the caudate nuclei may be interpreted as being consistent with HD, but is nonspecific and can be seen in a number of neurodegenerative conditions such as the NA syndromes.

Iron deposition in the basal ganglia indicates one of the conditions grouped under the term 'neurodegeneration with brain iron accumulation' (NBIA). Probably the commonest and the best-known of these is PKAN, in which the classic 'eye-of-the-tiger' sign was first reported. The particular vulnerability of the basal ganglia to metabolic disruptions may be due to high metabolic demands of these regions. In PKAN, this is due to the deficiency of acetylcoenzyme A synthesis. Other conditions in which iron deposition is seen are aceruloplasminemia (due to homozygous mutations of the ceruloplasmin gene) and neuroferritinopathy (due to heterozygous mutations of the gene for ferritin light chain). The rare Karak syndrome has been reported in a single family and is due to the same mutation of *PLA2G6* which causes neuroaxonal dystrophy.

Symmetric necrotic lesions of the basal ganglia in infancy and childhood suggest a mitochondrial disorder such as Leigh's syndrome. These can also be seen following an infectious illness, specifically *mycoplasma pneumoniae* infection, or parvovirus.

Functional imaging of cerebral blood flow using radionuclide tracers is not currently used on a diagnostic basis in chorea. Both hyper- and hypometabolic states have been found with various diagnoses.

Neurophysiological Testing

Electroencephalography can be informative, both in indicating whether there is global cerebral dysfunction, and whether there are focal abnormalities, either contributing to the movement disorder or as a secondary symptom, for example in young-onset HD, or one of the NA syndromes. In CJD, periodic lateralizing epileptic discharges (PLEDs) support the diagnosis.

Electromyography and nerve conduction studies can define whether there is a peripheral neuropathy, as can be seen in some of the inherited ataxias and the NA syndromes.

Management

If possible, treatment of chorea should be directed first at the underlying cause. If this is not possible, as for many of the neurodegenerative conditions, it should be determined whether chorea is disabling, or whether other aspects of the condition are more functionally limiting. It is vital to treat psychiatric symptoms, particularly depression in HD, in which suicide is common. When the involuntary movements of chorea are mild or moderate, they may not interfere with functioning.

Symptomatic medical treatment is usually aimed at reducing dopaminergic neurotransmission with dopamine-blocking or -depleting agents. Atypical neuroleptics are used in preference to typical neuroleptics, in light of the potential for tardive dyskinesia; however, the higher dopamine D2 receptor blocking activity of the classic neuroleptics may still be important. Tetrabenazine depletes dopamine from presynaptic terminals and may have some weaker blocking activity (although TD has never been reported with this agent). Patients taking this medication should be carefully monitored for parkinsonism and depression.

Patients may benefit from anticonvulsants such as valproic acid, carbamazepine, and levetiracetam, presumably through a membrane-stabilizing effect or an effect upon neurotransmitter release. Occasionally these medications may worsen involuntary movements. Therefore treatment requires individualization.

The glutamate NMDA-receptor antagonists, amantadine and riluzole, may be tried. These drugs presumably work by blocking glutamate overactivity of corticostriatal projections.

A small number of patients with chorea of various etiologies has been reported to respond to deep brain stimulation. However, the choice of targets has varied and includes the internal segment of the globus pallidus, the motor nuclei of the thalamus, and the subthalamic nucleus. In addition, the optimal frequency remains a subject of debate, as specific benefits have been shown at moderate (60 Hz) and high (130 Hz) frequencies.

There are reports of promising early results following transplantation therapies in HD; however, these will not halt disease progression.

Of most practical help to many patients and families are paramedical therapies. A team approach can be invaluable in identifying problems and developing

strategies to address them while empowering the patient. Early involvement of physical and occupational therapists is vital to maintain mobility and independence in activities of daily living. Speech and swallowing are often involved in the neurodegenerative disorders. Maintenance of communication is essential, as is nutritional evaluation to prevent weight loss.

Advances in molecular medicine have made it possible to diagnose many patients whose diseases were previously obscure. Correct diagnosis is of course essential for genetic counseling.

Chorea–acanthocytosis

R H Walker, JJ Peters Veterans Affairs Medical Center, Bronx, NY, USA; Mount Sinai School of Medicine, New York, NY, USA

Glossary

Acanthocytes – Contracted erythrocytes with thorny protrusions.
Chorea–acanthocytosis – An autosomal recessive neurodegenerative disease characterized by involuntary movements (chorea) and acanthocytosis.
Neuroacanthocytosis – A term for the group of neurological conditions in which there are abnormalities of red blood cell membranes resulting in thorny protrusions.

Definition

Chorea–acanthocytosis (ChAc) is one of the core neuroacanthocytosis syndromes (along with the X-linked McLeod syndrome). ChAc is inherited in an autosomal recessive manner, and is due to mutations of the gene *VPS13A* located on 9q21 which encodes for the protein chorein.

Acanthocytosis, the appearance of contracted red blood cells (RBCs) with thorny protrusions, is typically, but not invariably, present and is not required to make the diagnosis. The basis for this abnormality of RBC membrane structure is not well understood. The presence of elevated creatine kinase (CK) or liver enzymes supports the diagnosis and is more informative than the acanthocytosis in suggesting the diagnosis.

The neurologic features developed in young adulthood, but may be predated by the appearance of a variable spectrum of cognitive and psychiatric symptoms in late adolescence.

Pathogenesis

The relationship of decreased or absent chorein to neurodegeneration of the central and peripheral nervous systems is not known. Chorein is widely expressed throughout the brain and various internal organs. Its function is not known, but it may be involved in protein sorting and membrane structure. All mutations to date appear to result in total absence or markedly decreased levels of chorein; thus there do not appear to be any partial manifestations of the disease.

Neurodegeneration affects predominantly the caudate nucleus, putamen, and globus pallidus, in addition to the thalamus and substantia nigra. Neuropathological findings consist of gliosis of these regions, but no inclusion bodies of any nature have been detected. Striking atrophy of the head of the caudate nucleus, found on volumetric neuroimaging studies, may correspond with the development of obsessive–compulsive symptoms.

Epidemiology

ChAc is very rare; however, there are likely to be a number of undiagnosed cases. As of 2008, about 1000 cases have been identified worldwide. Cases have been reported from many countries, from many ethnic backgrounds; however, the incidence is remarkably high in Japan, suggesting a founder effect. There may also be increased incidence in Brazil. Clusters of cases may be found in isolated areas with a high degree of consanguinity, as has been reported in a French-Canadian community.

Clinical Features and Diagnostic Criteria

The neurological features of ChAc typically develop in the 20s–30s with slow progression over the next 2–3 decades. It is increasingly recognized that symptoms of the obsessive–compulsive spectrum, including tic disorders, may be the initial presentation, particularly in those developing the disease in adolescence. Severe self-mutilating lip and tongue biting is typical of ChAc. Other features of self-mutilation, such as finger biting and head scratching suggest a behavioral compulsion as the etiology of these features, rather than the movement disorder.

The progression of the cognitive impairment and the development of the movement disorder, which is often initially attributed to neuroleptics, may suggest the diagnosis in patients with psychiatric disease. Orofaciolingual dystonia can be quite severe. Dystonic protrusion of the tongue induced by eating is often prominent and extremely disabling. In addition to this, a variety of movement disorders may be seen, including chorea and parkinsonism. The gait can appear quite bizarre due to truncal dystonia and leg buckling.

Seizures are found in approximately 50% of patients and are often of temporal lobe origin. These may predate the appearance of other features by as much as a decade.

The development of peripheral sensorimotor neuropathy and areflexia supports the diagnosis of ChAc. The neuropathy, which along with the myopathy causes hypotonia and peripheral weakness, is often more debilitating than the involuntary movements. Nerve conduction studies may show either axonal loss with electromyographic findings of myopathy or may be normal.

Hepatosplenomegaly may be seen, although less frequently than in McLeod syndrome. Unlike McLeod syndrome, cardiac involvement is extremely unusual; however, autonomic dysfunction has occasionally been reported and may be a cause of cardiac arrhythmias and sudden death.

Differential Diagnosis

The differential diagnosis of ChAc depends upon the presentation. The syndrome of a movement disorder, peripheral neuropathy, seizures, and cognitive changes is similar only to X-linked McLeod syndrome; however, the presence of the self-mutilating lip and tongue biting is very strongly suggestive of ChAc. Self-mutilation of this nature may be seen in boys with Lesch–Nyhan syndrome; however, in these cases, the age of onset is very much younger. Patients with pantothenate kinase-associated neurodegeneration may develop lingual dystonia, but this diagnosis will be indicated by the finding of iron deposition in the basal ganglia ('eye-of-the-tiger') and confirmed by genetic testing.

The initial work-up may be that of a peripheral neuropathy or myopathy, especially if CK is elevated. Recognition of the syndrome may avoid the need for invasive and nondiagnostic tests such as muscle or bone marrow biopsy. Similarly, abnormalities of liver enzymes may prompt the performance of an unnecessary liver biopsy. If liver enzymes are elevated, Wilson's disease should be excluded as this is currently the only treatable neurodegenerative condition.

The involvement of siblings of both genders may indicate an autosomal recessive disorder, particularly in consanguineous families. Huntington's disease should be excluded, especially if there is a possibility of nonpaternity. In highly consanguineous populations, inheritance may appear pseudodominant. Autosomal dominant ChAc has been reported in Japan, but remains to be fully confirmed.

Diagnostic Work-up

ChAc may be suggested if acanthocytosis is found on peripheral blood smear (**Figure 1**). Sensitivity can be increased by incubating the RBCs with an equal volume of normal saline containing 10 μl ml^{-1} heparin for 30–120 min on a shaker. Electron microscopy of glutaraldehyde-fixed RBCs is confirmatory. However, the presence of acanthocytes in the neuroacanthocytosis syndromes is

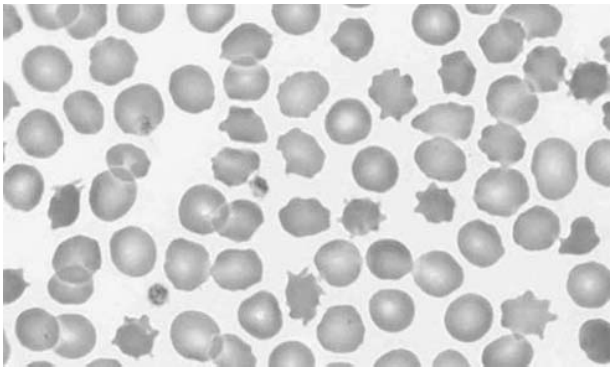

Figure 1 Acanthocytosis on peripheral blood smear. Courtesy of Dr. Hans H. Jung. Reprinted from Danek A and Walker RH (2005) Neuroacanthocytosis. *Current opinion in Neurology* 18(4): 386–392. Philadelphia, PA: Lippincott, Williams and Wilkins, with permission from Lippincott, Williams and Wilkins.

not constant, for reasons which are not well understood, and their absence does not preclude the diagnosis.

Elevated CK, often into the thousands, is very suggestive of either ChAc or McLeod syndromes.

Neuroimaging is often reported as being consistent with the diagnosis of Huntington's disease, with bilateral atrophy of the caudate nuclei.

The diagnosis of ChAc is made by performance of Western blot for chorein on a sample of peripheral blood. If no band for chorein is detected on the gel, the diagnosis is confirmed. This test is at present available on a research basis (see below for website). The diagnosis can be confirmed by sequencing of *VPS13A*; however, this gene is very large, with 73 exons and a variety of mutations have been found, making genetic screening challenging.

Electroencephalography may be helpful if seizures are a feature.

Management

Management is at present purely symptomatic. Self-mutilating lip and tongue biting can sometimes be managed by mouth guards. Feeding-induced tongue protrusion dystonia may respond to injections of botulinum toxin into the genioglossus. Chorea does not typically impair function as much as focal dystonia and peripheral neuromuscular abnormalities. Psychiatric and cognitive symptoms should be treated appropriately.

Results of deep brain stimulation have been variable, and the optimal site and stimulation parameters remain to be determined; however, low frequency stimulation of the globus pallidus pars interna may be beneficial.

Seizures usually respond to standard anticonvulsants, although lamotrigine and carbamazepine have been reported to worsen the involuntary movements.

Evaluation by a speech therapist is essential to minimize problems due to dysphagia and weight loss. Physical and occupational therapists can assist with difficulties with gait, balance, and activities of daily living.

Prognosis

ChAc is slowly progressive and ultimately fatal. Sudden death may be due to seizure, or possibly autonomic dysfunction, but there may be gradually progressive, generalized debility, as seen in Huntington's or Parkinson's disease, with patients succumbing to aspiration pneumonia or other systemic infections.

Chorea Gravidarum

F Cardoso, Internal Medicine Department, The Federal University of Minas Gerais, Belo Horizonte, Brazil

Glossary

Chorea – Abnormal involuntary movements that are brief, random, usually distal, and without purpose.

Epitopes – Antigens.

β-Hemolytic *Streptococcus* – Strains of *Streptococcus* that have the ability to induce autoimmune reaction and that cross-react with antigens of the brain, heart, joints, and skin.

Jones criteria – Set of clinical and laboratory criteria used to diagnose rheumatic fever.
Neuroleptics – Agents that block dopamine receptors.
Sydenham's chorea – Chorea resulting from autoimmune process triggered by β-hemolytic *Streptococcus*.

Definition and History

'Chorea' (derived from the Latin word choreus meaning 'dance') refers to abnormal involuntary movements that are brief, random, usually distal, and without purpose. Chorea gravidarum (CG) is the expression used to designate chorea occurring during pregnancy. This definition implies that CG is a syndrome with potentially numerous causes. The first description of CG was presumably made by Horstius in 1661. However, studies performed in the late nineteenth and early twentieth centuries, particularly by McCann in England and Wilson and Preece in the United States, were instrumental to forge the contemporary concept of CG.

Etiology and Pathogenesis

Gowers was the first to draw attention to the relationship between CG and rheumatic fever (RF). Currently, the hypothesis to account for the mechanism responsible for CG states that patients with a previous history of RF, not necessarily expressed by Sydenham's chorea (SC), are left with a subclinical dysfunction of the basal ganglia. Hormonal changes occurring during pregnancy lead then to the emergence of chorea. A similar phenomenon may occur with exposure to oral contraceptives. Although the precise mechanism leading to chorea in CG remains to be determined, it is speculated that hormones can change dopaminergic systems in the basal ganglia. For further details of the pathogenesis of SC, please refer to the entry on this subject.

In the remaining minority of patients where chorea during pregnancy is unrelated to RF, CG is merely a coincidence of other processes. Stroke, the most common cause of acute chorea in adults, can cause chorea as a result of lesions in the subthalamus and also in other areas. Vascular lesions associate with chorea are almost invariably consequence of hyperglycemia. This is particularly true of diabetes mellitus type II among Asian patients. The mechanism is not clear, but it seems to be related to microhemorrhages of the pallidum, which are visible on MRI scans. Systemic lupus erythemahosus (SLE), as well as primary antiphospholipid antibody syndrome, is believed to induce chorea and other neurological abnormalities by means of vasculitis. Infections (particularly AIDS, syphilis, and viral encephalitis) cause chorea either by direct lesion by the etiologic agent or by autoimmune mechanism. The latter seems to be the case in ADEM, where the process is often triggered by an infectious agent. Finally, prescription (antiepileptic drugs, dopaminergic agents and dopamine receptor blockers) or illicit drugs (cocaine and amphetamine) have also been described as causing chorea in pregnancy.

Epidemiology

Even up to the middle of the twentieth century, when RF and SC were an important public health problem throughout the world, CG was a rare condition. Even in the busy infirmary of Olser, he was able to find only five patients of whom just one had been personally examined by him. In 1932, it was estimated that there was an incidence of 1 CG for 2275 pregnancies. With the development of antibiotics and the sharp decline of frequency of RF and SC, the incidence of CG was down to 1:139000 pregnancies in 1968. In our unit, located in a part of the world where RF still remains a significant public health problem and where there is a special interest in chorea, CG accounts for less than 3% of all choreas.

Clinical Features and Diagnostic Criteria

Most patients develop chorea at pregnancy at ages less than 22 years. In fact, in our series of patients the median age of onset was 18 years with a range of 14–26. Gowers had already described that the onset of CG after age 24 is usually a recurrence of a previous episode. The movement disorder starts in the first two trimesters of the pregnancy in the majority of patients, being rare in the first and the last 3 months. The mean gestational age of our patients at the onset of CG was 10 weeks with a range of 4–24 weeks. As for the intensity of the movement disorders, earlier descriptions emphasize the occurrence of severe cases, which in fact meet criteria of ballism. In the large series of patients at the Federal University of Minas Gerais, however, the intensity of their chorea is comparable to that of the usual forms on SC unrelated to pregnancy. There are no descriptions of nonmotor neurological abnormalities, such as behavioral and cognitive changes in CG. The clinical experience indicates, nevertheless, that emotional labiality is common in pregnant women with chorea.

Nonneurological findings, however, have been recognized in CG since the early descriptions of chorea in pregnancy. Indeed, the occurrence of carditis, and less commonly, arthritis, led the first investigators of this condition to suspect the relationship between CG and SC.

The current diagnostic criteria of SC, which also apply to CG, are a modification of the Jones criteria: chorea with acute or subacute onset and lack of clinical and laboratory evidence of alternative cause. The diagnosis is further supported by the presence of additional major or minor manifestations of RF.

Differential Diagnosis

As long as chorea occurs during pregnancy, it is called CG, which implies that there is no differential diagnosis. One should bear in mind, however, that other hyperkinesias can occur during pregnancy. Recently, there are reports of dystonia and myoclonus with onset at pregnancy. The latter can be one of the first signs of adult-onset subacute sclerosing panencephalitis.

Diagnostic Work-Up

Pregnant women with chorea should undergo complete neurologic examination and diagnostic testing to investigate the myriad causes of chorea. Those are the tests helpful in the diagnostic workup of patients suspected to have rheumatic chorea: Tests of acute phase reactants such as erythrocyte sedimentation rate, C-reactive protein, leukocytosis; other blood tests like rheumatoid factor, mucoproteins, and protein electrophoresis; and supporting evidence of preceding streptococcal infection (increased antistreptolysin-O, antiDNAse-B, or other antistreptococcal antibodies; positive throat culture for group A *Streptococcus*; recent scarlet fever). These tests, however, are much less helpful in SC than in other forms of RF due to the usual long latency between the infection and the onset of the movement disorder. Anti-DNase-B titers, however, may remain elevated up to 1 year after strep pharyngitis. Heart evaluation (i.e., doppler echocardiography) is mandatory, because the association of SC with carditis is found in up to 80% of patients. The test of antineuronal antibodies for SC is not commercially available, being just performed for research purposes. Preliminary evidence, moreover, suggests that these antibodies are not specific to SC. Serologic studies for systemic lupus erythematosus and primary antiphospholipid antibody syndrome must be ordered to rule out these conditions. Neuroimaging helps to define the vascular nature of chorea, but, obviously, its use is limited in pregnancy.

Management

In some patients chorea is so mild, not associated with meaningful disability, that no treatment is necessary. Such a conservative approach is further supported by the finding that spontaneous remission in the last trimester of pregnancy occurs in up to one-third of patients. Treatment is mandatory in cases where chorea is more severe because of the high-risk of abortion. Despite the lack of evidence-based recommendations, the first-choice agents are dopamine receptor blockers. Most physicians caring for CG patients choose haloperidol.

Prognosis

Data of the early literature unanimously described an ominous prognosis of CG with up to 18% of the mothers dying during pregnancy or puerperium. With progress in gynecological and neurological care and a significant decline of the incidence of RF, the current mortality rate of CG is zero. In 30% of patients, there is spontaneous disappearance of chorea in the last trimester of the pregnancy. In the remaining patients, chorea disappears hours or few days after delivery. Patients who experienced CG not uncommonly have recurrence of chorea in future pregnancies.

Choreiform Disorders

B Ghosh, Bangur Institute of Neurosciences and Psychiatry, Kolkatta, India
C Diesta and O Suchowersky, University of Calgary, Calgary, Canada

Glossary

Basal ganglia – a group of nuclei (putamen, caudate, globus pallidus, subthalamic nucleus, and substantia nigra) that control the rate and pattern of movement.
Chorea – hyperkinetic movement disorder resulting in rapid unpredictable contractions of the limbs, face, and trunk. Slower writhing movements are called athetosis, and proximal flinging movements are called ballism.
Huntington's disease – hereditary adult onset neurodegenerative disorder associated with chorea, as well as cognitive and psychiatric changes.
Secondary chorea – chorea due to a toxic, metabolic, or structural problem, usually affecting the basal ganglia.
Tardive dyskinesia – stereotypic choreiform buccolingual movements due to exposure to neuroleptics, or other dopamine-blocking medications.

Definition and History

Chorea is a hyperkinetic movement disorder characterized by rapid, random contractions which may be continuous or intermittent, and are typically seen in the distal limbs, face, and trunk. The term is derived from the Greek word χορει´α, a circle dance. When the movements are more distal and sinuous, the term athetosis is used. Proximal flinging movements are referred to as ballism. All the three are likely part of the same movement continuum.

Current evidence suggests that chorea results from an imbalance between the indirect and direct basal ganglia circuitry. Due to the disruption of the indirect pathway, there is underactivity in the GABA-ergic pallidothalamic pathway, releasing thalamocortical activity and allowing hyperkinetic movements to occur. Enhanced activity of dopaminergic receptors may be responsible for the development of chorea at the level of the striatum. Distinctions based on the phenomenology between chorea, athetosis, and ballism are less important, as choreic syndromes are increasingly being classified based on the etiology.

Classification of Chorea According to Onset

Acute/Subacute Onset Chorea

Causes of acute/subacute onset of chorea are listed in **Table 1**. When chorea is sudden in onset, diagnostic considerations include metabolic factors such as hyperglycemia, hyponatremia, hypomagnesemia, hypocalcemia, hepatic failure, and renal failure. Acute chorea is also associated with exposure to toxins and substances of abuse including amphetamines, heroin glue sniffing, thallium, and mercury. A careful history eliciting drug use is important in any acute onset presentation of chorea (**Table 2**).

The most common cause of immune-mediated chorea is Sydenham chorea, a delayed complication of a group of beta hemolytic streptococcal infections occurring in 10% of cases of rheumatic fever. Chorea occurring during pregnancy is increasingly rare. Affected patients have usually had previous episodes of chorea associated with the use of oral contraceptives and/or a history of rheumatic fever. Central nervous system involvement in SLE occurs in 50–70% of cases, but chorea has been reported in less than 2% of these patients. Chorea is seen in about 1.3% of patients with antiphospholipid syndrome (APLS); generalized or hemichorea develops at an average age of 21 years with female predominance. In childhood, chorea can appear long before the other manifestation of SLE or APLS.

Chorea can be associated with other autoimmune diseases including Behcet disease, polyarteritis nodosa, isolated angiitis of the central nervous system, and primary Sjogren's syndrome. Hashimoto's encephalopathy with high antithyroid antibody titers can present with chorea. It has rarely been reported in paraneoplastic syndromes associated with Anti-Hu and anti-CRMP5 antibodies in patients with small lung carcinoma.

Other important causes of acute chorea are infections such as bacterial meningitis, encephalitis, tuberculous meningitis, tuberculoma, and aseptic meningitis. Hemichorea and hemiballismus are relatively common in AIDS because of toxoplasmosis abscesses in the basal ganglia, or direct HIV invasion. Lyme's disease has been reported to cause chorea. CNS infections may also present with gradual onset of chorea.

Chorea due to vascular causes is uncommon, affecting only 2% of stroke patients, with hemichorea as the usual manifestation. The subthalamic nucleus is the most

Table 1 Causes of acute/subacute onset chorea

commonly involved site because of either hemorrhage or ischemia. Lesions may occur in the subthalamus, striatum, and even cortex. Other uncommon causes include moyamoya disease, postpump chorea, and cerebral arteriovenous malformations. Acute onset generalized chorea has been reported with bilateral chronic subdural hematoma as a rare complication.

Chorea of Gradual Onset

Hereditary causes of chorea should be considered when it is gradual in onset. Of these, Huntington's disease (HD) is the most common in European populations, with a reported prevalence of up to10 cases per 100 000. It is inherited as an autosomal dominant trait and caused by mutation in a gene located on the short arm of chromosome 4. The mutation results in expansion of an unstable CAG repeat in the first exon, causing an expanded polyglutamine tract in the protein huntingtin. The disease is characterized by adult onset, and psychiatric, cognitive and behavioral problems, in addition to chorea. Other abnormalities include dystonia and slowness of voluntary gaze. With a very large expansion, onset can occur in childhood, the clinical features being seizures, Parkinsonism, and behavioral problems.

Dentatorubropallidoluysian atrophy is an autosomal dominant disorder due to an unstable CAG triplet repeat expansion in the open reading frame of a gene encoding for atrophin-1, located on chromosome 12p. The presentation is variable, depending on the age of onset and includes ataxia, choreoathetosis, dystonia, seizures, myoclonus, psychiatric disturbances and dementia. It is most common in Japanese populations. Other trinucleotide repeat disorders such as the spinocerebellar ataxias may be associated with adult onset chorea, as can other hereditary disorders such as HDL 1, 2, and 3, and neuroferritinopathy.

Benign hereditary chorea is an autosomal dominant condition with onset in infancy. It is nonprogressive and may improve with age. This disease is due to mutation in the TITF-1 gene on chromosome 14q.

Choreoacanthocytosis is a rare autosomal recessive disorder characterized by progressive orofaciolingual dyskinesia, tics, limb chorea, hypotonia, muscle atrophy, and absent or diminished reflexes. Onset is typically in adolescence or early adulthood. Laboratory testing reveals increased serum creatine phosphokinase and normolipoproteinemic acanthocytosis. Neuroimaging demonstrates progressive degeneration of the caudate and putamen. It results from mutations in VPS13A on chromosome 9q21, which encodes a large protein called chorein.

Wilson's disease (WD), an autosomal recessive condition, is caused by mutations to the gene coding for the copper transporting beta polypeptide (ATP7B), located on chromososme 13. It is biochemically characterized by low ceruloplasmin and total serum copper levels, increased 24 h urinary copper excretion, and abnormally high hepatic copper content. The mean age of onset of WD is the second to third decade of life, although it has sometimes been reported to be as late as 72 years of age. Patients present with extrapyramidal, cerebellar, and/or cerebral-related symptoms. Early diagnosis is critical because of the treatable nature of this disorder.

Table 3 Causes of gradual onset chorea

1. Genetic chorea
   a. Autosomal Dominant
      i. Huntington's disease
      ii. Benign hereditary chorea
      iii. Dentatorubropallidoluysian atrophy
      iv. Spinocerebellar ataxia (type 2, 3, 17)
      v. Neuroferritinopathy
      vi. HDL 1 and 2
   b. Autosomal Recessive
      i. Chorea-acanthocytosis
      ii. Wilson's disease
      iii. Ataxia telangectasia
      iv. HDL-3
   c. X-linked Recessive
      i. Lesch–Nyhan disease
   d. Mitochondrial disorders (maternally inherited)
2. Dopaminergic blocking agents (Tardive dyskinesia)
   a. Neuroleptic medications
      i. Typical neuroleptics (thioridazine, chlorpromazine, haloperidol, etc.)
      ii. Atypical neuroleptics (quetiapine, risperidol, olanzapine)
   b. Gastrointestinal Agents
      i. Metoclopramide
      ii. Prochlorperazine
3. Infectious causes
   a. Direct HIV infection of brain
   b. Creutzfeldt–Jakob disease
4. Miscellaneous causes
   a. Hyperthyroidism
   b. Polycythemia rubra vera
   c. Nutritional: Vitamin B12 deficiency

Ataxia-telangiectasia is an autosomal recessive disease that results from mutations in the ataxia-telangiectasia mutated gene (ATM) (11q22–23), which is involved in the repair of double-stranded DNA breaks. AT patients typically present with progressive cerebellar ataxia early in childhood. Associated features include neuropathy, oculomotor apraxia, chorea, dystonia, and myoclonus. Affected individuals later develop conjuctival telangiectasias and sinopulmonary infections as well as increased susceptibility to malignancy.

Lesch–Nyhan disease, an X-linked recessive disorder of purine metabolism, is due to deficiency of the enzyme hypoxanthine phosphoribosyltransferase. The disease is characterized by a childhood onset of self mutilation, choreoathetosis, hyperuricemia, and gout.

Chorea is a common feature of Leigh's disease in children, but few cases of chorea have been reported in mitochondrial cytopathies with adult onset.

A common cause of choreiform movements in adults is the use of dopamine-blocking agents and referred to as tardive dyskinesia. These are characterized by involuntary stereotypic repetitive movements affecting the mouth and tongue. The head, trunk, and extremities may be affected in more severe cases. It is more common in elderly females, and has an incidence of 24–56% of patients chronically treated with neuroleptics.

Rarely, chorea can be associated with hyperthryroidism, polycythemia rubra vera, and nutritional deficiency (Vitamin B12). See **Table 4** for a detailed list of causes of chorea of gradual onset.

Paroxysmal Chorea

There are four main types of paroxysmal chorea: (1) Paroxysmal nonkinesigenic dyskinesia; (2) Paroxysmal

Table 4 Paroxysmal choreoathetotic disorders affecting children

	Gene	*Provoking events*	*Duration of attack*	*Frequency*	*Treatment*	*Associated condition*
Paroxysmal nonkinesigenic dyskinesia	2q	Alcohol, caffeine, hunger, stress, fatigue	>5 min to hours	< Several times/day	Benzodiazepine gabapentin	Migraine; dystonia, dysarthria, dysphagia
Paroxysmal kinesigenic choreoathetosis	16q	Sudden movement, startle, hyperventilation	<5 min	May be 100/day	Carbamazepine or phenytoin	
Infantile convulsions and paroxysmal choreoathetosis	16q	Sudden movement, stress, excitement	<5 min	Variable, may be 100/day	Carbamazepine or phenytoin	Benign neonatal seizure
Choreoathetosis and spasticity	IP	Exercise, stress, fatigue, and alcohol	20 min	<5 times/day		Spasticity during and between attacks

Adapted from Mathews KD (2003) Hereditary causes of chorea in childhood. *Seminars in Pediatric Neurology* 10: 20–25.

kinesigenic choreoathetosis; (3) Infantile convulsions and paroxysmal choreoathetosis; (4) choreathetosis and spasticity. Most have onset before the age of 20 years and all are inherited as autosomal dominant conditions (**Table 4**).

Diagnosis of Chorea

Diagnosis involves a careful history, with assessment of whether the chorea is of acute or chronic onset, or paroxysmal, and examination for associated neurologic and systemic symptoms. It is important to note exposure to drugs, toxins, and presence of a positive family history. These features will help guide the investigations (see **Table 5**).

Table 5 Recommended investigations in patients with chorea

1. Basic workup: Complete blood count, electrolytes, calcium, magnesium, liver and renal function, thyroid function
2. Autoimmune causes: Antinuclear antibody, antiphospholipid antibody, ESR, antistreptolysin O titre
3. Infectious causes: Venereal Disease Research Laboratory test, HIV antibodies, Lyme antibodies, toxoplasmosis titers, CSF examination
4. Serum ceruloplasmin, serum copper and 24-hour urine copper: if onset is under the age of 40, especially with a family history of neuropsychiatric symptoms or a medical history of liver disease
5. CT scan of brain in suspected intracranial haemorrhage, cerebral calcifications
6. MRI: in rule to intracranial structural lesion, especially in the setting of acute choreiform movements
7. Electroencephalography: when need to differentiate between paroxysmal movement disorders and seizures
8. Genetic testing: DNA testing, HD, DRPLA, SCAs, blood smear for neuroacanthocytosis

Table 6 Medications for the management of chorea

A. Neuroleptics
  1. atypical-clozapine, olaanzapine, risperidone, quetiapine (high dose only)
  2. typical – chlorpromazine, thioridazine, etc.
B. Dopamine-depleting agents
  1. tetrabenazine
  2. reserpine
C. NMDA-antagonists
  1. amantadine
D. Anticonvulsants
  1. carbamazepine, oxcarbazepine
  2. topiramate
  3. levetiracetam
  4. sodium valproate
  5. gabapentin

Treatment of Chorea

The treatment of chorea depends on the underlying cause. Correction of metabolic or hormonal abnormalities, withdrawal of offensive drugs and toxins, and control of infections alleviate acute chorea in many cases. As Wilson's disease is a potentially treatable disease, early diagnosis and institution of treatment with a copper chelating agent are imperative. In Sydenham's chorea, prophylaxis for rheumatic fever needs to be considered. In autoimmune chorea, steroids may be of help. In hereditary choreas, genetic counseling is very important.

In cases of chronic and/or more severe choreiform movements, treatment with medications that suppress chorea may be needed (see **Table 6**). Most commonly, the dopamine-depleting and-blocking agents are recommended. In resistant cases, anticonvulsants or amantadine may be considered. Treatment should always be started at a low dose and increased very gradually to determine the minimum amount required for symptom control.

Climbing Behavior

M Angela Cenci, Lund University, Lund, Sweden

Glossary

Apomorphine – A wide-spectrum dopamine receptor agonist (i.e., an agonist of both D1- and D2-type dopamine receptors). Apomorphine is widely used in neuroscience research to achieve a pharmacological activation of brain dopamine receptors. As a medication, apomorphine is used in the treatment of Parkinson's disease. Apomorphine is a potent emetic (i.e., it induces vomiting) and should not be administered without an antiemetic such as domperidone.

Dopamine – Dopamine is a neurotransmitter occurring in a wide variety of animals, including both vertebrates and invertebrates. In the brain, it can activate five types of dopamine receptors – D1, D2, D3, D4, and D5, and their variants. Dopamine is produced in several areas of the brain, but the largest aggregates of dopamine-producing neurons are found in two midbrain nuclei named 'substantia nigra' and 'ventral tegmental area.' Dopamine is also a neurohormone released by the hypothalamus. Its main function as a hormone is to inhibit the release of prolactin from the anterior lobe of the pituitary. Severe dopamine deficiency in the striatum is the prime cause of parkinsonian motor symptoms (in particular, slowness of movement, poverty of movement, difficulty in movement initiation, resting tremor, rigidity).

Neuroleptics (antipsychotics) – Neuroleptics (also referred to as antipsychotics) are a class of drugs used to treat psychosis (which is typified by schizophrenia). Over time, a wide range of neuroleptics/antipsychotics have been developed. A first generation of drugs, known as typical antipsychotics, was discovered in the 1950s. The prototype of this class of drugs is haloperidol, a potent dopamine D2 receptor antagonist, producing significant motor side effects (parkinsonian motor features and tardive dyskinesia). The first atypical anti-psychotic, clozapine, was discovered in the 1950s, and introduced clinically in the 1970s. Atypical neuroleptics also have some antagonistic activity on dopamine receptors, but they encompass a wide range of additional receptor targets. A number of side effects have been observed in relation to specific atypical neuroleptic medications (e.g., weight gain, agranulocytosis). The development of new antipsychotics, and the relative efficacy of different ones, is an important ongoing field of research.

Noradrenaline – Noradrenaline, also called norepinephrine, is a catecholamine with dual roles as a hormone and a neurotransmitter. As a stress hormone, it is released from the adrenal medulla into the blood, and together with adrenaline (epinephrine) it mediates the so-called fight-or-flight response (increased heart rate, release of glucose from energy stores, and increased blood flow to skeletal muscle). As a neurotransmitter in the central nervous system and sympathetic nervous system, noradrenaline is released from the nerve endings of noradrenergic neurons into their target organs. The actions of norepinephrine are carried out via the binding to adrenergic receptors. Noradrenaline is synthesized from dopamine by the enzyme, dopamine β-hydroxylase.

Serotonin – Serotonin (often referred to as 5-hydroxytryptamine, or 5-HT) is a monoamine neurotransmitter in the central nervous system. Serotonin is produced in, and released from, the brainstem raphe nuclei, which send widespread and highly ramified projections to the entire brain and spinal cord. Serotonin is involved in a variety of neurobiological processes, such as the control of appetite, mood and anger, sleep and wakefulness, and cognition. Genetic variation in serotonin receptors and the serotonin transporter (which facilitates reuptake of serotonin into presynapses) have been implicated in neurological and psychiatric diseases. Brain serotonin projections show a variable degree of degeneration in both Alzheimer's and Parkinson's disease. Outside of the brain, serotonin is found extensively in the gastrointestinal tract. About 80–90% of the human body's total serotonin is found in the enterochromaffin cells in the gut where it regulates intestinal movements.

Stereotypies – Inflexible repetition of movement patterns or simple action sequences, which are not abnormal per se but become pathologic because they disturb or replace normal behaviors. In rodents, stereotypies are induced by treatment with apomorphine or psychoactive drugs such as amphetamine, and they include behavioral components such as licking, gnawing, grooming, and head nodding. In humans, stereotypies may be simple movements, such as body rocking, or more

complex actions, such as self-caressing, crossing and uncrossing of legs, and marching in place. Stereotypies occur in patients with mental retardation, autism spectrum disorders, or drug-induced dyskinesias.

Rodents can engage in vertical movements and climb on the enclosing walls of confined environments. This behavior occurs spontaneously as a part of normal exploratory responses, which are dependent on the integrity of ventral and dorsal striatum. Spontaneous climbing behavior increases in intensity and duration when animals are placed in a novel environment. Dopamine receptor agonists can be used to elicit robust climbing responses in a predictable manner, and drug-induced climbing is exploited in neuropharmacological research. In particular, apomorphine-induced climbing is used as a behavioral assay to test the efficacy of neuroleptic agents in mice. In this assay, mice are placed in a transparent cage lined with wire mesh, where they can move around by holding on to the wire mesh with their four paws. The time spent in climbing is monitored during the 40–50 min that follows an injection of apomorphine, which is given at doses below those causing continuous oral stereotypies. Pretreatment with both typical and atypical neuroleptics significantly attenuates apomorphine-induced climbing in this assay. Specific forms of nondrug-induced climbing have been exploited in behavioral tests that are widely used in neuroscience and neuropharmacology research. In the cylinder test of forelimb use asymmetry, rats or mice are placed in a relatively small glass cylinder, where they rear and lean on the walls of the cylinder using the forepaws for support. Forelimb use during this vertical exploration is assessed in short testing sessions by counting the number of supporting wall contacts executed independently with the right and the left paw. Cortical infarcts, traumatic lesions, or dopamine deafferentation in one cerebral hemisphere cause asymmetry in forelimb use during the climbing response, and specific therapeutic interventions ameliorate this deficit. Another form of climbing behavior occurs within the context of the forced swim test, which is widely used in the preclinical screening of antidepressant drugs. In this test, rodents are placed in an inescapable cylinder full of water, where they engage in three main forms of behavior, that is, immobility (passive floating), swimming (horizontal movement), or climbing (upward-directed movements of the forepaws along the walls of the swim chamber). Swimming behavior is increased by antidepressants that potentiate serotonergic neurotransmission, while climbing is increased by treatments that act primarily on the noradrenergic system. Also invertebrate model organisms exhibit forms of climbing behavior that are exploited for research purposes. The fly *Drosophila* climbs up the wall of a cylinder after being tapped to its bottom. This vertical escape response is called 'negative geotaxis,' and it is utilized to measure locomotor ability and to track age-related locomotor impairment in this organism.

Glossary

Cock-walk – A type of dystonic gait characterized by toe-walking, flexed elbows, and erect spine.
Manganese – A brittle metallic element that is essential for normal human function and is commonly used in steel production.
Manganism – A clinical syndrome caused by chronic exposure to manganese characterized by dystonia, parkinsonism, and neuropsychiatric disturbances.
Propulsion – A disorder of locomotion marked by a tendency to walk forwards.
Retropulsion – A disorder of locomotion marked by a tendency to walk backwards.
Talipes equinus – A congenital deformity of the foot in which the sole is permanently flexed so that walking is done on the toes without touching the heel to the ground.

Definition and History

Cock-walk refers to a type of dystonic gait characterized by toe-walking, flexed elbows, and erect spine; classically seen in manganism. The use of manganese (Mn) has been recorded as far back as the Stone Age when manganese dioxide was used as black pigment for cave paintings and in the Greco-Roman times, as a way to remove color from glass. Mn was not widely used in the production of goods until the late eighteenth century at which time it was discovered that Mn could be used as a metallic catalyst. It was with the use of manganese dioxide in the production of chloride for bleaching powder that James Couper described a peculiar neurologic condition in five patients exposed to manganese dust in 1837:

> During the height of the disease, the weakness of the contractile muscles was much greater in the legs than in the arms. It was of such nature that the patient reeled in walking and leaned forward when he wished to walk.

Despite being the first to describe what eventually will be known as manganism, Couper's observations fell into obscurity. It was not until the nineteenth century that the use of Mn exploded after the discovery that the addition of Mn to steel produced a steel alloy of superior strength and brittleness. Almost three-quarters of a century after Couper's descriptions, Rudolph von Jaksch renewed the interest in manganism in 1901 with his description of three individuals exposed to manganese dioxide dust:

> He felt stiffness in the knees which made pronounced bending of the legs impossible. At the same time, he found he could not walk backward without falling and speech became noticeably slow.

While von Jaksch was the first to coin the peculiar gait seen in manganism as cock-walk, he initially attributed the cases to an atypical form of multiple sclerosis. Later, von Jaksch correctly concluded that the cases were due to chronic Mn toxicity. In the ensuing 12 years, at least another 15 cases of manganism were described by Embden, Friedel, Seelert, and Casamajor, further outlining the details of this unique disorder. Today, Mn exposure continues to be a potential occupational hazard as Mn ranks as the fourth most used metal behind iron, aluminum, and copper.

Clinical Features and Pathophysiology

Manganism is a condition characterized by dystonia, parkinsonism, and neuropsychiatric changes due to chronic Mn exposure. Manganism shares many features with Parkinson disease (PD) including presence of bradykinesia, rigidity, and gait changes. However, important clinical features help to differentiate manganism from PD. One of the distinguishing features of manganism that is not typically seen in PD is the presence of early gait and postural dysfunction. Gait changes described in manganism include retropulsion, propulsion, freezing of gait, and a unique type of gait pattern, cock-walk. Other names have been used to describe the same phenomenon including démarche de coq, coq au pied, and von Jaksch's gait.

Seelert's description of this gait abnormality is considered classical for all cases of manganism:

> The feet touch the floor only with the region of the metatarsophalangeal joints. While walking, the knee joints are slightly flexed and the right leg is circumducted. Usually when using quick, lively gait, a curious posture is recognized, with the arms raised and abducted, and with the forearms flexed.

Cock-walk is a type of gait in which individuals have a tendency to walk on the metatarsophalangeal joint associated with an erect spine and flexed elbows. During a

normal gait cycle, the heel strikes the ground during the initial stance phase. As the stance phase progresses, weight is shifted forward towards the toes until the swing phase is reached. In cock-walk, the initial heel strike is lost due to abnormal ankle plantar flexion altering the normal gait cycle.

Cock-walk can occur unilaterally or bilaterally. While cock-walk is regarded as one of the most characteristic feature of manganism, the incidence of cock-walk varies per report. In a well-known series from Taiwan, only one out of six cases manifested with cock-walk. In an earlier and larger series from Egypt, over 50% presented with cock-walk, and in a more recent study in methcathinone users, 10 out of 23 patients had features suggestive of cock-walk. This variation in presentation does not appear to correlate with Mn levels.

Earlier explanations for cock-walk centered on a possible cerebellar role. However, most cases of cock-walk do not have evidence of cerebellar dysfunction on examination. While the exact pathogenesis of cock-walk is not known, dystonia is thought to be a leading explanation. Cock-walk is usually accompanied by increased tone in the legs unequally affecting agonist and antagonist muscles resulting in abnormal posturing around the ankle joint. It is possible that the abnormal posture seen in the spine and arms also reflects an underlying dystonic process. Another feature in cock-walk is task specificity, a characteristic frequently seen in dystonia. Descriptions of cock-walk point out that during normal stance, the feet appear to be flat on the ground, but after a few steps, the heels begin to rise with the center of mass shifted to the metatarsophalangeal joints. The other features of cock-walk such as the erect spine, flexed elbows, and abduction of the arms away from the trunk also appear to manifest with walking and not with normal stance. Finally, in animal models of chronic Mn intoxication, abnormalities of the extrapyramidal system, including dystonic postures were seen in monkeys exposed to manganese dioxide.

Differential Diagnosis

While there are other etiologies that can cause a propensity to walk on the metatarsophalangeal joint or toe-walking, cock-walk is unique in that it also has features of dystonic posturing in the spine and arms. In the pediatric literature, toe-walking can be due to a congenital deformity, talipes equinus or club foot. Cerebral palsy resulting in spastic diplegia is another important cause of toe-walking. Duchenne muscular dystrophy can also present with toe-walking that is thought to be due to muscle fibrosis leading to a fixed plantar flexion contracture. Other neuromuscular conditions, including a rare disorder, rippling muscle disease, have been associated with toe-walking. This autosomal dominant myopathy is characterized by muscle hypertrophy, peculiar rolling or rippling muscles, and muscle rigidity that can result in toe-walking, especially in the morning.

Dystonia is another important cause of toe-walking. This can include focal dystonias of the foot resulting in abnormal plantar-flexion while walking. Dopa-responsive dystonia (DRD) that results in a fluctuating course of dystonia is a unique disorder seen mostly in children. The majority of cases are due to a defect in the guanosine triphosphate (GTP) cyclohydrolase 1 enzyme which is necessary for the production of a cofactor in the conversion of tyrosine to levodopa. One of the most common manifestations of DRD is dystonia of the lower extremity that manifests with rigidity in the legs, dystonic posturing of the foot and a tendency to walk on the toes similar to cock-walk. Wilson disease is an autosomal recessive disorder due to abnormal copper accumulation in the liver and brain. Similar to manganism, Wilson disease also presents with parkinsonism, neuropsychiatric symptoms, and dystonia that can include lower extremity dystonia and toe-walking. The presence of Kayser-Fleischer rings and liver abnormalities help to differentiate Wilson disease from manganism. Certain brain disorders with abnormal iron accumulation can also present with an abnormal gait similar to cock-walk. Formerly known as Hallervorden–Spatz syndrome, neurodegeneration with brain iron accumulation (NBIA) encompasses a heterogeneous group of disorders characterized by dystonia, chorea, and brain iron accumulation. The most common cause of NBIA is Pantothenate kinase-associated neurodegeneration (PKAN) due to a defect in the pantothenate kinase 2 (PANK2) gene.

Conclusion

In summary, cock-walk is a unique type of dystonic gait classically seen in manganism. The major features of cock-walk include walking on the metatarsophalangeal joint associated with an erect spine and flexed elbows. A patient with known Mn exposure and presence of cock-walk should be considered a sine qua non for manganism.

Co-enzyme Q_{10}

A H V Schapira, Institute of Neurology, University College London, London, UK

Coenzyme Q_{10} (coQ_{10}) is a lipid-soluble component of virtually all cell membranes. CoQ_{10} is an isoprenylated benzoquinone and transports electrons from complexes I and II to complex III in the mitochondrial respiratory chain and can enhance oxidative phosphorylation. It is essential for the stability of complex III and also functions as an antioxidant.

CoQ_{10} deficiency has been implicated in several diseases, and CoQ therapy has been proposed as a treatment not only for these deficiency states, but also for other degenerative diseases.

Primary CoQ_{10} Deficiency

The first report of human disease associated with coQ_{10} deficiency was in a patient with encephalomyopathy and recurrent myoglobinuria with ragged red fibers and changes of lipid storage on muscle biopsy. Relatively severe coQ_{10} deficiency was then described in six patients with early-onset (age range birth – 16 years) myopathy and ataxia. Seizures, weakness, and mental retardation were described in some and cerebellar atrophy found in all. Genetic testing for Friedreich ataxia (FRDA) and spinocerebellar ataxia was negative, and inheritance was consistent with an autosomal recessive pattern. Muscle biopsy in these patients showed nonspecific abnormalities only, and in particular, no evidence of mitochondrial pathology. Residual muscle coQ_{10} levels were 26–35% of normal. Administration of coQ_{10} (300–3000 mg day^{-1}) resulted in significant improvement in the ataxia.

Subsequent assay of muscle coQ_{10} levels in 135 patients with genetically undefined childhood onset ataxia identified significantly reduced levels in 10%. All patients had cerebellar atrophy and some had seizures, developmental delay, and pyramidal features. Lactic acidosis in the ataxic patients is rare, and in contrast to the myopathic form, the muscle biopsy may appear normal. The same group subsequently described muscle coQ_{10} deficiency in two brothers with adult onset (age 29 and 39 years) progressive cerebellar ataxia with cerebellar atrophy and hypergonadotrophic hypogonadism. Muscle morphology showed neurogenic changes only. coQ_{10} 750–1200 mg day^{-1} resulted in improved ataxia, neurophysiology, and normal testosterone levels within 2 months. A pure myopathic form of coQ_{10} deficiency, without recurrent myoglobinuria but with mild mitochondrial changes on muscle biopsy has recently been described.

Friedreich Ataxia (FRDA)

FRDA is an autosomal recessive disease caused in 97% of patients by an abnormal expansion of the GAA repeat of intron 1 of the *frataxin* gene. The remainder are due to an expansion on one allele and a point mutation in the *frataxin* gene on the other. The *frataxin* gene product is a mitochondrial protein and the mutations lead to a loss of this protein. Deficiency of frataxin protein is associated with a decrease in mitochondrial respiratory chain complexes I, II, and III and aconitase activities in postmortem heart and skeletal muscle from FRDA patients. Various

markers have indicated increased oxidative stress and damage in FRDA patients including raised urine levels of 8-hydroxyl-2′-deoxyguanosine (8OH2′dG) suggesting elevated oxidative damage to DNA; decreased free glutathione levels in blood, suggesting extensive gluathionylation of proteins in response to oxidative stress; and raised plasma malondiadehyde (MDA) levels indicative of increased lipid peroxidation.

A 4 year open-label trial of CoQ in combination with vitamin E was completed with 10 genetically confirmed FRDA patients given 2100 IU day^{-1} vitamin E and 400 mg day^{-1}) CoQ_{10}. The International Cooperative Ataxia Ratings Scale (ICARS) was used to evaluate clinical progression, in addition to biomarkers of in vivo mitochondrial bioenergetics (cardiac and skeletal muscle ^{31}P MRS) and cardiac hypertrophy (echocardiography) to evaluate the effect of therapy. During the course of the therapy, all patients demonstrated an increase in serum vitamin E (2.2 – 6-fold increase over baseline) and CoQ_{10} levels (2.3 – 7.4-fold increase over baseline), demonstrating good bioavailability. Most remarkable was the improvement in cardiac (phosphocreatine: ATP ratio) and skeletal muscle (postexercise maximum rate of mitochondrial ATP synthesis, V_{max}) bioenergetics after 3 months of therapy, which was maintained throughout the 4 years of the trial. This clearly demonstrated that the combined vitamin E and CoQ_{10} therapy had a significant and prolonged benefit upon the defective mitochondrial function in these peripheral tissues. While the prolonged improvement in cardiac bioenergetics did not have any impact upon cardiac hypertrophy, fractional shortening showed a progressive improvement that reached significance after 3 years.

On the basis of these positive results, 50 FRDA patients were randomly divided into high (600 mg day^{-1} CoQ and 2100 IU vitamin E) or low (30 mg day^{-1} CoQ and 4 IU vitamin E) dose CoQ_{10}/vitamin E groups in a double blind controlled trial. Patients were assessed at baseline and every 6 months over 2 years. The change in ICARS was used as the primary end point. A post hoc analysis was made using cross-sectional data from 77 untreated FRDA patients. The results showed baseline serum CoQ_{10} and vitamin E levels were significantly decreased in the FRDA patients. During the trial, CoQ_{10} and vitamin E levels were significantly increased in the both dosage groups. The primary and secondary end points were not significantly different between the therapy groups.

The results of this study indicate that over 2 years 'high dose' CoQ_{10} and vitamin E have no benefit over the 'low dose' combination in terms of improving ICARS scores. The important and unexpected finding was plasma CoQ_{10} and vitamin E deficiency in FRDA. In a post hoc analysis, 49% (21/43) of the patients responded over the 2 years of the trial with improved ICARS compared to cross-sectional data, with equal numbers of responders in the two treatment groups. Of most significance was the observation that the responder patients had significantly lower baseline CoQ_{10} levels suggesting the clinical efficacy of the low- and high-dose therapies may relate to restoration of normal serum CoQ_{10} levels. The low-dose CoQ_{10} (30 mg day^{-1}) was sufficient to raise significantly the plasma levels in the patients to control levels. The cause of the CoQ_{10} deficiency may be related to an increased turnover because of excess free radical production. If this in turn contributed to the pathogenetic events underlying progressive neurodegeneration, 30 mg day^{-1} CoQ_{10} was sufficient supplement to restore levels and may have been the reason why differences were not seen between the treatment arms. Higher doses produced no additional benefit over the period of the trial.

Parkinson's Disease

The relationship between Parkinson's disease (PD) and mitochondria was first established with the identification of a deficiency in the activity of complex I in PD substantia nigra and subsequently in the peripheral tissues of patients. Complex I is the target of toxins known to produce parkinsonian features in humans, for example, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and anonnacin, and also the target of toxins used to produce animal models of PD, for example, rotenone and tetrahydroisoquinolines. The pathogenesis of PD also includes protein aggregation (Lewy bodies). Mitochondrial dysfunction will contribute to dysfunction of the energy-dependent ubiquitin proteasomal system (UPS) and oxidative stress will add to the substrate load. This combination has been shown to enhance dopaminergic cell damage and death.

Environmental and genetic factors known to be important in PD interact with mitochondrial function. As noted earlier, environmental toxins that induce dopaminergic cell death and parkinsonism in man and animal models inhibit complex I. Genetic causes of familial PD affect mitochondrial function. For instance, α-synuclein overexpression inhibits mitochondrial activity, parkin-knockout mice have a striatal respiratory chain defect, parkin-knockout flies have skeletal muscle mitochondrial abnormalities, and parkin-positive PD patients have complex I deficiency. Overexpression models of parkin have shown localization of the protein to mitochondria. DJ1 localizes to the outer mitochondrial membrane under conditions of oxidative stress and is thought to play a role in antioxidant defenses. Mutations in the PINK1 gene, causing autosomal dominant PD, have been described and the protein product localizes to the mitochondrion. The function of PINK1 is not known, but it is a protein kinase and mutations enhance sensitivity to UPS inhibitors and lower the threshold to apoptotic cell death. Thus, the current pathogenetic model of PD reflects a complex network of

interacting biochemical abnormalities that are in turn a consequence of genetic and environmental factors.

Based upon the evidence that mitochondrial dysfunction plays an important role in PD pathogenesis, it seemed reasonable to test the hypothesis that drugs that improve mitochondrial function might slow the progression of the disease. The first of these studies used a double blind placebo-controlled design and recruited 16–23 patients per arm to asses the efficacy of three doses of CoQ_{10} (300 mg day^{-1}, 600 mg day^{-1}, and 1200 mg day^{-1}) in early PD patients. Over a 16 month period, the highest dose group progressed at a lower rate in terms of the worsening of motor function and activities of daily living (United Parkinson Disease Rating Scale parts II and III) (UPDRS) compared to control, although much of this benefit was related to the activities of daily living component and was established very early in the trial. A futility analysis assessed coQ_{10}, using historic control data and the total score of the UPDRS and failed to show futility, that is, suggested that the compound was worthy of future study. However, the authors called into question the validity of their historic control data in the light of more recent placebo progression rates in the UPDRS, and with these, coQ_{10} did suggest futility. A small study of 28 treated PD patients supplemented with 360 mg day^{-1} of coQ_{10} showed a mild symptomatic motor effect over a period of 4 weeks. However, a larger study of 300 mg day^{-1} (which produced the same plasma levels as 1200 mg day^{-1} in the Shults study) found no symptomatic effect on the UPDRS. A large double blind study of high-dose CoQ_{10} in early PD is underway at the time of writing.

Cognitive Assessments and Parkinson's Disease

J G Goldman and B A Bernard, Rush University Medical Center, Chicago, IL, USA

Glossary

Apathy – Impairment in goal-directed behavior; may have affective, behavioral, and cognitive components.
Bradyphrenia – Slowness of mental processing.
Episodic memory – Memory that involves the ability to learn, store, and retrieve information related to ongoing experiences or events; typically includes memories that have a temporal and spatial context; conceptualized as an ability to transfer information from primary (short term) to secondary (long term) memory.
Executive function – A descriptive term comprising a broad range of cognitive processes including planning, initiating, and monitoring behavior. Executive functions include working memory, abstract reasoning, problem solving, and mental flexibility.
Luria sequence – A measure of motor programming in which the patient is required to repeat a series of hand movements, such as fist-edge-palm.
Punding – Activities of a compulsive, repetitious, and purposeless nature that may involve the assembly and disassembly of mechanics, collecting or sorting of objects; may occur in substance abuse but also with overactive dopaminergic stimulation in Parkinson's disease.
Stroop test – A test in which the patient is presented with a succession of names of colors printed in nonmatching inks and then asked to name the color of the ink as quickly as possible; performance on this test requires directed attention and inhibition of the tendency to read the word.
WAIS-IV – The latest revision of the Wechsler Adult Intelligence Scale; comprised of 10 different subtests that generate index scores for Verbal Comprehension, Perceptual Reasoning, Working Memory, Processing Speed, and Full Scale IQ.
Working memory – A limited-capacity memory storage system for retaining information over a matter of seconds and for performing mental operations on the contents of this store.

The Neuropsychological Assessment

Neuropsychological Issues in PD

Besides the motor dysfunction, Parkinson's disease (PD) is associated with nonmotor features affecting cognition,

behavior, and mood. Cognitive changes range from mild impairment to dementia and commonly affect domains including executive function, attention, visuospatial/perceptive function, and memory. PD patients may exhibit slowed information processing; deficits in planning, switching tasks, or multi-tasking; forgetfulness; and subfluency or word-finding difficulties. Although PD dementia is typically considered as a predominantly dysexecutive syndrome, some studies have reported more severe deficits and greater memory dysfunction with PD patients, thereby exhibiting a phenotype more similar to Alzheimer's disease (AD). The pathology of PD dementia is likely heterogeneous with contributions from Lewy bodies, Lewy neurites, and brainstem degeneration, as well as neurofibrillary plaques and tangles. Mild cognitive changes have been reported in 20–40% of early or de novo PD patients, and dementia may occur in about 40% of patients, although estimates vary depending on study methodologies.

Behavioral issues in PD encompass hallucinations, psychosis, impulse control disorders, mood disorders, and apathy. Hallucinations occur in about a third of PD patients treated with chronic dopaminergic medications and likely are related to both extrinsic (e.g., medications) and intrinsic factors (e.g., cognition, disease duration). Psychosis occurs less frequently and is often coupled with cognitive impairment; common delusions are those of infidelity, paranoia, or misidentification syndromes. Impulse control disorders include pathological gambling, hypersexuality, binge eating, compulsive shopping, punding, and other repetitive and reward-seeking behaviors. This disorder may relate to excessive D3 stimulation, particularly with dopamine agonists. Apathy, defined as an impairment in goal-directed behavior, occurs in 16–40% of PD patients. It may be linked to executive dysfunction and may occur with or without depression.

Mood disorders such as depressed mood, depression, dysthymia, anxiety, and panic disorder are common in PD and occur throughout different stages of the disease. Depression and anxiety may even be some of the very earliest manifestations of PD, reflecting early brainstem degeneration with alteration of noradrenergic and serotonergic systems (i.e., Braak PD pathological staging II). In addition, mood disorders can occur as intrinsic to the disease, reactive disorders related to having PD, and as nonmotor fluctuations or wearing off of dopaminergic medication effects.

Reasons for Neuropsychological Referral

When PD patients are referred for a clinical neuropsychological evaluation, the referral questions often are:

1. Does the patient have cognitive impairment or dementia?
2. Is there an underlying mood disorder?
3. Are these nonmotor features consistent with PD or are there other contributory factors (e.g., AD, cerebrovascular disease, toxic/metabolic syndromes, delirium)?

Neuropsychological referrals may provide information on diagnosis, deficit localization, and quantifiable data on cognitive impairment or neuropsychological function. In PD patients, neuropsychological testing also may be performed as part of a presurgical evaluation for surgical interventions such as deep brain stimulation. Serial clinical neuropsychological evaluations may permit assessment of cognitive change over time, effects of interventions such as medication changes on cognition, and guidance for therapies and decisions about the patient's condition. In addition, neuropsychological testing is an important part of many PD motor and nonmotor research studies.

The Neuropsychological Evaluation

PD patients referred for neuropsychological evaluation receive a clinical interview and neuropsychological testing. In the interview, demographic information (e.g., age, education, gender, handedness, occupation history, current and prior function) is collected to help to establish an estimate of premorbid level of functioning. Information regarding the patient's movement disorder, other health information such as medication use and social history, and motor status (e.g., 'on' or 'off') may be pertinent. A battery of paper-and-pencil neuropsychological tests is typically administered to address the referral question. These neuropsychological tests are chosen for adequate reliability, validity, sensitivity, and specificity, as well as satisfactory normative data. Selection of neuropsychological tests that can be administered orally and that can thus minimize motor demands may be important when testing patients with PD and other movement disorders who have bradykinesia, tremor, or dyskinesias. It is important to consider issues such as medication effects, comfort, fatigue, and sleepiness, particularly in PD patients, as well as impairment in sensory function (vision and hearing). In addition to addressing cognitive issues, patients are interviewed for emotional changes, primarily depression and anxiety, and other behavioral problems. Obtaining collateral history from an informant (e.g., spouse, relative, or caregiver) comprises an important part of the interview, especially in cognitively impaired patients.

The typical neuropsychological battery consists of a measure(s) of global cognitive functioning as well as assessments of a range of cognitive domains. These cognitive domains broadly include memory, executive function, attention, language, and visuospatial function. Examination of memory may include testing episodic, semantic, procedural, and working memory function. Neuropsychological tests may assess verbal learning and memory, visual learning and memory, free and cued recall, and working memory

function. Examination of executive function may include tasks for set elaboration and planning, set shifting, and set maintenance as well as other frontal lobe functions. Other cognitive aspects examined include intellectual functioning, processing speed, sensory-perceptual functions, and motor speed.

Specific Cognitive Assessments in PD

Although there are numerous neuropsychological tests available, this section will highlight selected, specific cognitive assessments that are often used in PD evaluations.

Global Cognitive Function

A variety of neuropsychological instruments has been used to evaluate global cognitive function or screen for dementia or cognitive impairment in PD. Among others, these tests include the Mini-Mental Status Examination (MMSE), Mattis Dementia Rating Scale (DRS), the Cambridge Cognitive Assessment (CAMCOG), Scales for Outcomes in Parkinson's disease-cognition (SCOPA-cog), Parkinson Neuropsychometric Dementia Assessment (PANDA), Parkinson's Disease – Cognitive Rating Scale (PD-CRS), Montreal Cognitive Assessment (MoCA), and the Alzheimer's Disease Assessment Scale-cognitive (ADAS-cog).

The MMSE, a 30-point test, is a quick screening exam for cognitive impairment; questions assess orientation, attention, recent memory, language, and visuoconstruction. Since the MMSE is relatively insensitive to executive dysfunction, a cut off score of <25 has been proposed for PD dementia in a recent article by the Movement Disorders Society (MDS) Task Force. The MMSE is affected by age and education for which normative data are available.

The DRS provides a more comprehensive assessment of global cognitive function, particularly with increased sensitivity to the dysexecutive syndrome of PD, and is comprised of five subscales: Attention, Initiation/Perseveration, Construction, Conceptualization, and Memory. The DRS takes about 20 min; has age and education normative data; and has been used in longitudinal assessments of cognitive function.

The CAMCOG is a 107-point complete cognitive assessment, which tests eight different cognitive domains (orientation, language, memory, attention, praxis, calculation, abstract thinking, and perception). Overall scores less than 80 have been suggested as a cut-off for dementia; it has demonstrated greater sensitivity and specificity for the diagnosis of dementia compared with the MMSE. Administering a revised version of the CAMCOG (the CAMCOG-R) to a community population of PD patients, Athey et al. found that the CAMCOG-R detected a wide range of cognitive ability in those PD patients previously deemed not having significant cognitive impairment by MMSE. In a 2006 follow-up study, Athey and Walker reported a decline of 3.9 CAMCOG-R points over a 13-month period in their PD cohort.

The SCOPA-cog was developed as a short, practical instrument that was sensitive to the cognitive deficits of PD; its main use, as described by Marinus et al., was for research situations or the assessment of cognitive change, rather than as a screening tool or diagnostic instrument. The SCOPA-cog includes 10 items that encompass memory (nonverbal and verbal), attention, executive function (Luria maneuver, dice task, animal fluency), and visuospatial function (figure completion). Administration time is about 10–15 min, and the SCOPA-cog correlates highly with the CAMCOG and MMSE.

The PANDA is a short (8–10 min) screening tool for detecting neuropsychological dysfunctions in PD patients in clinical practice. The instrument includes four cognitive tasks (word pair associate learning with immediate and delayed recall, alternating verbal fluency, visuospatial imagery, and working memory/attention using number sequencing) plus a depression questionnaire. In their 2008 study of 124 PD patients and 108 neurologically normal controls, Kalbe et al. report high specificity and sensitivity of the cognitive tasks for PDD (91% and 90%) and a sensitivity of 77% for cognitively impaired PD (both PDD and PD with mild cognitive impairment).

The PD-CRS was designed to evaluate the full spectrum of cognitive deficits associated with PD. The PD-CRS includes 10 subcortical items (attention, working memory, Stroop test, phonemic, semantic, alternating, and action verbal fluencies, immediate and delayed verbal memory, clock drawing) and 2 cortical items (naming, clock copying) with an administration time ranging from 13 to 31 min. Paragonabarraga et al. report that the PD-CRS showed a strong concurrent validity with the DRS, sensitivity and specificity for diagnosing PDD of 94% and 94%, and a differentiation of a mildly cognitive impaired PD group on tasks of alternating verbal fluency and delayed verbal memory.

The MoCA was developed as a short (10-min) cognitive screening tool to aid clinic physicians in the detection of mild cognitive impairment. Subsequently, the MoCA has been applied to PD patients and compared with the MMSE in PD in several studies. The MoCA, a 30-point test, evaluates orientation, verbal memory, attention (serial 7's, target detection using tapping, and digit span), visuospatial function (clock drawing, cube copying), language (naming, repetition), and frontal functions (modified Trail Making Test Part B, verbal fluency, and abstraction task). In the PD studies, the MoCA appears to have a greater sensitivity than the MMSE to mild cognitive impairment.

Although the ADAS-cog is primarily used in AD settings including trials with cholinesterase inhibitors and other cognitive medications, it is included in this section

as it was used as the primary outcome measure in a large multicenter, double-blind, placebo-controlled trial for 24 weeks of rivastigmine in patients with mild to moderate PD dementia. The ADAS-cog is a 70-point test with 11 parts (7 performance items and 4 clinician-rated items assessing memory, language, praxis, and orientation) and can take 30–45 min to administer. In the PD trial comparing rivastigmine and placebo, patients receiving rivastigmine had a mean improvement of 2.1 points in the ADAS-cog, whereas control subjects had a 0.7-point worsening, thereby reflecting changes similar to those seen in patients with AD.

Memory

The memory deficits of PD have generally been considered to reflect the underlying subcortical-frontal disturbances, in contrast to mesial temporal lobe dysfunction more typically seen in the deficits of episodic memory in AD. Encoding and retrieval deficits, in contrast to storage deficits, characterize the impaired recall in PD. In addition, PD patients perform worse when the material is not semantically organized or requires internally generated retrieval strategies. Thus, PD patients often perform better on cued recall or recognition tasks compared to AD patients, although more severe PD dementia patients may also be impaired on cued recall. When testing memory function in PD, it may be useful to control for the encoding and retrieval of information.

Tests of verbal memory typically include trials of list learning, followed by immediate recall, delayed recall, and recognition tests. Some verbal memory tests such as the California Verbal Learning Test-II (CVLT-II), Hopkins Verbal Learning Test-Revised (HVLT-R), and Free and Cued Recall Test incorporate semantic categories (e.g., kitchen utensils, sports), which may aid in encoding and retrieval. Other commonly used verbal memory tests include the Rey Auditory Verbal Learning Test (RAVLT) and the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) word list. The CERAD word list is a brief 10-word list that the patient reads and that has been shown to differentiate normal control subjects from mild dementia. The HVLT-R is a word list in which 12 words belonging to three categories aid in recall. These word lists differ in the number of words (10–15 words), use of semantic categories, number of trial presentations (3–5), and delayed recall. Time intervals for delayed recall tasks vary from about 15–30 min.

The Free and Cued Recall Test as described by Grober and Buschke may be particularly useful in memory evaluation in PD, because it controls encoding and retrieval with the same semantic cues. It has been proposed to differentiate encoding deficits of AD from the retrieval impairment of frontal/subcortical dysfunction. In this task, encoding of items is controlled by having the subject point to and read aloud each of the items to be learned, in response to its semantic category cue. All the 16 items must be retrieved before proceeding to the memory tests of free and cued recall. For items not produced during free recall, the semantic cue is provided to facilitate retrieval. Free and cued recall scores are then compared.

Most measures of nonverbal memory, typically employing visual memory, unfortunately are not 'pure' measures and involve language to some degree. Many tests of visual memory also involve a visuomotor component, such as drawing. In the Visual Reproduction subtest of the Wechsler Memory Scale-IV (WMS-IV), patients are shown a series of designs on cards, for 10 s each. Patients are asked to draw the designs from memory for an immediate trial, as well as a 30-min delayed trial. The WMS-IV includes a new subtest, Designs, which is an attempt to develop a 'purer' measure of visual memory. In the Designs subtest, the patient views a stimulus card with 2–8 designs placed on a 4×4 grid. After viewing the stimulus card for 10 s, the patient is required to pick out the correct designs from a group of cards which includes foils, and place in the right location as in the stimulus picture. This subtest also has a 30-min delayed trial.

Working memory is often described as a 'mental workspace' that holds information while it is being processed. Working memory theories cite three principal components: a Central Executive System that controls and coordinates the other systems via strategy and integration, an Articulatory Loop System that circulates verbal information during processing, and a Visuospatial Scratchpad that temporarily stores and manipulates visuospatial information. Working memory can be evaluated using the Digit Ordering test or the Digit Span and Letter-Number Sequencing subtests from the WAIS-IV. In the Digit Ordering test, subjects are read a random selection of digits and are asked to reorder them by repeating them in ascending order. In the Digit Span task, the subject recalls increasing lengths of digits first forwards, then backwards, then in ascending order. While repetition of digits forward relates more to attention, reversed order digit span and sequencing of digits assess working memory, as the numbers must be temporarily stored for mental manipulation. The Letter-Number Sequencing subtest involves ordering increasing lengths of random numbers and letters, with the numbers in order first, followed by the letters in alphabetical order.

Executive Functions

Executive function refers to the mental processes that underlie goal-directed behavior. It includes planning, conceptualization, flexibility of thinking, insight, judgment, self-monitoring, and regulation. Frontal/subcortical circuitry, including the basal ganglia and prefrontal cortex, is integral for executive function. PD cognitive impairment and dementia are characterized by a

dysexecutive syndrome. Many of the executive functions are also related to attention and working memory.

Tests of executive function can be categorized as those related to working memory, conceptualization, set activation, set shifting, and set maintenance. Conceptualization abilities, set elaboration and planning can be tested by conceptualization subscales of the DRS, similarities tasks (e.g., Similarities from the WAIS-IV), which involve the presentation of word pairs in increasing difficulty to ascertain verbal concept formation or the Wisconsin Card Sorting Test (WSCT; Heaton, 1981), which often serves as a paradigm for testing executive function. The WSCT requires subjects to sort cards according to one criterion (color, form, number) that they must figure out based on the examiner's feedback on whether their response is correct or not. After 10 consecutive correct responses, the examiner shifts the rule without telling the subject and the subject must deduce the new rule. The WSCT tests not only conceptualization but also set shifting and set maintenance. Performance is impaired in PD dementia and some nondemented PD.

Tests of set activation, set shifting, and set maintenance in PD include verbal fluency, Trail Making Test (TMT; Reitan, 1955), Stroop Test (Golden, 1978), Odd Man Out test (Flowers & Robertson, 1985), Symbol Digit Modalities Test (Smith 1991), among others. Verbal fluency tasks provide insight as to activation strategies, attention, and temporary storage of information. Retrieved words can be semantic/category (e.g., animal naming) or phonological/letter (e.g., words beginning with the letters F, A, and S). Typically, patients are asked to name as many words as possible for the designated category or letter in trials of 60 s. Verbal fluency is impaired in PD dementia, and in some, but not all studies, to a greater degree than in AD. The TMT, originally part of the Army Individual Test Battery, and incorporated into the Halstead-Reitan test battery, has two parts: Part A, which involves linking a series of randomly positioned numbers in consecutive order (i.e., 1–2–3, etc.) and Part B, which involves joining a series of randomly positioned numbers and letters alternately in a respective sequence (i.e., 1-A-2-B-3-C, etc). Both nondemented PD, including de novo PD, and demented PD may exhibit deficits on the TMT. The Stroop Test is considered to reflect cognitive flexibility or set-shifting abilities and is often impaired in PD patients. In the Stroop interference condition, subjects are presented with names of colors printed in a color other than is the word (e.g., the word blue is printed in green ink) and asked to say aloud the color of the word, thereby inhibiting the tendency to read the word.

Attention

Attentional processes may be impaired in PD. Often tests of attention, however, are linked to those associated with vigilance, working memory, and processing speed. Furthermore, attention may be affected by medications, sleep disturbances, and fatigue, as well as intrinsic disease processes. Measures of attention may include simple tests such as Digit Span Forward or more complicated assessments such as the Coding (previously called Digit Symbol) subtest from the WAIS-IV and the Symbol Digit Modalities Test. PD patients are impaired on tests that make greater demands on attention. Fluctuations in attention are a striking feature of dementia with Lewy bodies but also may be evident in some patients with PD dementia. In the Coding subtest, patients copy symbols that are paired with numbers. The Symbol Digit Modalities Test is similar to the Coding subtest, although the patient is copying numbers paired to symbols over 90 s. The SDMT also has an oral version that may be especially well suited for PD subjects with significant motor impairment.

Language

Assessment of language usually includes aphasia-type tests with evaluations of expressive language, receptive language, and repetition. Measures of expressive language are sensitive to cortical functions and the progression of dementia. Visual confrontation naming, a measure of expressive language, is typically preserved in PD. In the Boston Naming Test, patients are asked to name line drawings of items that vary in level of familiarity. As previously discussed, verbal fluency, another measure of expressive language that overlaps with executive function, is often impaired in PD. Receptive language is assessed by tests of verbal comprehension, including following commands. Verbal repetition is assessed by the patient repeating phrases and sentences.

Visuospatial Function

Impairment in visuospatial (or visuoperceptual) abilities refers to the inability to appreciate the relative position of stimuli and objects in space, to integrate those objects into a coherent spatial framework and to perform mental operations involving spatial concepts. Visuospatial impairment is reported to be common in PD. Some tests of visuoperception require a motor component and are called visuoconstructive tasks. Such visuoconstructive tasks require either drawing or manipulation of test materials (e.g., WAIS-IV Block Design). Common drawing tasks include the Clock Drawing Test, and copying complex figures, such as the Rey Complex Figure Test. Tests of visuoconstruction are typically timed, therefore patients with PD are at a disadvantage on these tests, due to both the degree of motor disturbance and bradyphrenia. However, visuoperception may be affected even when motor demands are minimized. The Raven's Progressive Matrices

test, a measure of perceptual problem-solving, has been reported to be impaired in patients with PD. However, this test requires a high degree of conceptualization, which may be affected by the executive dysfunction seen in PD. Visuoperception is more impaired in PDD than nondemented PD or AD, but in several studies, visuoperception is similarly impaired compared with dementia with Lewy bodies.

Other

The Frontal Assessment Battery (FAB) provides a short (10 min), bedside test of 6 tasks of general frontal lobe function. The tasks relate to conceptualization, mental flexibility, motor programming, sensitivity to interference, inhibitory control, and environmental autonomy. Although this battery overlaps with other tests of conceptualization (Similarities of the WAIS-IV) and lexical fluency (FAS test), these tests are brief, including only 3 similarities and one letter, 'S.' Furthermore, the FAB addresses motor components with the Luria sequence, a tapping task presented with conflicting instructions, a 'Go-No-Go' task for inhibitory control, and prehensile behavior. The FAB scores demonstrated sensitivity to frontal lobe function, good psychometric properties, and correlated with the DRS and features of the Wisconsin Card Sort test when administered to 121 patients with frontal lobe dysfunction (including PD, corticobasal degeneration, progressive supranuclear palsy, frontotemporal dementia, and multiple system atrophy) and 42 normal controls.

Proposed Test Batteries and Diagnostic Guidelines

In recent years, there have been several organizations that have proposed batteries of neuropsychological tests (e.g., Parkinson's Disease Data and Organizing Center, Movement Disorders Society Task Forces), published critiques and recommendations for various cognitive and behavior rating scales (e.g., Movement Disorders Society, practice parameters by the American Academy of Neurology, NINDS/NIMH Work Group), and presented revised clinical diagnostic criteria for PD dementia (e.g., Movement Disorders Society Task Force). References are provided under Further Reading, and these proposed test batteries and diagnostic guidelines will be discussed briefly.

Parkinson's Disease Data and Organizing Center's (PD-DOC)

The Parkinson's Disease Data and Organizing Center (PD-DOC) is supported by the National Institute of Neurological Disorders and Stroke (NINDS) and administered by the University of Rochester. PD-DOC aims at facilitating and promoting collaborative clinical research in PD through a shared database of clinical, environmental risk and neuropathological data from PD subjects. The PD-DOC Cognitive/Behavioral battery, one part of the PD-DOC Core Data Set, includes the following: a Cognition/Behavior Questionnaire, the Mini Mental State Exam (MMSE), the Hopkins Verbal Learning Test, the Controlled Oral Word Association Test (COWAT), the Letter-Number Sequencing Test (LNS), the Geriatric Depression Scale (GDS-15), and the Neuropsychiatric Inventory Questionnaire (NPI-Q_). The proposed battery incorporates several widely used tests, but has limited visuospatial measurements.

Movement Disorders Society (MDS) Task Forces

In 2007, Emre et al. published clinical diagnostic criteria for PD dementia on behalf of a Movement Disorders Society (MDS) Task Force on PD dementia. The proposed criteria for the diagnosis of probable or possible PD dementia differ from criteria for dementia due to PD (294.1) in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV). The MDS criteria do not specifically require a memory deficit and state that impairment in at least two of the four core cognitive domains (impaired attention that may fluctuate, executive functions, visuospatial functions, and free recall memory that usually improves with cueing) should be present. In addition, there is a greater emphasis on behavioral symptoms such as apathy, depressed or anxious mood, hallucinations, delusions, and excessive daytime sleepiness.

In a follow-up article to the MDS criteria for PD dementia, the MDS Task Force for PD dementia addressed recommended diagnostic procedures for PD dementia. Dubois et al. propose practical guidelines based on a two-level process depending on the clinical scenario and expertise of the evaluator. Level I diagnostic recommendations, suited for the clinician who requires a simple, practical, and relatively quick set of tests, included a diagnosis of PD based on the Queen's Square Brain Bank criteria, development of PD prior to dementia onset, MMSE below 26, cognitive deficits severe enough to impact on daily living, and impairment in at least two tests (months reversed or seven backward, lexical fluency or clock drawing, MMSE pentagons, or 3-word recall), in the absence of major depression, delirium, or other abnormality. Additional testing that would provide greater neuropsychological detail, called Level II testing, is proposed for neuropsychological evaluation, clinical monitoring, research studies or pharmacological trials. Level II testing proposed several test options that could be used to assess cognitive and neuropsychiatric domains including global efficiency (Mattis DRS); executive function: working memory (Digit Span, Spatial Span [CANTAB], Digit Ordering test), conceptualization (Similarities, Wisconsin CST), set activation (verbal fluency), set shifting (Trail Making Test), set maintenance (Stroop Test, Odd Man Out), and behavioral control

(prehension behavior); memory (Rey Auditory Verbal Learning Test, Free and Cued Recall Test), Instrumental function: language (Boston Naming Test), visuoconstructive (Clock Drawing), visuospatial (Benton Line Orientation Test, Fragmented Letters from the Visual Object and Space Perception (VOSP) battery; and neuropsychiatric functions: apathy (Apathy Scale), depression (MADRS, Hamilton, Beck Depression Inventory, GDS-15), and visual hallucinations (Parkinson Psychosis Questionnaire), psychosis (NPI).

Other working groups

Critiques of rating scales for anxiety, depression, apathy, and psychosis and guidelines for diagnostic criteria have been published by several MDS Task Forces as well as NINDS/NIMH Work groups, among others. Clinimetric properties of the rating scales for these neuropsychiatric aspects in PD were systematically reviewed by MDS Task Forces. Proposed diagnostic criteria for depression and psychosis in PD are delineated in 2 papers by the NINDS/NIMH Work groups.

American Academy of Neurology (AAN) Practice parameters

In 2006, the AAN published an evidence-based review on the evaluation and treatment of depression, psychosis, and dementia in PD. Regarding screening for PD dementia, the authors reported one Class I and one Class III study. In the Class I study, the Cambridge Cognitive Examination and MMSE were administered to 126 PD subjects, 44% of whom had PD dementia. The CAMCOG and MMSE had similar sensitivities (95% and 98%, respectively); however, the CAMCOG was more specific (94% vs. 77%) but also took longer to administer. In conclusion, the MMSE and CAMCOG were recommended to be considered as screening tools for dementia in PD patients (Level B).

Other Considerations for Neuropsychological Assessment

It is important to consider other factors that may influence the neuropsychological, particularly the cognitive, assessment. Medications such as anticholinergics, sedatives, pain medications, among many others, may affect cognitive performance on tests. The effects of dopaminergic medications on cognitive function are highly variable with reports of no effect, worsening, and of improvement. Depression and anxiety may also influence test performance and cognitive function. Furthermore, sleep disturbances (nocturnal disruption and excessive daytime sleepiness) are found to have increasingly important effects on cognition.

Besides cognitive tests, the neuropsychological evaluation includes a brief psychiatric assessment. Although specific psychological rating scales are beyond the scope of this article, information from the patient and informant is usually obtained on depression, apathy, anxiety, hallucinations, and compulsive behavior.

Conclusions

In summary, the neuropsychological evaluation in PD comprises various tests aimed at assessing a number of cognitive domains. The evaluation documents whether cognitive impairment or dementia is present. Neuropsychological assessment is helpful in differential diagnosis, monitoring the course of disease progression, determining the possible benefits of cognitive interventions, and identifying psychological issues that may become the focus of treatment.

Complex I Deficiency

D K Simon, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA

Glossary

Complex I – One of five multisubunit complexes of the mitochondrial electron transport chain involved in oxidative phosphorylation to generate ATP.
Cybrid – Cytoplasmic hybrid ('cybrid') cell lines that express mtDNA from an exogenous source.
Free radical – A highly reactive atom or molecule with an unpaired electron that tends to react with and damage other molecules.
Haplogroup – A set of DNA sequence variants that are found together in individual members of a population.
Heteroplasmy – A mix of wild-type and mutant mitochondrial DNA within the same cell or tissue.
MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) – A toxin that inhibits the activity of complex I of the mitochondrial electron transport chain.
Oxidative stress – A condition of excess reactive oxygen species (free radicals) resulting in cellular damage.
Somatic mtDNA mutation – A mitochondrial DNA mutation that was acquired rather than inherited.

Definition and History

Parkinson's disease (PD) is a complex disorder that results from the combined and interactive effects of multiple genetic and environmental factors (**Figure 1**). As our understanding of these diverse genetic and environmental influences increases, a convergence of data points towards an important role for mitochondrial complex I (CI) dysfunction in PD. CI, known also as NADH:ubiquinone oxidoreductase, is a multisubunit enzyme located in the inner mitochondrial membrane that is a component of the mitochondrial electron transport chain and catalyzes the transfer of electrons from NADH to coenzyme Q10 (ubiquinone). This process is coupled to the generation of a proton gradient that is used for the generation of ATP. There is a decrease in CI proteins in the substantia nigra (SN) of PD patients, and CI activity in this brain region is impaired. This CI dysfunction is an early feature of PD and is not a consequence of PD medications as it is present in early untreated patients. Within the brain, there appears to be specificity of the CI defect for the SN. On the other hand, reports of a CI defect in platelets indicate that there may be a systemic defect in CI activity in PD. CI activity in the SN is reported to be normal in multiple system atrophy, suggesting that it is not a non-specific consequence of neurodegeneration.

The presence of a CI defect in PD does not necessarily imply a causal relationship. CI dysfunction could be secondary to the degenerative process that occurs in PD, or could be an incidental feature. Data from CI inhibitors help to address this issue. The first data indicating that experimental inhibition of CI can lead to parkinsonism came from the identification of 1-methyl-4-(2′-methylphenyl)-1,2,3,6-tetrahydropyridine (MPTP). MPTP is a toxin that inhibits CI activity and induces dopaminergic neuronal death and parkinsonism in multiple animals, including in humans following accidental self-injection by human IV drug abusers. However, MPTP also has other actions, leaving uncertainty as to its mechanism of toxicity. Subsequent studies revealed that another specific inhibitor of CI, rotenone, induces progressive and preferential degeneration of dopaminergic neurons following systemic administration over 4 weeks in rats. This confirms that induction of a CI defect can reproduce a key feature of the pathology of PD, and that even systemic inhibition of CI activity can preferentially affect dopaminergic SN neurons.

These data raised the possibility that CI dysfunction in the SN in PD may play an important role in the pathogenesis of PD, thus leading to a search for the origin of the CI defect in PD. Mitochondrial CI dysfunction could result from environmental toxins, genetic factors, or both. Genetic factors might include mutations in nuclear-encoded mitochondrial genes or in genes encoded on the mitochondrial genome. The mitochondrial genome is maternally inherited, and some studies have suggested a maternal bias in PD inheritance, with a greater likelihood of having an affected mother when a parent of a PD patient is also affected. However, results have been inconsistent, and this remains a controversial issue. In an experimental approach to testing the hypothesis that mitochondrial genetic abnormalities might account for the CI defect in PD, cytoplasmic hybrid ('cybrid') cell lines expressing mtDNA have been prepared from PD patients. These cybrid cell lines also manifest CI deficiency, a finding now confirmed by at least three research groups, indicating that the defect can be transmitted via mtDNA, thus suggesting that mtDNA mutations account for the defect.

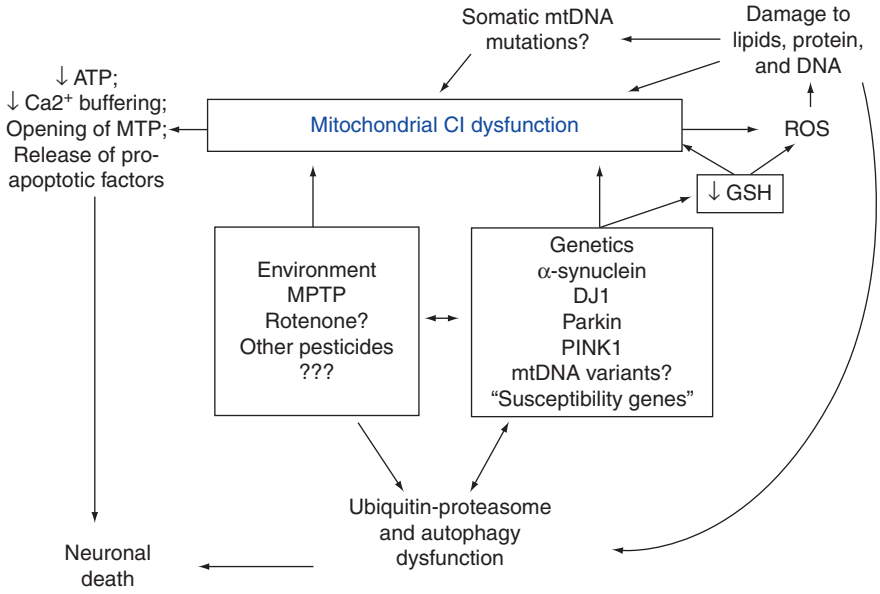

Figure 1 Factors contributing to neuronal death is Parkinson's disease.

Based in part on these results from studies of cybrid cell lines, a set of studies examined the possibility of *inherited* mtDNA mutations in PD patients. A common A to G variant at nucleotide position 10398 in the mtDNA gene encoding the ND3 subunit of CI has been reported to be present at a lower frequency in PD patients, suggesting that this variant may influence PD risk. On the other hand, results have been inconsistent across studies, and the role of this variant in PD remains uncertain. Similarly, variable results have been reported for the association of specific mitochondrial haplogroups with PD. Familial parkinsonism with SN neuronal loss has been reported in association with an inherited G11778A complex I mutation, a mutation more commonly associated with Leber's hereditary optic neuropathy. Familial parkinsonism is also seen in association with multiple somatic mtDNA deletions caused by a mutation in the mitochondrial DNA polymerase gene, Polγ. However, other studies looking at inherited mtDNA mutations in typical idiopathic PD patients have failed to identify pathogenic mtDNA mutations in the vast majority of patients, leaving an apparent discrepancy between results from studies of mtDNA versus the cybrid studies. As a result of this discrepancy, the specific role of inherited mtDNA mutations in the CI defect in PD remains uncertain.

More recently, research has focused on the possibility that acquired (somatic) mtDNA mutations might accumulate with age, eventually reaching levels sufficient to cause mitochondrial dysfunction and neuronal death. Such point mutations may be individually rare, and thus not detectible by standard sequencing methods, yet might accumulate to reach high aggregate levels. Levels of large mtDNA deletions indeed accumulate with age in SN neurons and are reported to reach relatively high levels, with ~43% of mtDNA molecules harboring a mutation in controls compared to 52% in PD, though this difference was of borderline significance ($p = 0.06$). mtDNA deletion levels were higher in cytochrome *c* oxidase deficient neurons, suggesting that the deletions may contribute to mitochondrial dysfunction in these neurons. Low-level (generally 1% or less) heteroplasmy for mtDNA point mutations in the mitochondrial gene encoding the ND5 subunit of CI has been reported to be common in frontal cortex tissue from PD patients but rare in controls. However, this finding requires verification, and the significance of such low-level mutations remains uncertain. Thus, additional data are needed to clarify the role of somatic mtDNA point mutations and/or mtDNA deletions in PD.

An alternative (or additional) cause of the CI defect in PD may be a deficiency of L-γ-glutamyl-L-cysteinylglycine (glutathione). Glutathione is the predominant intracellular thiol antioxidant. Glutathione is deficient at very early stages of PD, even prior to a detectible defect in CI activity. Induction of glutathione deficiency in cell lines and in mice leads to a specific defect in CI activity, raising the possibility that the glutathione deficiency in PD may contribute to CI dysfunction. Pesticide exposure represents another potential cause of CI dysfunction. Some pesticides such as rotenone are CI inhibitors, raising the possibility that environmental factors may also contribute to the CI defect in PD. However, neither glutathione deficiency nor pesticide exposure as a cause of the CI defect in PD would account for the ability to transfer the CI defect to cybrid cell lines expressing mtDNA from PD patients. It is likely that multiple factors contribute to mitochondrial impairment in PD, and our

understanding of the cause of the CI defect in PD remains incomplete.

CI dysfunction may contribute to the pathogenesis of PD by several mechanisms. CI dysfunction leads to an increase in the production of damaging oxygen free radicals. Consistent with this, levels of oxidative damage to protein, lipids, and DNA are increased in the SN in PD. mtDNA, owing to its close proximity to the site of free radical generation and due to its lack of protective histone proteins, is particularly susceptible to oxidative damage, and thus levels of oxidative damage to mtDNA in the SN rise sharply with age and even more so in PD. Impaired CI activity could also lead to reduced generation of ATP, and indeed cybrid cell lines expressing mtDNA from PD patients generate less ATP. Mitochondria also serve roles in buffering transient rises in intracellular calcium, and can mediate apoptosis, providing additional potential mechanisms by which complex I impairment may influence neuronal viability.

Oxidative stress may link CI dysfunction to other mechanisms associated with PD, for example by contributing to proteasome dysfunction and by enhancing the toxicity of alpha-synuclein. Conversely, some genetic causes of PD are linked to mitochondrial dysfunction and oxidative stress. Autosomal recessive PD due to mutations in DJ-1 may result from loss of DJ-1's normal function to stimulate glutathione synthesis. Loss of function of either parkin or PINK1 (a mitochondrial protein kinase), both causes of autosomal recessive PD, leads to mitochondrial structural abnormalities in experimental animals. Thus, a diverse set of data converge on mitochondrial dysfunction, and in particular on dysfunction of mitochondrial CI, in the pathogenesis of PD.

Complex Regional Pain Syndrome

Robert J Schwartzman, Drexel University College of Medicine, Philadelphia, PA, USA

Glossary

Allodynia – An innocuous mechanical or thermal stimulus is perceived as painful.

Central sensitization – A process similar to long-term potentiation (LTP) in which enhanced synaptic transmission, not dependent on a continued afferent input, occurs.

Cytokines – Cytokines are a category of signaling proteins and glycoproteins produced by hematopoietic and nonhematopoietic cell types.

They have pro- and antiinflammatory effects both on the adjoining cells and throughout the organism.
Hyperalgesia – An increased perception of pain to a painful stimulus.
Hyperpathia – An increased threshold to a painful stimulus that once exceeded, causes pain that reaches maximum intensity very rapidly, is overwhelming, and is not stimulus bound.
Long-term depression (LTD) – Weakening of a neuronal synapse (often from low frequency stimulation of A-delta fibers) that lasts from hours to days.
Long-term potentiation (LTP) – The persistent increase in synaptic efficacy following high-frequency stimulation of A-delta or C-fiber afferents.
Microglia – Central nervous system (CNS) cells that are the main form of acute immune defense in the CNS.
Wind-up – The progressive amplification of a synaptic response after repeated stimulation of afferent fibers.

Definition and History

Complex regional pain syndrome (CRPS), formerly known as reflex sympathetic dystrophy (RSD), was first described by Silas Weir Mitchell in Union soldiers during the American Civil War. It is a term that describes a severely painful condition that follows soft tissue, bone, or nerve injury. The pain does not respect a nerve or root distribution (regional), exceeds the expected magnitude and duration of the inciting event, and is often burning in quality. It is associated with autonomic dysregulation, neurogenic edema, a movement disorder and trophic changes of affected areas. The process spreads over time and may become generalized. Early in its course, it is primarily inflammatory with autonomic dysregulation and neurogenic edema predominant. As it progresses, pain, the movement disorder, atrophy, and dystrophy become more prominent manifestations. Early it is a peripheral process but over time there is centralization with CNS dysregulation of the somatosensory, autonomic, and motor systems.

In CRPS I, terminal nociceptive afferent and C and A-delta fibers are involved in soft tissue and bone whereas in CRPS II, major peripheral nerves are injured.

Epidemiology/Risk Factors

CRPS I occurs in 1–2% of fractures and 1–5% of patients following peripheral nerve injury. An early population-based study from Olmstead County Minnesota demonstrated an incidence of approximately 5.5 per 100 000 person years at risk. A more recent population-based study from the Netherlands reported an incidence of 40.4 for females and 11.9 for males per 100 000 person years at risk. CRPS I is much more prevalent than CRPS II (SII), and injury to the central somatosensory system is the inciting cause in approximately 10% of patients. All studies report a female preponderance of 4:1, the average age of onset occurs between 37 and 50 years of age, and the upper extremity is slightly more involved than the lower. Fractures, sprains, nerve traction injuries, and surgical trauma comprise the majority of initiating events. A great number of patients had been casted prior to the onset of CRPS.

Clinical Features

The statistical technique of factor analysis, which combines statistically relevant combinations of signs and symptoms in a syndrome, has demonstrated four derived factors for CRPS: (1) spontaneous and evoked pain (allodynia, hyperalgesia, and hyperpathia); (2) temperature asymmetry and color change; (3) edema and sweating asymmetry; and (4) motor dysfunction and trophic changes. In a patient with two of four signs and three of four symptoms, a diagnosis of CRPS can be made with 0.85 sensitivity and 0.69 specificity.

Cluster analysis, in which the patterns of CRPS signs and symptoms in groups of patients are analyzed, revealed three statistically distinct subgroups: (1) a mild predominant vasomotor syndrome; (2) a limited neuropathic pain and sensory syndrome; and (3) a severe spreading syndrome containing all factors. If one symptom for each factor and one or more signs in two or more factors are present, the sensitivity is 0.70 and the specificity is 0.96.

In the initial stages of the illness, the extremity is most often warm and associated with neurogenic edema and sympathetic paralysis. As the process centralizes and spreads, patients demonstrate increasing dynamic and static mechano-allodynia, and a spontaneous burning pain often accompanied by a deep aching pain in the muscles and joints, which is frequently interposed with lancinating pain. Cold thermo-allodynia is more common than that due to heat. All patients have difficulty in maintaining smooth precise movements and are weak. An exacerbation of the normal physiologic tremor, spasms, myoclonic jerks, increased reflexes, and dystonia are commonly seen. Edema may persist along with color change, as the extremity becomes cold, cyanotic, hyperhidrotic, and discolored from livedo reticularis and mottling. Severe muscle, bone, skin, and cartilage atrophy destroy the extremity. Nails become thickened and ridged, and there is loss of hair in the affected area. Late-stage patients suffer hyperpathia

in which pain thresholds are higher, but once exceeded, reach maximum intensity too quickly and are not stimulus bound.

Other common signs and symptoms that are not well characterized are (1) sensitization of plexi and nerve roots; (2) fatigue; (3) cognitive dysfunction; (4) syncope and persistent tachycardia; (5) migraine headache; (6) sensitization of the intercosticobrachial nerve (anterior chest wall pain); (7) dysphagia (cricopharyngeus dysfunction); (8) blurred vision; (9) body perception disturbance; (10) dizziness; (11) neglect-like and distorted body perceptions; (12) skin lesions; (13) difficulty in initiating and controlling micturition (when both legs are involved); (14) irritable bowel symptoms and gastroparesis; (15) dysynchiria (pain evoked in the affected area by watching the unaffected area being manipulated); and (16) decreased perceptual learning.

Diagnostic Procedures

CRPS I and II are clinical diagnoses arrived at by factor analysis as noted above. Confirmatory tests are (1) bone X-ray; (2) bone scintigraphy; (3) skin temperature; and (4) magnetic resonance imaging. It should be emphasized that negative results do not disprove the diagnosis of CRPS. Other tests that are also helpful in diagnosis are (1) quantitative and autonomic sensory testing; (2) autonomic function tests (infrared thermometry and thermography; quantitative sudomotor axon reflex tests (QSART), thermoregulatory sweat tests); and (3) laser Doppler flowmetry under controlled body thermoregulation.

Plain X-rays and bone densitometry studies reveal (1) patchy demineralization of periarticular bone and diffuse osteoporosis; (2) bone cysts and subperiosteal bone resorption; and (3) increased endosteal resorption of cortical bone. These changes are most frequently seen in late stages.

Patients suffering from CRPS for less than one year demonstrate (1) early accelerated blood flow into the affected extremity; (2) increased diffuse activity during the blood pool phase; and (3) increased periarticular uptake in the delayed static phase. The study is positive in less than 50% of patients and becomes less effective with disease duration.

MRI demonstrates joint effusions, edema along tissue planes, and in soft tissue. Bone marrow edema is inconsistently present in acute phases and absent in long-standing disease. Sympathetic blocks should be performed early both to establish if the process is sympathetically maintained and for therapy. Underlying maintaining features, such as a poorly healed fracture, neuroma, nerve entrapment, and recurrent disc, are the source of a persistent nociceptive barrage and must be addressed for successful treatment.

Pathophysiology of CRPS

CRPS most often follows injury to peripheral nerves or to their terminal twigs in tissue. The injury induces an afferent barrage of 50–100 Hz which is maintained by an inflammatory soup of cytokines, prostaglandins, protons, bradykinin, serotonin, and neurotrophic factors released from inflammatory and immune cells as well as from the blood. The peripheral C-fiber and A-delta fibers that are injured are sensitized by the activation of intracellular kinases A(PKA) and C(PKC) as well as by the phosphorylation of tetrodotoxin (TTX)-resistant sensory neuron-specific sodium ion channels (SNS). This decreases their activation threshold and the rate of deactivation, and increases their inward sodium current. There is a dynamic interplay from the injured area to the dorsal root ganglia by means of antegrade and retrograde transport. There is concomitant induction of microglia at the injured segmental spinal levels which then secrete inflammatory cytokines and activate astrocytes. These processes may perpetuate and amplify the initial response to injury. New information suggests that immune cells from the site of injury may invade the spinal cord, become fully active, and contribute to this immune response. Free radicals (nitric oxide, aldehydes, and hydroxyl radicals) generated from tissue injury and Wallerian degeneration may also contribute to further injury at the site of injury and in the dorsal horn (DH).

The injury barrage itself or the activation of a specific set of mechano-insensitive C-fibers releases the magnesium block of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor allowing Ca^{2+} influx into the nociceptive neuron. The concentration of Ca^{2+} achieved and its spatiotemporal sequence of entry determine if the pain transmission neurons (PTN) will demonstrate long-term potentiation (LTP) with increased sodium inward currents, or long-term depression (LTD) in which synaptic activity is depressed. These cascades are extremely complicated and depend on aspects of glutamate clearance, post synaptic density signaling, lateral or synaptic placement of AMPA receptors, and upregulation of NMDA receptor subtypes. The intracellular enzymatic cascades initiated by the Ca^{2+} influx, prominently featuring phosphokinases and phosphatases, determine the novel gene expression that produces abnormal sodium channels and proteins that are axonally transported and inserted into the affected axons of pain transmission neurons. These molecular events that induce peripheral and central sensitization of nociceptive afferents and pain transmission neurons, then lead to spontaneous pain, an increase in the size of their receptive fields, a lowered firing threshold of contiguous PTNs, and abnormal pain processing. A substantial experimental literature has demonstrated structural changes in dendritic spines that correlate with late-stage LTP (enlarged spines) and LTD (shrunken

spines). These structural changes, in addition to the death of inhibitory DH neurons, may contribute to the intractability of late-stage illness. The only human spinal cord material of a CRPS patient demonstrates loss of neurons at the appropriate level (L5 of the original injury with generalized CRPS of 20 years duration), as well as bilateral activation of microglia and astrocytes throughout the cord, but most prominently at L5.

The sympathetic nervous system has a prominent role in maintaining pain in a significant proportion of patients with early CRPS. Anatomic connections between efferent sympathetic fibers and the somatic and pain systems are made in the dorsal root ganglia and in the periphery. Sympathetic fibers derived from blood vessels in the DRG sprout and form baskets around large mechanoreceptive neurons and innervate small, thinly myelinated nociceptive afferents. At the site of injury, there is adrenoreceptor activation of nociceptive afferents sensitized from the adrenal release of epinephrine, as well as indirect effects on these fibers from mediators such as bradykinin, neurotrophic factors, and prostanoids. In addition to sympathetic peripheral nociceptive coupling, adrenergic neurons are pivotal in pain processing at several cortical and brainstem levels. The recent ischemia-reperfusion model of CRPS is compatible with the role of autonomic dysfunction in the pain of CRPS. Most importantly, sympatholysis, early in the course of illness when the pain is sympathetically maintained, has cured a subset of patients.

Early in the process, there is evidence of peripheral inflammatory neurogenic edema related to nociceptive axonal release of vasoactive neuropeptides, increased axon reflex vasodilatation, and disordered endothelial cell function. Sympathetic paralysis and neurogenic edema appear to be the major cause for the warm-affected extremity seen in acute CRPS. In chronic phases of the illness, the extremity is cold and cyanotic due to vascular changes that include increased sensitivity of affected blood vessels to circulating catecholamines, from upregulation of adrenoreceptors, a decrease of neurotransmitter uptake, changes in second messenger systems, and endothelial cell dysfunction.

The use of Doppler fluxmetry has demonstrated loss of control of skin blood flow when sympathetic activation is induced by the cold pressor test or the Valsalva maneuver in CRPS patients. These patients also lose normal sympathetically mediated wave-like fluctuations in venous tone (vasomotion). Recovery of sympathetic vasoconstrictor activity has been shown in one study to coincide with recovery from acute CRPS I.

Under strictly controlled environmental conditions (22–24 °C room temperature, 30° supine position for 30 min), temperature side asymmetry of >2.2 °C is 76% sensitive and 100% specific for the diagnosis of CRPS. Laser Doppler assessment of skin blood flow during whole body warming or cooling has demonstrated (1) an acute phase (mean disease duration of 4 months) with higher skin perfusion and temperature; (2) an intermediate phase (mean duration of 15 months) in which the affected limb was either warmer or colder than the contralateral extremity; and (3) a 'chronic' phase (>28 months) in which the extremity is cold and demonstrates less sympathetically controlled thermoregulatory blood flow.

The quantitative sudomotor axon reflex test (QSART) and the thermoregulatory sweat test (TST) have been shown to be abnormal in CRPS. In acute CRPS (5 weeks), both demonstrated greater sweating, but at >7 years, only the TST demonstrated asymmetry. Sweat glands under normal conditions respond to cholinergic stimulation. Iontophoresis of an α-adrenergic agonist induced significantly increased sudomotor output in CRPS-affected limbs but not in unaffected or control limbs. This is evidence that adrenoreceptor activation may occur in systems not normally under adrenergic control. Alternatively, calcitonin gene-related peptide (CGRP), released during the course of neurogenic inflammation, may also directly stimulate the sweat glands.

The movement disorder of CRPS I and II is seen to some degree in virtually all patients. At the spinal level, experimental studies demonstrate SP and CGRP in the dorsal, ventral, and intermediolateral columns of the spinal cord. They induce (in vitro) prolonged depolarization of anterior horn cells (blocked by $GABA_b$ agonists) and may modulate the gain of the nocifensor withdrawal reflex. The sympathetic system has profound effects on the strength of skeletal muscle contraction (Orbeli effect), neuromuscular transmission, anterior horn function, and spinal cord reflexes. The intrafusal fibers of the muscle spindle and ventral horn motor efferents are sympathetically innervated. A dramatic improvement of motor function has been demonstrated in a subset of CRPS patients following sympathetic blockade.

Electrophysiological studies in CRPS patients with dystonia demonstrate impaired reciprocal inhibition, a decreased threshold of the tonic and phasic components of the stretch reflex, and diminished vibratory inhibition of the H reflex. These patients also have impairment of DH interneuronal circuits that mediate presynaptic inhibition. There is evidence that the (HLA)-DR13 genotype may predispose to multifocal or generalized dystonia in these patients.

The tremor of CRPS is often seen with other components of the movement disorder and (1) has a frequency of 3–7 Hz, (2) is most often intentional but may be postural kinetic, and (3) is an enhancement of the normal physiologic tremor.

Central plastic changes occur in the sensorimotor system during the course of CRPS, as demonstrated by fMRI, SPECT, PET, and magnetoencephalographic studies. The impairment of sensorimotor integration is demonstrated by (1) motor cortical disinhibition; (2) kinematic deficits in target reach and grip; and (3) a mismatch

between sensory input and motor efference. The other aspects of the movement disorder of CRPS that are not well characterized are the difficulty of initiating and maintaining precise movements, myoclonus and spasm as well as increased reflexes.

The dystrophic changes noted in long-standing CRPS patients have been ascribed to the activation of osteoclastic mechanisms and elastases by SP, CGRP (bone inflammatory changes), the destructive effects of free radical generation, and a decrease of nutritive blood supply to the affected areas.

COMT Inhibitors in the Treatment of Parkinson's Disease

E V Encarnacion, Texas A & M College of Medicine/Scott & White, National Parkinson Foundation Plummer Movement Disorders Care Center, Temple, TX, USA
R A Hauser, University of South Florida, National Parkinson Foundation Parkinson's Disease and Movement Disorders Center of Excellence, Tampa, FL, USA

Glossary

Area under the curve (AUC) – The overall amount of drug in the blood after a dose.
Basal ganglia – Collection of nuclei deep to the white matter of cerebral cortex, including the putamen, caudate, nucleus accumbens, globus pallidus, substantia nigra, subthlamic nucleus.
Bioavailability – The extent or rate of the administered drug that reaches the systemic circulation that becomes available at the physiological site of action.
Bioequivalence – The property wherein two drugs are expected to be essentially the same in bioavailability and effects.
Blood–brain barrier (BBB) – A physiological mechanism between the brain parenchyma and blood that alters the permeability of capillaries that restricts the passage of various substances while allowing the passage of essential substances.
Chorea – Involuntary, random, jerky, irregular, writhing movements.
Choreiform – Characteristic of chorea.
C_{max} (maximum concentration) – The highest concentration of drug in the blood that is measured after a dose.
Dystonia – Sustained muscle contractions that cause twisting and repetitive movements or abnormal postures.
Dystonic – Characteristic of dystonia.
Glucuronidation – The detoxification pathway in the liver in which glucuronic acid is conjugated with toxins.
$t½$ (half-life) – The time required for the concentration of the drug in the body to be reduced by one-half.
T_{max} (time to maximum concentration) – The time C_{max} occurs.

Background/History

Replacing striatal dopamine is the principal pharmacologic strategy in the management of the motor features of Parkinson's disease (PD). Dopamine does not cross the blood–brain barrier (BBB) so its precursor, levodopa, was investigated as a potential dopamine replacement therapy. The introduction of oral levodopa by Cotzias in 1967 constituted a major breakthrough that paved the way for additional pharmacological agents. Levodopa is the most efficacious agent for the treatment of the motor features of PD and is effective in early as well as advanced disease. Every patient eventually requires it to maintain adequate function. However, as the disease advances, many patients on long term levodopa therapy experience motor complications which consist of wearing 'off' motor fluctuations, when the patient's motor response does not last to the next levodopa dose, and choreiform or dystonic involuntary movements known as dyskinesias. The development and expression of motor complications are closely related to the combination of disease severity and the peripheral pharmacokinetics of levodopa, with its relatively short plasma elimination half-life of about 60 min. Postsynaptic striatal dopamine receptors are normally exposed to relatively constant dopamine stimulation. Achieving a prolonged levodopa response requires the uptake of levodopa into remaining nigro-striatal neurons, conversion of levodopa to dopamine, and subsequent storage and controlled release. As dopamine neurons are lost, this storage and slow release capacity is diminished, resulting in a shortening of the duration of the clinical response which more directly reflects the levodopa half-life. When this occurs, postsynaptic dopamine receptors become exposed to nonphysiologic pulsatile dopamine stimulation from levodopa administration, resulting in a cascade of intracellular changes that alter basal ganglia output and cause the clinical expression of dyskinesia. Therefore, attempts have been made to deliver levodopa in a more continuous fashion to reduce wearing off episodes and avoid the development of dyskinesia.

COMT inhibitors modify levodopa's bioavailability by extending its plasma elimination half-life and allowing more levodopa to be delivered to the brain over time, thereby providing more continuous, sustained stimulation of striatal dopamine receptors. In patients with wearing off motor fluctuations on levodopa, the addition of a COMT inhibitor reduces 'off' time, increases 'on' time, and allows a reduction in the levodopa dose. The first generation COMT inhibitors were disappointing, but the second generation compounds tolcapone (Tasmar) and entacapone (Comtan), were found to be more potent

and selective and are currently used in clinical practice. Tolcapone was introduced in 1997 and entacapone in 1998. Because of rare but potentially fatal hepatoxicity associated with tolcapone but not entacapone, tolcapone's use has been restricted, while entacapone is more widely used. This chapter will discuss the development of these COMT inhibitors, the clinical studies that established their place in the management of PD, and current and future status.

Mechanism

COMT is a widely distributed enzyme found in the brain, liver, kidney, erythrocytes, and gastrointestinal tract. In the brain, it is found in glial cells but not in nigrostriatal dopamine neurons. Its function is not specific to the dopamine system and it is also involved in the peripheral metabolism of other catecholamines (adrenaline and noradrenaline).

Levodopa is actively transported through the mucosa of the proximal small bowel where it competes with other large amino acids for systemic absorption. Once absorbed into the bloodstream, it is transported across the BBB with less than 1% of the ingested amount entering the brain. Levodopa is metabolized mainly by two enzymes: (1) by aromatic acid decarboxylase (AADC) to dopamine and (2) by COMT to 3-*O*-methyldopa (3-OMD). To reduce gastrointestinal side effects, including nausea, that are due to the peripheral metabolism of levodopa to dopamine, dopa decarboxylase inhibitors (DCI), such as carbidopa and benserazide, were introduced. Since then, levodopa has been routinely combined with a DCI to reduce nausea and increase central bioavailability. Still, only 10% of administered levodopa enters the brain. When administered with a DCI, the main route of peripheral levodopa metabolism is via COMT to form 3-OMD which is devoid of dopaminergic activity. The addition of a COMT inhibitor to levodopa/DCI increases the elimination half-life of levodopa and increases its central bioavailability.

Tolcapone

Tolcapone (3,4dihydroxy-4′-methyl-5-nitrobenzophone) is a nitrocatechol-type compound and a selective and reversible inhibitor of COMT. It is lipophilic and crosses the BBB to a limited degree. It is rapidly absorbed and highly protein bound with a half-life of 2–3 h and a time to reach peak concentration (Tmax) of 1.5–2 h. When given together with levodopa/DCI, tolcapone increases the bioavailability and plasma elimination half-life of levodopa and the area under the curve (AUC). It does not affect peak plasma concentration (Cmax) or Tmax. Tolcapone is almost completely metabolized, glucuronidation being the most important route of metabolism. It is excreted in urine and feces. Large, multicenter studies in PD patients experiencing motor fluctuations on levodopa/DCI showed that the addition of tolcapone to levodopa/DCI significantly reduces 'off' time, increases total 'on' time, improves motor function, and allows a reduction in levodopa/carbidopa dosage and frequency, compared to placebo. Benefits of tolcapone were also observed in patients with a stable response on levodopa/carbidopa (i.e., without motor fluctuations), with significant reductions in United Parkinson's Disease Rating Scale (UPDRS) scores for activities of daily living and motor function.

Tolcapone is indicated as an adjunct to levodopa/carbidopa for the treatment of parkinsonian signs and symptoms. Because of the risk of fatal hepatotoxicity, it should ordinarily be used in patients experiencing fluctuations who are not responding to other adjunctive therapies.

Entacapone

Entacapone is also a nitrocatechol-type compound and a selective and reversible inhibitor of COMT. Unlike tolcapone, entacapone does not cross the BBB. It is readily absorbed across the intestinal mucosa and is highly protein bound, with a plasma elimination half-life of 0.4–0.7 h. Entacapone 200 mg given 4–6 times daily with levodopa produced a 33% reduction in COMT activity. The administration of entacapone with levodopa/carbidopa immediate release (IR) increases levodopa AUC by 35–40%, and prolongs the levodopa half-life by 1.3–2.4 h. Entacapone does not significantly influence levodopa/DCI Tmax and Cmax. A similar pharmacokinetic effect is seen when entacapone is used with levodopa/carbidopa controlled release.

A double-blind, placebo controlled trial of PD patients with motor fluctuations on levodopa/carbidopa revealed that the addition of entacapone compared to placebo provided a significant increase in 'on' time per day of approximately 1 h, while another study using a similar protocol demonstrated an increase in the mean daily 'on' time by 1.4 h. Both studies allowed a 12% reduction in levodopa dose. Other studies in patients with motor fluctuations demonstrated that the addition of entacapone to levodopa/DCI increased 'on' time and improved motor function as measured by the UPDRS and increased quality of life. In patients with motor fluctuations on levodopa/DCI, the addition of either entacapone or cabergoline (a long acting dopamine agonist) similarly improved UPDRS scores, quality of life as measured by the Parkinson Disease Questionnaire (PDQ)-39, and reduced daily 'off' time. However, the reduction in 'off' time occurred faster in the entacapone group than the cabergoline group. Entacapone has also been demonstrated to provide some benefit for patients who have a

stable response to levodopa (i.e., not experiencing motor fluctuations), including motor improvement and improvement in several quality of life measures. Entacapone is indicated as an adjunct to levodopa/DCI to treat patients experiencing end-of-dose wearing-off. It has no antiparkinsonian effect on its own. It can be combined with immediate or sustained release levodopa/carbidopa.

Levodopa/Carbidopa/Entacapone (Stalevo)

Stalevo combines levodopa, carbidopa, and entacapone in one tablet. It was approved based on demonstration of bioequivalence with levodopa/carbidopa plus entacapone and would therefore be expected to provide the benefits of adding entacapone to levodopa/carbidopa and also offer increased convenience because less pills are required. The majority of fluctuating patients given Stalevo or levodopa/DCI given in combination with entacapone experienced clinical improvement and over 80% experienced a reduction in fluctuations compared to levodopa/DCI treatment alone, but patients preferred one tablet, Stalevo, rather than taking two tablets, levodopa/carbidopa plus entacapone. Patients suboptimally controlled with levodopa/carbidopa controlled release (CR) can also be switched to Stalevo with improvements in motor function and quality of life.

Stalevo is currently indicated for patients with wearing off motor fluctuations on levodopa/DCI. However, two studies have examined its effects as first line therapy in early PD. The first-step studydemonstrated that Stalevo 100 three times a day (TID) provided greater symptomatic benefit than levodopa/carbidopa 25/100 TID without increasing motor complications. However, the recently completed Stalevo Reduction in Dyskinesia Evaluation (STRIDE–PD) trial showed that treatment with Stalevo compared to levodopa/carbidopa in early PD was not associated with a delay in the appearance of dyskinesia.

Current and Future Clinical Implications

Tolcapone should only be used in patients with motor fluctuations refractory to treatment with other medications including entacapone. The initial tolcapone dose is 100 mg TID and this can be increased to 200 mg TID, if necessary. When using tolcapone, liver function tests must be monitored during the first 6 months and periodically thereafter. Entacapone comes in 200 mg tablets and is routinely administered with each dose of levodopa/DCI to a usual maximum of 8 tablets (1600 mg) per day.

Stalevo is available in dose combinations of levodopa/carbidopa/entacapone 50/12.5/200 mg (Stalevo 50), 100/25/200 mg (Stalevo 100), 150/37.5/200 mg (Stalevo 150), and 200/50/200 (Stalevo 200). It provides increased convenience and reduced pill burden compared to levodopa/carbidopa plus entacapone administered separately. Replacing levodopa/carbidopa with Stalevo in patients with mild-to-moderate wearing-off is simple and can be done safely with or without decreasing the levodopa dose. Since COMT inhibition increases levodopa bioavailability, side effects from increased dopaminergic stimulation may occur. These include an increase in dyskinesias or nausea. The levodopa dose may be reduced in an effort to ameliorate these side effects. Diarrhea is the most frequent non-dopaminergic adverse event. Dark yellow to reddish-brown discoloration of urine can also be seen. Overall, COMT inhibitors may be better tolerated than dopamine agonists.

Stalevo was found to be more efficacious in controlling parkinsonian symptoms than levodopa/carbidopa in early PD when administered at the same levodopa dose, without increasing motor complications. The STRIDE-PD, however, did not determine that Stalevo causes less dyskinesia than levodopa/carbidopa when given in early disease. There is great interest in further smoothing levodopa delivery to the brain in an effort to further reduce the occurrence of motor fluctuations and dyskinesias. This might be brought about by the development of longer duration, high efficacy COMT inhibitors, or novel levodopa medication formulations.

Concentric Needle EMG

S Zimnowodzki, Rush University Medical Center, Chicago, IL, USA

Glossary

Concentric needle EMG (CNEMG) – One of the types of commonly used EMG needles for standard EMG studies.
Monopolar needle EMG – Another type of commonly used EMG needle for standard EMG studies.
Motor unit action potential (MUAP) – An electrical potential generated by contracting muscle fibers innervated by the same motor unit.
Stiff-person syndrome – A movement disorder characterized by increasing muscle-induced rigidity resulting from continuous muscle contraction, which can be recorded by either a monopolar or concentric needle EMG.

Definition

Electromyograms (EMGs) have been used in the diagnosis of neuromuscular disorders for over 30 years. The test includes two parts: one part is called the Nerve Conduction Study (NCS). An analogous name is the Nerve Conduction Velocity (NCV). In this part of the test, an electrical stimulator is placed on the skin and current is applied to a sensory or motor nerve (via percutaneous stimulation), creating an action potential in order to assess various nerve functions, such as measuring the velocity of nerve conduction and amplitude of an evoked response.

The second part is the EMG. This part of the test is conducted by inserting a needle into a muscle to record muscle potentials. Thus, the needle EMG is essentially a recording electrode. While both portions of the test are commonly performed, the test is often called by the second part of the test: the EMG.

The two most common EMG needles used for performing the study are the concentric needles (CNEMG) and monopolar needles. The difference between them is that the CNEMG contains the active and reference electrodes, while the monopolar needle contains only the active electrode, and thus requires a reference electrode – typically placed on the surface of the skin near the monopolar needle – to complete the recording circuit. Depending on the examiner, either needle can be used, as each records fairly similar potentials from the muscle.

How EMGs 'work' is based on the fact that skeletal muscles generate electricity, and it is this electrical activity that the EMG records much the way electrocardiogram (EKG) electrodes are used to record the electrical activity of cardiac muscle, except that EKG electrodes are placed on the surface of the skin, while the needle EMG is placed directly into the muscle.

In normal muscle physiology, an electrical discharge is produced while the muscle cells contract (depolarizes), generating a motor unit action potential (MUAP). The electrical discharge is picked up by the needle EMG and is transmitted to a digitalized screen where the interpreter can view this electrical potential and determine whether it is a 'healthy' discharge or an unhealthy one. In addition to the visual assessment of the MUAP, the electrical discharge is converted to sound, which assists the interpreter in characterizing the health of the discharging muscle potential.

In addition to assessing the muscle's electrical potential during active contraction, it is also evaluated in the relaxed state. Normally, healthy muscles at rest do not produce electrical discharges, except for a few physiologically important exceptions. On the other hand, when muscles have lost their innervation or have been directly damaged, a spontaneous depolarization of the muscle cells, called fibrillation potentials, occurs.

Aside from its traditional uses, EMGs have also been increasingly used to assist in the evaluation of patients with movement disorders by expanding the accuracy of the physical examination by allowing the examiner to evaluate conditions that are not easily discernable to the naked eye.

Examples of needle EMG in the evaluation in movement disorders include involuntary movements such as myoclonus, dyskinesias, or dystonias. Other examples include assessment of tremors such as essential tremors, cerebellar tremor, or exaggerated physiological tremor. Evaluations further include assessment of tone, including the stiff-person syndrome.

It should be noted that either the monopolar or concentric needle can be used to assess movement disorders, although, in the author's opinion, the compact nature of the concentric needle is better suited to assess these conditions. Some movement disorders are better evaluated with a surface EMG recording electrode. It is the type of condition assessed that dictates which recording method is best used for evaluating a particular movement disorder.

In the example of stiff-person syndrome, the stiffness results from continuous muscle contraction, making it difficult for individuals to move quickly or fluidly. Sensory stimulation induces an increase in spasms. With time, patients may even become bed bound, imprisoned by their spasms, which are often painful. The needle EMG findings reveal normal motor unit potential; however, the motor units discharge incessantly in both agonist and antagonist muscle groups, which is a not a feature normally seen in healthy individuals.

In summary, traditional intramuscular needle EMG recording electrodes or surface recording electrodes have been used to improve the diagnostic accuracy of certain movement disorders.

Confocal Microscopy

D A Peterson, Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA

Glossary

Aperture – An opening placed into the optical path to allow only part of the light to pass. The aperture can be of varying sizes or shapes. The construction of the aperture and the position it is placed within the optical path can specifically narrow down the light that passes to exclude out of focus light.

Fluorescence – The property of some molecules to absorb light at a certain wavelength (the excitation illumination wavelength) and to subsequently release that energy at a longer wavelength (the emission wavelength). The difference between these wavelengths allows the specific signal to be discriminated from the background.

Fluorescent probes – A general term to indicate any of a number of molecules that have specific properties of fluorescence. By designing these probes to bind to antibodies or be expressed by genes, one can surmise that the protein or gene expression of interest is located where the fluorescent signal is located.

Optical path – The pathway that the light travels from the source to the specimen and then on to the detector. The lenses, apertures, and filters placed in this light path will determine what wavelengths of light are seen and what spatial resolution of tissue imaging can be achieved.

Definition and History

Confocal microscopy is a specialized form of standard fluorescence microscopy (also called widefield fluorescence microscopy) that uses particular optical components to generate high-resolution images of material stained with fluorescent probes. There were many attempts in the later half of the twentieth century to achieve improved image resolution for fluorescence microscopy by use of various apertures, however the availability of high intensity lasers and sensitive electronic detectors resulted in the production of commercial confocal microscopes in the early 1990s. The enormous advantage in image resolution and detection made possible by commercially produced laser scanning confocal microscopes led to widespread adoption of their use. Confocal microscopy differs from conventional widefield fluorescence microscopy in that the optical path is designed to place in front of the image detector (photomultiplier tube or camera) an aperture (opening) at a point where the image is focused in conjunction with the focal plane of the image. By correctly placing this aperture in the same focal position as the collected image and adjusting the size of the aperture to match the numerical aperture of the objective lens that is collecting the image, it is possible to screen out light from outside the true focal plane of the objective lens. The term confocal derives from the coincidence of these two focal planes (objective lens focus point and the focus point where the aperture is placed). The result is the removal of out-of-focus light, providing a crisp image with the maximal resolution possible for the objective lens being used. With oil-immersion lenses having a numerical aperture of 1.3 or 1.4, it is possible to obtain axial resolution (optical depth of field) below 0.5 μm thickness. Based upon the thinness of the optical depth and the ability to generate successive registered focal planes by fine advancement of the focus position between subsequent images, one can build what is called a z-series. This is simply a series of focal planes (movement in the z axis) at a known interval of focus through a specimen that is in a fixed position (no movement in the x–y axis). Because these images are in spatial registration, they provide a three-dimensional sample of the tissue or cells being examined. As a result, an optical sectioning is performed, making it more attractive to employ tissue sections cut thicker (greater than 30 μm) and to use the optical ability of the confocal microscope as an optical 'microtome' to reveal structural details in three-dimensions.

For investigators of movement disorders, the confocal microscope provides a powerful way to extend the analytical abilities of cellular and histological studies. The use of fluorescent probes permits the localization of substrates without interference with each other as long as certain conditions are met (see below). Thus, it is possible to examine a field of cells in vitro or in vivo and detect unambiguously which cells contain which signal or if a cell coexpresses two or more signals. This is an advantage over using chromatic stains as one darker or denser colored substrate may obscure the presence of a lighter substrate. Furthermore, darker substrates above or below the focal plane may mask detection of signal using brightfield microscopy. Therefore, staining with fluorescence provides for the detection of more information about the spatial distribution of signal within cells or tissue, while confocal microscopy permits very high spatial resolution of those signals without ambiguity. Confocal microscopy is the tool of choice when it is necessary to identify the phenotype of a cell in conjunction with its coexpression of other markers or proteins. For example, it can be used to determine expression of TH-positive cells or the identity of fibers innervating target regions. With the range of tract tracing substrates and fluorescent reporter genes now available, the analytical possibilities are even further enhanced.

In addition to the insertion of an aperture at the correct point in the light path, there are some other aspects to the design of confocal microscopes that differ from conventional brightfield or fluorescence microscopes. The light source must be of high intensity and provide for specific wavelengths of illumination. This is most often achieved by using a combination of lasers to provide a distribution of excitation illumination across the visible spectrum. These types of confocal microscopes are referred to as laser scanning confocal microscopes and the choice of lasers with which they are outfitted will define which fluorophores can be used for staining tissue. This type of confocal microscope scans the laser across the specimen, as the name indicates, and the specimen is thus sampled one point at a time. The emitted light from activation of the fluorophore is then collected by the objective lens, where it passes through an emission filter to narrow the signal to the desired spectral width before being focused through the aperture onto a photomultiplier tube. This type of light detector reads out the intensity of the light and the value of that signal is mapped to its position in the scan so that the computer software controlling the process builds up an image of the focal plane on a pixel-by-pixel basis.

Another increasingly popular type of confocal microscope, the spinning disk type, illuminates the specimen with widefield illumination from a high intensity arc lamp or filament. Specific excitation filters limit the spectra used to excite the stained cells or tissue, however, the

user can easily change these providing more flexibility to the investigator for the choice of fluorophores. Both the excitation light and the returning emission light are focused to a point where they pass through an aperture to achieve confocality (i.e., removal of out-of-focus light). As the name suggests, this type of confocal does not use a fixed aperture, but rather a series of apertures (circular or linear openings) arranged in a certain spatial array that is spun at high speed. Thus only a small portion of these apertures are within the light path and only a portion of the specimen is being illuminated at any given moment. The collected light is then focused on a high-sensitivity camera that builds up an image until all areas of the field of view have been covered. The spinning disk confocal does not achieve quite the same high degree of axial resolution as a laser scanning confocal, but it does provide for more flexibility in selection of wavelengths and the spinning disk scanning process is substantially faster than the laser scanning process, making it more suitable for detecting physiological events or for facilitating high-throughput imaging studies.

While confocal microscopy is a powerful tool, there are some common pitfalls that the user must consider and potential artifacts that must be recognized. The following points are recommended as best practices for using confocal microscopy:

- Specimen preparation is critical for obtaining accurate images and protocols should be carefully developed and faithfully followed to insure reproducibility. Appropriate controls should be included to ensure specificity of labeling.
- Fluorophores should be chosen that have narrow spectral profiles of excitation and emission and whose peak values are distinctly separate both from each other and from any other fluorophores to be used.
- When imaging, fluorophores should be excited separately and their emission evaluated for potential contamination of signal (bleedthrough) into other detection channels.
- Detection settings in the software should be adjusted in accordance with an objective scale, such as a signal histogram, to ensure that the detections settings use the entire dynamic range of the detector and that no signal (and potential data) is lost at either the high or low ends of the histogram. Oversaturation (making the image too bright and crowding data off the high end of the histogram) is one of the most common user mistakes when using a confocal microscope.
- Users are cautioned against believing everything that appears on the screen when using a confocal microscope. All detections settings should be critically evaluated for the possible production of an imaging artifact. Appropriate controls should be imaged in comparison. The image obtained should be clearer than its appearance by eye down the eyepieces, but there should be no substantial disagreement between visual observation and digital imaging. Let your eyes be the reality check!
- Other sources of analysis should be evaluated when possible and compared to the imaging data for validation.

Cortical Myoclonus

E A Shamim, Georgetown University Hospital, Washington, DC, USA; National Institutes of Health, Bethesda, MD, USA
C Toro, National Institutes of Health, Bethesda, MD, USA

Glossary

Epilepsy – A seizure disorder.
Myoclonus – Brief, mostly irregular, focal, multifocal, or generalized muscle jerks that have their origin in the cortex or subcortex in most instances.
Pyramidal – The motor system controlling strength of movement. This two-part neuronal pathway travels from the motor cortex into the subcortex in the internal capsule, then through the brainstem where it crosses at the level of the medulla and travels in the lateral corticospinal tract. At the spinal cord levels, the second cell in this system is located in the anterior horn of the spinal cord and exits as spinal roots, spinal nerves, and finally peripheral nerves to activate muscles. The hallmark of pyramidal tract lesions is weakness.

Clinical Syndrome

The word myoclonus is derived from mŷs for muscle, and clonus is Greek for 'violent, confused motion.' As its name implies, it is characterized by transient, sudden, nonvolitional irregular or rhythmic movements. Although lesions in the peripheral nervous system can lead to this, it is usually considered a central nervous system phenomenon defined by electromyogram (EMG) muscle bursts of 50–300 ms leading to disruption of posture or movement. These characteristics help distinguish it from the other more complex brief involuntary movements like chorea, dystonia, or tics. In certain situations such as tics, irregular amplitude tremor oscillations, or brief fragments of other movement disorders, it might be impossible to differentiate from myoclonus on clinical grounds alone. In these circumstances, electrophysiological techniques become necessary to properly classify these disorders.

Using electrophysiological criteria, Halliday, in 1976, proposed the first classification of myoclonus into three distinct groups: pyramidal, extrapyramidal, and segmental. He characterized the pyramidal type as having EMG activity occurring 15–40 ms after the electroencephalographic (EEG) activity. He postulated the cortex as the site of origin with further propagation via the pyramidal tract. Pyramidal myoclonus is now referred to as cortical myoclonus or cortical positive myoclonus or epileptic myoclonus. In this form of myoclonus, EMG bursts of short duration occur with synchronous agonist/antagonist activation pattern and with EEG correlates consisting of a somatotopically organized cortical discharges typically 20–40 ms before EMG onset. 'Giant' somatosensory evoked potentials (SEPs) and enhanced transcortical reflexes (C-Reflex) are also a part of the electrophysiological features of cortical myoclonus. Cortical myoclonus is found in a variety of acquired, genetic, metabolic, and degenerative disorders.

Pathophysiology

Many excellent reports have studied the pathophysiology of cortical myoclonus using EEG, EMG, transcranial magnetic stimulation (TMS), and magnetoencephalography (MEG) techniques. Most studies suggest an abnormal hyperexcitability of the cortex, in particular, the sensory, motor, and visual cortices. Despite it being largely a cortical phenomenon, the precise pathology remains unclear.

Hyperexcitablity of the motor cortex has been demonstrated using electrodiagnostic techniques. Jerk-locked averaging is a well established technique to study myoclonus. The technique averages EEG activity aligned to EMG onset. In cortical myoclonus, a premyoclonus spike can be detected in the averaged EEG signal prior to the jerks. Refinements in EEG source localization can be ascertained by studying dipole source localization or by using MEG. These studies indicate a source in the motor cortex as well as in the sensory cortex. TMS studies have strengthened the premise of cortical involvement. In these studies, a motor-evoked potential (MEP) can be produced by placing a coil on the scalp and running an electric current through it. The current produces a magnetic pulse that can be directed to a desired location to illicit a motor response. MEP amplitudes are measured in response to the magnetic stimulation. A variant of this technique uses paired pulse stimulation. Two magnetic pulses are generated at varying intervals. A conditioning stimulus 1–6 ms (ISI of 1–6 ms) prior to the test stimulus produces a smaller MEP. In patients with cortical myoclonus, conditioning responses with ISI of 3 and 5 ms exhibit a reduced suppression of the MEP. It is speculated

that these findings suggest an aberrant function in the cortical GABAergic inhibitory circuits.

Sensory cortex hyperexcitability also appears to be important in the pathophysiology of myoclonus. Measuring cortical potentials in response to peripheral sensory stimulation is commonly performed to study the integrity of the central nervous system and the technique is commonly referred to as SEPs. 'Giant' SEPs (P25–P33) are known to occur in patients with cortical myoclonus and suggest hyperexcitability of the sensory cortex. Similar to the TMS paired pulse paradigm, SEP can also be administered in this fashion. SEP suppression is seen at an ISI of $\leq$100 ms in healthy individuals. In some patients with myoclonus, suppression was not observed, and in some cases, facilitation was noted suggesting a dysfunction of the sensory cortical inhibitory circuits leading to hyperexcitability in the cortex.

There is ample evidence to suggest aberrant excitability in the motor and sensory cortices in patients with cortical myoclonus. The underlying pathology though unclear is being studied in great detail using advances in electrodiagnostic techniques. Recent evidence suggests that interhemispheric interactions between the motor cortices appear to be important. The molecular and biochemical abnormalities underlying the hyperexcitablity are yet to be defined.

Treatment

The pharmacological management of cortical myoclonus includes Clonazepam, valproic acid, primidone, and piracetam. Newer agents such as Levetiracetam (an analogue of piracetam) and γ-hydroxybutyric acid (GHB) are also effective antimyoclonic therapies.

Cortical Sensory Dysfunction and the Parietal Lobe

P J Tuite and J Konczak, University of Minnesota, Minneapolis, MN, USA

Glossary

Astereognosia – Inability to recognize things by touch.
Exteroception – Perception of stimuli originating outside the body, for example, vision, touch, olfaction.
Interoception – Perception of stimuli originating inside the body, for example, hunger, thirst, visceral sensations.
Proprioception – Perception of the position and movement of body or its parts.
Pseudoathetosis – Involuntary writhing movements due to proprioceptive deficits.
Simultanagnosia – Inability to synthesize visual information into a complete picture.

Introduction

The parietal lobe is part of a sensory system comprising peripheral receptors, neural pathways, and neurons of several supraspinal centers (cerebellum, basal ganglia, parietal lobe) that process visual and somatosensory information. The somatosensory modalities include proprioception (e.g., perception of body and limb positions), interoceptive sensory modalities such as temperature and pain perception, and touch. Classically, touch has been defined as an exteroceptive sense. However, in recognition that touch perception is based on several modalities, the term somatic senses is also commonly used. It is known that the parietal lobes mediate exteroceptive and proprioceptive perception, while interoceptive sensations are also associated with activations of the right insular cortex. This article will focus primarily on the parietal

lobe, and the effect of parietal lobe lesions on cognitive, perceptual, and motor function.

One of the primary roles of the parietal cortex lies in the integration of somatosensory and visual information that is needed for movement planning and control. In addition, specific areas of the parietal lobe are relevant for cognitive processes such as reading comprehension, and logical and mathematical thinking. One of the first comprehensive accounts of parietal lobe function was published in 1953 by the British neurologist Macdonald Critchley whose insights were based largely on the study of patients with parietal lesions. Since then, numerous researchers attempted to correlate behaviors with parietal and subcortical neural activity in humans and animals using an array of psychophysical, electrophysiological, and brain imaging techniques.

Neuroanatomical Subdivisions of the Parietal Lobe

The parietal lobe is a region of the cerebral cortex between the frontal and occipital lobes. Its principal areas include the *primary somatosensory cortex* (PSC) comprising the postcentral gyrus (Brodmann areas 1, 2, 3), the superior parietal lobule (areas 5 and 7), the parietal operculum (area 43), the supramarginal gyrus (area 40), and the angular gyrus (area 39). Two functional zones of the parietal lobe can be distinguished: an anterior zone (Brodmann's areas 1, 2, 3, 43) and a posterior zone which includes the remaining areas. The posterior zone is also known as the *posterior parietal cortex* (PPC).The PPC receives afferent projections from the somatosensory cortex, the premotor and motor cortices. In addition, area 7b of the PPC receives visual, somesthetic, proprioceptive, auditory, vestibular signals, as well as input from oculomotor and cingulate regions. The PPC has efferent projections to the prefrontal area 46, the frontal motor cortical areas (4, 6, and 8), the cingulate gyrus, the basal ganglia, and the cerebellum. It is thought that the close reciprocal connections between prefrontal and parietal areas indicate the importance of this functional loop for the control of spatially guided behavior. This role is underlined by the existence of a major projection known as the *dorsal visual stream* which is believed to encode visual information in an egocentric reference system necessary for planning goal-directed movement.

In addition to distinguish between anterior and posterior parietal zones, a lateralization of functions between the right and left parietal lobes is found. Classically, the dominant (usually left) parietal lobe is involved in language and mathematical processing. Lesions of the left parietal lobe result in anomia, alexia, apraxia, agraphia, acalculia, finger agnosia, and right-to-left disorientation. *Gerstmann's syndrome* is characterized by the latter four features, and is often associated with an angular or a supramarginal gyral lesion. The nondominant (typically right) parietal lobe is thought to be involved in spatial cognition. Lesions may result in contralateral neglect of a part of the body or space, constructional and dressing apraxia, difficulty with cube counting, impaired paper cutting, poor map reading, and astereognosia. When there are bilateral PPC lesions, features of *Balint's syndrome* may be present including *simultanagnosia* (inability to perceive more than one object at a time), *optic ataxia* (incoordination of hand and eye movement), and *optic apraxia* (inability to refixate the eyes voluntarily).

Assessment of Parietal Lobe function

This section reviews some of the most common syndromes and clinical symptoms associated with parietal lobe damage such as apraxia, pseudoathetosis, cortical sensory loss, alien limb, and proprioceptive impairments.

Assessment of parietal function may include *somatosensory thresholds* (e.g., two-point discrimination/tactile sensation), *tactile recognition* (e.g., Sequin-Goddard form board and tactile patterns), *complex visual perceptual tasks* (e.g., Golin incomplete figures and Mooney closure test), *neglect*, *spatial relationships*, language (e.g., speech and reading comprehension using token tests), and *apraxia* (e.g., Kimura box and others discussed later). Another task which appraises frontal and parietal function as it relates to space is the Semmes test of extrapersonal space.

Signs and Symptoms of Parietal Lobe Dysfunction

Neglect

The neglect syndrome, also called hemiagnosia-hemineglect or spatial neglect, is a neurological condition that manifests itself as a deficit in attention to and awareness of one side of the body or extrapersonal space. Most commonly, right parietal lobe damage leads to neglect of left-sided body parts and the left visual field. The impairments in attention to the left side can also occur in the auditory, proprioceptive, and olfactory domains. Right-sided neglect after left parietal damage is rare; likely reflecting the specialization of the left hemisphere for language.

Cortical Sensory Loss

Cortical sensory loss may appear to a patient or a clinician as a symptom due to a peripheral nerve, plexus, or root lesion with clinical symptoms such as numbness or tingling; however, on examination there are no primary sensory findings. There is, rather, impairment in joint position sense and two-point discrimination as well as findings of agraphesthesia and astereognosia.

Pseudoathetosis and Cortical Sensory Dysfunction

Athetosis is a slow writhing movement that is not associated with sensory loss; whereas, pseudoathetosis is clinically indistinguishable from athetosis except for the additional finding of proprioceptive sensory changes. An assortment of different neuropathological lesions, including parietal pathology, can manifest as pseudoathetosis. From Salih's work, lesions in thalamic lemniscal projecting fibers to somatosensory S1 areas 2 and 3a result in altered discriminative sensations, for example, impaired proprioception with relative preservation of other sensory modalities.

Alien Limb Phenomenon

There is controversy as to what constitutes an alien limb, but classically it is thought to include spontaneous movements that are minimally affected by volitional movement and may require restraint by the contralateral hand. Sometimes, pseudoathetosis or simple arm levitation is mistaken as a diagnostic sign of an alien limb.

Proprioceptive Deficits in Parkinson's Disease (PD)

Kinesthesia refers to the conscious awareness of active and passive limb movements and limb or body position. It is often used interchangeably with the terms proprioception or muscle sense. Recent work has shown that individuals with mild to moderate PD have elevated thresholds for detecting changes in limb position, passive motion, and weight perception. In addition, PD patients may exhibit delayed proprioception-related potentials in the somatosensory cortex. While PD is known to affect the basal ganglia, it is also known that the basal ganglia receive massive parietal lobe input. Thus, the observed kinesthetic deficits may be understood as a parietobasal ganglia dysfunction.

Apraxia

Apraxia is the loss of the ability to perform a motor task despite intact motor and sensory functions, and absence of a language disorder. A more specific definition of apraxia as obtained from Zadikoff and Lang and Geschwind and Damasio includes one or all of the following: 'failure to produce the correct movement in response to a verbal command, the failure to correctly imitate a movement performed by an examiner, the failure to perform a movement correctly in response to a seen object, and the failure to handle an object correctly.'

Contextual definitions of apraxia include ideomotor, limb, buccofacial, ideational, limb-kinetic, apraxia of speech and oculomotor apraxia, gait apraxia, and so on. The anatomical bases of these clinically distinct entities are, as expected, quite disparate. For the sake of this discussion, we will focus primarily on ideomotor limb apraxia, ideational, and limb-kinetic apraxia.

Limb-kinetic apraxia is defined as the loss of hand and finger dexterity resulting from the inability to connect or isolate individual movements, and is accompanied by frontal and/or parietal pathology. *Ideomotor apraxia* is an impairment in goal-directed movement, and typically associated with left hemisphere frontoparietal lesions or/and accompanying pathology of deep white matter or parts of the basal ganglia (often striatal) fibers. For example, the person with ideomotor apraxia cannot show how to salute or brush his/her teeth. *Ideational apraxia* is defined as the impairment in knowing what to do, and there are accompanying content errors. The person is unable to create a plan for or appreciate the idea of a specific movement; for example, they cannot pick up a pen and write something. Pathology often involves the left parietotemporal and parietooccipital regions.

Apraxia may be assessed by the *Florida Apraxia Screening Test* (FAST), and the revised version, FAST-R The FAST-R battery consists of a variety of measures such as demonstration of gestures (e.g., how to salute, make a fist) and the use of tools (e.g., scissors, hammer, bottle opener, glass, comb and hair brush, salt shaker, saw, screwdriver, spoon), and signaling to others (e.g., stop, come here, go away, wave goodbye). A variety of errors (content, temporal, spatial) can clarify the degree of impairments. Other means to assess apraxia include the *De Renzi test*, *Goldenberg's test of apraxia* (which assesses impairment in imitation of meaningless gestures of hands, imitation of meaningless gestures of fingers, performance of meaningful gestures on demand, and pantomime of tool use), and the *Kimura box*.

In the realm of movement disorders, there are a variety of conditions that are accompanied by apraxia, the most notable of which is *corticobasal degeneration* (CBD) also (clinically) known as *corticobasal syndrome* (CBS). Other conditions such as PD, progressive supranuclear palsy, Huntington's disease, dementia with Lewy bodies, and multiple system atrophy may also manifest apraxia. On the basis of the above clinical features, we will further discuss CBD/CBS which may prominently feature parietal dysfunction.

Corticobasal Syndrome and Corticobasal Degeneration

CBS and CBD represent clinical and pathological entities, respectively, that are due to brain dysfunction involving the cortex (primarily the parietal lobes) and the basal ganglia; hence, this syndrome was formerly known as corticobasal ganglionic degeneration (CBGD). CBS represents a clinical entity with numerous possible underlying pathologies of which CBD is the most common pathology. Clinical diagnostic criteria proposed for CBS include the presence of all of the following: (1) insidious onset and progressive course; (2) no identifiable cause;

(3) cortical dysfunction (requiring the presence of one of the following: focal or asymmetrical ideomotor apraxia, alien limb phenomenon, cortical sensory loss, visual or sensory hemineglect, constructional apraxia, focal or asymmetric myoclonus, apraxia of speech/nonfluent aphasia); extrapyramidal dysfunction (at least one of the following: focal or asymmetrical appendicular rigidity without prominent and sustained response to levodopa or/and focal asymmetrical appendicular dystonia). Supportive findings from neuropsychological testing, MRI/CT scanning, or positron emission tomography (PET)/single photon emission computed tomography (SPECT) scanning may be helpful in making a clinical diagnosis.

Using diffusion-weighted imaging MRI methods, researchers have distinguished patients with a clinical diagnosis of CBS from other atypical parkinsonian syndromes (100% sensitivity and specificity) based on the presence of hemispheric asymmetry. Another study employing the MRI method, voxel-based morphometry, showed evidence of frontoparietal grey and subcortical grey matter atrophy in individuals who had CBD on autopsy.

The cause of CBS is unknown, and it is usually a sporadic condition. Rarely there have been cases where a genetic mutation or gene linkage has been found. Unfortunately, there is no obvious curative treatment for CBS, and management is primarily symptomatic.

Summary

The parietal lobes are involved in the processing of visual and somatosensory information that is essential for movement planning and spatial cognition. The posterior parietal area is important in the visual guidance of movements of the limbs, head, and eyes along with mental planning of movements. Part of the parietal lobe appears to play a role in mathematical reasoning and reading comprehension. Dysfunction of the parietal lobes may result in features such as cortical sensory loss, apraxia, which may also constitute features of a CBS.

Cortical Tremor

E A Shamim, Movement Disorders Program at Georgetown University Hospital, Washington, DC, USA; National Institute of Neurological Disorders and Stroke at the National Institutes of Health, Bethesda, MD, USA
C Toro, National Institute of Neurological Disorders and Stroke at the National Institutes of Health, Bethesda, MD, USA

Glossary

Myoclonus – Brief, sudden, shock-like, involuntary movements caused by muscular contractions or inhibitions.
Tremors – Rhythmic oscillatory movements.

Clinical Syndrome and Terminology

As a clinical syndrome, the term cortical tremor is most commonly associated with the condition now known as familial cortical myoclonic tremor with epilepsy (FCMTE). FCMTE has previously been referred to by many names, including autosomal dominant cortical

myoclonus and epilepsy, benign adult familial myoclonic epilepsy, familial adult myoclonic epilepsy, familial cortical myoclonic tremor, familial cortical tremor with epilepsy, familial essential myoclonus and epilepsy, familial benign myoclonus epilepsy of adult onset, myoclonic tremor, and heredofamilial tremor and epilepsy. The lack of familiarity with this group of disorders has led not only to confusing names but also to misdiagnosis.

FCMTE was first reported less than 20 years ago. Although 50 Japanese and European families are known to have this malady, it was first described in a Japanese family in 1990 by Ikeda et al. The condition is characterized by fast rhythmic jerks of small amplitude, involving fingers and hands. Because of the postural 9 Hz rhythmicity, with electrophysiological characteristics of cortical myoclonus, this entity was called 'cortical tremor.' The rhythmic movement disorder that is enhanced with the assumption of a posture-like outstretching the hands can easily be confused with other tremor disorders, specially, essential tremor.

FCMTE has several characteristics that distinguish it from other disorders. The tremor movements have a wide range of age of onset, and can occur in children from 10 years of age to late-middle-aged adults. The rhythmic movements are usually the first symptom that brings patients to medical attention. These movements can be provoked by posture, movement, emotional stress, and a lack of sleep, but they can also be present at rest and may involve the head and trunk. Epilepsy is usually the second symptom to appear. In a minority of patients (<20%), epilepsy may precede the tremulous movements. In about 80% of the reported cases, the epilepsy consists of generalized tonic–clonic seizures, but other forms of seizures have also been reported, including absence, myoclonic, and complex partial. The seizures respond well to antiepileptic medications. Mental retardation in children and mild cognitive impairment, night blindness, and migraine headaches in adults have been reported as part of the clinical syndrome.

Pathophysiology

The pathophysiology of cortical tremor is not entirely understood. Cortical hyperexcitability and its responsiveness to antiepileptic medications suggest that GABA receptors may be involved. All the 50 families studied to date show an autosomal dominant pattern of inheritance. The families appear to share a distinct locus within their family and geographical region, but the locus is different in other parts of the world. The Japanese families have an association with chromosome 15, the Italian family with chromosome 2, the Spanish family with chromosome 8, and the Dutch family with chromosomes 2 and 8. It is speculated that this disorder may fall into a class of channelopathies.

Diagnosis

Electrodiagnostic criteria are essential in confirming a cortical disturbance as the origin to the tremor phenomena. The surface electromyographic studies (EMG) demonstrate repetitive, 8–13 Hz frequency burst of 50 ms duration, which can be induced by posture. Polyspike and wave patterns have been reported in 94% of patients and 48% unaffected relatives in routine electroencephalographic studies (EEG). A giant cortical sensory-evoked potential (SEP) can be produced by median nerve stimulation in 84% of patients from one family. The stimulation of the median nerve also demonstrates a long-latency C-reflex response in most of the patients. The jerk-locked back averaging of the EEG triggered by tremor-related EMG bursts reveals a cortical potential preceding the myoclonic jerks in 60% of the patients.

Patients with otherwise typical cortical myoclonus, regardless of their etiology, may experience tremor of the activated limbs when asked to perform an isometric effort. The electrophysiological characterization of their tremor reveals findings similar to those found in patients with FCMTE. This provides further links between FCMTE and cortical myoclonus.

Treatment

Most symptoms of FCMTE can be controlled effectively with antiepileptic medications. Clonazepam, valproate, primidone, phenobarbitol, and, more recently, levitiracetam are very effective in reducing the myoclonic jerks and seizures. Beta blockers provide no benefit in this condition. In individual patients, carbamazepine and phenytoin may also be effective.

Corticobasal Degeneration

D E Riley, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Glossary

Alien limb – A sign seen in many cases of corticobasal degeneration whereby the arm or leg engages autonomously in complex acts and appears to have 'a mind of its own.'
Corticobasal degeneration – A neurodegenerative disease of later life exhibiting asymmetric signs reflecting dysfunction of both cerebral cortex and basal ganglia.
Tau – A hyperphosphorylated microtubule-associated protein that is typically seen in brain cells of corticobasal degeneration and some other neurodegenerative disorders.

Definition and History

Corticobasal degeneration (CBD) is a degenerative disease of the nervous system. The first reports by Rebeiz and colleagues in 1967 and 1968 called this disorder 'corticodentatonigral degeneration with neuronal achromasia' to describe the pathologic findings in their three cases. Subsequent autopsied cases have not detected involvement of the dentate nucleus, and this portion of the name was discarded. No additional reports of this disease were published until 1985, when Watts and colleagues coined the term 'corticobasal ganglionic degeneration.' Gibb and colleagues added three more autopsied cases in 1989 under the name 'corticobasal degeneration,' a name that has stuck because of its brevity. In 1990, Riley and colleagues detailed the clinical findings in 15 patients with pathologic findings from the two autopsy-verified cases, using the term 'cortical–basal ganglionic degeneration.' This report was influential for the systematic organization of clinical findings into distinct groupings that have been adopted by later authors and remain in use today. It also published the first sets of diagnostic criteria, imaging, electrophysiological findings, and brain biochemistry.

Since this report, CBD has become a well-recognized syndrome in the field of movement disorders. However, as recognition grew, it became simultaneously clear that the classical clinical presentation may accompany other pathologic entities, while the originally described pathologic findings can be associated with atypical syndromes. For this reason, the clinical features of CBD are now known as the 'corticobasal syndrome' (CBS), while CBD is used to refer to the pathologically confirmed disease, somewhat analogous to the relationship between 'parkinsonism' and 'Parkinson's disease.'

Pathogenesis/Pathophysiology

While the specific etiology (or etiologies) is unknown, CBD belongs to a group of degenerative disorders characterized by abnormal intracellular accumulation of hyperphosphorylated microtubule-associated protein 'tau', collectively known as 'tauopathies'. The tau that accumulates in CBD consists exclusively of four-repeat isoforms, the same as in progressive supranuclear palsy. These two diseases also share a common haplotype and genotype profile in the *tau* gene, suggesting a common etiology. However, immunoblot analysis of brain extracts shows distinctive patterns of tau fragments in each disorder, consisting of different amino acid terminals at the carboxyl end of tau. Thus, different intracellular proteolytic processing of aggregated tau may underlie the clinical and pathological differences between the two diseases.

Gross autopsy findings in CBD include cerebral atrophy, often asymmetric and predominating in the medial frontal and parietal lobes, and substantia nigra pallor. Microscopic features include swollen ('ballooned') poorly staining ('achromatic') neurons in the cerebral cortex, most numerous in the superior frontal, precentral, and postcentral gyri. Unlike Alzheimer's or Pick's disease, two other well-known tauopathies, CBD shows no discrete inclusion bodies in cerebral cortical cells, although diffuse or granular tau-positive staining in neurons or glial cells may be present. In fact, tau immunoreactivity is widespread, and predominates in distal astrocytic cellular processes (known as 'astrocytic plaques') rather than in neuronal cell bodies. Astrocytic plaques are most abundant in prefrontal and premotor cortex, and the caudate nucleus. In the substantia nigra, findings include neuronal loss, depigmentation, extraneuronal melanin, and gliosis. Here there may be occasional basophilic neuronal inclusions known as 'corticobasal bodies,' which can be found in other deep nuclei and probably represent tangle-like structures. Degenerative changes in the putamen, caudate nucleus, globus pallidus, and subthalamic nucleus are common though not universal.

The Office of Rare Diseases of the National Institutes of Health of the United States of America has published consensus neuropathologic criteria for CBD diagnosis.

These validated criteria emphasize the importance of tau-immunoreactive lesions in neurons, glia, and cell processes in the neuropathologic diagnosis of CBD. Minimal pathologic features required for a diagnosis of CBD include a combination of (1) cortical and striatal tau-positive neuronal and glial lesions, especially astrocytic plaques and thread-like lesions in both white matter and gray matter and (2) neuronal loss in focal cortical regions and in the substantia nigra.

Epidemiology/Risk Factors

CBD typically begins in the seventh decade. Clinical onset before the age of 55 is unusual. Men are slightly more likely to develop CBD than women. No ethnic or geographic preponderance is known. Data regarding incidence and prevalence of CBD are speculative, in large part due to misdiagnosis. It appears, however, from both clinical and pathologic case series that CBD occurs much less commonly than progressive supranuclear palsy, the disease with which it is most often compared and confused.

Hereditary cases are rare. There have been no documented *tau* mutations in sporadic CBD, but *tau* gene polymorphisms may play an etiologic role. Patients with CBD have a significantly higher prevalence of the H1/H1 genotype in the *tau* gene. Several mutations in the *tau* gene have been associated with hereditary cases of clinical CBS or pathologic CBD. Apart from age and genetics, no other risk factors for CBD have been identified.

Clinical Features and Diagnostic Criteria

The essence of the cortocobasal syndrome is the finding of asymmetric clinical features combining dysfunction in both cerebral cortex and basal ganglia, developing insidiously and gradually progressive. The cerebral cortical manifestations most often encountered are apraxia, cortical sensory loss, and the 'alien limb' phenomenon. The last symptom refers to a limb that engages autonomously in complex acts and appears to have 'a mind of its own.' Basal ganglia manifestations of CBD almost always include akinesia and rigidity, with the latter often pronounced. Another common basal ganglionic feature is dystonia. Clinical manifestations of uncertain localization include an irregular-amplitude action tremor and focal reflex myoclonus, with the former often evolving into the latter. Other manifestations include impaired ocular and eyelid motility, dysarthria, and corticospinal tract signs. All of these features typically present unilaterally and remain highly asymmetric throughout the course. One limb (more often the arm than the leg) or side may be affected for years before there is spread to other body parts. Pain may be prominent, especially if there is severe dystonia. Dementia and aphasia have been increasingly recognized as primary or secondary clinical manifestations of CBD, to the point that they are no longer considered atypical presentations. Their nonspecific nature contributes to the poor accuracy of premortem diagnosis.

Numerous schemes of diagnostic criteria for CBS exist. All incorporate these clinical principles. There are no consensus criteria for clinical diagnosis. The following are the 2002 criteria of Kumar and colleagues.

Mandatory Inclusion Criteria

1. Chronic progressive course
2. Asymmetric at onset (includes speech dyspraxia or dysphasia)
3. Presence of:
   a. 'higher' cortical dysfunction (apraxia, cortical sensory loss, or alien limb) and
   b. movement disorders (akinetic-rigid syndrome resistant to levodopa, plus limb dystonia or spontaneous and reflex focal myoclonus).

Qualifications (Descriptions) of Clinical Features

- *Rigidity:* easily detectable without reinforcement;
- *Apraxia:* more than simple use of limb as object; clear absence of cognitive or motor deficits sufficient to explain the disturbance;
- *Cortical sensory loss:* preserved primary sensation, asymmetric;
- *Alien limb phenomenon:* more than simple *levitation*;
- *Dystonia:* focal in limb; present at rest at onset;
- *Myoclonus:* reflex myoclonus spreads beyond stimulated digits.

Exclusion Criteria

1. Early cognitive disturbances other than apraxias, or speech or language disorders (this may exclude some patients who have CBD pathology, but more often excludes other pathologies);
2. Moderate-to-severe global dementia while the patient remains ambulatory;
3. Responsiveness to levodopa other than mild worsening on withdrawal;
4. Downgaze palsy (including loss of downward optokinetic nystagmus) while the patient remains ambulatory;
5. Typical parkinsonian rest tremor;
6. Severe autonomic disturbances;
7. Sufficient and appropriately located lesions on imaging studies to account for the clinical disturbances.

Differential Diagnosis

The typical CBD patient is aged in their sixties with asymmetric apraxia, akinesia, rigidity, dystonia, and tremor or myoclonus, resulting in the characteristic 'stiff, dystonic, jerky, useless hand.' The highly asymmetric presentation and the cerebral cortical manifestations of the CBS usually distinguish it from every other parkinsonian disorder. However, autopsy studies demonstrate that, not only does CBD present with manifestations different from the classical motor syndrome, but the clinical syndrome (CBS) occurs with disturbing frequency in association with other pathologies. The lack of diagnostic laboratory studies or biological markers compounds the problem, making clinical diagnosis treacherous. Indeed, in one autopsy series, only one of three patients clinically diagnosed with CBS had the characteristic pathologic changes of CBD, and only one of four with histological verification had been correctly identified during life. This poor correlation between CBS and CBD undermines every conclusion based on studies of CBS that was not corroborated by pathologic confirmation, including many of the statements in this chapter.

The greatest source of error leading to inability to recognize CBS is the failure to examine for cerebral cortical dysfunction (cortical sensory loss and apraxia). Other distinctive features of CBS are focal reflex myoclonus, and focal dystonia at rest. Conversely, symmetric presentation, a rest tremor, or responsiveness to levodopa makes CBD an unlikely pathologic diagnosis. The presence of dementia is a potential diagnostic trap. Many CBD patients become demented, and autopsy series indicate that many CBD patients exhibit a predominantly demented presentation. However, patients with the CBS who had dementia represent a disproportionate number of those who turn out to have Alzheimer's or Pick's disease at autopsy. One could exclude patients with early and prominent dementia from a clinical diagnosis of CBS, at the risk of diminished diagnostic sensitivity.

As previously stated, the 'classical' clinical picture (CBS) described is not specific to CBD and has been associated with a variety of other pathologic entities. The most common and difficult false-positive diagnoses have been made in patients with progressive supranuclear palsy who have significant apraxia, and those with Alzheimer's or Pick's disease who have prominent parkinsonian features. The most difficult false-negative diagnosis occurs in a CBD patient with dementia and few or no lateralizing manifestations. Such a patient is much more likely to be diagnosed with Alzheimer's disease. Frontotemporal dementia with parkinsonism linked to chromosome 17 may also produce the CBS; the distinguishing features here are usually the positive family history and young onset.

CBD has more in common with progressive supranuclear palsy than any other disorder, but they do have important clinical and pathological differences. Most striking from a clinical standpoint is the axial distribution of progressive supranuclear palsy versus the unilateral presentation and asymmetric course of CBD. Apraxia or hemidystonia in a patient with progressive supranuclear palsy may lead to a false diagnosis of CBS. Overlap disorders with biochemical and pathological features of both diseases, or combining features of CBD and other disorders, occur surprisingly frequently. Such cases highlight the need for more definitive diagnostic criteria than clinical or pathologic findings.

Diagnostic Workup/Tests

There are no diagnostic tests for CBD. Some laboratory findings may provide supportive data, but it is unclear to what extent they improve diagnostic accuracy. Thus, all diagnostic testing is optional, with relevance determined by the individual patient's clinical presentation.

Anatomic imaging rarely discloses unexpected focal lesions. The most common finding of conventional MRI in CBD patients is asymmetric cerebral atrophy, particularly in parasagittal and paracentral regions, more prominent on the side opposite to that of greater clinical involvement. Hyperintensity in the white matter of affected gyri on T2-weighted, proton density, and fluid-attenuated inversion recovery (FLAIR) images may be found. Basal ganglia MRI abnormalities are far less common than convexity atrophy, but putamenal atrophy has been reported.

Metabolic imaging studies of many stripes may support the clinical impression of involvement of both cerebral cortex and basal ganglia, as well as identify other involved structures. Functional MRI may detect abnormalities in motor and parietal cortex prior to the development of structural abnormalities. Proton magnetic resonance spectroscopy may demonstrate significantly reduced *N*-acetylaspartate/creatine-phosphocreatine ratios in centrum semiovale, and reduced *N*-acetylaspartate/choline in the lentiform nucleus and parietal cortex. Cerebral blood flow (CBF) SPECT scanning with 99mTc-hexamethyl propyleneamine oxime (HMPAO) may show asymmetric frontoparietotemporal cortical, striatal, and thalamic hypoperfusion. Widespread reduction in CBF was observed in frontal, parietal, and temporal cortices, basal ganglia, and thalamus and pontocerebellar regions with 99mTc-ethyl cysteinate dimer (ECD) SPECT scanning. PET with tracers of dopamine storage capacity and oxygen metabolism can demonstrate depressed cortical oxygen metabolism in the superior and posterior temporal, parietal, and occipital associated cortices, as well as in the posterior frontal lobe. Striatal ^{18}F-fluorodopa uptake may be asymmetrically reduced in the caudate nucleus and putamen. ^{18}F-fluorodeoxyglucose studies can demonstrate asymmetric cortical hypometabolism. Imaging defects in anterior

cingulate gyrus, superior parietal lobule, and supplementary motor area appear to correlate with apraxia. PET with PK11195 has demonstrated microglial activation in areas typically involved in CBD.

The characteristic pattern of pathologic lesions in CBD is associated with a variety of deficits on formal neuropsychological testing, most notably in the areas of praxis and executive function. Patients may additionally show any combination of deficits of attention, dynamic motor execution, verbal fluency, explicit learning without retention difficulties, constructional and visuospatial difficulties, acalculia, frontal lobe dysfunction, and nonfluent aphasia. Memory faculties are relatively preserved. Depression may also be a common finding.

CBD has been studied with a multitude of neurophysiological approaches. Ocular motility studies typically show prolonged saccade latency but preserved saccadic velocity and amplitude, in contrast to progressive supranuclear palsy. However, occasional CBD patients exhibit a supranuclear gaze palsy late in the course of their illness. The focal reflex myoclonus of the CBS is produced by two to four short-duration bursts of muscle contraction simultaneously in antagonistic muscle pairs. Back-averaged electroencephalography shows no time-locked cortical discharges. In CBD patients with myoclonus, somatosensory-evoked potentials are normal, while long-latency reflexes are exaggerated. Shortened latency and synchronous activation of additional muscles is consistent with focal reflex myoclonus. Transcranial magnetic stimulation can enhance cortical excitability and increase transcallosal transmission. Its ability to inhibit ipsilateral muscle contraction has been associated with radiologic evidence of corpus callosum atrophy and neuropsychologic deficits of attention and verbal fluency.

Management

The management of CBD is usually a disheartening process. The etiology remains unknown, and thus no curative treatment has been developed. There is no intervention that will alter the progressive nature of the disease, and opportunities for symptomatic relief are limited. Some motor symptoms are amenable to medication therapy, even if only to a modest extent. Levodopa may improve parkinsonian symptoms, although not to the degree one sees in Parkinson's disease. Dystonia may be partially treatable with botulinum toxin injections or clonazepam, and myoclonus with levetiracetam, clonazepam, or valproate. There are no known therapies for any of the cerebral cortical manifestations of CBD.

Nevertheless, there are other opportunities for physicians to provide some benefit to patients and their families. One way in which physicians can improve a patient and caregiver's quality of life is to take on responsibilities beyond the narrow scope of subspecialty care. These might include treatment of depression and other psychiatric needs, filling out forms for various bureaucracies (multiple types of insurance, medical equipment, caregiver absences from work, ambulance transport, etc.), assisting with entry into skilled nursing facilities, and conducting surveillance for infection or other complications of immobility. When there is nothing else to be done, often simply lending a sympathetic ear to caregivers is enough to earn expressions of gratitude.

As with other degenerative diseases that are largely untreatable, one challenge to long-term management of CBD is simply maintaining contact with the patient. It becomes progressively more difficult to provide motivation to return for further evaluation, while both patient and caregivers may grow frustrated and discouraged with the limitations of available treatment, and increasing disability makes travel to the clinic more burdensome. However, it is critical that clinicians do not lose track of patients and miss an opportunity for postmortem examination, which remains mandatory to confirm the diagnosis in every suspected CBD patient.

Prognosis

The most encouraging aspect of the course of CBD that one can share with patients is that the progression occurs slowly, measured in months or years rather than weeks or days. The life expectancy of CBD patients is between 5 and 10 years from onset, although disease courses as short as 2 years and longer than 10 have been reported in autopsy-confirmed cases. Quality of life in the last several years of illness is often quite limited.

Creutzfeldt–Jacob Disease

P Gambetti, G Puoti, I Cali, Q Kong, and W Zou, Case Western Reserve University, Cleveland, OH, USA

Glossary

Ataxia – Inability to coordinate voluntary movements leading to unsteady movements and staggering gait; most often associated with lesions of the cerebellum.
Cellular Prion protein (PrP^C) – A normal protein especially abundant in the brain that by changing shape or conformation may become abnormal and cause sCJD and other prion diseases.
Myoclonus – A sudden twitching of muscles or parts of muscles, without any rhythm or pattern.
PrP^{Sc} types 1 and 2 – Conformationally distinct isoforms of PrP^{Sc} that are associated with phenotypically distinct subtypes of sCJD; together with the methionine/valine polymorphism at codon 129 of the PrP gene, PrP^{Sc} types 1 and 2 determine the five subtypes of sCJD.
Scrapie Prion Protein (PrP^{Sc}) – The abnormal form of PrP^C that may be generated spontaneously in sCJD, by a genetic defect in familial CJD, or by contact of endogenous PrP^C with exogenous PrP^{Sc} in CJD acquired by infection.
Sporadic Creutzfeldt–Jakob disease (sCJD) – The most common type of a group of fatal diseases commonly called prion diseases which affect mainly the brain and are usually characterized by cognitive deterioration and loss of motor skills resulting in jerky movements.

Definition and History

Creutzfeldt–Jakob disease (CJD) is the most frequent phenotype of a group of fatal illnesses called transmissible spongiform encephalopathies or prion diseases. Its incidence is about 1 per 1 000 000 cases of the general population per year; and it is unique in having three etiologies: sporadic or idiopathic, genetically determined, or acquired by infection.

Alfons Maria Jakob in 1920 first reported three patients with progressive dementia associated with cortical, striatal, and spinal degeneration. Hans Gerhard Creutzfeldt reported a similar case in the same year. The eponym 'Creutzfeldt–Jakob disease' (Creutzfeldt–Jakobsche Krankheit) was coined by Walther Spielmeyer in 1922. Of the eight cases originally presented – seven by Jakob and one by Creutzfeldt – only three cases reported by Jakob are now accepted as CJD. Friedrich Meggendorfer is credited as having first described a familial case of CJD in 1930, a case which was later confirmed by genetic analysis. Kuru, a prion disease acquired by cannibalism, was discovered in 1957. The disease was observed to have features comparable to scrapie, a transmissible disease of sheep. These similarities led to a series of experiments designed to test the transmissibility of kuru and CJD, and the term transmissible spongiform encephalopathies (TSE) was thereafter applied to this entire set of diseases. The contemporary era of TSE dates from 1982, when the discovery of the prion protein provided the foundations for the protein only or prion hypothesis.

Pathogenesis

The key tenet of the prion hypothesis is that the prion protein (PrP^C) is converted into an isoform named scrapie prion protein (PrP^{Sc}), a prion which has a different conformation and is pathogenic. This central pathogenetic event is shared by all three forms of prion diseases. In sporadic CJD (sCJD), the PrP^{Sc} is believed to be formed randomly, perhaps as a lapse in the so-called quality control mechanism whereby cells detect and eliminate abnormally conformed proteins. In the genetically determined or familial CJD (fCJD), the formation of PrP^{Sc} results from a mutation in the PrP gene which encodes for an abnormally conformed and unstable PrP with the propensity to convert into PrP^{Sc}. Finally, CJD acquired by infection arises from contact between exogenous PrP^{Sc} and endogenous PrP^C, which requires that the two isoforms be compatible so that they can interact; it is this interaction that triggers the conversion of PrP^C to PrP^{Sc}. For example, in variant CJD (vCJD), the form of CJD acquired by eating prion-contaminated beef, the first critical requirement is that there be an affinity between the bovine PrP^{Sc} and the human PrP^C, which makes it possible for the two PrP isoforms to interact and for the human PrP^C to undergo the first conversion into PrP^{Sc}. Therefore, while the exogenous PrP^{Sc} acts as the primer for the initial human PrP^C conversion, the newly formed human PrP^{Sc} induces the autocatalytic reaction, which leads to propagation of the prion infection.

The pathogenetic mechanism of prion disease in general and of prion diseases individually, can only be fully understood if key characteristics of PrP^C and PrP^{Sc} are appreciated. PrP^C is a well conserved protein of the central nervous system (CNS) and other tissues of mammals as well as of other species. In humans, in its mature form PrP^C is a relatively small protein of 209 amino acids (residues 23–231) and accounts for ~0.01% of all brain proteins. PrP^C is processed in cells as a secretory protein. Most of the PrP^C carries a glycolipid anchor by which it is attached to the external surface of the cell plasma membrane (**Figure 1**). This site thus exposes the PrP^C to interaction with any extracellular ligand, the exogenous PrP^{Sc} of course being of special relevance. PrP^C also carries two sites of nonobligatory *N*-glycosylation that engender the diglycosylated, monoglycosylated and unglycosylated PrP^C glycoforms. Structurally, human PrP^C includes an N-terminal flexibly disordered 'tail' (23–124) and a globular domain (125–228). The globular domain contains three α-helices located at residues 144–228 and interspersed with two short anti-parallel β-sheets at residues 128–131 and 161–164.

Overwhelming evidence indicates that when PrP^C converts to PrP^{Sc} the β-sheet regions expand at the expense of the adjacent α-helical segment(s). With the expansion of the β-sheet component, PrP^{Sc} may acquire at least five

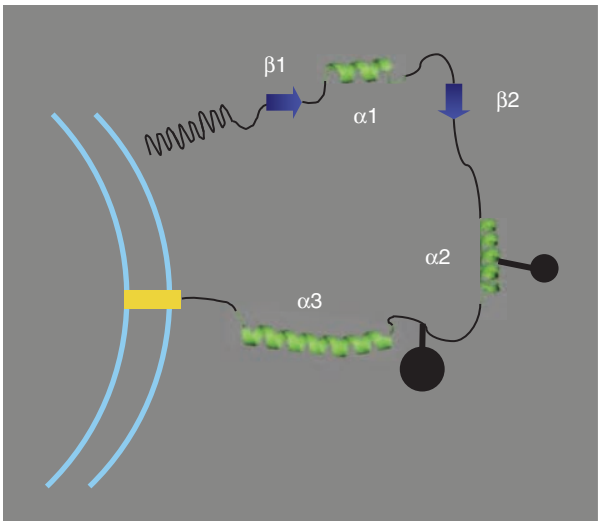

Figure 1 PrP^c on the cell surface. PrP^c is attached to the plasma membrane of the cell and hangs in the extracellular space. The cell plasma membrane is represented by the two curved blue lines. The yellow block represents GPI anchor. The two blue arrows represent the two β-strands. The three green ribbons identify the α-helixes. The N-linked glycans at residues 181 and 197 are shown as black lollipops. The PrP^c structure is based on the NMR study of recombinant human PrP.

distinctive molecular attributes: (1) insolubility in detergents, (2) propensity to aggregate, (3) acquisition of various degrees of resistance to digestion with proteases, which may result in (4) generation of PrP^{Sc} fragments of different sizes and/or with different ratios of the three glycoforms, and finally, (5) acquisition of various degrees of infectivity and pathogenicity. A sixth feature is the PrP^{Sc} amino acid sequence, which of course reflects that of the mother PrP^C. Cumulatively, these characteristics (and probably others not yet identified) play a key role in determining what are called prion strains, which in human prion diseases comprise distinct species of PrP^{Sc} each of which is associated with a distinct disease phenotype. Although all the molecular features designated above are measurable and important, only two have been demonstrated as the most consistent in their association with distinct disease phenotypes, and thus, have played a significant role in the current understanding of CJD: first, the sequence of the PrP^{Sc} as determined by codon 129 of the PrP gene and second, the size of the PrP^{Sc} protease-resistant fragment.

The PrP gene has several polymorphisms, the most common and best known of which is the methionine (M)/valine (V) polymorphism at codon 129. In the general Caucasian population, 52% of individuals are M homozygous (MM), 36% are heterozygous (MV) and 12% are V homozygous (VV). This polymorphism modifies the phenotype in human prion diseases. Therefore, subjects who are MM at codon 129 (129MM) (i.e., they carry exclusively the PrP isoform with M at the amino acid

position 129) present with a sCJD phenotype which is different from that of 129VV subjects.

As for the PrP^{Sc} size, extensive analysis of the protease-resistant fragment of PrP^{Sc} (hereafter identified as $rPrP^{Sc}$) has revealed that the great majority sCJD patients have either one of two types of $rPrP^{Sc}$, which are easily distinguishable by their electrophoretic mobility; these are referred to as type 1 and 2. Again, sCJD patients carrying $rPrP^{Sc}$ type 1 are likely to have a disease phenotype different from those carrying type 2. The difference in electrophoretic mobility that results in a relative molecular weight of 21 kDa and 19 kDa for types 1 and 2, respectively (when referred to the mobility of the unglycosylated isoform) stems from distinct major sites of PrP^{Sc} cleavage following treatment with proteinase K (PK), the commonly used protease in $rPrP^{Sc}$ analyses: amino acid residue 82 for type 1 and residue 97 for type 2. The finding that the same protease cleaves two protein isoforms having the same amino acid sequence at two different cleavage sites indicates that the two isoforms have distinct conformations which generate different proteolytic fragments. This conclusion was recently born out by duplication of types 1 and 2 in bioassays and in vitro, and by direct conformation assay. Therefore, the finding that the primary and the secondary structures of PrP^{Sc} (i.e., the amino acid sequence and the conformation) are determinants of the disease phenotype as well as of the major prion strains is compatible with the protein-only hypothesis according to which all that is required for PrP^{Sc} to replicate itself while retaining diversity is encrypted in the protein structure rather than in nucleic acids.

Shortly after the original description of CJD, variants of the original form were proposed reflecting the heterogeneity of the clinical and histopathological features of sCJD. In addition to the original CJD, referred to as typical or myoclonic, at least six additional variants were subsequently recognized, including Heidenhain or visual, amyotrophic, dyskinetic, thalamic, cerebellar or ataxic, corticostriatal, and panencephalopathic. More recently, two additional variants, the cognitive and affective, have been recognized. It is obvious that diagnosis of a rare disease for which there is no definitive clinical diagnostic test, and which may moreover manifest in nine different presentations poses a herculean task for clinicians. However, now this task is facilitated through the identification of fairly accurate phenotypic determinants such as the PrP patient's genotype and the PrP^{Sc} type, both of which now allow for classification of CJD subtypes on the basis of molecular features rather than objective clinical or histopathological characteristics.

In 1999, we used the combination of the genotype at codon 129 (identified as MM, MV, and VV) and the PrP^{Sc} type 1 or 2 to distinguish five phenotypes in sCJD, along with a sixth phenotype that we named sporadic fatal insomnia (sFI). These six phenotypes are easily distinguishable by clinical and histopathological features such as type, severity, and topography of the lesions along with the pattern and distribution of the PrP immunostaining.

Clinical and Histopathological Phenotypes

sCJDMM(MV)1

sCJDMM1 and MV1 are phenotypically indistinguishable and are therefore grouped together as sCJDMM (MV)1.

Prevalence

This subtype accounts for about 70% of all cases of sCJD.

Clinical features

The mean age at onset of symptoms is 65 years (range 42–91); the average disease duration is 4 months with a range of 1–36 months. The most common presentations (70% of cases) include cognitive impairment; less common presentations include ataxia, mental signs, and visual signs (field defects, distortion, cortical blindness). Unilateral onset of neurological signs occurs in about 25% of cases. Ataxia, myoclonus, and pyramidal signs are usually evident as the disease progresses. In about 80% of the cases, the EEG shows periodic sharp wave (PSW) complexes within the first 3 months of disease. The detection of the 14–3–3 protein in the cerebrospinal fluid (CSF) has a sensitivity of about 95%. MRI shows T2-weighted cortical and basal ganglia involvement in up to 58% of the cases; however, with diffusion-weighted imaging (DWI) the percentage increases to 75%. Cerebellar and thalamic hyperintensity is usually not observed.

Histopathology

The most common and defining characteristics are moderate fine spongiform degeneration (SD) (**Figure 2(a)**) and astrogliosis in most gray matter structures but more pronounced in the cortex than in basal ganglia and thalamus, and more prominent in the occipital than in the frontal cortex. The hippocampal gyrus is spared. SD is prominently present in the entorhinal cortex. The cerebellum shows moderate to minimal SD in the molecular layer and no atrophy of the cortex. The substantia nigra (SN) is not affected.

PrP immunohistochemistry

There is a fine punctate (synaptic) immunostaining pattern occasionally intermixed with small clusters of larger granules or a 'coarse' pattern (**Figure 2(d)**). The staining intensity matches the severity of the SD. The cerebellar molecular layer shows the distinct pattern of 'brush stroke.' The dentate nucleus and the SN commonly are unstained.

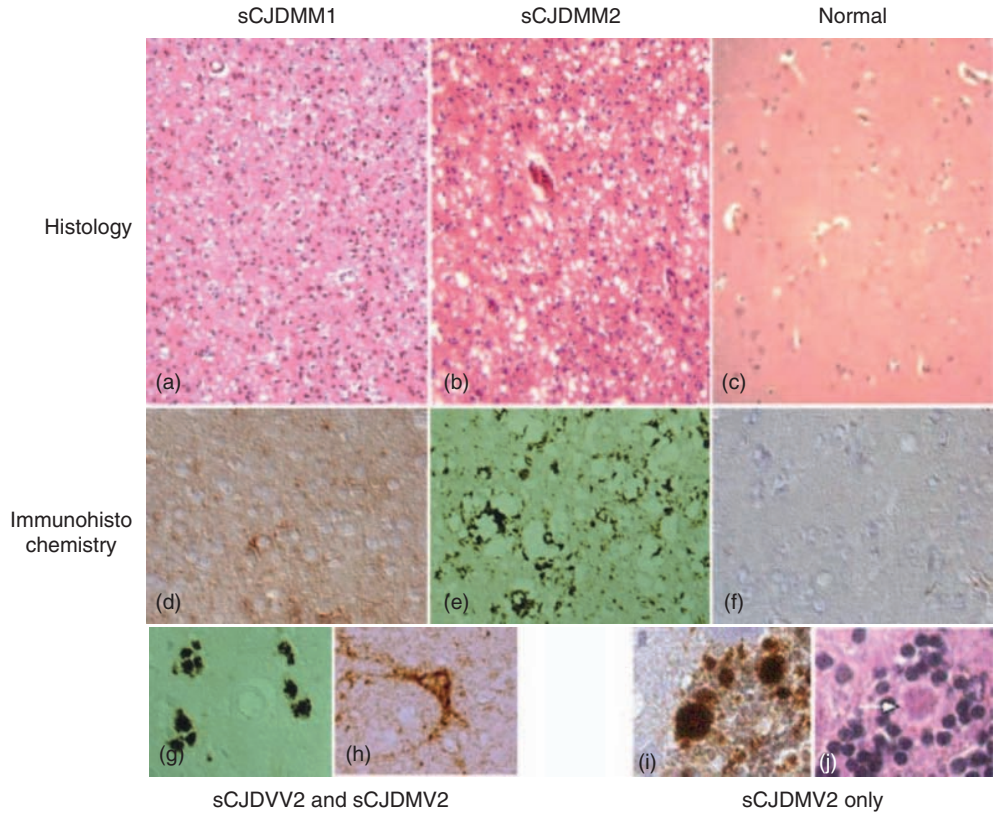

Figure 2 Histopathology and immuno-histochemistry of sCJD subtypes. Histopathology (Hematoxilin and eosine) shows spongiform degeneration (SD) in two sCJD subtypes with a remarkable difference in vacuoles size: fine (SD) is seen in sCJDMM1 (a) while large/confluent vacuoles are characteristic of sCJDMM2 (b). The normal cerebral cortex shows no SD (c). Immuno-histochemistry discloses fine punctate (synaptic) immunostaining pattern of PrP immunoreactivity in sCJDMM1 (d), while coarse staining with characteristic perivacuolar PrP-immunoreactivity in commonly seen in sCJDMM2 sub-type (e). The control, non prion disease brain shows no PrP immustaining (f). Plaque like (g) and perineuronal (h) PrP-immunoreactivity is the characteristic staining of both MV2 and VV2 sub-types; while kuru plaques, shown in immunohistochemical (i) and histopathological (j) preparation, are seen exclusively in MV2 cases. Characteristic histo-pathological and immune-histochemical features make the sCJD subtypes distinguishable at histological examination.

sCJDVV1

Prevalence

This subtype accounts for about 1% of all cases of sCJD.

Clinical features

The mean age at onset is 37 years (range 19–55) and the average disease duration is 21 months (range 10–49), which identifies this subtype as early onset. Presentation is characterized by dementia mainly of the frontotemporal type. Myoclonus, pyramidal signs, and ataxia eventually appear as the disease progresses. EEG shows no PSW complexes. The 14–3–3 test is positive in 100% of cases. MRI shows signal increase in the cerebral cortex in 100% and in <30% in basal ganglia.

Histopathology

The hallmarks are the severity of the SD and astrogliosis along with the presence of 'ballooned' neurons. The severity of SD is similar in the basal ganglia and cerebral cortex, where it is more pronounced in the frontal than in the occipital lobes; less prominent in the thalamus. The SD distribution in the hippocampal formation is similar to that of sCJDMM(MV)1. The cerebellum and the SN are virtually spared.

PrP immunohistochemistry

The staining (with antibody 3F4) is extremely light and free of the cluster of larger granules or 'coarse' patterns. The cerebellar cortex and SN are usually unstained.

sCJDMM2

Prevalence

This subtype accounts for about 5% of all cases of sCJD.

Clinical features

The mean age at onset is 65 years (range 49–77), and the average disease duration is 16 months (range 9–36). The presentation is dominated by cognitive impairment of the focal type (aphasia, apraxia, spatial disorientation,

frontal signs) in one-third of the cases. As the disease progresses, myoclonus, and pyramidal signs also become common; and parkinsonism and seizures are present in about 30% of the cases. Ataxia is uncommon. The EEG never shows PSW complexes. The 14–3–3 test is positive in 75% of cases. MRI demonstrates cerebral cortical hyperintensity, whereas in the thalamus the signal is generally unchanged.

Histopathology

The hallmark of this subtype is the much larger and often confluent vacuoles of SD (**Figure 2**(**b**)), easily distinguishable from those of all the other sCJD subtypes, although fine SD may also be present. The cerebral cortex in the various lobes is similarly affected but the hippocampal gyrus is spared. Basal ganglia and thalamus are less affected while cerebellum and SN are spared.

PrP immunohistochemistry

The two dominant staining patterns consist of round loose plaque-like deposits, along with staining of the rims of the large vacuoles (**Figure 2**(**e**)). The staining is very intense in the cortex and subcortical nuclei; the cerebellum shows occasional clusters of plaque-like staining in the molecular layer while the SN is unstained.

sCJDVV2 and sCJDMV2

The phenotypes of these two subtypes are very similar and are therefore reported together.

Prevalence

sCJDVV2 accounts for about 16%, and sCJDMV2 for about 9% of all sCJD.

Clinical features

The mean age at onset is about 60 years (range 41–81); the average disease durations are 17 months (range 5–72) for sCJDMV2 and 6 months (range 3–18) for sCJDVV2. Ataxia is the invariable presenting sign in both subtypes. Cognitive impairment is always present and is often preceded by mental signs in sCJDMV2 cases while it is observed in just one-third of sCJDVV2 patients. As the disease progresses, myoclonus and pyramidal signs affect the majority of patients. Aphasia and apraxia are common in sCJDMV2, but absent in sCJDVV2 patients. In both subtypes, the EEG shows PSW complexes in $<10\%$ of the cases and the sensitivity of the 14–3–3 test is $<80\%$. MRI thalamic hyperintensity is common (up to 86% on DWI), allowing for differentiation of sCJDMV2 from sCJDVV2.

Histopathology

The SD is of the fine type and exhibits similar distribution in the two subtypes. The cortex is much less affected than the basal ganglia and thalamus and the frontal is more affected than the occipital lobe. The hippocampal gyrus shows extensive SD. The cerebellum has SD in the molecular layer and the SN is also affected. The difference between the two subtypes resides in the cerebellum. In contrast to sCJDVV2, sCJDMV2 shows no atrophy of the granule cell layer and contains kuru plaques in the superficial zone of the granule cell layer (**Figure 2**(**l**)).

PrP immunohistochemistry

In addition to the fine punctate immunostaining, there are scattered plaque-like aggregates and characteristic perineuronal staining made of small granules dotting the surface of the neuronal cell body and processes (**Figure 2**(**g**) and (**h**)). The intensity of the immunostaining is related to the severity of the lesions. The hippocampal gyrus and the SN are immunostained. The immunostaining pattern of the cerebellum is distinct in the two subtypes. Although in both subtypes the granule cell layer is heavily and preferentially stained, the staining predominantly exhibits tight aggregates in sCJDMV2 and loose plaque-like formations in sCJDVV2.

sCJD with co-occurrence type 1 and 2 (sCJD1–2)

Clinical features

PrP^{Sc} types 1 and 2 may coexist in up to $\sim$40% of cases with sCJD. Type 1 appears to be better represented than type 2 in MM sCJD subjects, while type 2 is more evident in VV subjects. The clinical and histopathological phenotypes reflect those of the predominant PrP^{Sc} type. For example, sCJDMM1–2 subjects with predominant type 1 are likely to have a phenotype similar to that of the sCJDMM1 subtype.

Diagnostic Tests

This section provides a synopsis of diagnostic tests. The EEG consistently shows the characteristic PSW complexes only in sCJDMM(MV)1. The 14–3–3, a widely used CSF test commonly based on Western blot, is helpful in the differential diagnosis of sCJD from other rapidly progressing dementia conditions. With some exceptions, the great majority of studies report an overall sensitivity of 90% or more and a specificity of 50% or less. Therefore, the 14–3–3 test over-diagnoses sCJD. The sensitivity varies according to the sCJD subtype: it is over 95% in sCJDMM1 and around 80% in sCJDMV2 and sCJDVV2. MRI should be used along with the 14–3–3 test to rule out focal brain destructive conditions that often results in a positive 14–3–3. Other CSF tests include tau, neuronal specific enolase and S100 and are the other protein markers most frequently used. Tau, the most studied, has a slightly overall lower sensitivity of 80–90% and a higher specificity of 70–80% than those of 14–3–3 (**Table 1**).

MRI plays an increasingly important role in the diagnosis of sCJD, and might become the test of choice in

Table 1 sCJD subtypes: phenotypic features

Subtype	*Prevalence (%)*	*Clinical features*	*Diagnostic test*	*Histopathology*
MM(MV)1	70	*Onset*: 65 years (42–91); *duration*: 4 months(1–36) *presentation*: cognitive impairment, ataxia, mental and visual signs; *later stage*: myoclonus, ataxia, and pyramidal signs	*EEG*: PSW in 80% of cases 14–3–3: 95% positivity *MRI*: cortical and BG signal increase in up to 58% of cases (75% with DWI)	Widespread fine SD and minimal astrogliosis more pronounced in cortex, especially occipital and entorhinal, than BG and thalamus; hippocampal gyrus and SN not affected; fine punctuate immunostaining with occasional small clusters of larger granules matching in intensity the severity of the SD; 'brush stroke' pattern in cerebellar molecular layer; dentate nucleus and the SN are unstained
VV1	1	*Onset*: 37 years (19–55); *duration*: 21 months (10–49) *presentation*: dementia of frontotemporal type; *later stage*: myoclonus, pyramidal signs, and ataxia	*EEG*: No PSW 14–3–3: 100% positivity *MRI*: signal increase in cerebral cortex in 100% and BG in 30% of cases	Severe SD and astrogliosis with 'ballooned' neurons; SD similar in BG and cerebral cortex, more severe in frontal lobe; thalamus affected; SD distribution in hippocampus similar to sCJDMM(MV)1; cerebellum and SN spared; immunostaining very light and cluster-free; cerebellum and SN unstained
MM2	5	*Onset*: 65 years (49–77); *duration*: 16 months (9–36) *presentation*: cognitive impairment; *later stage*: myoclonus, pyramidal signs, seizures; ataxia uncommon	*EEG*: No PSW 14–3–3: 75% positivity *MRI*: increased cerebral cortical intensity; no thalamic abnormalities	SD with much larger and confluent vacuoles; fine SD sometime present; cerebral cortex similarly affected; hippocampal gyrus spared; BG and thalamus less affected; cerebellum and SN spared. Two immune staining patterns: (1) round loose 'plaque-like' deposits; (2) staining of large vacuole rims; occasional plaque-like staining in cerebellar molecular layer; SN unstained
VV2 MV2	16 9	*Onset*: 60 years (41–81); *duration*: 6 months (3–18) [sCJDVV2], 17 months (5–72) [sCJDMV2] *presentation*: ataxia in all cases; cognitive impairment often with mental signs in 100% sCJDMV2 and in 30% of sCJDVV2 cases; *later stage*: myoclonus and pyramidal signs; aphasia and apraxia common in sCJDMV2, absent in sCJDVV2	*EEG*: PSW in 10% of cases 14–3–3: 80% positivity *MRI*: thalamic hyperintensity in up to 86%; DWI different in sCJDVV2 and sCJDMV2	Fine SD in deep cortical layers less severe than in BG and thalamus; frontal more affected than occipital lobe; extensive SD in hippocampal gyrus, moderate in cerebellum; SN affected. sCJDMV2: kuru plaques in cerebellum with no atrophy; sCJDVV2: atrophy no kuru plaques. Fine punctuate, scattered plaque-like and perineuronal immunostaining; patterns often laminar in the cortex; tight aggregates cerebellar immunostaining in sCJDMV2; loose plaque-like in sCJDVV2

sCJD. Hyperintensity of the basal ganglia in T2-weighted images is characteristic. Emerging, and more sensitive, techniques such as FLAIR (fluid-attenuated inversion recovery) and DWI have demonstrated cortical signal increase, thus increasing overall MRI sensitivity and specificity in specialized centers to over 90%.

Treatment

The first drug studies of CJD were undertaken almost 40 years ago and since then dozens of drugs have been tested. Yet no effective treatment has been found. Nevertheless four compounds have been (or are currently being) studied with sufficient rigor and in an adequate number of patients.

Quinacrine, once widely used antimalarial drug, was found to block formation of PrP^{Sc} in infected cell cultures. A recent patient-preference trial on all forms of CJD showed acceptable level of tolerance but no effect on the clinical course of CJD. Flupirtine maleate, a centrally acting nonopioid analgesic, has been tested in a randomized double-blind study of subjects with the diagnosis of probable CJD. Treated patients showed a significantly slower rate of cognitive deterioration but no significant difference in survival time. Administration of doxycycline, a member of the tetracycline group, to sCJD patients under compassionate treatment has been reported to more than double survival compared to untreated sCJD subjects. A phase II, multicenter, randomized, double-blind study is ongoing.

Acknowledgments

Our most heartfelt thanks go to the families of the CJD patients that made this review possible. The authors also want to thank Dr. Miyuki Shimoji for preparing **Figure 1**. Cyanides

C G Goetz, Rush University Medical Center, Chicago, IL, USA

Chemistry and Exposure Information

Hydrocyanic acid is one of the most rapidly acting poisons, and it is therefore used especially as a suicidal or homicidal agent. Cyanide intoxication also occurs accidentally during fumigation, including fire inhalation, electroplating, and gold or silver ore extraction. Free hydrocyanic acid or cyanogenetic glycosides are produced by choke–cherry trees and other plants, and accidental poisoning is due to the ingestion and chewing of the toxic

seeds. Cyanides are general protoplasmic poisons producing asphyxia by inhibiting the action of energy-generating respiratory enzymes throughout the body. Benzyl cyanides inhibit dopamine beta hydroxylase, the synthetic enzyme for the neurochemical, norepinephrine. They also induce a brief stimulation of the central nervous system that is rapidly replaced by a paralyzing action. In addition, cyanides interact with the dopamine metabolite, 3,4-dihydroxyphenylacetaldehyde (DOPAL), to generate a biologically active compound (cyanohydrin adduct) that may contribute to its neurotoxicity.

Clinical Signs of Intoxication

Within 10 min of the ingestion of lethal doses of cyanide, victims lose consciousness, exhibit generalized convulsions, and die within 2–5 min. Most often, the toxic effects appear more slowly with some agitation, salivation, anxiety, confusion, and nausea. These symptoms are accompanied by vertigo, headache, unsteady gait, and a feeling of stiffness in the lower extremities. Seizures may develop and appear to relate to a depletion of the energy generating compound, adenosine triphosphate (ATP). Breathing is stentorian; the face is flushed and then cyanotic; and the pupils are dilated. Respiration frequently ceases before the heart stops, and death usually ensues within 15 min to 1 h. Recovery may occur when treatment is instituted rapidly. If patients survive the first hour, they usually recover completely, although some experience weakness, unsteady gait, headache, difficulty in speaking, and drowsiness. There is a high degree of individual susceptibility to cyanide intoxication, but some patients have survived even after the ingestion of 6 g of potassium cyanide, although as little as 0.13 g can be lethal.

After the inhalation of gaseous hydrocyanic acid, the victim develops nausea, vomiting, and difficulty in breathing. Unconsciousness supervenes, and within 10 min, respiratory failure and death may occur. Survivors typically have parkinsonian features, with masked facial expression, severe hypophonia, bradykinesia of limbs and trunk, and unsteady gait due to postural reflex compromise. Tremor is not always present and can have a mixed rest/postural/kinetic character. Some patients have additional cognitive alterations and some have added cerebellar features of poor coordination and slurred speech, which superimpose on parkinsonian hypophonia. MR scans show damage to the globus pallidus, putamen, midbrain, and cerebellum. The evidence of hemorrhagic necrosis develops within 6 weeks of intoxication and cystic degeneration is a late finding. The sensorimotor cortex can also be involved in pseudolaminar necrosis. ^{18}F-fluoro-dopa positron emission tomography scans can reveal a symmetrical reduction of activity in two anatomical areas, the caudate nucleus and putamen. Glucose metabolism scans show regional reductions in the putamen, temporo-parieto- occipital cortex, and cerebellum. With chronic potassium cyanide exposure, MR spectroscopy and SPECT may be more useful in documenting abnormalities when the standard MR scan does not reveal extensive abnormalities. Cyanide intoxication can also cause a different syndrome without parkinsonism: cerebellar dyssynergia, ataxia and accompanying malaise, weakness, visual disturbances, and muscle pains. Vertigo and unusual periods of fluctuating consciousness have also been observed. Finally, chronic cyanide intoxication caused by a long-standing ingestion of the cassava root has also been linked to tropical amblyopia and tropical ataxic neuropathy. Cassava is the tuberous root of the shrublike plant *Manioc palmatea*, and this plant contains a high concentration of glycoside, which is metabolically transformed into cyanide by the action of hydrolase activated by handling, heating, or bruising the tubers. Farmers and subjects in close contact with cassava have been affected most frequently. Clinically, this chronic intoxication is manifested by optic atrophy, bilateral nerve deafness, and spinal cord damage with weakness and loss of vibratory and touch sensation and diffuse polyneuropathy involving distal nerves. The lower limbs are most frequently involved and show marked weakness and wasting. In terms of signs of movement disorders, an occasional patient reveals cerebellar findings of staggering gait, poor coordination, and slurred speech. In an area of Mozambique, where an epidemic of spastic paraparesis developed in association with cassava ingestion, high urinary thiocyanate and decreased inorganic sulfate excretion were documented. These findings suggested a high cyanide exposure and have further added evidence to the hypothesis that cyanides may relate to the pathogenesis of some types of spinal ataxia and peripheral nerve lesions heretofore considered to be idiopathic or of unknown cause.

In the 1970s, the anticancer drug, laetrile, was used in many areas of the world, and at its height, an estimated 20 000–50 000 people used the drug on a yearly basis. The drug induced many cases of cyanide toxicity, most notably, a mixed neuropathy–myelopathy with ataxia and dyssynergia occurring in some patients. The toxicity of laetrile related to cyanide release during the metabolism of amygdalin, a major component of the drug.

Patients usually recover spontaneously from poisoning due to cyanide gas inhalation if they can be brought into open air before respiration ceases. Artificial respiration is imperative if there is interruption of breathing. For specific treatment, the National Poison Center network recommends sodium nitrite, amyl nitrite, and sodium thiosulfate, with close attention to blood pressure.

Cylinder Test (Paw Reach Test)

S B Dunnett, Cardiff University, South Wales, UK

Glossary

6-OHDA – 6-Hydroxydopamine, a neurotoxin that induces selective degeneration of catecholamine neurons, frequently used following injection into the vicinity of midbrain dopamine neurons to induce an animal model of Parkinson's disease.

L-dopa – L-dihydroxyphenylalanine, the active precursor for the neurotransmitter dopamine, and the prototypical drug for treatment of Parkinson's disease.

MCAO – Middle cerebral artery occlusion, a frequently used method to induce focal stroke in the brain of experimental animals.

The cylinder test was introduced in the mid-1990s by Timothy Schallert as a simple and sensitive test of spontaneous limb use for applications in rat lesion models of Parkinson's disease. The test turns out to be useful for assessing the sensorimotor consequences of a range of unilateral lesion models, in particular when induced by stereotaxic injection of toxins or focal ischemia. The test relies on the spontaneous tendency for rodents, when placed in a novel environment, to explore by rearing to look around. When tested in a confined space, the rats will place their forepaws against the wall to maintain stability and place their paws back on the floor to balance as they descend. A normal rat will typically use both paws equally, with the splaying of the digits as the paw contacts the wall, but unilateral brain damage typically yields impairments in the use of the contralateral limb, with the forearm held loose or against the body and the paw more clenched.

The Cylinder Test

The cylinder test (**Figure 1**) involves placing the animal into a transparent Perspex cylinder ~20 cm in diameter and 30 cm high (sufficient to allow free rearing and turning but to avoid the animal climbing out). An angled mirror is placed behind the cylinder so that the animal's movements can be observed at all angles. Typically, the rat is placed into the cylinder and movements video recorded for a fixed period, say 5 min, for subsequent analysis in terms of the number and duration of rears, number and duration of left and right paw contact with the wall surface, and whether the animal uses one or both paws for weight bearing when it descends from rearing.

The simplest outcome measure is to express the time or number of wall contacts with the ipsilateral paw as a ratio of total time or contacts with both paws. For some purposes, such as tracking recovery of function or effects of experimental therapeutics, this simple ratio measure is the most practical. For other purposes, such as comparing

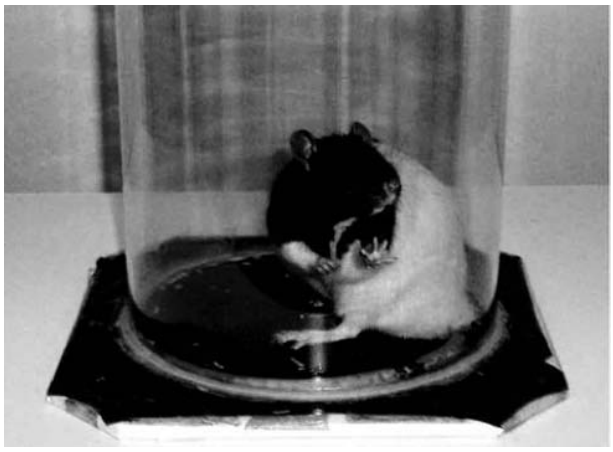

Figure 1 Rat in the cylinder test. Note that as the rat rears, it typically places one or both paws against the cylinder wall to stabilize its balance. In this example, the animal is placing with the left paw and holding back the right paw, which is a characteristic posture following lesions in the left basal ganglia or nigrostriatal pathway.

the profile of deficits after different lesions, Schallert advocates using a combination of measures involving both simultaneous and independent use of the two limbs for contacting the wall when rearing, for weight shifting, for regaining center of balance while turning, and both simultaneous and independent use of the two limbs for landing. Providing an even more fine-grain analysis, Whishaw and colleagues have used Eshkol–Wachman movement notation to characterize in detail horizontal movements, vertical movements, head scanning, turning, forelimb progression during a vertical scan, and weight shifting on the hind limbs during vertical progression.

Although most experimental work using the cylinder test has been undertaken in rats, a few studies have successfully adapted the test to mice and small monkeys (marmosets).

Key Results

Unilateral lesions at multiple levels of the motor systems of the brain are seen to produce asymmetries in limb placing in the cylinder test, including lesions in the nigrostriatal pathway, the striatum, the somatosensory and motor areas of neocortex, and focal ischemia by middle cerebral artery occlusion (MCAO) affecting the striatum and the sensorimotor cortex, the rubrospinal tract, and cervical spinal cord. Although all lesion types have somewhat similar effects in reducing the use of the contralateral limb for placing, stabilization, and balance as the animals rear to explore their environment, and for landing after a rear, considerable differences have been recorded in the degree of spontaneous recovery. Although several of the lesion syndromes routinely exhibit significant or complete recovery and return of bilateral limb use in cylinder exploration, deficits may be long-lasting, in particular after nigrostriatal and cervical lesions.

The cylinder test has been widely used for the investigation of novel therapeutic strategies, in particular in MCAO models of stroke. Thus, for example, conventional Parkinsonian treatments such as L-dopa or dopamine receptor agonists can produce improved limb use in the cylinder test in the acute period following lesion, although longer-term recovery is confounded by competition from the abnormal involuntary movements induced by chronic treatment with L-dopa. A number of studies have reported good functional benefit in the cylinder test by viral transfection of trophic molecules such as glial cell line-derived neurotrophic factor (GDNF) providing neuroprotection of the intrinsic system against acute toxin-induced degeneration, whereas recovery in cell transplantation studies have in most cases proved more disappointing on this functional measure, clearly illustrating the different mechanisms of neuroprotection and repair provided by these alternative strategies. There is, however, evidence that recovery following cell replacement may be promoted by environmental enrichment.

Cystatin B

A-E Lehesjoki, Folkhälsan Institute of Genetics and University of Helsinki, Helsinki, Finland

Glossary

Allele – One member of the different forms of a gene.
Alternative splicing – Variation in the splicing of RNA in which the exons of the primary gene transcript are separated and reconnected to produce a variety of structurally different RNA molecules, which when translated result in different protein isoforms.
Cathepsin – An enzyme that degrades polypeptides and contains either a cysteine or an aspartic acid amino acid in the enzyme's active site.
Cysteine protease: – An enzyme that degrades polypeptides and contains a cysteine amino acid in the enzyme's active site.
Dodecamer repeat – A stretch of DNA that consists of 12 structural units of DNA, the nucleotides, and that occurs in more than one consecutive copy on the DNA strand.
Founder effect – The loss of genetic variation when a new colony is formed by a very small number of individuals from a larger population.
Northern blot analysis – A molecular biological method to study gene (RNA) expression that is based on detection of RNA molecules with hybridization probes after size separation by gel electrophoresis.

Introduction

Unverricht–Lundborg disease (EPM1; OMIM 254800) is an autosomal recessively inherited disorder and the most common single cause of progressive myoclonus epilepsy worldwide. Mutations in the CSTB gene (*CSTB*) encoding Cystatin B, a cysteine protease inhibitor, are responsible for the primary defect in the majority of EPM1 patients. Gene identification in EPM1 has made possible molecular diagnostics in the majority of patients, elucidation of the cellular function of the CSTB protein, and studies of the EPM1-associated disease mechanisms, which are reviewed here.

The Cystatin B Gene

The *CSTB* gene contains three exons with a ubiquitously expressed mRNA of approximately 0.8 kb in northern blot analysis. Two potential transcription start sites are located 67 and 78 nucleotides downstream of the dodecamer repeat element in the promoter. *CSTB* is alternatively spliced with at least five isoforms of unknown physiological significance, some of which show tissue specificity.

EPM1-Associated *CSTB* Gene Mutations

Ten mutations have been reported to underlie EPM1 (**Table 1**). The most common of these is an unstable expansion of a polymorphic 12-nucleotide, dodecamer, repeat (5′-CCCCGCCCCGCG-3′), in the promoter region of *CSTB*. Control individuals have two or three copies of the repeat, whereas EPM1-associated alleles contain between 30 and approximately 125 copies. This mutation is found in approximately 90% of the disease alleles worldwide and in homozygous form in the majority of the patients, especially in populations with a founder effect. So far, only one EPM1 patient without the expansion mutation has been described. The dodecamer repeat expansion mutation seems to show no correlation between the number of repeats and either disease severity or the age of onset.

In vitro studies have indicated a significantly reduced *CSTB* promoter activity in the presence of the expansion mutation. Compatible with these data, the expansion results in a significant downregulation of *CSTB* mRNA expression in vivo with less than 10% of expression from that in controls. Consequently, the CSTB protein expression and its inhibitory activity are also significantly reduced in cells of EPM1 patients.

The other EPM1-associated *CSTB* mutations change single amino acids, affect splice sites, or predict truncated proteins (**Table 1**). With the exception of the p.G4R substitution mutation, these mutations have been reported to occur in compound heterozygous form with the repeat expansion. All three reported amino acid substitution mutations are likely to affect the interaction of the CSTB protein with its target cysteine proteases. Alternatively, they may change the stability or life span of the inhibitory effect of CSTB. *CSTB* mRNA and protein expression data suggest that reduced CSTB expression is the primary pathological consequence in the majority of EPM1 mutations, with a possible exclusion of the amino acid substitution mutations.

The Cystatin B Protein

Human CSTB protein consists of 98 amino acids comprising a molecular weight of approximately 11 kDa and it

[a]Reported in the literature or known to the author.

is widely expressed in different tissues and cell types. CSTB belongs to family 1 of the cysteine protease inhibitor superfamily, the cystatins, which are small molecular weight single polypeptide chain proteins that do not contain carbohydrate side chains or disulphide bonds. CSTB inhibits in vitro several lysosomal cysteine proteases, cathepsins, by tight, reversible binding and thereby contributes to their activity. The main function of cathepsins is nonselective degradation of intracellular proteins, but they also participate in antigen processing and apoptosis. Decreased inhibitory activity of CSTB, through reduced gene and protein expression, has been shown to correlate with enhanced activity of cathepsins B, L, and S in EPM1 patient cells, providing in vivo evidence for cathepsins being regulated by CSTB.

Cytoplasmic, lysosomal, and nuclear localization has been reported for wild-type CSTB protein with somewhat controversial results between different studies, possibly due to the different cellular models and antibodies used. In proliferating human primary myoblasts and in differentiated nonproliferating myotubes, CSTB localization seems to be dependent on the differentiation status of the cells with only cytoplasmic localization in myotubes but both lysosomal and nuclear localization in myoblasts. Available data suggest that CSTB is attached to the outer side of the lysosomal membrane rather than within the lysosome, although this would need to be experimentally verified.

Amino acid substitution mutations that are likely to express a structurally and functionally altered protein in patients have been utilized in cellular expression studies to give insight into the physiological function of CSTB. Such mutant proteins, when transiently expressed in cells, fail to associate with lysosomes implying that the lysosomal association is essential for the physiological function of CSTB and that a loss of this association contributes to the molecular pathogenesis of EPM1. As all the three amino acids that are known to be altered in patients likely affect binding of CSTB to cathepsins, it may be that the loss of lysosomal association is a consequence of altered binding to cathepsins: a hypothesis, which awaits experimental verification.

Cystatin B-Deficient Mice – A Model for EPM1

The Cystatin B-deficient mice with targeted disruption of the mouse *Cstb* gene mimic the human phenotype reasonably well. The mice develop myoclonic seizures during sleep by one month of age and progressive ataxia by six months of age. No tonic–clonic seizures, photosensitivity, or spike-wave complexes in EEG have been observed in the mice. The genetic background has a clear impact on the clinical outcome, implying that genetic factors influence the phenotype.

The neuropathological hallmark in the *Cstb*-deficient mice is a severe progressive loss of cerebellar granule cells due to apoptotic death. There is a less marked neuronal apoptosis in the hippocampal formation and entorhinal cortex in young animals and a widespread cortical and white matter gliosis in older mice. In addition, the superficial neurons of the prosubiculum in the cerebral cortex display prominent cellular atrophy, which is similar in seizure-prone and seizure-resistant mouse backgrounds. These data suggest that CSTB has an endogenous neuroprotective role and that EPM1 should be classified as a primary neurodegenerative disorder, with specific neuronal populations affected and both neuronal death and dysfunction contributing to the phenotype.

The *Cstb*-deficient mouse model has been utilized in studies aiming at understanding the related disease mechanisms. Studies in hippocampal slice preparations from these mice have revealed latent hyperexcitability,

which may be due to a loss of GABAergic cells and a subsequent loss of inhibition, and which may relate to EPM1 onset. Moreover, *Cstb*-deficient mice have an increased susceptibility to kainate-induced seizures. They show a shorter latency to seizure onset, more severe seizures and a more severe neuronal damage compared with wild-type littermates. As CSTB expression also increases in response to hippocampal kindling, it can be hypothesized that CSTB acts as a physiological safeguard and that loss of its activity not only triggers neurodegeneration but also makes neurons more susceptible to prolonged seizure-induced cell death contributing to disease progression in EPM1. Finally, cerebellar granule neuron degeneration is reduced in *Cstb*-deficient mice from which the *Cathepsin B* gene is also genetically removed, with no effect on the ataxia and seizure phenotypes. It is thus likely that cathepsin B is one contributor to the apoptotic phenotype resulting from CSTB deficiency.

Conclusion

Loss-of-function mutations in *CSTB* are the primary defect in EPM1. Available evidence implies lost lysosomal association of CSTB as an important contributing factor to the disease pathogenesis. Moreover, cathepsins, especially cathepsin B, are likely to have a role in the molecular pathology of EPM1. CSTB seems to have an endogenous neuroprotective role with different neuronal populations having different sensitivity to CSTB deficiency. The physiological function and the disease mechanisms of EPM1 remain to be elucidated.

Deep Brain Stimulation

B Ford, Columbia University Medical Center, New York, NY, USA

Introduction

Deep brain stimulation (DBS) is an outgrowth of stereotactic lesion surgery for Parkinson's disease (PD) that began in the 1940s. With advances in technology, brain mapping, neurosurgical technique, and brain neurophysiology, DBS was developed to relieve symptoms of tremor, rigidity, and bradykinesia in patients with PD. Since its introduction as an effective treatment for tremor in the 1990s, DBS has been successfully applied to several other neurological and psychiatric disorders.

To date, tens of thousands of patients with essential tremor (ET), PD, and dystonia have been successfully implanted, worldwide, with DBS devices to control symptoms of tremor, rigidity, dystonia, bradykinesia, and drug-induced dyskinesias. A single electrode controls symptoms on the opposite body side, and DBS can be performed on one or both sides of the brain. DBS has proven more effective at suppressing tremor than any medical treatment to date. For individuals with advanced PD complicated by wearing off motor fluctuations and dyskinesias, DBS can yield important benefits in symptom control and quality of life that are not achievable by medication adjustment alone.

In addition to neurological applications, DBS is being investigated as a treatment for chronic pain, depression, obsessive–compulsive disorder (OCD), and Tourette syndrome (TS).

To date, there is no evidence that DBS modifies disease or prevents disease progression. DBS remains a treatment approach that works by suppressing the symptoms, and is used only for those symptoms that do not adequately respond to medication.

This article will briefly review the development of DBS as a neurosurgical treatment, the technical aspects of DBS, electrophysiology, and application to several common neurological and psychiatric disorders, with an emphasis on movement disorders: PD, tremor, and dystonia.

DBS Components and Techniques

The deep brain stimulator device consists of three parts: an electrode with a linear tetrad of platinum iridium ring contacts, an extension wire, and a programmable implantable pulse generator (IPG), or battery. Guided by neuroimaging studies and intraoperative neurophysiological mapping, the stimulating electrode is inserted under local anesthesia through a skull burr hole into a deep brain structure. The electrode is anchored at the skull, and connected by a lead extension that is threaded subcutaneously through the muscles of the neck, and attached to the IPG, or battery, implanted in the chest wall below the clavicle.

The DBS electrode can be interrogated and programmed percutaneously using a handheld device placed over the IPG. Various electrical settings can be manipulated: the configuration of contacts in the quadripolar electrode, the voltage amplitude, pulse width, and frequency. In theory, the device allows more than 40,000 combinations of electrical parameters but in clinical practice, assuming accurate electrode placement, therapeutic results are produced by a limited set of readily identifiable settings. The device provides only stimulation, and has no sensing capability that might allow more sophisticated synchronization with brain electrophysiology.

Development of DBS

The origins of DBS began over a 100 years ago with the development of the first stereotactic apparatus by Horsley and Clark for brain surgery in animals. Innovative neurosurgeons began to treat abnormal involuntary movements, including chorea, dystonia, and tremor, by excising parts of the human cortex. It was American neurosurgeon Meyer who made the seminal observation in the 1940s

that lesioning parts of the basal ganglia could successfully reduce tremor *without resulting in weakness or paralysis*. In the ensuing decades, neurosurgeons created different lesions in many areas of the basal ganglia, including the globus pallidus, caudate, thalamus, subthalamic nucleus (STN), and ansa lenticularis to reduce the symptoms of dystonia, tremor, rigidity, and chorea.

Microelectrode recording for brain mapping was developed by Narabayashi in the 1960s. The use of intraoperative stimulation of brain targets in preparation for ablative surgery revealed that high-frequency stimulation of the thalamus could suppress tremor on the opposite side of the body. As an alternative to lesion surgery, high-frequency stimulation of deep brain structures was first introduced in the 1970s. In 1991, Benabid reported that continuous high-frequency stimulation of the ventral intermediate (VIM) thalamus produced long-term tremor suppression.

DBS was shortly thereafter applied to the surgical targets previously shown by lesion techniques to be most effective for controlling movement disorder: VIM thalamus for tremor, globus pallidus interna (GPi) for PD and dystonia. On the basis of DeLong's research that a lesion of the STN could reverse the signs of experimental parkinsonism in a primate, this nucleus was targeted for stimulation in patients with PD. DBS proved to be safe and efficacious at all three target sites: VIM thalamus, GPi, and STN. The technique was approved by the FDA as a standard therapy for treating essential tremor (1997), PD tremor (1997), advanced PD (2002), and dystonia (2003).

Electrophysiological Effects of DBS

On the basis of observation that DBS replicated the effect of ablative surgery in the thalamus, globus pallidus, and STN, it was initially assumed that DBS worked by suppressing electrical activity in brain structures through neuroinhibition. It seems more likely that DBS exerts a variety of effects on brain tissue, with different actions on white matter tracts and cell bodies. No electrophysiological model currently accounts for all of the effects and consequences of DBS in brain tissue, which can be influenced by lead location, electrode configuration, and firing rate. At a subcellular level, electrical stimulation appears to activate or inhibit nerve terminals by changing electrical thresholds for voltage-dependent channel function and release of neurotransmitter. Effects on individual nerve fibers may include the orthodromic activation of cortical structures, or the antidromic activation of cerebellar fibers and other components of the basal ganglia. Through its local effects at the point of stimulation, DBS can bring about immediate and long-term widespread changes in neuronal network activity and cerebral blood flow. As noted, the current brain electrode is purely stimulating, and has no recording or monitoring function that might enable selective stimulation effects.

DBS Applications in Neurology and Psychiatry

To date, only three neurological applications of DBS are clearly defined: PD, ET, and dystonia. In addition, several successful minor applications of DBS to movement disorders have been reported in small series, including VIM stimulation to suppress the tremor of multiple sclerosis and GPi stimulation for myoclonus-dystonia.

An outgrowth of sustained neurosurgical innovation for the treatment of PD and dystonia, the neurological applications of DBS are supported by many decades of empirical ablative surgery. In addition, DBS exploits the existing knowledge of neuroanatomy and neurophysiology within brain circuitry that is well-defined by radiolabeling experiments and functional imaging.

By contrast, the neuropsychiatric applications of DBS have a different history, and are not supported by a wealth of experience of neurobiological understanding. Unlike movement disorders, psychiatric illness does not appear to result from a focal neuroanatomical or biophysiological deficit, such as the degeneration of nigral dopamine-containing cells in PD.

There are few animal models of psychiatric disease. Many of the cognitive and behavioral aspects of psychiatric disease cannot be studied in animals, and may be unique to humans. The brain substrate of psychiatric disorders, including depression and OCD, is not conceptualized as closely connected neuronal structures but instead comprises vast networks of cognitive, emotional, behavioral, and motoric brain circuitry. The best studied model is one that proposes five separate but entwined cortico-striato-thalamocortical loops that link the basal ganglia, limbic system, and frontal cortex.

Patient selection is not well defined in the application of DBS to psychiatric disease, and randomized long-term follow-up studies are lacking. Moreover, the surgical approach to psychiatric illness is freighted with substantial ethical concerns. As a result, in 2009, DBS treatment of psychiatric illness does not stand on the same firm ground of extended clinical practice, empirical observation, and scientific understanding that characterizes the treatment of tremor and PD.

Neurological Disorders

Parkinson's Disease

DBS of the STN, GPi, and VIM thalamus are used for treating the symptoms of PD. The effects of DBS at these

targets vary, and the outcome of surgery depends critically on patient selection and accurate electrode placement. STN and GPi DBS have the broadest antiparkinsonian effects, and are the targets of choice for patients with advanced disease complicated by wearing off motor fluctuations and dopaminergic dyskinesias.

The antiparkinsonian effect of STN and GPi DBS can generally be predicted by the response to individual doses of levodopa: if a patient experiences a temporary relief of rigidity, bradykinesia, or tremor from levodopa, DBS will yield a similar response. For patients with parkinsonism that does not respond, even temporarily, to individual doses of medication, DBS is unlikely to succeed. In randomized comparison, DBS at both sites produces comparable efficacy, and carries equivalent risk of complication. Both target sites are effective at reducing dyskinesias but GPi stimulation appears to suppress dyskinesias *directly*, whereas the reduction in dyskinesias following STN stimulation is attributed in most cases to reducing medication intake postoperatively.

VIM thalamic stimulation is reserved for the treatment of tremor-predominant PD and patients with medication-refractory tremor. A subset of individuals with PD experiences disabling tremors that do not respond to even suprathreshold doses of levodopa, but their tremors can sometimes be controlled by VIM DBS. The primary limitation of this target site is that it has few effects on bradykinesia or rigidity: for individuals with generalized parkinsonism, VIM stimulation will not be adequate to control all the motor symptoms of their disease.

Long-term studies of DBS are in progress. The largest series provide 5-year follow-up that document long-term reductions of tremor, bradykinesia, and rigidity, with concomitant long-term improvements in quality of life. However, PD is a progressive neurodegenerative disease, and many patients develop long-term complications of speech impairment, postural instability, gait freezing, truncal flexion, and dementia – symptoms that do not respond to DBS.

Since its introduction as a standard therapy for advance PD, a consensus has emerged regarding patient selection (see **Table 1**). Individuals most likely to benefit from DBS are those with a clinically definite diagnosis of idiopathic PD and a robust response to individual doses of levodopa. Ideal candidates for surgery are in good physical and psychological health, have no significant medical complications, do not experience frequent falls or dementia, and have a good social or family support network.

Table 1 Patient selection for DBS in Parkinson's disease

Good candidate for DBS	*Poor candidate for DBS*
Typical PD, with tremor	Atypical parkinsonism
Good response to individual doses of levodopa	Poor response to levodopa
Dyskinesias	Dementia or apathy
Wearing off motor fluctuations	Depression or anxiety
Good general health	Severe medical illness
Strong family and social support network	Poor social support

Individuals who are not suitable candidates for DBS surgery are those with atypical forms of parkinsonism, such as multiple system atrophy (MSA) or progressive supranuclear palsy (PSP), patients who do not respond to levodopa, and patients with dementia, frequent falling due to freezing or retropulsion, psychosis, depression, and a poor network of social or family support.

In the past decade, the literature of DBS treatment for PD has matured from a simple assessment of short-term efficacy and complication rates to deeper issues relating to patient selection, timing of surgery, and new targets. In many series, the best outcomes of DBS were observed in young patients. Nonetheless, there is no strict exclusion on the basis of age if the other features indicating a favorable prognosis are present. Patients over 70 years are more likely to experience early falling, cognitive decline, and medical illnesses, however, and the long-term results of DBS in the older cohort are not likely to last as long.

The potential risks and complications of DBS surgery fall into three categories: (1) intraoperative complications, (2) adverse effects due to electrical stimulation, and (3) hardware-related breakdown and malfunction. The most serious potential complications of DBS include intraoperative hemorrhage or stroke caused by brain mapping or electrode insertion. At major centers with substantial experience using DBS, the risk of these serious complications is estimated at less than 5% per electrode insertion. Additional serious complications include infections of the implanted apparatus, seizure, and postoperative confusion. Individuals with preexisting dementia are considered at risk for postoperative cognitive impairments, most often in the domains visuospatial processing, executive function, verbal fluency, and attention. Infections of the apparatus may begin at any part of the hardware, but most frequently result from skin erosion at the battery implant in the chest. Infection may require removing part of the hardware or explanation of the entire apparatus, in combination with antibiotic therapy.

Complications of stimulation tend to occur during programming, and are reversible. Temporary shocking or tingling sensations, muscular spasms or contractions, speech difficulties, balance problems, unusual cephalic sensations, dizziness, and visual disturbances can all occur during stimulation. Acute, reversible feelings of sadness and despair can be triggered by DBS, as can impulsivity and euphoria, depending on the location of the contacts and the device settings. Both STN and GPi stimulation can induce dyskinesias that are similar to dopaminergic dyskinesias. Finally,

some individuals treated with DBS have become chronically depressed and committed suicide in the months and years following surgery.

Potential problems with DBS hardware include unexpected deactivation, premature battery failure, and fracture of the extension lead, or disruption of its connections sites. In addition, the lifespan of the battery ranges between 3 and 5 years under normal usage, and must therefore be replaced periodically.

The primary limitations of DBS as a treatment for PD are (1) surgical risk, (2) its lack of effect on disease progression, and (3) its relatively restricted application to those individuals with the ideal set of clinical criteria. DBS does not slow or halt disease progression, and it is not effective for some of the most disabling aspects of the disorder, including dementia, postural instability, and gait freezing. Recognizing these limitations, clinical investigators are searching for additional brain targets to help medication-resistant symptoms and signs of PD, such as the zona incerta. Stimulation of one experimental target, the pedunculopontine nucleus (PPN), is currently being investigated for its effect on gait freezing.

Dystonia

Dystonia, a rare disorder of twisting postures, is classified into primary and secondary forms. The prototype primary dystonia is caused by a gene mutation in the *TorsinA* gene, and designated DYT1 dystonia. Primary dystonia is for the most part a nonsymptomatic disorder, although some individuals may manifest behavioral disturbances, such as anxiety or OCD. Affected individuals typically experience the onset of dystonia during childhood.

Secondary forms of dystonia are those disorders caused by a variety of inherited or acquired conditions, including hypoxia, trauma, vascular events, and metabolic and genetic disorders, such as Wilson's disease or pantothenate kinase deficiency (PKAN). Affected individuals with secondary dystonia often experience neurological impairments in multiple systems, manifesting as developmental delay, seizures, spasticity, neuropathy, parkinsonism, and ataxia. With the exception of dopa-responsive dystonia, most dystonic disorders tend to be resistant to medical therapy.

GPi DBS has been effective for primary dystonia, including DYT1 dystonia. The stimulation is required bilaterally, and has been successfully performed even in small children. Pallidal stimulation has also been used in several other dystonic syndromes, including tardive dystonia and various metabolic disorders, such as myoclonic dystonia. The reported short-term results of GPi stimulation in metabolic disorders, such as Lesch-Nyhan disease and PKAN, document symptomatic relief of dystonia, but the underlying neurodegenerative disease remains untreated and is progressive.

Essential Tremor

ET, one of the most common movement disorders, typically presents with action tremors of the hands. The disorder is progressive, often familial, and may result in generalized, disabling tremors that can affect all manual activities. ET can cause tremors of the face, voice, neck, legs, and trunk. Some patients with ET develop an associated rest tremor, and manifest a tremor-predominant form of PD. Other individuals develop a tremor disorder with features of cerebellar disease, including ataxia and dysarthria.

Thalamic DBS is effective for suppressing tremors in patients with even advanced ET. The procedure can be performed unilaterally or bilaterally. Potential adverse effects of VIM stimulation, especially when performed bilaterally, include dysarthria and ataxia.

Psychiatric Disorders

Depression

The neuronal substrate of depression is not clearly defined but involves several cortical, subcortical, and limbic networks. On the basis of functional neuroimaging studies indicating abnormal hyperactivity of the subgenual cingulate gyrus (Brodmann area 25, or Cg25) in sadness and depression, Mayberg proposed stimulation of this brain region as a treatment for severe depression. Her influential case report of bilateral cingulate DBS in six patients with medication-refractory and electroconvulsive therapy (ECT)-resistant depression demonstrated a dramatic and sustained mood improvement in four patients. Antidepressant effects in responders were associated with a marked reduction in local cerebral blood flow, as well as network effects in limbic and cortical sites, measured using positron emission tomography.

The effectiveness of Cg25 in a few individuals with depression supports the concept that activity in a widespread limbic-cortical circuit can be modified therapeutically by electrical stimulation delivered at a single point. The Mayberg report ignited widespread interest in treating depression using DBS, and large-scale clinical trials are underway.

Additional targets for treating depression include the ventral striatum/nucleus accumbens region, associated with reward mechanisms, and the inferior thalamic peduncle. As noted, the treatment of depression using DBS is fraught with ethical complexity, as the ability for a severely depressed individual to provide informed consent may be compromised by his emotional state. Moreover, the rare complication of suicide among individuals who undergo DBS is more likely to occur in severe, medication-resistant depression.

Obsessive–Compulsive Disorder

OCD is a common psychiatric disorder in which patients experience disabling, repetitive, purposeless urges and thoughts that interfere with scholastic, occupational, and social functioning. The disorder can be severely debilitating and refractory to all forms of conventional treatment, including therapy and medication. Like depression, the neurobiological substrate of OCD is considered to involve interconnected cortico-striato-thalamocortical loops that modulate neuronal activity between parts of the orbitofrontal and anterior cingulate cortices, as well the medial, dorsomedial, and anterior thalamic nuclei. Preliminary applications of DBS to OCD have targeted the anterior limb of the internal capsule, with limited benefits overall but some improvement in individual patients.

Tourette Syndrome

TS is a complex neuropsychiatric disorder characterized by the presence of chronic motor and vocal tics that begin in childhood or adolescence. Individuals may also manifest severe behavioral disturbances that include attentional deficits, hyperactivity, OCD, anxiety, impulsivity, disinhibition, aggression, personality disorder, and substance abuse. The treatment of TS must be aimed at the clinical issues causing the most disability and distress, which vary from patient to patient, and may fluctuate over time. One individual may experience severe, uncontrollable tics, while for a different patient, hyperactivity or obsessive–compulsive behaviors may be the most significant clinical features.

The application of DBS to TS is described in a small clinical literature, consisting mainly of case reports and small series that show reductions in tics and OCD symptoms. The brain targets for DBS in Tourette are not well-defined but for tic suppression, the most frequently stimulated brain targets are the internal segment of the globus pallidus (GPi) and the centromedian-parafascicular complex and ventral oral nuclei of the thalamus. No target has been compared to any other, and a global picture of the effects of DBS on all aspects of the disorder has not yet emerged. The application of DBS to TS requires a careful multidisciplinary approach that involves neurology and psychiatry. There is no clear concensus regarding patient selection but those with severe personality disorders or substance abuse addiction are not considered as suitable candidates.

Other Disorders

DBS is used in the treatment of a growing variety of other neurological, psychiatric, and medical disorders that do not overlap with the subspecialty of movement disorders. DBS has long been used to control pain syndromes, and the current stimulating electrode is an outgrowth of spinal stimulation technology for chronic back pain. DBS of the periaqueductal gray (PAG) region and somatosensory thalamus has improved intractable pain in patients suffering from neuropathic pain and painful dysesthesias, back pain, phantom limb pain, central pain syndromes, and intractable cluster headache.

Epilepsy has long been a focus of neurosurgical treatments and technology, including surgical removal of epileptogenic brain tissue, transcranial magnetic stimulation, and vagus nerve stimulation. In addition, direct stimulation of medial temporal lobe structures in temporal lobe epilepsy has been explored as a potential DBS application.

The neurobiology of obesity implicates brain appetite and satiety centers of the lateral hypothalamus and ventromedial hypothalamus, as well as the nucleus accumbens, all potential DBS targets for the treatment of morbid obesity. By exerting direct effects on the brain's reward centers, DBS may offer a theoretical advantage over bariatric surgery and other weight-reducing approaches that do not curb the desire to eat.

Conclusions

The successful application of DBS to neurological and psychiatric disease resulted from the convergence of innovation in several fields during the latter half of the twentieth century: medical engineering, neurosurgery, neuroradiology, and neurophysiology. Improvements in stereotactic surgical technique, reductions in surgical morbidity, advances in brain mapping and neuroimaging, and refinements in medical engineering lead have resulted in successful treatment for PD tremor, rigidity, bradykinesia, and dyskinesias, as well as ET and dystonia. In recent years, medication-resistant depression, OCD, TS, and other conditions have become the focus of DBS therapy. To date, DBS have proven effective at suppressing symptoms but it does not modify disease mechanisms, or prevent underlying progression. It seems likely that new applications and brain target sites will be discovered, even as the technology becomes more sophisticated, effective, and physiologically compatible with brain circuitry.

Dementia with Lewy Bodies

D J Burn, Newcastle University, Newcastle upon Tyne, UK

Glossary

α-synuclein – A presynaptic protein that is abnormally distributed in axons and neuronal cell bodies in DLB and a major component of Lewy bodies.
Cholinesterase inhibitor – A drug which blocks the degradation of acetylcholine to increase cholinergic neurotransmission in the brain. Donepezil and galantamine inhibit acetylcholinesterase while rivastigmine additionally inhibits butyrylcholinesterase. Galantamine is additionally an allosteric modulator of nicotinic receptors.
Lewy body (LB) – An eosinophilic intracytoplasmic inclusion body, characteristic of Parkinson's disease and dementia with LBs.
Lewy body dementia – A 'catch all' term encompassing dementia associated with Parkinson's disease and dementia with Lewy bodies.
Neuroleptic sensitivity – A potentially life-threatening adverse reaction to antipsychotic drugs described in dementia with Lewy bodies and characterized by sedation, immobility, rigidity, postural instability, falls, and increased confusion.

Definition and History

Dementia with Lewy bodies (DLB) is a primary neurodegenerative dementia, characterized by a variable combination of fluctuating cognition (FC), neuropsychiatric disturbance, and Parkinsonism. Autonomic dysfunction and sleep disorders may also be prominent features, with the former contributing to falls. Through a combination of dementia and, frequently, extrapyramidal features, DLB bridges the worlds of movement disorders, dementia, and geriatric psychiatry.

The first case reports of DLB appeared in 1961, when Okazaki published a report of two patients, aged 69 and 70 years, presenting with dementia who died shortly afterward with severe extrapyramidal rigidity. Autopsy showed Lewy body (LB) pathology in the cerebral cortex. With the advent of antiubiquitin immunocytochemical staining methods, the frequency and distribution of cortical LBs could be defined more easily, and the clinico-pathological boundaries of DLB began to emerge. More recently, α-synuclein antibodies have revealed even more extensive pathological changes in DLB and have demonstrated a neurobiological link with other synucleinopathies, Parkinson's disease (PD), and multiple system atrophy.

The nature of functional disability differs between Alzheimer's disease (AD) and DLB, with additional impairments in mobility and self-care in DLB being mainly attributable to extrapyramidal motor symptoms. Consideration of these is important in assessment and management. Furthermore, patients with DLB have a poorer quality of life and consume more resources than patients with AD, thereby, making the impact of this dementia syndrome even more striking. Exquisite, not infrequently fatal, sensitivity to neuroleptic drugs and encouraging trial results for cholinesterase inhibitor drugs highlight the importance of an accurate diagnosis of DLB.

Pathogenesis/Pathophysiology

Etiology and Pathophysiology

The etiology of DLB is unknown. Triplication of the α-synuclein gene can lead to a DLB-like phenotype in some families, presumably through a dose-effect, but this mechanism is not a common cause of DLB. A higher

frequency of mutations in the *GBA* gene, which encodes glucocerebrosidase, has been found in several case-control series of DLB and PD. Such mutations may represent a risk factor for LB disorders, although the relatively small sample sizes for DLB cases to date have yielded widely differing mutation frequencies (3.5–23%). The ε4 allele frequency is elevated in DLB, similar to that found in AD, and the presence of this allele is associated with a more rapid progression of cognitive impairment. There are subtle differences in the ApoE4 allele frequencies between AD and DLB, with a higher ε2 allele frequency and a reduced frequency of the ε4/4 genotype in DLB. Differences in the ApoE4 frequencies may account for some of the differences between the two diseases in terms of clinical presentation and pathology, but it is unlikely that one single genetic determinant accounts for the differences between DLB and AD.

The presynaptic protein α-synuclein is a major component of cortical and subcortical LBs and neurites. α-synuclein antibodies label greater numbers of cortical and hippocampal CA2/3 LNs and intraneuronal inclusions than ubiquitin, including fine granular and diffuse deposits and LBs, indicating that the accumulation of α-synuclein precedes its ubiquitination. The presence of other neuronal proteins within LBs may provide further clues to their formation. Cytoskeletal proteins, such as neurofilaments and microtubules may become trapped within the α-synuclein fibrillary aggregates. The presence of ubiquitin, a cofactor in the ubiquitin–proteasome system of intracellular proteolysis, and catalytic enzymes may constitute part of a cell stress response to eliminate abnormal and damaged proteins from cells. Chaperone proteins, such as parkin (a ubiquitin-protein ligase), torsin A, and heat shock proteins (e.g., HSP70), known to participate in refolding misfolded proteins and/or directing proteins toward degradation have been also localized in brain stem and cortical LBs and neurites. These findings, together with the evidence that the ubiquitin–proteasome pathway is impaired, could indicate that altered protein handling leads to accumulation of damaged α-synuclein within LBs and to neuronal degeneration. Lysosomal-mediated autophagy may provide a 'back-up' mechanism for the overloaded ubiquitin–proteosomal system. Induction of autophagy may represent a potential therapeutic target to assist with clearance of the abnormal protein load.

Pathology

High LB loads and cortical senile plaque counts are found in the majority of patients with DLB. There is no evidence of significant neocortical tau pathology, paired helical filaments, or neurofibrillary tangles in 80–90% of DLB cases. Whether DLB is considered to be a variant of AD depends upon the pathological definition of AD applied. When using the 1996 DLB criteria (which required only the presence of LB for the pathologic diagnosis) and the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) criteria for AD (a definition of AD that is heavily dependent upon plaque density), 77% of cases would fulfill both pathological diagnoses. By contrast, 80–90% of cases would *fail* to fulfill definitions of AD reliant upon numbers of neocortical neurofibrillary tangles. These findings, together with clinical studies showing higher clinical diagnostic accuracy for DLB patients with low-burden AD pathology, have led to a revision of neuropathological criteria for diagnosing DLB. This combines the National Institute on Aging (NIA)/Reagan criteria and the modified Consensus DLB guidelines, based on semiquantitative assessment of α-synuclein pathology. The revised criteria acknowledge that a pathological diagnosis of both diseases should be made on a probabilistic basis, taking into account the extent and the contribution of the different pathological findings (**Table 1**). A diagnosis of DLB therefore becomes less likely as AD-related pathology, staged by NIA/Reagan criteria, increases.

Clinicopathological Correlations

The severity of cognitive impairment in DLB is positively correlated with the density of cortical LBs in frontal and temporal lobes and with the density of LNs in the hippocampal CA2 field, though not with LB density in anterior cingulate cortex. Profound neuronal loss and extensive LB/α-synuclein pathology in the nucleus basalis of Meynert is also likely to contribute to the dementia.

Table 1 Assessment of likelihood of LB and Alzheimer pathologies to be associated with DLB clinical syndrome

	Alzheimer type pathology		
Lewy body pathology	*NIA/Reagan low (BST 0–II)*	*NIA/Reagan intermediate (BST III–IV)*	*NIA/Reagan high (BST V–VI)*
Brain stem predominant	Low	Low	Low
Limbic (transitional)	High	Intermediate	Low
Diffuse neocortical	High	High	Intermediate

Modified from McKeith I, Dickson D, Lowe J et al. (2005) Diagnosis and management of dementia with Lewy bodies. Third report of the DLB Consortium. *Neurology* 65: 1863–1872.
DLB, dementia with Lewy bodies; BST, Braak stage; NIA, National Institute on Aging.

FC shows no correlation with LB density in either neocortical, paralimbic, or nigral areas. In patients with DLB and well-formed visual hallucinations, high LB densities are found in the amygdala and parahippocampus, with early hallucinations relating to higher densities in parahippocampal and inferior temporal cortices. Depression, frequently reported in DLB, appears not to be associated with cortical and subcortical LBs. DLB cases with parkinsonism have neuronal loss in the ventrolateral tier of the substantia nigra similar in severity to that seen in PD, in contrast to only mild or moderate neuronal loss in DLB cases without parkinsonism.

Epidemiology

Between 15% and 20% of all cases of the elderly with dementia reaching autopsy have DLB, making it the second most common cause of degenerative dementia after AD. Prevalence estimates for DLB, depending on case criteria, range from 0% to 5% with regard to the general population, and from 0% to 30.5% of all dementia cases. DLB incidence has been estimated at 0.1% a year for the general population and 3.2% a year for all new dementia cases.

Clinical Features and Diagnostic Criteria

Cognitive Impairment

The characteristic syndrome of DLB may be summarized as a 'dysexecutive–visuoperceptual' dementia. There is, however, heterogeneity of cognitive deficits within the LB dementia spectrum, with 56% and 55% of patients with Parkinson's disease dementia (PDD) and DLB, respectively, having a so-called 'subcortical' cognitive profile compared with only 33% of patients with AD. Conversely, 30% of patients with PDD and 26% of those with DLB are classified as having a 'cortical' profile, according to the Dementia Rating Scale. DLB is characterized by increased variability in performance on cognitive tasks, within and between patients and when compared to age-matched controls and patients with AD. This variability is particularly evident in executive and attentional tasks.

Simple global measures of performance (e.g., the mini-mental state examination, MMSE) are usually equivalent to those of patients with AD of comparable severity, perhaps reflecting the insensitivity of these measures to attentional impairments. Patients with DLB tend to perform better than patients with AD on verbal memory and orientation tasks. Performance on visual tasks, particularly recognition tasks, is consistently more impaired than in AD. These differences are more pronounced in the earlier disease stages.

Rate of progression, as evidenced by change in global cognitive measures such as the MMSE or Cambridge Cognitive Examination (CAMCOG), is equivalent to or faster to that seen in AD and vascular dementia, with a decline of 4–5 MMSE points per year.

Fluctuating Cognition

Fluctuating cognition (FC) occurs in 80% or more of people suffering from DLB, 30–60% of individuals with vascular dementia, and 20% of people with AD. It may present in several ways, depending upon the severity and diurnal pattern. Carers of patients with DLB describe spontaneous, periodic, and transient episodes of fluctuation, affecting functional abilities quite different from the more prolonged, situation-dependent variability seen in AD. In PDD, attention is the single strongest cognitive predictor of activity of daily living status, matching the strength of the effects of motor functions. Evaluation of FC requires careful questioning of patients and carers. Several clinical scales have been validated to quantify FC in DLB such as The Clinician Assessment of Fluctuation Scale and The Mayo Fluctuations Composite Scale. In the latter instrument, informant endorsement of three of four questions (Does the patient experience excessive daytime sleepiness? Do they sleep more than 2 h during the day? Do their words occasionally come out jumbled? Are there times when they stare into space for long periods?) has a positive predictive value of 83% for a diagnosis of DLB versus AD. FC may also be an important determinant of poor prognosis, according to a retrospective analysis of 243 autopsy-confirmed cases of DLB and PDD.

Psychiatric Symptoms

At least 80% of patients with DLB experience neuropsychiatric symptoms, such as visual hallucinations, auditory hallucinations, delusions, delusional misidentification, and depression. Visual hallucinations are the most common symptom, with a mean frequency of 50% (range, 13–80%) in prospective studies, compared with 20–30% of AD patients with AD. The person with DLB typically sees adults, children, or animals of normal size, sometimes with accompanying auditory hallucinations, which are far less frequent in AD. Tactile hallucinations are uncommon, but do occasionally occur. Delusions have a frequency of 55–70% in DLB with common themes being paranoid ideation, such as spousal infidelity, and 'phantom boarder' (believing strangers are living in the house). Major depression occurs in 19% of DLB cases at presentation, with nearly 50% of patients experiencing depressive symptoms at some stage of their illness.

Extrapyramidal Features

Parkinsonian features at presentation in DLB have been reported in 10–78% of cases, while 40–100% of patients display extrapyramidal signs at some stage of their illness. Differences are most likely to represent ascertainment bias and the variable definition of clinical phenomenology. Significant parkinsonism is more frequent in DLB than in AD or vascular dementia. A postural instability–gait difficulty (PIGD) motor phenotype is overrepresented in DLB (and dementia associated with PD) compared with PD patients with no dementia. In one cross-sectional study, 69% of 26 patients with DLB were classified as PIGD phenotype, compared with only 30% of 38 patients with PD. The involvement of brainstem cholinergic nuclei, notably the pedunculopontine nucleus, may be responsible for the expression of this phenotype. Reduced rest tremor, greater symmetry of signs, myoclonic jerks, and a reduced response to levodopa have all been reported in DLB, although these features have not been universally confirmed.

Sleep Disorders

Rapid-eye-movement (REM) behavior disorder (RBD), characterized by loss of normal skeletal muscle atonia during REM sleep with resultant motor activity and 'acting out of dreams,' affects up to 80% of patients with DLB. This is similar to other synucleinopathies such as PD or multiple system atrophy, but contrasts with AD, where RBD is relatively uncommon. Intriguingly, RBD may precede the onset of other features of DLB by several years (mean of 11, range 5–23 years in one series), suggesting pathological involvement of sites remote from those mediating cognitive and motor impairments. Interviewing the bed-partner using the Mayo Sleep Questionnaire has high sensitivity (92%) and specificity (100%) for the diagnosis of RBD, although video polysomnography remains the 'gold standard' diagnostic test.

Autonomic Features

Autonomic dysfunction with cardiovascular instability or orthostatic hypotension may occur in DLB and may contribute to recurrent falls. Over one-third of patients with DLB suffer more than 20 falls per year. The abnormal cardiovascular autonomic function, which may predate the onset of parkinsonism and dementia by several years, or develop with other clinical features. Orthostatic hypotension and carotid sinus hypersensitivity are common in DLB and associated with burden of hyperintense lesions on magnetic resonance imaging (MRI) brain scanning. Patients with DLB have impaired sympathetic and parasympathetic function on autonomic testing, and also reduced cardiac uptake of ^{123}I-*meta*-iodobenzylguanidine (^{123}I-MIBG), a marker of postganglionic myocardial sympathetic innervation (see below).

Urological symptoms and urodynamic abnormalities are common in DLB and result not only from dementia and immobility but also from central and peripheral somato-autonomic dysfunction. Urgency and urge incontinence are more frequent in DLB cases compared with AD, with up to 90% of DLB patients affected. This may relate to greater subcortical pathology in DLB, leading to disinhibition of pontine micturition centers. Other autonomic symptoms include constipation, erectile dysfunction, and dysphagia.

Consensus Criteria for DLB

Consensus clinical diagnostic criteria were first published in 1996 and subsequently updated in 1999 and, most recently, in 2005 (**Table 2**). The central feature of DLB is a dementia syndrome typically characterized by prominent attentional, executive, and visuospatial deficits. A diagnosis of 'probable DLB' requires the presence of two or more of three core clinical features (fluctuating attention and alertness, recurrent visual hallucinations, Parkinsonism), together with the variable presence of suggestive or supportive features. RBD, severe neuroleptic sensitivity and abnormal dopamine (DA) uptake on single photon emission computed tomography (SPECT) or positron emission tomography (PET) imaging comprise 'suggestive features.' They have similar diagnostic weighting to core features but require further validation before being considered sufficient for a diagnosis of probable DLB in the absence of core features. Features considered as supportive of a diagnosis of DLB (listed in **Table 2**) lack specificity because they may also occur in a variety of other disorders.

Differential Diagnosis

Possible differential diagnoses for DLB include AD, vascular dementia, delirium secondary to systemic or pharmacological toxicity, prion disease, or other neurodegenerative syndromes (e.g., progressive supranuclear palsy and progranulin mutations). The most common diagnostic difficulty encountered is in discriminating DLB from AD. Consensus guidelines for the clinical diagnosis of DLB have been shown to have prospective diagnostic accuracy at least as good as those for AD. It is recommended that they are applied as early in the disease course as possible, when their discriminatory ability may be greatest. The inability of moderately cognitively impaired patients with DLB to copy pentagons accurately has been reported to have a sensitivity of 88% and a specificity of 59% compared with AD, suggesting this may be a useful and simple clinic-based screening test. Extrapyramidal signs are highly suggestive, because parkinsonism is uncommon in early AD or vascular

Table 2 Revised criteria for the clinical diagnosis of DLB

1. *Central feature (essential for a diagnosis of possible or probable DLB)*
   Dementia defined as progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention, executive function, and visuospatial ability may be especially prominent
2. *Core features (two core features are sufficient for a diagnosis of probable DLB, one for possible DLB)*
   FC with pronounced variations in attention and alertness
   Recurrent visual hallucinations that are typically well formed and detailed
   Spontaneous features of parkinsonism
3. *Suggestive features (if one or more of these is present in the presence of one or more core features, a diagnosis of probable DLB can be made. In the absence of any core features, one or more suggestive features is sufficient for possible DLB. Probable DLB should not be diagnosed on the basis of suggestive features alone)*
   REM sleep behavior disorder
   Severe neuroleptic sensitivity
   Low dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET. imaging
4. *Supportive features (commonly present but not proven to have diagnostic specificity)*
   Repeated falls and syncope
   Transient, unexplained loss of consciousness
   Severe autonomic dysfunction, e.g., orthostatic hypotension, urinary incontinence
   Hallucinations in other modalities
   Systematized delusions
   Depression
   Relative preservation of medial temporal lobe structures on CT/MRI scan
   Generalized low uptake on SPECT/PET perfusion scan with reduced occipital activity
   Abnormal (low uptake) MIBG myocardial scintigraphy
   Prominent slow wave activity on EEG with temporal lobe transient sharp waves
5. *A diagnosis of DLB is less likely*
   In the presence of cerebrovascular disease evident as focal neurologic signs or on brain imaging
   In the presence of any other physical illness or brain disorder sufficient to account in part or in total for the clinical picture
   If parkinsonism only appears for the first time at a stage of severe dementia
6. *Temporal sequence of symptoms*
   DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism (if it is present). The term Parkinson's disease dementia (PDD) should be used to describe dementia that occurs in the context of well-established Parkinsonian disease. In a practice setting the term that is most appropriate to the clinical situation should be used and generic terms such as LB disease are often helpful. In research studies in which distinction needs to be made between DLB and PDD, the existing 1-year rule between the onset of dementia and parkinsonism DLB continues to be recommended. Adoption of other time periods will simply confound data pooling or comparison between studies. In other research settings that may include clinicopathologic studies and clinical trials, both clinical phenotypes may be considered collectively under categories such as LB disease or α-synucleinopathy

Modified from McKeith I, Dickson D, Lowe J et al. (2005) Diagnosis and management of dementia with Lewy bodies. Third report of the DLB Consortium. *Neurology* 65: 1863–1872.

dementia, while the presence of visual hallucinations and visuospatial/constructional dysfunction may also have good predictive value for the diagnosis of DLB. Care must be taken in attempting to interpret motor signs in the demented patient, however. To the inexperienced clinician, paratonic rigidity ('Gegenhalten') may be mistaken for lead-pipe or cog-wheel rigidity, while ideomotor apraxia can be misinterpreted as bradykinesia. A short-stepped, hesitant 'glue gait' may occur in vascular dementia, although arm swing is usually relatively preserved (in contrast with the LB dementias).

The DLB Consortium recommended that if a patient has had motor symptoms of PD for more than 1 year prior to the diagnosis of dementia, then a diagnosis of PDD is most appropriate. If mental symptoms occur within 12 months of onset of motor disability, then a primary diagnosis of DLB is more appropriate. This approach is also consistent with recent guidelines for the clinical diagnosis of PDD. It should be remembered, however, that attempts to draw absolute boundaries between DLB and PDD, such as the 12-month rule, are only arbitrary conventions designed to help in clinical practice and research. These dementias share similar underlying neurodegenerative pathologies, including abnormal α-synuclein deposition and formation of Lewy neurites/bodies. PDD and DLB are therefore likely to represent a spectrum of LB syndromes. In some situations, for example, pathological studies and clinical trials, it may be more appropriate to consider both PDD and DLB under a common term such as 'LB dementias.'

Diagnostic Investigations

Clinical examination and investigations should establish the presence of cognitive, psychiatric, and neurological signs

and exclude hematological, biochemical, or pharmacological causes. The EEG is usually abnormal in DLB, with a greater degree of background slowing compared with AD, but this is too nonspecific to be of use in an individual case. Transient slow wave (delta) activity can be seen in the temporal lobes of 50% of DLB cases (compared with 18% in AD) and is associated with FC. Other studies have shown no significant EEG differences between DLB and AD. EEG spectrum studies using Fourier analysis have suggested variable changes in power spectra and coherence, but these findings require further confirmation.

Analysis of cerebrospinal fluid (CSF) proteins (total tau, phosphorylated tau, amyloid) is currently confined to research studies and does not add to diagnostic accuracy in the individual patient. Levels of β-amyloid 1–40 or 1–42 do not distinguish DLB from AD, although recent studies suggest that other β-amyloid peptides (e.g., the ratio of beta 1–42 to beta 1–38) may have greater discriminatory value. An oxidized α-helical form of β-amyloid, thought to be formed as a result of interaction between β-amyloid peptides and α-synuclein, may be significantly increased in DLB. CSF neurofilament proteins and serpins do not differentiate DLB from AD.

Imaging

Structural neuroimaging

The use of computed tomography (CT) is normally restricted to the exclusion of other significant comorbidities such as chronic subdural hematoma or cerebrovascular disease.

On MRI of the brain, the main structural imaging change noted in DLB is relative preservation of the hippocampus and medial temporal lobe compared to the reduction seen in AD. This may at least partly account for the relative preservation of mnemonic function in DLB. Although hippocampal volume is reduced by only 15% compared to controls, and considerably less than the 40% reduction seen in AD, these differences are based upon group studies and, overall, have low diagnostic sensitivity (40%). Other MRI changes reported for DLB include atrophy of the putamen and basal forebrain, with relative preservation of cortical grey matter compared to patients with AD. No consistent pattern has emerged from studying the rate of volume loss over time using serial MRI. White matter lesions are increased in DLB, as in AD although the effects on cognitive function have not yet been determined. In summary, structural MRI can highlight group differences in DLB compared with AD, but these changes lack sufficient sensitivity to be diagnostically useful in an individual patient.

Functional neuroimaging

PET studies of glucose metabolism and SPECT investigations using blood flow markers such as Tc-HMPAO demonstrate many similarities to the patterns seen in AD, limiting the diagnostic value of these investigations. Biparietal hypoperfusion in DLB is more extensive than in patients with AD, matched for age and dementia severity, particularly in Brodmann area 7, an area that mediates important aspects of visuospatial function. Occipital hypometabolism on PET and hypoperfusion on PET and SPECT are strongly associated with DLB and localize to primary visual cortex as well as visual association areas (Brodmann areas 17–19). A sensitivity of 90% and specificity of 80% has been reported for occipital hypometabolism in separating DLB from AD, although only 11 DLB cases were examined in the study that led to this conclusion. In a larger SPECT study, occipital hypoperfusion had reasonable specificity (86%) in distinguishing DLB from AD and controls, although sensitivity was suboptimal at 64%.

Labeling of muscarinic acetylcholine receptors using ^{123}I-iodo-quinuclidinyl-benzilate (QNB) shows variably increased binding in the LB dementias, but the diagnostic value of this finding is uncertain and the ligand is not currently widely available.

A key neurochemical finding in DLB is the loss of dopamine transporter (DAT) in the caudate and putamen, reflecting the loss of nigrostriatal dopaminergic afferent projections. Several SPECT and PET ligands are now available to permit in vivo imaging of the DAT density. Changes may be quantified by visual inspection, semi-quantitative or automated quantitative techniques. A large, multicenter phase III trial of (123)I-2β-carbomethoxy-3β-(4-iodophenyl)-*N*-(3-fluoropropyl)nortropane (FP-CIT) SPECT compared DLB and non-DLB dementia (predominantly AD). Abnormal scans had a sensitivity of 77.7% for detecting clinically probable DLB, with a specificity of 90.4% for excluding non-DLB dementia and an overall diagnostic accuracy of 85.7%. Because of the robust nature of this and several other smaller studies, abnormal DAT activity in the basal ganglia on FP-CIT SPECT scanning has now been incorporated into the Consensus Criteria for DLB as a suggestive feature.

FP-CIT SPECT binding may be more evenly reduced across the striatum in DLB, compared with PD, due to greater loss in the caudate head, while there is also a relative lack of asymmetry in DLB cases. Reduced DA D_2 receptor density in basal ganglia using ^{123}I-iodobenzamide has been reported in DLB but use of this ligand cannot be recommended for diagnostic purposes.

^{11}C Pittsburgh Compound B (PIB) PET has recently been used to study in vivo β-amyloid burden in DLB and other degenerative dementias. In general, cortical PIB binding appears to be markedly elevated in AD, regardless of disease severity. In DLB, PIB binding may be generally lower than in AD and more variable. Areas of significant tracer increase in DLB have been reported to be cortical

association areas, cingulate, and striatum. Interestingly, cortical PIB binding in PDD may not be increased compared with normal age-matched controls.

Cardiac imaging

As described above, autonomic dysfunction is common in DLB. Cardiac scintigraphy, using ^{123}I-MIBG, permits some quantification of postganglionic sympathetic innervation. The use of ^{123}I-MIBG scintigraphy has demonstrated in three studies that a reduction in cardiac uptake has high sensitivity and specificity for a diagnosis of DLB compared to AD, although larger multicentre studies are required to confirm the utility of this finding. Furthermore, several common, comorbid problems encountered in the elderly patient may confound interpretation of ^{123}I-MIBG scans include diabetes and ischemic heart disease.

Management

General Considerations

Establishing an accurate and timely diagnosis is fundamental to planning management and treatment interventions in DLB. Identifying and evaluating the significance of key symptoms is a useful approach to take, while a problem list of cognitive, psychiatric, and motor disabilities should be established, in addition to the usual assessments of function, risk, and carer burden.

The importance of educating patients and carers about the nature of the symptoms of DLB cannot be overemphasised. A range of 'nonpharmacological' strategies may be effective, several of which may be delivered by the carer after appropriate training. Strategies for cognitive symptoms include orientation and memory prompts and attentional cues. For psychiatric symptoms, options include explanation, education, reassurance, and targeted behavioral interventions. Motor impairments may benefit from physiotherapy and mobility aids, although there is currently no solid evidence base for these suggestions. Patient and carer support associations may also provide important resources and written material.

Symptomatic Drug Treatments

There are no disease-modifying pharmacological therapies yet available for DLB and only symptomatic treatments are currently available. There is often a therapeutic 'tension' as the treatment of one symptom may potentially exacerbate another, underlining the need to prioritize problems, and only to treat with drugs if absolutely required. For example, patients treated with antipsychotic medication, especially those with high D_2 receptor antagonism, frequently experience an exacerbation of parkinsonian symptoms. More significantly, ~50% of DLB patients who receive neuroleptics experience life-threatening adverse effects, termed neuroleptic sensitivity and characterized by sedation, immobility, rigidity, postural instability, falls, and increased confusion. Deterioration can be rapid, and patients are unable to maintain adequate fluid and food intake. The reaction is associated with a poor outcome and a two- to threefold increase in mortality.

Because of the risk of neuroleptic sensitivity, the use of antipsychotic agents in the DLB patient should not simply be a 'knee-jerk' response. Factors exacerbating psychosis, such as intercurrent infection, should be identified and excluded. The use of anticholinergics to manage urinary symptoms should be avoided if at all possible. If relevant, gradual dose reduction or even withdrawal of antiparkinsonian drugs should be considered, at least on a trial basis. If there is still no improvement, or severity of symptoms necessitates more urgent action, then a cautious trial of an antipsychotic agent may be considered. Even the newer 'atypical' antipsychotics may be associated with neuroleptic sensitivity, especially as the dose is increased. Until more robust clinical trial data are available specific recommendations are limited, but overall, atypical antipsychotics are probably safer than traditional agents in DLB. Low dosing may be more important than the use of any specific drug. Although trial data are lacking, cholinesterase inhibitors may actually prove to have greater antipsychotic potential in DLB than many existing atypical antipsychotic agents. Other novel antipsychotic drugs, which operate via alternative neurochemical systems, such as pimavanserin (ACP-103), are currently being evaluated in the LB dementias.

Functional impairment in DLB is related to the severity of Parkinsonism. 3,4-Dihydroxyphenylalanine (L-dopa) is generally well tolerated in DLB patients and can produce worthwhile benefit, although motor responsiveness is generally less than that observed in PD. Younger DLB cases may be more likely to respond to dopaminergic treatment. The use of L-dopa was not associated with adverse cognitive or neuropsychiatric effects after 3 months of treatment in one study.

Clonazepam may be effective in suppressing the motor features of RBD but does not restore REM-sleep atonia. The drug may be associated with excessive daytime drowsiness, so the lowest possible dose should be used (0.25 mg nocte initially) if treatment of RBD proves to be necessary. Melatonin may also be beneficial in patients who fail to respond to clonazepam or who are unable to tolerate therapeutic doses. Further work is needed to investigate the role of cholinesterase inhibitors as a treatment approach for RBD.

Cholinesterase inhibitors

Open label studies of cholinesterase inhibitors (ChEIs) in DLB patients have shown improvements in both cognitive and noncognitive symptoms with donepezil, rivastigmine,

and galantamine without significant deterioration in motor function. Moreover, treatment efficacy has been demonstrated for up to 96 weeks. Apathy, anxiety, impaired attention, hallucinations, delusions, sleep disturbance, and cognitive test performance are the most frequently cited treatment–responsive symptoms in DLB patients treated with ChEIs. A retrospective comparative analysis of donepezil, rivastigmine, and galantamine suggested that there was no compelling evidence to recommend one ChEI over another. Open label studies have also helped guide clinical practice to date, in the absence of more rigorous data. Thus, in patients with advanced DLB, a further increase from 10 to 15 mg of donepezil daily, while carefully monitoring for adverse events, may be a strategy to treat recurrent neuropsychiatric symptoms. If ChEIs are to be discontinued in DLB, this should be done gradually (over several weeks). The use of ChEIs does not significantly influence the ability of 123I-FP-CIT SPECT to distinguish DLB from AD, despite the fact that there have been reports of these drugs reducing radioligand binding to the DAT receptor in animal studies.

A multicenter, randomized placebo-controlled trial of rivastigmine included 120 patients with a clinical diagnosis of probable DLB and MMSE score of greater than 10. Participants received up to 12 mg day^{-1} of rivastigmine or placebo for 20 weeks. A four-item subscore of the neuropsychiatric inventory (NPI-4, the sum of scores for delusions, hallucinations, apathy and depression) was used as the primary efficacy measure. Approximately twice as many patients taking rivastigmine (63.4%) than placebo (30.0%) showed at least a 30% improvement from baseline on their NPI-4 scores (p=0.001), with psychotic features resolving almost completely in over half of the treated patients. These symptoms rapidly reemerged during a 3-week wash-out period. Nonsignificant improvements were also seen at 20 weeks in MMSE score and clinical global change-plus rating, in favor of the rivastigmine-treated group. Parkinsonian signs did not worsen on treatment, although an emergent tremor was noted in four rivastigmine-treated patients. Predominant adverse effects were cholinergic in nature and the frequency of nausea (37%), vomiting (25%), anorexia (19%), and somnolence (9%) was significantly higher in the rivastigmine-treated patients. Most adverse events were rated as either mild or moderate, however, and only 7 of 59 patients receiving the ChEI withdrew for this reason (not significantly different from the placebo-group).

The presence of visual hallucinations in DLB may predict a good treatment response to rivastigmine, as evidenced by improved attention measures on computerized assessment system. Similar results were obtained from a later double-blind study of rivastigmine in PDD. Donepezil also improves power of attention, continuity of attention and reaction time variability (a measure of FC) in the LB dementias. Approximately 25% of DLB patients will have treatment-resistant visual hallucinations. The presence of delusions may predict this resistance, according to one small observational study.

Neurochemical postmortem studies have shown that DLB cases with visual hallucinations have lower levels of cortical choline acetyltransferase, particularly in temporoparietal regions, compared with DLB patients without visual hallucinations. This may allow greater clinical improvements to occur, with cholinergic replacement therapy having a more marked effect upon a lower neurochemical baseline. Interestingly, cognitive reaction time (calculated by subtracting simple from choice reaction times), does not seem to be improved by rivastigmine. Such variability in the responsiveness of different cognitive parameters to ChEIs may give an insight into their neurochemical basis. Thus, it may be postulated that failure to improve choice reaction time by cholinomimetic therapy is because this is also dopaminergically mediated, perhaps via loss of mesocortical dopaminergic projections.

Finally, there is some evidence that the use of ChEI drugs antemortem may be associated with less cortical β-amyloid deposition. The clinical relevance of this finding is unknown, although a variety of biologically plausible mechanisms may be invoked to account for this observation. The data are certainly not robust enough at present to classify ChEIs as 'disease modifying' however.

Memantine

Open label studies for the noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist memantine have given conflicting results for DLB, with some reporting benefit and others significant worsening that was reversed upon discontinuation of the drug. A randomized-controlled trial of memantine in PDD and DLB has recently completed recruitment and the results of this study will hopefully resolve whether this drug has a place in the management of DLB.

Prognosis

Cognitive test scores seem to decline by a mean of 10% per annum, a rate similar to that of AD. Extrapyramidal features worsen by 10% per year, although the decline is probably more rapid in the earliest disease stages. Neuropsychiatric features, particularly hallucinations, tend to be present from the onset and to persist throughout the disease course.

A prospective study comprising 315 participants confirmed that while DLB increased the risk of mortality compared with AD (hazard ratio 1.88, 95% confidence limits 1.4–2.5), there was no difference in the rate of cognitive decline. This suggests that 'noncognitive' factors play a significant role in determining death in DLB.

Survival time after dementia diagnosis was 7.3 years for DLB versus 8.5 years for AD. Men with DLB had a shorter survival time than women in this study. DLB cases overall had a similar risk of institutionalization and survival in long-term care facilities compared with AD.

A retrospective analysis of 243 autopsy-confirmed cases of DLB and PDD revealed a median survival of 5 years from symptom onset. Male gender was again associated with shortened survival in this analysis. Additionally, older age at onset, FC, and visual hallucinations at onset predicted shorter survival. Associated Alzheimer pathology also shortened survival. These features are presumably the selected out DLB cases from the pooled LB dementia group.

Dementia, Movement Disorders

J G Goldman, Rush University Medical Center, Chicago, IL, USA

Glossary

Atypical parkinsonism – Parkinsonian disorders that share features of Parkinson's disease (e.g., bradykinesia, rigidity, gait/postural impairment) but exhibit other atypical features such as rapid progression, poor response to dopaminergic therapy, early falls, oculomotor abnormalities, early autonomic failure, pyramidal and cerebellar signs, hallucinations, early cognitive impairment, and apraxia; examples include progressive supranuclear palsy, corticobasal degeneration, and multiple system atrophy.

Cortical dementia – Dementia syndromes characterized by greater deficits in memory,

language, and higher cortical functions; examples include Alzheimer's disease, Pick's disease.
Executive function – A descriptive term comprising a broad range of cognitive processes, including planning, initiating, and monitoring behavior. Executive functions include working memory, abstract reasoning, problem solving, and mental flexibility.
REM behavior disorder – A sleep disorder or more specifically, a parasomnia, manifested by enactment of dream behavior and maintenance of muscle tone during REM sleep; may be an early manifestation of neurodegenerative disease.
Subcortical dementia – Dementia syndromes characterized by greater deficits in executive function, attention, and processing speed; related to disruption of frontal–striatal circuitry; examples include Parkinson's disease, Huntington's disease, and progressive supranuclear palsy.
Synucleinopathy – A neurodegenerative disorder with accumulation of α-synuclein in the brain; examples include Parkinson's disease, dementia with Lewy bodies, and multiple system atrophy.
Tauopathy – A neurodegenerative disorder with tau-positive inclusions on neuropathology; often present with dementia and/or parkinsonism; examples include progressive supranuclear palsy, corticobasal degeneration, frontotemporal dementias.
TDP-43 – Or transactive response (TAR)-DNA binding protein 43 – a protein normally expressed in the nucleus; functions as a transcriptional repressor and splicing regulator.
Wisconsin Card Sorting Test – A neuropsychological test of executive functions (i.e., conceptualization, set shifting, and set maintenance); requires subjects to sort cards according to one criterion (color, form, number) that they must figure out based on the examiner's feedback on whether their response is correct or not. After 10 consecutive correct responses, the examiner shifts the rule without telling the subject and the subject must deduce the new rule.

Introduction

Dementia, generally defined as the presence of cognitive impairment in more than one cognitive area that reflects a significant change from previous level of function and significantly interferes with social, occupational, or other daily functioning, can occur as a main feature of several movement disorders. It may precede the onset of motor features in some movement disorders or occur primarily with advanced disease in others. Dementia may be the core feature in some movement disorders, but in others, may be secondary to greater motor dysfunction. Clinically, the cognitive deficits in movement disorders often manifest themselves as impaired executive function, attention, working memory, and processing speed, thereby suggesting frontal–subcortical involvement or a subcortical dementia. However, in other movement disorders, greater episodic memory and cortical deficits can be seen. In this article, movement disorders associated with dementia or cognitive impairment will be reviewed and grouped by the movement disorder phenomenology. Since many of these movement disorders are discussed in greater detail in other articles, this article will focus specifically on the dementia or cognitive features of only selected movement disorders, their related clinical features, pathogenesis, and treatments.

Dementia, Parkinsonism

Parkinson's Disease (PD)

History

In his *Essay on the Shaking Palsy* (1817), James Parkinson wrote that 'the senses and intellects were uninjured.' Of course, since his case series consisted of six patients of whom only three were examined personally, it is not surprising that he concluded that cognition was spared. About 50 years later, observations by the French neurologists Trousseau and Charcot revealed that cognition indeed was affected. Nonmotor features such as cognitive impairment and dementia are now widely recognized in PD as common and potentially disabling complications.

Clinical features

Cognitive dysfunction in PD encompasses a broad spectrum of clinical deficits and severity, affecting both nonmemory and memory domains and ranging from mild impairment to severe dementia. PD cognitive impairment and dementia (PDD) prototypically reflect a subcortical syndrome with greater executive dysfunction, attention and visuospatial deficits, and fewer abnormalities in memory and other cortical domains. The cognitive profile of mild to moderate PDD is generally marked by these features, although there is greater heterogeneity and cortical profiles in some. Memory, particularly declarative memory, is less impaired, and typically aphasia, apraxia, or agnosia are lacking. Recent diagnostic criteria for PDD reflect the greater emphasis on nonmemory cognitive domains and on behavioral features (e.g., apathy, mood disturbances, hallucinations, delusions, and excessive daytime sleepiness) that frequently accompany PD.

Many studies demonstrate that PDD differs from Alzheimer's disease (AD). For example, compared with AD

patients, PDD patients perform worse on measures of executive function, attention, and visuospatial function. However, the PDD patients typically perform better on verbal memory tests and have a better performance on recognition or cued components of verbal tests than on free recall. Greater hallucinations, fluctuations, REM behavior disorder, excessive daytime sleepiness, and depression have been reported in PDD compared with AD. Some PDD patients, however, may exhibit significant memory impairment, global deficits, and a severe dementia more similar to AD; cortical cognitive profiles or global impairment was identified in about 30% of their PDD patients by Janvin et al. In terms of cognitive phenotype, PDD may be more similar to dementia with Lewy Bodies (DLB) than to AD, although whether PDD and DLB represent distinct entities or a spectrum of Lewy body disorders is often debated.

Nondemented PD patients also exhibit cognitive dysfunction, as characterized by a milder phenotype of many cognitive deficits seen in PDD. Patient complaints typically include slowed processing, difficulty with multitasking or planning, decreased attention and concentration, and sometimes, word finding trouble. Nondemented PD patients may have difficulty in tasks that require cognitive sequencing, planning, or set maintenance or shifting to novel stimuli (i.e., executive functions). PD patients generally have more difficulty with internally generated cued behavior and benefit from external cues. Decreased information content of spontaneous speech, impaired comprehension of complex sentences, and impaired verbal fluency may occur and represent frontal lobe functions of concept formation, set shifting, attention, and working memory.

Many risk factors have been proposed for PDD but often with inconsistent results. In longitudinal studies, the most consistent risk factors for PDD have been older age, more severe parkinsonism (particularly postural instability and gait disturbance), and mild cognitive impairment at baseline. Other factors such as older age at disease onset, education, male gender, depression, and hallucinations have not been consistently found. Genetic features such as the APOE4 genotype also yield conflicting results in PDD.

Epidemiology

Prevalence estimates of PDD are about 40%, although epidemiologic studies vary in ascertainment methods, sample populations, and neuropsychological criteria used. Systematic review of PD prevalence studies by Aarsland et al. estimates that PDD accounts for 3–4% of dementia in the population, occurring in about 150–500/100 000 in those over age 65. Longitudinal studies demonstrate the cumulative prevalence of PDD. In a longitudinal, community-based study in Norway by Aarsland et al., PDD was present in 26% at baseline, 52% at 4 years, but in 78.2% at 8 years. Another longitudinal study of PD in Sydney by Hely et al. reported cognitive decline in 84% and dementia, as defined by impairment in short-term memory and two other cortical areas, sufficiently severe to affect occupational and social functioning, in 48% at 15-year follow-up. Subsequently, 20-year data from the Sydney study reported that 83% of the surviving patients were demented; once dementia was diagnosed, the median survival was 54 months. Community-based series reveal incidence rates of PDD ranging from 95.3 to 112.5 per 1000 person-years of observation with an increased relative risk (RR) of almost six times compared with normal, age-matched controls. PDD is associated with increased morbidity and mortality. More recently, studies have focused on the epidemiology of milder cognitive impairment in PD. In a community, population study identifying new cases of parkinsonism in the United Kingdom, Foltynie et al. found that 36% of their PD cases who had cognitive tests were cognitively impaired but not demented. Application of modified Petersen's criteria (1999) for mild cognitive impairment to PD cohorts have revealed about 20–50% with PD mild cognitive impairment.

Pathogenesis/pathophysiology

The neuropathology of PDD remains somewhat controversial but overall, PDD has three main pathological hallmarks that may act individually or collectively: brainstem degeneration, cortical and limbic Lewy bodies, and concomitant AD pathology.

In the six progressive stages of PD pathology described by Braak et al., stage 3 involves the presence of Lewy bodies and Lewy neurites in the substantia nigra, pedunculopontine nucleus, raphe nuclei, and basal forebrain nuclei, perhaps reflecting the earliest pathological correlates of PDD. Increased counts of Lewy bodies and Lewy neurites in the entorhinal, hippocampal, and amygdalar regions of the temporal mesocortex and in prefrontal and high-order sensory association neocortical areas occur in Braak's PD stages 4–6. Mini-mental State Examination (MMSE) scores correlate with these stages; in Braak's cohort of 88 PD patients, at stage 3, 75% had a MMSE score <25. Increased cortical Lewy bodies and Lewy neurites correlate with greater PDD severity and lower MMSE score. Overall, AD pathology was low in the PD cohort but others, including Jellinger and colleagues have found greater AD pathology with concomitant neurofibrillary tangles (NFT) and neuritic plaques in the entorhinal cortex, hippocampus, and cortical regions.

The neurochemistry and neuroanatomy underlying PD cognitive dysfunction likely represents complex interactions among the dopaminergic, cholinergic, serotoninergic, noradrenergic, and glutaminergic systems and frontal–subcortical and cortical regions. Cholinergic deficits may be more pronounced in PDD than AD; there is decreased ChAT activity in the cerebral cortex of PDD and neuronal loss in the nucleus basalis of Meynert. Use of cholinesterase inhibitors in dementia is rooted in the involvement of the cholinergic system in learning, memory, and attention.

Dopaminergic deficits also impact on cognition through frontal–striatal pathways, influencing specific circuits such as the prefrontal cortex, particularly the dorsolateral prefrontal cortex, which plays a critical role in executive function and working memory; the anterior cingulate, which is involved in attention, response initiation, inhibition, and apathy; and the lateral orbitofrontal cortex, which contributes to decision making, reward, impulse control disorders (ICD), and mood.

Treatment

Dopaminergic medications used to treat PD motor symptoms exert variable effects on PD cognition. Studies have reported no change in cognitive slowing or reward-associated learning, whereas others have demonstrated improvement in alertness and arousal, working memory, planning tasks, cognitive flexibility, and apathy. However, some have reported worsening in tests with choice reaction times and increased sleepiness. Anticholinergics worsen cognition and should be avoided in older PD and those with cognitive impairment.

The first report of cholinesterase inhibitors in PDD was published as early as 1996 with a small open label study of tacrine. Subsequently, donepezil, rivastigmine, galantamine, and memantine have been studied; however, sample sizes have been relatively small and treatment durations, often less than 12 weeks. To date, the largest trial has been with rivastigmine, a dual cholinesterase inhibitor, published by Emre et al. in 2004. The trial enrolled 541 mild-moderate PDD patients of whom 410 completed; rivastigmine (or placebo) was given as 3–12 mg day^{-1} over 24 weeks. PDD patients treated with rivastigmine had a statistically significant mean improvement in their Alzheimer's Disease Assessment Scale (ADAS-cog) score (2.1 points), compared with a 0.7 point worsening in those receiving placebo, as well as a statistically significant improvement in the Alzheimer's Disease Cooperative Study-Clinician's Global Impression of Change (ADCS-CGIC) compared with the placebo group. The most frequent adverse events were nausea, emesis, and tremor.

Dementia with Lewy Bodies (DLB)

History

The first report of DLB by Okazaki et al. in 1961 featured two patients with dementia and a marked rigidity who had cortical Lewy bodies. Over the years, advances in immunostaining for ubiquitin and α-synuclein have improved identification of Lewy bodies and Lewy neurites. Consensus criteria for the clinical and pathological diagnosis of DLB were published initially in 1996 by McKeith et al., and most recently revised in 2005. The revised criteria incorporate additional information on clinical features such as REM behavior disorder and neuroleptic sensitivity, functional imaging studies demonstrating reduced striatal dopamine transporter activity, and pathological guidelines for the regional distribution of Lewy bodies and Lewy neurites and evaluation of concomitant AD pathology. The distinction between DLB and PDD remains a subject of debate and research interest. Although DLB and PDD may represent a spectrum of Lewy body disease, the '1-year rule,' as applied in the literature as well as this section, defines DLB as a dementia syndrome with the later development (after at least 1 year) of parkinsonism.

Clinical features

The central feature of DLB is a dementia defined as a progressive cognitive decline that significantly impacts on normal social or occupational function. The clinical cognitive deficits are largely subcortical in nature with predominant executive dysfunction, attentional deficits, and impaired visuospatial abilities. Prominent or persistent memory impairment may not necessarily be present in the early stages but typically occurs with disease progression. Thus, the cognitive profile of DLB encompasses both subcortical and cortical impairments. In contrast to AD, DLB patients perform worse on measures of executive function, verbal fluency, and visual perception and constructional praxis, but better on tests of naming and verbal memory. MMSE score, however, does not reliably discriminate between DLB and AD. As such, the cognitive deficits of DLB are more similar to those found in PDD. The annual rate of cognitive decline in DLB, as measured by global cognitive tests such as the MMSE, may be faster than that of PDD and AD.

Other core features in the DLB diagnostic criteria include fluctuating cognition with pronounced variation in attention and alertness, recurrent visual hallucinations, and spontaneous features of parkinsonism. Furthermore, suggestive features such as REM behavior disorder, severe neuroleptic sensitivity, and low dopamine transporter uptake in the basal ganglia on functional neuroimaging and supportive features such as repeated falls and syncope, severe autonomic dysfunction, hallucinations in other modalities, delusions, depression, and specific neuroimaging and electrophysiologic correlates have been proposed; these neuropsychiatric, motor, and autonomic features are discussed in other articles.

Pathogenesis/pathophysiology

DLB is characterized by widespread Lewy bodies, especially in cortical and limbic regions. The density of cortical and limbic Lewy body pathology positively correlates with the severity of cognitive impairment in DLB. Cholinergic degeneration in the basal forebrain is apparent. Amyloid pathology also may be seen in DLB as detected on neuropathology and with neuroimaging studies using amyloid tracers such as Pittsburgh Compound B, but its contribution to the clinical symptoms is unclear. NFT are present in some DLB, but the low burden of AD pathology in DLB

cases suggests that AD does not fully explain the dementia of DLB. In fact, the likelihood that the observed neuropathology explains the DLB clinical phenotype is directly related to the severity of Lewy-related pathology and inversely related to the severity of concurrent AD-type pathology. At postmortem investigation, distinction between DLB and PDD may be difficult due to the presence of diffuse abnormalities. However, neuronal loss in the substantia nigra and possibly the striatum may be greater in PDD. Other factors that may contribute to the pathogenesis of dementia in DLB include age, genetics (APOE4 genotype, extra copies of the α-synuclein gene), regional distribution of pathology (temporal and frontal lobe), and degree of amyloid burden and AD pathology.

Treatment

Cholinesterase inhibitors have been reported to improve neuropsychiatric symptoms in DLB without significant motor side effects. Initial open-label studies with donepezil, galantamine, and rivastigmine were followed by a large, multicenter, randomized, double-blind, placebo-controlled trial of rivastigmine by McKeith et al. in 2000. This trial included 120 probable DLB patients (92 completed) who received rivastigmine (up to 12 mg day^{-1}) or placebo for 20 weeks, followed by a 3-week rest. Analysis of the 92 observed cases revealed a greater improvement in neuropsychiatric symptoms, as measured by the Neuropsychiatric Inventory-4 (measuring delusions, hallucinations, apathy, and depression), in the rivastigmine group compared with the placebo group. MMSE score and clinical global change score improved in the rivastigmine group, but this did not meet statistical significance. Performance on computerized cognitive assessments was faster and better in the rivastigmine treated group, particularly on attentional tasks. After drug discontinuation, differences between the two groups tended to disappear. Side effects included tremor, nausea, emesis, and somnolence and were greater in the rivastigmine group. Given concern for neuroleptic sensitivity and worsened parkinsonism, it is important to note that rivastigmine did not appear to worsen parkinsonism. To date, memantine use in DLB has been reported only in case reports or small studies, with conflicting results, including worsening of hallucinations and psychosis in some.

Progressive Supranuclear Palsy (PSP)

History

Although descriptions of the clinical features of PSP may have been noted by Charcot and Dutil in the late nineteenth century, the disease was first reported in 1963 by Steele, Richardson, and Olszewski as a new syndrome characterized by parkinsonism, marked vertical gaze paresis, dementia, and axial rigidity. Diagnostic criteria, proposed in the 1990s, for probable PSP require the presence of a gradually progressive disorder with an age of onset of 40 or later, vertical supranuclear ophthalmoparesis, and prominent postural instability with falls in the first year of symptoms (with the presence of the first criterion plus either of the latter two for possible PSP). None of the proposed diagnostic criteria specifies cognitive or behavioral features. Early cognitive impairment with apathy, abstract thought impairment, decreased verbal fluency, imitation behavior, or frontal release signs are recognized as part of probable PSP but perhaps overshadowed by prominent motor and balance disturbances.

Clinical features

The cognitive deficits in PSP typically reflect frontal–striatal pathology and represent a subcortical dementia. Cognitive impairment may be mild but is often present on neuropsychological testing. In the first year, 20–50% of cases may have cognitive slowing, and cognition declines as the disease progresses. The initial presentation of cognitive and behavioral symptoms may result in a diagnosis of dementia other than PSP. The hallmark of cognitive impairment or dementia in PSP is a dysexecutive syndrome with deficits in planning, processing, solving problems, forming concepts, social cognition, and verbal fluency. In addition, there may be perseveration, reflecting set shifting and concept formation problems. PSP patients have greater difficulty with verbal fluency than PD or AD, in some studies. In addition, PSP patients perform poorly on tasks such as the Wisconsin Card Sorting Test, Trail Making Test, and Luria sequence. They may have impaired problem-solving abilities, proverb interpretation, similarities, abstract concepts, and picture arrangement. Similar to other subcortical dementias, declarative memory function is less affected in PSP. Although PSP patients may have impaired immediate and delayed recall on memory tests such as the California Verbal Learning Test, when the encoding of items is controlled by use of a semantic category cue and recall performed with the same semantic cues, the recall performance improves. This suggests that the problem is not one of mesial temporal lobe memory function but rather encoding or retrieval.

In addition, behavioral disturbances may be prominent features in PSP. These behaviors include apathy, disinhibition, depression, anxiety, and perseveration. Apathy may be the initial symptom and unrelated to depression. Frontal lobe reflexes such as grasp, imitative, and utilization behaviors may occur. PSP patients may be unable to stop an automatic motor program once it has been started. Dubois et al. have termed this the 'applause sign,' which can be tested at bedside by asking the patient to clap three times consecutively. PSP patients clap several more times, indicating faulty frontal–striatal pathways and inhibition. The 'applause sign' discriminates PSP from frontotemporal dementia (FTD) and PD, correctly identifying 82% of the PSP versus FTD patients and 75% of the PSP versus PD patients.

Pathogenesis/pathophysiology

The neuropathology of PSP reveals midbrain and mild frontal atrophy, findings that also may be apparent on structural neuroimaging in vivo. Histopathological findings include neuronal loss and gliosis affecting mostly subcortical structures. However, abundant NFT and/or neuropil threads especially in the striatum, pallidum, subthalamic nucleus, basis pontis, dentate nucleus, and prefrontal cortex are the primary hallmark of PSP, and pathological tau in PSP is characterized by the four repeat isoform. The subcortical distribution and ultrastructure of NFT in PSP differ from those found in AD. NFT and tufted astrocytes can be found in premotor and motor cortices as well as dentate granule hippocampal cells, which may correlate with aging and dementia. The prefrontal areas, however, demonstrate relatively little NFT or neuronal loss. It has been suggested that the cognitive dysfunction seen in PSP relates to subcortical tau pathology, disruption of frontal pathways (e.g., dorsolateral prefrontal cortex, anterior cingulate, and orbitofrontal cortex), and basal forebrain cholinergic projecting neurons. Dementia, however, does not clearly correlate with ChAT activity. Striatal pathology may disrupt output from the striatopallidal complex to the frontal lobes, thereby contributing to the cognitive impairment in PSP. Serotonergic and noradrenergic systems seem to be relatively unaffected in PSP.

Treatment

Pharmacological agents studied in PSP cognitive impairment are based on the cholinergic hypothesis and damage to cholinergic striatal, basal forebrain, and brainstem neurons. Two randomized, double-blind, controlled trials with the cholinergic agents physostigmine and RS-86 showed mild or no efficacy in PSP. In a randomized, double-blind, placebo-controlled crossover trial, Litvan et al. studied donepezil 10 mg day^{-1} in 21 PSP patients over 6 weeks with a 1-month washout period. There was no significant difference in global cognitive measures, MMSE, NPI total, the Selective Reminding Test, or attention tests. Although Double Memory Test scores improved while taking donepezil, motor function and activities of daily living/mobility scores worsened, thus suggesting minimal cognitive benefit and risk of motor worsening. Fabbrini et al. found no cognitive benefit in a small, open-label study of donepezil in six PSP patients, but did not report motor worsening. Future treatment strategies in tauopathies may include inhibitors of tau phosphorylation and aggregation, increased tau clearance, antitau directed immunotherapy, or interference of tau splicing but these remain to be seen.

Corticobasal Degeneration

History

In 1967, Rebeiz et al. described the syndrome known as corticobasal degeneration (CBD) in three patients with a progressive asymmetric parkinsonian syndrome with apraxia and pathological features of contralateral frontoparietal atrophy, neuronal loss, and 'ballooned neurons.'

Clinical features

Like PSP, CBD is a 4-repeat tauopathy with features of parkinsonism and cognitive impairment or dementia. Although there may be overlap, CBD tends to present either with progressive asymmetric rigidity and apraxia, sometimes accompanied by dystonia, myoclonus, cortical sensory loss, and alien limb phenomenon or with a predominant dementia syndrome. These two different presentations of CBD explain why sometimes these patients are referred to movement disorders specialists, and other times, to dementia clinics. In the more common, motor variant, dementia is relatively uncommon but develops in about 25%. In these patients, neuropsychological findings typically demonstrate impaired executive function, verbal fluency, praxis, and visuospatial functioning, thereby reflecting the frontal–striatal, frontal, and parietal circuitry. Learning and memory are less affected. Compared with AD patients, CBD patients performed worse on tests of attention, praxis, and motor function; however, they performed better on tests of immediate recall. Depending on the hemispheric lateralization, language may be variably affected in CBD. The apraxias associated with CBD are discussed in other articles.

The dementia syndrome of CBD shares features with fronto-temporal dementia and primary progressive aphasia. In these cases, CBD presents with early and severe cognitive impairment with frontal lobe features (executive dysfunction and poor attention) that progresses to a more generalized dementia with cortical features involving memory, language, and behavioral disorders (e.g., personality changes, inappropriate behavior, repetitive or compulsive activities); this may be accompanied by parkinsonism, corticospinal involvement, and incontinence. The different dementia presentations of CBD depend on the underlying cortical localization. When the lateral dominant frontal lobe is affected, early symptoms may be orofacial apraxia and speech impairment. When the superior temporal gyrus is involved, the presentation resembles primary progressive aphasia. Language difficulty may be seen in CBD, most commonly problems with language expression, including trouble with finding words or naming. In some patients, reading, writing, and calculation abilities may be impaired. Differential diagnosis may include FTD and parkinsonism linked to chromosome 17 (FTDP-17), depending on the family history and possibly, the age of onset.

Pathogenesis/pathophysiology

Neuropathology of CBD reveals asymmetric parietofrontal or frontotemporal cortical atrophy; these findings may be apparent on structural and functional neuroimaging studies during life. Neuronal loss is prominent in those affected

cortical gyri. Microscopically, tau-positive astrocytic plaques and thread-like inclusions are found in gray and white matter, including the superior frontal gyrus, superior parietal gyrus, pre- and postcentral gyri, and striatum. The selective involvement of cortical regions in CBD and subcortical structures correlates with the motor, cognitive, and behavioral signs and symptoms of CBD. Achromatic, ballooned neurons are commonly associated with CBD. Similar to PSP and other tauopathies, tau is thought to be an important factor in the pathogenesis of CBD, with hyperphosphorylation of tau contributing to the disruption of microtubule binding. Clinical and genetic studies demonstrate overlap among PSP, CBD, and FTDP-17.

Treatment

To date, there are no specific treatments for the dementia of CBD. Lessons from treatments studied in the FTDs may be informative. Future studies may explore tau-related interventions.

Parkinsonism–Dementia Complex of Guam

History

The parkinsonism-dementia complex (PDC) of Guam, a term introduced by Hirano et al. in 1961, comprises a family of diseases marked by clinical and pathological features of amyotrophic lateral sclerosis (ALS), parkinsonism, and dementia. In the 1940s, the Chamorro population in Guam, the largest of the Mariana islands in the Western Pacific, was noted to have an increased prevalence of motor neuron disease. Subsequently, another neurodegenerative condition, characterized by the onset of parkinsonism and dementia in middle-age, was identified in the Chamorros, some of whom also had the ALS syndrome themselves or in their family history. The Chamorros called this syndrome *lytico-bodig*: *lytico* for the progressive paralysis that resembled ALS and *bodig* for the parkinsonism, sometimes occurring with dementia. Between 1940 and 1965, this syndrome was a leading cause of death in adult Chamorros. Similar phenotypes to the Guamanian lytico-bodig have been recognized in isolated villages in the Kii peninsula of Japan and in western Papua New Guinea. Over the years, the ALS/PDC syndrome has been a source of great interest for epidemiological, environmental, and genetic studies.

Clinical features

In the ALS/PDC syndrome, there is a range of clinical phenotype from a more prominent motor neuron/ALS presentation to parkinsonism and dementia. In the ALS phenotype, the age of onset is about 46 years with a mean range from 20 to 70 years, with a male predominance; the mean disease duration is 4 years. In those with the parkinsonian-dementia phenotype, the age of onset is in the 50–60s, with a greater male–female ratio compared with the ALS cases. Parkinsonian features include bradykinesia, rigidity, tremor, flexed posture, and shuffling gait; loss of smell, drooling, sweating, and sleep disturbances have been reported. Progressive cognitive dysfunction includes mental slowness, personality changes, memory impairment, and mood disorders, leading to a severe dementia. Pigmentary retinopathy may occur in about 50%. About 45% have a positive family history of ALS or PDC. Over the years, decreased incidence of the ALS/PDC syndrome along with an increase in the onset age has been reported, although this is not well understood. Treatment is symptomatic with rehabilitative therapies and levodopa, if indicated.

Pathogenesis/pathophysiology

Gross pathological features of the ALS/PDC syndrome include prominent cerebral atrophy including the temporal and frontal lobes, hippocampus, and rostral brainstem tegmentum. NFT are seen in the mesial temporal lobe, basal ganglia, and locus ceruleus and demonstrate a different laminar distribution from those in AD, with more tangles in the superficial cortical layers. NFT have been found in nondemented Chamorros at higher frequencies than in Western populations. The tangles contain insoluble tau composed of 3-repeat and 4-repeat, in contrast to the 4-repeat isoform found in PSP. Lewy bodies and plaques have been typically absent. Anterior horn cells demonstrate degeneration and ubiquitin positive inclusions. More recently, Hasegawa et al. and Geser et al. reported TDP-43, transactive response (TAR)-DNA binding protein 43, which has been found in frontotemporal lobar degeneration with ubiquitinated inclusions (FTLD-U) and ALS, in dystrophic neurites, neuronal and glial inclusions in ALS/PDC. In addition, some of the tangles, astrocytes, and oligodendroglial coiled bodies in ALS/PDC have stained positively with antibodies to LRRK-2, a protein associated with genetic forms of PD and microtubule protein kinase function.

Theories related to the ALS/PDC syndrome have included environmental factors such as calcium and/or magnesium deficiency and the cycad hypothesis among others; however, much debate about the pathogenesis of this syndrome remains. The original cycad hypothesis by Whitting (1963) proposed that the disease related to environmental exposure to the toxins from *Cycas micronesica*, a Guamanian false sago palm from which fading flour was made. Possible explanations for the cycad toxicity included consumption of the cycad nut itself, which contains β-Methylamino-L-alanine (BMAA) toxin as well as increased toxin exposure by consumption of the Guamanian flying fox, which has higher concentrations of the BMAA toxin. Decreasing incidence of ALS cases may parallel the decline in the flying fox population in Guam. The cycad theory has remained controversial.

Dementia, Chorea

Huntington's Disease

History

In his paper 'On Chorea' (1872), George Huntington described features of a hereditary chorea in eastern Long Island, New York noted also by his father and grandfather. Besides the hereditary nature, presence of chorea, and adult onset, Huntington described neuropsychiatric disturbances with 'a tendency to insanity and suicide' and wrote that with disease progression 'the mind becomes more or less impaired, in many amounting to insanity.'

Clinical features

Huntington's disease (HD), an autosomal dominant neurodegenerative condition caused by a polyglutamine (CAG) expansion in the *huntingtin* gene on chromosome 4, is characterized by a triad of chorea, dementia, and behavioral disturbances. The cognitive impairment of HD generally represents a subcortical syndrome with frontal–striatal deficits resulting in impaired executive function, processing speed, attention, and concentration. Cognitive inflexibility, difficulty with switching 'sets,' and perseveration may occur. Early cognitive changes are frequently accompanied by behavioral disturbances such as depression, anxiety, irritability, and apathy. The cognitive and psychiatric features may be significant indicators of functional status. Since the average age of onset for HD is 35–40 years and many HD patients may still be working at the time of disease manifestation, impairment in executive functions (e.g., planning, sequencing, organizing, and carrying out multistep or complex tasks) can significantly affect occupational performance. HD patients are impaired on tests of executive function, attention, and mental flexibility such as Symbol Digit Modalities Test, verbal fluency tasks, Trail Making Test Part B, and Stroop Interference Test. As the disease advances, dementia progresses with greater executive dysfunction and memory impairment, although aphasia and agnosia are not typically present. Although HD patients may have mild to moderate memory impairment, the memory deficits relate more to faulty encoding and retrieval processes than to a storage defect. Comparison of AD and HD patients on immediate and delayed recall memory tests highlights this distinction. Similar to other subcortical dementias, HD patients perform better on recognition and with semantic cues than on recall. In contrast to mildly demented AD, HD patients also exhibit impaired motor skill learning and probabilistic learning. Cognitive changes in asymptomatic *HD* gene carriers have been variably reported and await further study.

Pathogenesis/pathophysiology

Neuropathology studies in HD reveal marked caudate and putamen atrophy as well as some cortical atrophy. Medium spiny neurons projecting from the striatum to the external pallidum are preferentially lost. Intraneuronal inclusions, representing huntingtin protein aggregates, are prominent in the striatal and cortical neurons. The exact mechanism by which the CAG repeat expansion causes disease is not fully understood but likely involves a toxic gain of function. The *HD* gene is expressed in neuronal tissues such as the striatum, cortex, substantia nigra, cerebellar Purkinje cells, angular gyrus of the parietal lobe, thalamus, and hypothalamus. The subcortical cognitive deficits in HD are generally thought to reflect disruption of frontal–striatal loops. There is also associated neuronal degeneration in frontal and temporal lobes that may contribute to dementia.

Treatment

Studies of pharmacological agents for HD cognition also have focused on the cholinesterase inhibitors, donepezil, and rivastigmine. In a randomized, double-blind, placebo-controlled study of donepezil 10 mg day^{-1} administered to 30 nondemented HD patients, Cubo et al. did not detect any significant improvement in cognition (as measured by the ADAS), chorea, or quality of life. A small open-label study with donepezil in HD patients with moderate to severe cognitive change was hampered by its open-label design, small sample, and large drop-out rate. De Tommaso et al. evaluated rivastigmine in a small, open-label, randomized controlled study of 21 HD patients (14 treated with rivastigmine), finding a small, although probably not clinically meaningful, but statistically significant improvement in MMSE score of 1 point. Overall, these studies, despite methodological issues, suggest that cholinesterase inhibitors have little effect on cognitive and motor symptoms in HD, although further rigorous study is needed.

Dementia, Tremor

Fragile X-associated Tremor-Ataxia Syndrome

History

In recent years, Fragile X-associated Tremor-Ataxia syndrome (FXTAS) has been identified as a newly recognized neurodegenerative disorder. The story of this entity began with clinical observations of progressive neurological disorders in the grandfathers of children with fragile X mental retardation syndrome. The grandfathers, who were later found to harbor premutations of 55–200 CGG repeats in the fragile X mental retardation 1 (*FMR1*) gene, developed variable presentations of neurological features that included action tremor, gait and limb ataxia, parkinsonism, polyneuropathy, autonomic dysfunction, and dementia, beginning in their 50–60s. Many of these patients were previously diagnosed as having essential tremor (ET), parkinsonism, or multiple system atrophy.

Additional clinical, radiological, pathological, and genetic features in both male and female premutation carriers have been described.

Clinical features

In addition to tremor, ataxia, and parkinsonism, cognitive deficits are common in males with FXTAS. The initial cognitive deficits relate to executive dysfunction, although a generalized dementia with more cortical features may occur, particularly with advanced disease. Cognitive deficits may already be apparent at the time of diagnosis with tremor, ataxia, or parkinsonism. The rate of cognitive decline appears to be variable but awaits further study. Dementia has been reported to develop in at least 50% of cases. Diagnostic criteria for FXTAS recently proposed by Berry-Kravis et al. also incorporate moderate to severe working memory deficits and executive dysfunction as a minor clinical criteria.

Overall, the cognitive deficits described include impairment in attention, executive function, and working memory as well as declarative and procedural learning. Similar to other frontal subcortical dementias, the executive dysfunction of FXTAS manifests itself as impairment in planning, processing, and achieving goal-directed behavior. Grigsby and colleagues have shown in several studies that individuals with FXTAS have lower scores on WAIS-III Performance (nonverbal IQ), measures of executive function, and processing speed, compared with age- and education-matched controls. In addition, males with FXTAS perform worse than controls on MMSE, tests of executive function, working memory, declarative memory, processing speed, temporal sequencing, and visuospatial function; Grigsby et al. noted that language and verbal comprehension were spared. A retrospective, chart review comparing neuropsychological tests of language, phonemic fluency, and digit span in FXTAS patients with dementia matched by age, education, gender, and dementia stage to patients with AD did not reveal any significant differences between the two patient groups. With more advanced disease, greater impairment in declarative memory can be seen. Visuospatial function, constructional praxis, and language appear to be largely unaffected in FXTAS.

Although most of the literature focuses on male FXTAS patients, progressive cognitive decline has been reported in some female FXTAS carriers with impaired executive function, judgment, perseverations, and memory. Since FXTAS is less common in females, true estimates of the prevalence and characteristics of cognitive impairment and dementia in female FXTAS carriers remain to be seen.

Pathogenesis/pathophysiology

Genetic studies have identified that FXTAS is due to a premutation in the *FMR1* gene with CGG repeat lengths of 55–200, whereas Fragile X mental retardation is caused by a full mutation with expansion lengths >200 CGG repeats. In contrast to the Fragile X mental retardation in which the CGG repeat expansions lead to methylation and transcriptional silencing of the *FMR1* gene, levels of FMR1 mRNA are elevated in premutation carriers, thereby, suggesting a possible toxic 'gain of function' mechanism. Neuropathology in mice and humans demonstrates eosinophilic, ubiquitin-staining, intranuclear inclusions in neurons and astrocytes throughout the brain, including frontal regions and hippocampus. The hippocampal and frontal cortex inclusions may underlie some of the cognitive dysfunction, and also possibly mood disturbances, seen in FXTAS.

Treatment

To date, pharmacological treatments for the cognitive dysfunction associated with FXTAS have focused on those agents already approved for AD and PDD, namely cholinesterase inhibitors, but controlled trials are lacking. Anecdotal reports suggest that the cholinesterase inhibitors (e.g., donepezil, galantamine, rivastigmine) and the NMDA antagonist, memantine, may be helpful, although rigorous trials are lacking. In a questionnaire study of different medications used by FXTAS patients, Hall et al. reported that 2/6 patients on venlafaxine and 3/9 patients on cholinesterase inhibitors reported 'slowing of cognitive decline.' Since increased tremor has been reported with cholinesterase inhibitor use, including in the PDD studies, this side effect should be monitored. In addition, medications that may be used to treat tremor, parkinsonism, and ataxia (e.g., benzodiazepines, primidone, amantadine, and dopaminergic agents) can cause sedation and confusion, particularly in the elderly and those with baseline cognitive impairment. As a result, these agents should be started with low doses and increased gradually, while monitoring for side effects.

Essential Tremor

Clinical features

Although the hallmark of ET is an action tremor, recent studies suggest a more heterogeneous clinical and pathological phenotype of ET. Reported nonmotor features have included executive dysfunction and memory impairment similar to AD. Population-based studies have examined the association between ET and dementia. In a Spanish population study, Benito-León et al. sought to determine whether ET is associated with prevalent dementia. The authors identified all persons with dementia and ET in central Spain (as part of the Neurological Disorders in Central Spain Study), finding 31 of 273 ET cases (11.4%) to have dementia as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn (DSM-IV) compared to 204 of 3382 non-ET controls (6.0%). Adjusting for age, stroke, and education, the ET cases with tremor onset after age 65 years were 70% more likely to be demented than

controls (OR = 1.70, 95% CI = 1.04–2.76). Another study by the same group assessed the risk of incident dementia in ET, following 3891 nondemented ET cases and controls prospectively (mean duration of follow up, 3.2 years). Based on DSM-IV criteria, 16 or 206 ET cases (7.8%) developed incident dementia compared to 145 of 3685 controls (3.9%) (adjusted RR 1.66, 95% CI = 0.99–2.80). ET cases with tremor onset after age 65 years were twice as likely to develop dementia.

Pathogenesis/pathophysiology

Furthermore, postmortem studies of ET patients demonstrate mixed pathologies. A subset of ET cases have demonstrated brainstem Lewy bodies (including the locus ceruleus). Other ET cases exhibit cerebellar changes with Purkinje cell loss, increased torpedoes, and Bergmann glia. In a series of 33 postmortem ET cases, higher CERAD plaque scores were uncommon and none of the cases or controls met NIA-Reagan pathological criteria for AD; however, further examination of the pathology and cognitive status is needed. The findings of dementia in ET also appear to be distinct from the Fragile X Tremor-Ataxia syndrome with FMR1 premutations, which can manifest itself as the middle-age onset of a combination of tremor, parkinsonism, ataxia, and dementia.

Dementia, Ataxia

Dementia may accompany several different ataxia syndromes, including FXTAS (discussed under section 'Dementia, Tremor'), spinocerebellar ataxia type 17 (SCA17), dentatorubral-pallidoluysian atrophy (DRPLA), and Creutzfeldt–Jacob disease (discussed in other Encyclopedia articles), among others. Although cognitive impairment can be evident in other ataxias such as the autosomal dominant spinocerebellar ataxias type 1, 2, 3, 6, or 21, this section highlights SCA17 and DRPLA as ataxias associated with prominent dementia syndromes. Clinically, cognitive dysfunction in the cerebellar disorders typically resembles a dysexecutive syndrome and may be accompanied by affective symptoms; as such, it has been termed a 'cerebellar cognitive affective syndrome.' The exact mechanism of cognitive dysfunction in cerebellar syndromes is not fully elucidated but implicates the cerebrocerebellar, cortico-striatal-thalamocortical, and frontal circuitry.

Spinocerebellar Ataxia Type 17 (SCA17)

Clinical features

SCA17 is an autosomal dominant neurodegenerative disorder characterized by cerebellar gait ataxia and dementia with the development of limb ataxia, bradykinesia, and hyperreflexia over several decades. The age of onset ranges from 19 to 48 years, with a mean onset age of 33 years. The cognitive features reported in SCA17 have included slowed thinking, impaired memory, and intellectual decline. Intellectual deterioration has been reported in up to 80%. Cognitive symptoms also frequently occur early in the disease course; presenting symptoms vary with some pedigrees manifesting greater initial dementia, ataxic, DRPLA-like, HD-like, or parkinsonian phenotypes. In 1999, Koide et al. described a 14-year-old Japanese female with progressive ataxia and intellectual deterioration beginning at age 6 years, who was found to have a de novo expansion of the CAG of the TATA-binding protein (*TBP*) gene. Subsequently, deterioration of intellectual function or dementia, sometimes at the onset, was found in other SCA17 pedigrees. Other studies have reported similarities to HD due to the presence of dementia, psychiatric disturbances, and chorea. Besides the cognitive decline, psychiatric symptoms, ranging from depression or personality changes, to aggression, hallucinations, or psychosis, may occur.

Pathogenesis/pathophysiology

SCA17 is caused by expansion of a CAG/CAA repeat coding for a polyglutamine stretch of the *TBP* gene on chromosome 6q27. TBP is a general transcription initiator factor; proposed pathogenetic mechanisms of the CAG repeat expansion include effects on transcriptional initiator factor or promoting toxic functions. Brain MRI reveals marked cerebellar atrophy and mild cortical atrophy. Positron emission tomography (PET) and single photon emission computed tomography (SPECT) imaging studies performed on two unrelated SCA17 patients by Minnerop et al. demonstrated a significantly reduced glucose metabolism in the putamen, a reduced dopamine transporter activity in the basal ganglia, and a pronounced reduction in the putamen. A MRI voxel-based morphometry study by Lasek et al. in 12 patients with SCA17, six of whom had dementia, revealed gray matter atrophy in the cerebellum, basal ganglia, and frontal and temporal lobes, compared with normal controls. The neuropsychological test scores correlated with atrophy of the nucleus accumbens, whereas personality changes correlated with frontal cortex and limbic region atrophy. Neuropathology reveals moderate cerebellar degeneration, neuronal intranuclear inclusions, and mild to moderate changes in the basal ganglia and cortical regions. The widespread cortical and subcortical involvement depicted on imaging and pathological studies likely underscores the cognitive deterioration and other neurological manifestations.

Dentatorubral–Pallidoluysian Atrophy

Clinical features

DRPLA is an autosomal dominant ataxia with phenotypic similarities to the spinocerebellar ataxias, progressive

myoclonic epilepsies, and HD, depending on the age of onset. Clinical features of ataxia and dementia are present regardless of the age of onset. Inverse correlation between age of onset and CAG repeat length and anticipation, particularly with paternal transmission, occur. The age of onset is variable, ranging from childhood to late adulthood but on average, symptoms occur around age 30. Patients with symptom onset at age less than 20 share a phenotype with progressive myoclonic epilepsy, as seizures and myoclonus are present in addition to ataxia and dementia. Those patients with the symptom onset after age 20 are more likely to resemble either spinocerebellar ataxias or HD due to chorea and psychiatric symptoms. Cognitive features are generally similar to a subcortical dementia with psychomotor retardation, executive dysfunction, and mild memory deficits. Psychiatric symptoms include mood disorders, apathy, irritability, childish behavior, and occasionally hallucinations or psychosis. DRPLA is relatively common in Japan with a prevalence rate of 0.2–0.7 per 100 000 and is present in the United States as a variant, Haw River syndrome that has been reported in African-American kindred in North Carolina.

Pathogenesis/pathophysiology

DRPLA is caused by a polyglutamine CAG repeat mapped to chromosome 12p and encoding a cytoplasmic protein, atrophin-1. Mutant DRPLA proteins with polyglutamine expansions likely act by toxin 'gain of function.' Neuropathological examination reveals degeneration in the dentate, red nucleus, subthalamus, and globus pallidus and accumulation of atrophin-1 in neuronal nuclei. Other neuropathological studies have not found neuronal loss in the nucleus basalis of Meynert or clinico-pathological correlation between dementia and this cholinergic structure. Rather, the widespread degeneration in cortical, subcortical, and cerebellar regions may be responsible for dementia.

Conclusion

Dementia and milder cognitive impairment are common features in movement disorders and can have a profound effect on the patient and the caregiver, morbidity, and mortality. Although predominantly characterized as subcortical dementia syndromes with hallmarks of executive dysfunction, attentional difficulties, and visuospatial disturbances, some of the dementias present as more cortical profiles with memory, language, and praxis affected or evolve into a mix of cortical and subcortical deficits as the disease progresses. Unfortunately, at this stage, pharmacological treatments to address symptoms are limited, and disease-modifying treatments are lacking. Providing supportive care for the patient and the caregiver, addressing safety issues and driving, and managing behavioral issues such as psychosis are essential components in the care of the demented patient. Further understanding of the underlying pathophysiology of these dementia/movement disorder syndromes may yield improved treatments.

Dentatorubropallidoluysian Atrophy

C C Diesta, R Ranawaya, and O Suchowersky, University of Calgary, Calgary, AB, Canada

Glossary

Anticipation – The symptoms occur earlier with successive generations.
ATN 1 gene – A gene, located on chromosome 12, that codes for a protein called atrophin 1. A mutation in this gene, due to an expansion in the CAG repeating sequence, results in DRPLA.
Autosomal dominant – A hereditary condition that is passed on from parent to child and does not 'skip' generations. One copy of the abnormal gene is enough to cause the condition.
CAG repeat – A repeating genetic sequence of three nucleotides cytosine, adenosine, and guanine that codes for the amino acid glutamine.
Chorea – An involuntary movement disorder characterized by brief, rapid movements. Can affect the arms, legs, trunk, and face.
Dentatorubropallidoluysian atrophy (DRPLA) – Also known as dentatorubropallidoluysian atrophy. An autosomal dominant neurodegenerative disorder characterized by ataxia, myoclonus, and dementia.
Myoclonus – Involuntary, rapid, lightning type of abnormal movements.

Definition and History

Dentatorubropallidoluysian atrophy (DRPLA) is a rare autosomal dominant neurodegenerative disorder characterized by cerebellar ataxia, myoclonic epilepsy, choreoathetosis, and dementia. The age of onset and clinical presentation depend on the size of the expanded CAG mutation in mutated gene. The condition was originally described in the Japanese population in the 1970s.

Pathology

In autopsies of affected brains in DRPLA, a combined degeneration of the dentatorubral and pallidoluysian systems of the central nervous system is seen. There is a pronounced neuronal loss also in the globus pallidus, striatum, and subthalamic (Luys body), red, and dentate nuclei in addition to Purkinje cell degeneration. Autopsy study of the white matter lesions showed diffuse myelin pallor, axonal preservation, and reactive astrogliosis in the cerebral white matter.

Epidemiology

Most cases originate from Japan, where its prevalence is 0.2–0.7 per 100 000. While rare outside Japan, it has been described in individuals and families of European and other Asian descent. In the United States, families of African descent have been described, the condition being referred to as the Haw River syndrome.

Genetics

DRPLA is an autosomal dominant disorder with high penetrance. The genetic mutation has been characterized as an expansion of a CAG repeat in the ATN1 gene on chromosome 12p13. This gene produces a 190 kDa protein known as Atrophin-1, a nuclear protein with putative nuclear localizing signals. The mutation, due to an expansion of the triplet repeat results in an expanded polyglutamine tract, The expression of the mutant protein encoded by ATN1 results in a frequent formation of peri- and intranuclear aggregates with apoptotic cell death, suggesting that processed mutant proteins are more toxic to cells than full-length proteins (gain of function mutation).

The normal alleles of the DRPLA gene have 8–35 CAG repeats, while abnormal alleles have 49–93 repeats. The greater the number of repeats, the more severe the symptoms and the earlier the onset. The expansion also results in instability in the repeating sequence. Thus, in the transmission of mutant alleles from parent to child, the number of CAG repeats may increase particularly with paternal transmission. This can result in anticipation, meaning that affected offspring develop symptoms with an earlier onset in successive generations. This can be as much as 26–29 years earlier when the gene is inherited from affected fathers and 14–15 years earlier from affected mothers.

Clinical Features and Prognosis

The onset of DRPLA ranges from the first to seventh decade of life, with a mean onset of 30 years. The cardinal symptoms of DRPLA are cerebellar ataxia, myoclonic epilepsy, choreoathetosis, dystonia, and dementia. The clinical features can be diverse even within individuals in the same family. The age of onset and clinical features correlate well with the extent of the genetic abnormality (CAG repeat). For example, infantile DRPLA has been described with extreme expansion of CAG repeat.

Juvenile-onset disease (<20 years of age at onset) typically presents with symptoms consistent with progressive myoclonus epilepsy. Absence and atonic seizures are occasionally observed as well. Seizures and myoclonus are typical of the early adult-onset type (21–40 years of age), while cerebellar ataxia, choreoathetosis, and dementia are major features in the late adult-onset type (onset after the age of 40). Psychosis may sometimes be a presenting feature. Cervical dystonia was the presenting feature in one family. Corneal endothelial degeneration has been described.

In all cases, DRPLA is a slowly progressive condition. Individuals develop ataxia and/or movement disorders such as chorea, increasing difficulties with gait and balance, and cognitive dysfunction. While motor and cognitive problems are invariably present, emotional features, such as affective disorder and psychosis, are more variable. In juvenile-onset patients, epilepsy may become more severe over time and difficult to treat. Patients eventually become bedridden, with death resulting from complications such as infection.

Clinical Vignette

A 35-year-old Japanese-Canadian female presented with complex partial and generalized seizures at 17 years of age. This was followed by changes in personality and mild cognitive impairment associated with depression and behavioral changes. She later developed generalized choreiform movements and ataxia. Her seizures were reasonably controlled with valproic and carbamazepine; risperidone was given for abnormal movements. As she grew older, the choreiform movements decreased but cognitive and behavioral problems worsened. Quetiapine was substituted for respiridone for behavioral symptoms. She developed increasing difficulties with gait and ataxia, and eventually became anarthric and bedridden by 30 years of age. Genetic testing showed 17 repeat expansions on one allele and 65 repeats in another allele in the DRPLA gene.

Review of the family history revealed that her son also had developed problems with epilepsy at 5 years of age. Her father had developed gait ataxia and mild dementia at the age of 50. Both were shown to have expanded alleles consistent with DRPLA on genetic testing.

Differential Diagnosis

The diagnosis of DRPLA is based on characteristic clinical findings, positive family history, and confirmation by the detection of an expansion of a CAG/polyglutamine tract in the ATN1 (DRPLA) gene on genetic testing.

Clinically, DRPLA may be difficult to distinguish from Huntington's disease and the dominantly inherited spinocerebellar ataxias (SCA 2,3,17). A history of ataxia as an early symptom as well as atrophy of the cerebellum and brainstem (particularly pontine tegmentum) on imaging study can be helpful in differentiating Huntington's disease form DRPLA; presentation with chorea and atrophy of the caudate nucleus favors the diagnosis of Huntington's disease. DRPLA shares many clinical and pathological features with the spinoceberellar ataxias. Both ataxia and psychotic symptoms are common in both SCA17 and DRPLA and have been noted in some SCA7 cases. SCA 2 and 3 have clinical features such as chorea, dystonia, cerebellar ataxia, and pyramidal signs. Retinal degeneration is unique in SCA 7. Currently, molecular genetic testing is available to distinguish among these diagnostic considerations.

Wilson's disease or hepatolenticular degeneration is an autosomal recessive disease that can present in early to mid adulthood with symptoms of chorea, dystonia, and cognitive impairment. Elevated 24-h urine copper levels and decreased ceruloplasmin confirms the diagnosis of Wilson's disease. Genetic comfirmation is also available.

For onset of symptoms before the age of 20, other diagnositic considerations should include juvenile onset Parkinson's disease, drug-induced movement disorders, Lafora disease, Unverricht–Lundborg disease, neuronal ceroid-lipofuscinosis, MERRF, sialidosis, Gaucher disease, neuroaxonal dystrophy, pantothenate kinase associated neurodegeneration, familial essential myoclonus, postinfectious (Sydenham) chorea, neuroacanthocystosis, and Vitamin E deficiency.

Management

DRPLA is a slowly progressive disorder, with no known cure and no identified treatments that slow the rate of progression. Treatment is symptomatic and supportive, similar to other disorders such as Huntington's disease and the spinocerebellar ataxias. Seizures are treated with antiepileptic drugs in a standard manner. Psychiatric problems are addressed with appropriate psychotropic medications. If chorea is severe, dopamine-depleting or-blocking agents may be used. Gait and balance problems may benefit from intervention from physiotherapy, and dysphagia should be assessed by a speech pathologist. Eventually, patients will require institutional care. Support and counseling for family members should be considered. As with other similar disorders, care in an interdisciplinary movement disorders clinic would be recommended.

Genetic Counseling

As with all hereditary disorders, the diagnosis of DRPLA has implications on the whole family. When a positive family history is known, genetic counseling is strongly

recommended to inform all the family members of their risks of inheriting the gene. Presymptomatic genetic testing can be offered to those individuals wishing to know whether they have inherited the gene, through Medical Genetics clinics. If there is no known family history, or the diagnosis has not been made in the family previously, a full family history needs to be taken to determine whether any other family members may be affected. Early death of the parent before the onset of symptoms, misdiagnosis, adoption, or late onset of the disease may mask a positive family history. In these circumstances, genetic assessment and counseling are again important to determine whether there may be other family members at risk or affected.

Depression and Parkinsonism

L Marsh, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Glossary

Affective (mood) disorder – One of a group of psychiatric syndromes in which the primary and essential feature involves persistent and pervasive episodic disturbances of mood, either depression or elation, accompanied by emotional, cognitive, behavioral, psychomotor, somatic, vegetative, and functional changes. The most common affective disorders include major depression and bipolar disorder. Some definitions consider anxiety disorders a type of affective disorder. Affective disorders also include mood disorders that are induced by medications or illicit substances or that occur in the context of a general medical condition. Affective disorders may involve single or recurrent episodes of illness.

Antidepressant – Any number of medications used to treat major depressive disorders. Commonly used classes of antidepressants include tricyclic or heterocyclic antidepressants, serotonin reuptake inhibitors, and serotonin–norepinephrine reuptake inhibitors.

Antipsychotic medication – Can be used synonymously with the term *neuroleptic* medication. These include a group of medications used to treat psychotic symptoms in psychiatric disturbances, including mood disorders associated with psychotic features (hallucinations and delusions). Antipsychotic medications are sometimes used to augment the effects of an antidepressant for treatment refractory depressive disorders or as a mood stabilizer in patients with bipolar disorder or

recurrent major depression. Antipsychotics that block dopamine type II receptors are associated with drug-induced parkinsonism.

Bipolar affective disorder – A chronic affective illness characterized by fluctuations between depressive and manic episodes at different times. Clinical subtypes include depressive and hypomanic episodes or episodes of hypomania or mania induced by antidepressant medications.

Dysthymia (dysthymic disorder) – A term for a chronic mild depressive disturbance that is less severe than major depression. Treatment may involve antidepressants and/or psychotherapy.

Major depression – Refers to a unipolar mood disorder involving one or more depressive episodes in which a depressed mood and loss of interest and/or sense of enjoyment are associated with vegetative symptoms (appetite and sleep disturbances), loss of energy, problems with concentration and indecisiveness, and distressing emotional changes such as feeling of guilt, worthlessness, and suicidal ideation.

Minor depression – A term used to refer to a depressive disturbance of at least 2 weeks duration in which there is a presence of two to five of the DSM-IV-TR symptom criteria for major depression, including depressed mood, diminished interest, weight change, sleep disturbance, psychomotor changes, fatigue, feeling worthless, poor concentration, and recurrent thoughts of death.

Mood stabilizers – Any number of medications used to treat bipolar affective disorder or to prevent or limit mood instability in patients with recurrent unipolar depressive disorder. Can be associated with parkinsonism. Medications used as mood stabilizers include lithium, sodium valproate, carbamazepine, oxcarbazepine, and lamotrogine.

Definition and History

This article focuses on the clinical manifestations and management of depression in the context of parkinsonism. When parkinsonism and depression co-occur, the differential diagnosis includes a primary motor disorder, a psychiatric disorder, a medication side effect, or an interaction between these causes. Awareness of these relationships increases the likelihood of recognition, diagnosis, and treatment of both movement and mood disorders.

The term 'depression' refers to a mood state characterized by sad and gloomy emotions, but it is often used synonymously with the term 'depressive disorder.' Whereas frustration, embarrassment, sadness, grief, and demoralization are all potential emotions in an individual, depressive disorders are distinguished by their severity and impact or because they involve episodes of pervasive and persistent mood change accompanied by characteristic nonmood emotional, cognitive, and somatic signs and symptoms.

Parkinsonism refers to a group of motor symptoms and signs, including slowed movements (bradykinesia), resting tremor, and muscular rigidity. About 40% of patients with parkinsonism have idiopathic Parkinson's disease (PD), 20% have drug-induced parkinsonism (DIP), and 14% have Parkinson's-related neurodegenerative disorders (i.e., Parkinson's-plus syndromes). Importantly, DIP occurs in patients with or without preexisting movement disorders and can be mistaken for idiopathic PD. Alternatively, when there is underlying PD, DIP can present as new onset parkinsonism or exacerbate the existing motor signs. Parkinsonism is also associated with psychiatric disorders, age-related changes, environmental toxins, and infectious agents.

James Parkinson, in his 1817 *Essay on the Shaking Palsy*, asserted "the senses and intellect are uninjured" in the condition that eventually was to be called PD. Explicit associations between depression and PD were suggested by Pierre Janet in 1924, though he attributed mood changes to a psychological reaction. However, biological links between parkinsonism and depression were described in early medical writings. Parkinsonism, referred to as psychomotor retardation in the psychiatric literature, is a distinctive feature of depressive disturbances. Its similarities to PD stimulated research on basal ganglia abnormalities and its functional connections in major depression. For example, the slowed gait, limited gestures, hunched posture, expressionless face, and latent, quiet, and monotonous speech of major depression can be indistinguishable from the bradykinesia, hypokinesia, hypophonia, postural abnormalities, and hypomimia of nondepressed PD patients. Cognitive difficulties, fatigue, weight loss, and sleep disturbances also characterize both conditions.

Pathogenesis/Pathophysiology

Multiple lines of evidence suggest that depression in PD is related to the underlying disease, although psychological adjustment explains symptoms in some patients. Several studies show a higher lifetime prevalence of depression, with depression conferring a greater risk for developing PD. When evident before diagnosis of PD, depression occurs, on average, 4–6 years earlier. As early signs of PD can be overlooked when patients present with psychiatric complaints, such findings underscore the importance of initial and serial motor examinations for parkinsonism in adults with depression. After PD is diagnosed, occurrence of depression at all stages of PD

indicates that disability alone is not a cause of depression. Biological studies of PD-depression provide evidence for frontal–subcortical hypometabolism and disproportionate degeneration of ventral tegmental dopamine neurons and monoamine neurotransmitter systems (serotonin and norepinephrine). These findings form a basis for the treatment strategies.

Epidemiology/Risk factors

An estimated 40–50% of PD patients have depressive disturbances, although many are unrecognized or undertreated. About half of those affected have major depression and the remainder experience nonmajor forms of depression (minor depression, dysthymia, and subsyndromal depression, or major depressive episodes as a feature of bipolar disorder). There are no consistent disease-specific risk factors for depressive disturbances, other than PD itself. Greater cognitive impairment, female sex, and a personal history of depression before PD onset are associated with higher risk. Psychological factors may be relevant.

DIP is most commonly caused by dopamine-blocking antipsychotic agents, but all agents used to treat mood disorders are associated with DIP. In the general population, prevalence of DIP in response to antidepressants and other mood disorder treatments is unknown. In a series of PD patients, 4.5% had antidepressant-associated DIP, suggesting it as relatively uncommon. The likelihood of antidepressant-associated DIP is greatest with selective serotonin reuptake inhibitors (SSRIs), followed by imipramine-type medications, and then other antidepressants (e.g., the monoamine oxidase (MAO) inhibitor phenelzine, trazodone, and amoxapine). Valproate, a mood stabilizer, is underrecognized as a cause of DIP. Lithium also causes DIP. Antidepressants, lithium, and antipsychotics, can increase physiological tremor. Typically, improvement of depression is associated with a reduction in PD motor deficits and physical disability. Thus, motor and disability assessments before initiating psychiatric medications provide a baseline for identifying DIP, which may otherwise be difficult to identify in the context of preexisting and fluctuating motor deficits.

Research on psychopathology is limited, but depressive disturbances occur in all the Parkinson's-plus syndromes, that is, progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), multiple system atrophy (MSA), certain frontotemporal dementia (FTD) syndromes, and dementia with Lewy bodies (DLB).

Clinical Features and Diagnostic Criteria

Depressive disorders in PD resemble idiopathic depressive disorders; it is unclear whether PD-depression has a distinct symptom profile. Most commonly, and consistent with Diagnostic and Statistical Manual IV-Text Revision (DSM-IV-TR) criteria, depressive episodes involve a sad, blue or depressed mood, and anhedonia or withdrawal from one's usual interests. Not all patients experience sadness, leading some to contest they are 'not depressed.' Anhedonia, the experience of a reduced sense of pleasure in things or activities that ordinarily have that effect, is a core feature of depressive syndromes and frequently occurs in the absence of sadness. Other important emotions or ideational features include excessive and inappropriate feelings of guilt, feelings of failure, pessimism, beliefs of decreased self-worth, hopelessness, and helplessness. Anxiety and irritability are common, but have less specificity to depressive syndromes. Emotional blunting, or reduced emotional reactivity, is often observed. Several studies note high rates of anxiety and comorbid anxiety disorders.

Suicidal thoughts and behaviors were traditionally regarded as less common in PD relative to the general population. Recent reports refute this. Suicidal ideation or death ideation (the wish to die without intent to kill oneself) was present in up to 30% of patients in one series and associated with presence of major depression or more severe depressive symptoms. An international multicenter retrospective survey showed increased suicide risk associated with subthalamic nucleus deep-brain stimulation (DBS) in patients with PD as compared to the general population. Depression, being unmarried, and a history of impulse control disorders or dopaminergic medication abuse were independently associated with attempted suicides after DBS. Suicide attempts were also associated with younger age, younger age onset of PD, and a previous suicide attempt. Postoperative depression was the single factor associated with completed suicides.

In addition to mood changes, depressive syndromes involve persistent nonaffective changes that distinguish depressive episodes from nonpathological mood states. Among these are five of the nine DSM-IV-TR criteria for a major depressive episode (disturbances in sleep, appetite, energy or fatigue, psychomotor activity, or cognition). Because these symptoms occur in PD, mood disorders can be overlooked when symptoms are attributed to PD only and ideational features of depression are not elicited.

Overlapping clinical features account, in part, for nonrecognition of depression in PD patients or early PD in patients with depression, respectively. Occurrence of depression at all stages of PD suggests that depressive syndromes are not simply emotional reactions to the diagnosis or motor symptoms. Depressive disturbances also present as prodromal syndromes or early manifestations of PD, before its diagnosis is established and motor signs are subtle, if evident at all.

Drug-induced bradykinesia, rigidity, tremor, and hypomimia can be easily regarded as depressive signs. Thus, DIP is often unrecognized, though it is an important cause of imbalance, reduced dexterity, and embarrassment. This is especially the case for the elderly,

women, and individuals with central nervous system pathology or a family history of idiopathic PD. Important distinctions are that DIP is usually bilateral and tremor is less frequent (~35% vs. 80% in PD). Onset of DIP occurs acutely after drug exposure (within hours to days), subacutely (i.e., within weeks), or months to years after ongoing drug exposure. However, DIP usually resolves slowly, over several months, after withdrawal of the offending agent. Symptoms persist in patients with underlying PD.

Differential Diagnosis

Several mood disturbances in PD need to be distinguished from major and nonmajor depressive episodes. About 75% of patients with on–off motor fluctuations experience prominent mood fluctuations, usually depression or anxiety in the 'OFF' period. Hypomania or elation can also occur in the 'ON' state. Anxiety disorders, which often accompany depressive disorders, can be misdiagnosed as depressive disturbances. Emotional indifference and lack of initiative and curiosity define the presence of apathy in PD. Apathy is often a feature of depressive syndromes, but it can occur as an independent disorder. Cognitive impairment, whether mild or consistent with dementia, affects activity levels, and patients may appear apathetic. Up to 50% of patients have pathological crying that occurs as an independent symptom or as a feature of depressive disorders, delirium, or benzodiazepine use.

Depressive disturbances also occur in Parkinson-plus syndromes. In PSP, apathy and disinhibition are the most common psychiatric presentations in addition to depression, emotional lability with pathological laughter or crying (pseudobulbar affect), and irritability. Apathy in PSP is often mistaken for depression, which affects management. In CBD, depression is more common relative to its prevalence in PSP. Apathy, disinhibition, and delusions may co-occur with depression as separate syndromes. Psychiatric manifestations of MSA, a clinically heterogeneous group of Parkinson's-plus syndromes, have received limited attention. Affective disturbances occur, including early in the disease. Some series suggest that depression is less prevalent in MSA relative to PD. Clinically significant depressive symptoms, based on rating scale scores, are seen in up to 40% of patients, and impact quality of life.

FTD, a primary dementia syndrome characterized by behavioral changes and disinhibition, can involve parkinsonian signs. Apathy, disinhibition, euphoria, and behavioral changes are common. Depression and anxiety disorders occur less, although their rates may be higher in the primary progressive aphasia variant of FTD.

DLB, another primary dementia syndrome, is associated most commonly with parkinsonism and hallucinations, but other psychiatric disturbances can be present. Depression may be evident early in the course of DLB, and is now considered a supporting diagnostic criterion for DLB. In case series, prevalence of depression is greater in DLB as compared to Alzheimer's disease, but comparable to that in PD.

Diagnostic Work-Up/Tests

Evaluation of depression begins with a thorough history, diagnostic interview, and physical examination that also ascertains evidence of past psychiatric disturbances, even if untreated, and the role of medications, medication changes, surgery, or medical conditions in the clinical presentation. Even with nondemented patients, it is often useful to involve a caregiver or significant other as a source of collateral history about the patient's symptoms and changes in level of function from baseline. Assessment for current and past suicidal ideation or behavior is critical when depression is suspected. Diagnostic uncertainty, treatment-resistant depression, suicidal ideation, psychosis, and comorbid psychiatric conditions such as panic disorder or mania should prompt psychiatric referral. As a minimum, routine laboratory tests to rule out physical illnesses associated with mood changes include complete blood count (CBC), chemistry panel, thyroid profile, urinalysis, rapid plasma regain (RPR), and erythrocyte sedimentation rate (ESR). In nonpsychiatric practices, depression symptom screening tools can be used to facilitate depression detection and further inquiry into mood changes. No optimal instrument is identified; the Geriatric Depression Scale and Beck Depression Inventory are commonly used.

Management

Treatment for depressive disorders requires targeted and individualized approaches. Nonpharmacologic treatments include illness education, various forms of psychotherapy, rehabilitative strategies involving occupational, physical and speech therapies, and social support. The antiparkinsonian regimen should be optimized, especially if there are motor and mood fluctuations. Medical conditions or delirium should be addressed. Caregiver involvement enhances treatment compliance and provides additional perspectives on the patient's status and treatment response.

Psychiatric medications used to treat depression include the range of antidepressants. Evidence regarding pharmacological treatment of depressive disturbances in PD is still being gathered. Open-label studies of SSRIs suggest they are well-tolerated and efficacious, but methodologically limited placebo-controlled trials have failed to show their greater efficacy in PD. Recent well-designed

but brief (4–8 weeks duration) placebo-controlled trials in PD patients with major depression suggest that tricyclic antidepressants (nortriptyline and desipramine), which inhibit reuptake of serotonin and norepinephrine, were adequately tolerated and more effective than placebo in reducing depressive symptoms; SSRIs had delayed effectiveness (citalopram) or were no more efficacious than placebo (paroxetine). These findings contrast with usual clinical practice, which is to use SSRIs as first-line therapy because of the risk of cardiac conduction delays with tricyclic antidepressants. Trials of dual action nontricyclic antidepressants and SSRIs are underway and studies of other antidepressant classes are needed. For example, mirtazapine, a norepinephrine and serotonin antagonist, has side effects of increased appetite and sedation, and is often used when weight loss and insomnia are prominent symptoms.

Additional treatment strategies for geriatric depression have not been formally studied in PD. Electroconvulsive therapy, which improves parkinsonism, is used for severe depression with vegetative signs or psychosis. Mood stabilizers are used to treat bipolar disorder, augment antidepressants in treatment-refractory cases, or limit relapses in recurrent unipolar depression. Antianxiety medications, namely benzodiazepines, should be limited to short-term use, if at all. Atypical antipsychotics are used for troublesome hallucinations, delusions, or psychotic depression. Quetiapine is usually the first choice, and clozapine is the second option. Other antipsychotics are not well-tolerated in PD.

There are several important side effects and drug interactions with antidepressant treatment. First is the potential for hypertensive crisis or serotonin syndrome when antiparkinsonian monoamine oxidase inhibitors (selegeline and rasagaline) are used with antidepressants. However, clinical experience suggests that this effect is rare, consistent with the selective inhibition of MAO-B, not MAO-A, at antiparkinsonian doses, and that the combination is generally safe. Other common side effects include orthostasis, gastrointestinal upset, sedation, and the range of anticholinergic and benzodiazepine side effects, particularly confusion and increased fall risk. As discussed, parkinsonism can be aggravated by some antidepressants, lithium, sodium valproate, amoxapine, and antipsychotics.

Depression treatment in Parkinson-plus conditions involves similar strategies as for PD. Depression in PSP may be more treatment refractory, possibly because of the predominance of apathy. Antidepressants, though not always effective, and caregiver education are mainstays of treatment in CBD. Reported treatments in MSA include antidepressants and electroconvulsive therapy. Antidepressants are also used in DLB, but SSRIs, also used for behavioral disturbances, have variable effects on depression. Cholinesterase inhibitors may benefit apathy and anxiety in addition to cognition and psychosis.

Prognosis

Depression has a major influence on the clinical course of PD and related disorders. When unrecognized or incompletely treated, depression adversely affects motor deficits, function, cognition, quality of life, caregiver burden, and economic status as well as emotional well-being. In early PD, depression has greater influence than motor deficits as to when antiparkinsonian medications are started. Depression, along with cognitive impairment and psychosis, is more disabling than motor features as PD progresses. Adverse effects of depression are ameliorated by remission of the depressive episode, whether spontaneously or in response to adequate treatment.

Diffusion Tensor Imaging in Parkinson's Disease

G T Stebbins, Rush University Medical Center, Chicago, IL, USA

Glossary

Anisotropic diffusion – Diffusion that is directional in nature. High anisotropy equals high diffusion in one direction. Low anisotropy equal similar diffusion directions in all directions.
Fractional anisotropy – The degree to which diffusion is anisotropic. Fractional anisotropy of 1.0 represents planar diffusion in one direction, while fractional anisotropy of 0.0 represents completely random diffusion.
Mean diffusivity – The degree of diffusion irrespective of direction: translational diffusion.

Definition and History

Diffusion tensor imaging (DTI) is a magnetic resonance imaging (MRI) technique that measures the diffusion of hydrogen. This technique has been applied to studies of cardiac function and orthopedic integrity. However, its most common use is in the study of cerebral tissue integrity. In 1995, Peter Basser published his seminal article describing the principles of DTI. The technique is based on the fact that changes in cerebral integrity induce changes in brain water content. As MRI is based on excitation and relaxation of hydrogen atoms, this altered water content affects the MRI signal. DTI imaging makes it possible to examine alterations in the microstructure of cerebral tissue in vivo; in addition to volumetric changes, it can determine whether the remaining normal appearing cerebral matter is really normal.

Molecular Diffusion and DTI

DTI is based on sensitizing the MR signal to the movement of hydrogen on the order of several microns through the application of diffusion-weighted gradients in at least six noncollinear gradients simultaneously, and measuring the direction and magnitude of hydrogen movement. The application of six noncollinear gradients allows for the examination of diffusion characteristics irrespective of the head position. The three-dimensional geometry of the diffusion in a particular volume element (voxel) can be described by a mathematical construct called a 'tensor' that can be represented by a 3×3 matrix. From the diffusion tensor in each voxel, one can derive three eigenvalues defining the magnitude of the diffusion system and the three associated eigenvectors (λ_1, λ_2, and λ_3) that describe the direction of the diffusion system. The average of the three eigenvalues represents the mean molecular motion (mean diffusivity) that is affected by the barriers to diffusion, but does not provide information on the directionality of the diffusion. Based on the ratio of the three eigenvectors, the intravoxel direction of hydrogen diffusion can be determined. This scalar measure is termed fractional anisotropy (FA) and can range from 0 to 1, with 0 indicating completely random diffusion (isotropic diffusion) and 1 representing completely directional diffusion (anisotropic diffusion). CSF has extremely low FA values, because hydrogen is free to diffuse in any direction. Gray matter has low FA, because cellular structures (e.g., cell membrane, organelles) impede the free diffusion of hydrogen, but these structures do not promote organized, directional diffusion. Highly organized white matter tracts have high FA, because hydrogen diffusion is directionally constrained by the tract's cellular organization. Tractography is a technique that utilized the measures of intervoxel directional diffusion to develop models of cerebral white matter pathways.

The individual eigenvalues generated from the tensor model of diffusion may provide additional information about specific cellular structures. High FA is associated with a large primary eigenvalue (λ_1) and smaller secondary and tertiary eigenvalues (λ_2 and λ_3). Decreases in λ_1 are associated with axonal damage in nonhuman models, while increases in the average of λ_2 and λ_3 are associated with damage to the myelin sheath surrounding

axons. These difference in axial diffusion (λ_1) and radial diffusion (average of λ_2 and λ_3) may be applicable to humans, although no direct testing of this has been completed to date.

Interpretation of DTI in Neural Tissue

When the barriers to free diffusion of hydrogen degenerate, mean diffusivity increases. When that degeneration occurs in structurally organized tissue, such as white matter tracts, mean diffusivity increases and FA decreases because of a loss of the directionality of diffusion. When the damage occurs in white matter, the interpretation of DTI results is fairly clear: decreased FA represents a loss of organized structure. However, when the damage occurs in gray matter, the interpretation of changes in FA is not very straightforward. Damage to gray matter could result in increased gliosis, astrocytic alterations, and other necrotic changes. Such changes could result in a decreased FA because of the increased diffusion direction-potential in the three planes, or in increased FA because of increased structural uniformity.

DTI in Parkinson's Disease

Studies using DTI in Parkinson's disease (PD) have examined both white matter and gray matter, and have investigated motor, cognitive, and affective function as well as differential localization of brainstem nuclei. Most of the DTI studies are with patients, although a few have used nonhuman models of PD. For example, one study used a 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) intoxication model in rodents to study changes is the substantia nigra. This study found that FA in the substantia nigra was significantly lower in the animals treated with MPTP compared with control animals.

Similar findings in humans have recently been reported. In one study, de novo (untreated) patients with PD were imaged using DTI, along with healthy controls. Regions-of-interest were drawn on the rostral, middle, and caudal substantia nigra, and DTI values of FA extracted from these regions. The study reported 100% sensitivity and specificity for differentiating PD from controls.

These studies applied DTI to the examination of the substantia nigra, a gray matter structure. A reason for a decrease of directional diffusion (e.g., decreased FA) in this gray matter structure is not immediately apparent, because there is little organized structure in healthy gray matter to be disrupted by PD. The decrease in FA may represent inclusion of both gray and white matter in the regions of investigation, with an associated decrease in the organization of the included white matter. Indeed, the average FA value in the human studies far exceeded the usual value reported in human gray matter. However, the studies demonstrated this change in FA with exposure of MPTP in the rodent and the presence of PD in humans, and therefore, this remains an active area of research.

DTI examinations of white matter integrity in PD have not presented a coherent picture. Some studies have found a decreased FA in selected regions along the nigral-striatal tract and supplemental motor area and anterior cingulum of the frontal lobes. However, another study found whole brain FA to be increased in patients with PD. The reasons for these conflicting finding are not known, but probably relate to the differences in PD samples, DTI scanning parameters, and methods of assessing FA (region of interest vs whole brain).

DTI in the Study of Nonmotor Symptoms of PD

An interesting application of DTI in patients with PD is the study of nonmotoric symptoms. DTI has been used to examine the relationship between regional diffusion and cognitive function in PD. One study found that parietal FA inversely correlated with performance on the Wisconsin Card Sorting test, a measure of concept formation and cognitive flexibility. The authors postulated that the decreased FA in parietal regions reflected impairments in the frontal/parietal network involved in executive function. A study of Parkinson's disease dementia (PDD) found that decreased FA in the posterior cingulum was associated with impaired cognitive status.

Another nonmotoric symptom in patients with PD is affective status. Diffusion differences between depressed and nondepressed patients with PD were examined in the orbital frontal, prefrontal, occipital, parietal, posterior cingulum, and anterior cingulum. The only region that demonstrated a significant difference was in the anterior cingulum. The authors suggest that the decreased FA in the anterior cingulum may reflect impaired functional status that could be responsible for the increased apathy in the depressed patients.

Conclusion

DTI is an evolving MRI technique that shows promise in the study of PD. Early results suggest that DTI may be used as a proxy measure of substantia nigra integrity, including the nigro-striatal tract. Additionally, decreased in organized diffusion, as measured by FA, may be related to the nonmotoric symptoms of PD, including cognitive dysfunction and depression. Advances in DTI technology, such as increased spatial resolution and advanced analytic methodologies, ought to provide additional applications for the study of PD.

Direct Pathway

J W Bogenpohl and Y Smith, Emory University, Atlanta, GA, USA

Glossary

Basal ganglia – A group of interconnected subcortical nuclei, including the striatum, globus pallidus, subthalamic nucleus, and substantia nigra, that play a role in motor, limbic, and cognitive functions.

Chorea – Term derived from the Greek that means 'a kind of dance.' Involuntary movements characterized by irregular non-repetitive and non-rhythmic contractions of muscles. Primary motor deficit seen in patients with Huntington's disease.

Dopamine – A monoamine neurotransmitter produced mainly in the substantia nigra and ventral tegmental area, known to be important for motor control, reward, and learning; it stimulates two families of receptors: the excitatory D1 family and the inhibitory D2 family.

GABA – Gamma-aminobutyric acid; the main inhibitory neurotransmitter in the central nervous system.

Globus pallidus – Brain structure in the telencephalon part of the basal ganglia circuitry. Comprises an external and an internal segments, respectively called GPe and GPi. Use GABA as neurotransmitter. GPi is one of the two output structures of the basal ganglia to the thalamus and brainstem.

Huntington's disease – Genetic neurodegenerative disorder named after George Huntington who described the disease in 1872. Results from mutation in the gene that encodes for the protein Huntingtin. Characterized by severe loss of neurons in the striatum and the cerebral cortex. The main motor symptoms include uncoordinated involuntary jerky movements of different body parts (chorea) and cognitive deficits. Can be diagnosed by genetic testing.

Parkinson's disease – The second most common neurodegenerative disease, after Alzheimer's disease, characterized by severe, often idiopathic, degeneration of the nigrostriatal dopaminergic projection. Symptoms include bradykinesia, akinesia, muscle rigidity, resting tremor, cognitive impairment, and depression.

Putamen – Large core structure of the basal ganglia located in the telencephalon. With the caudate nucleus, it forms the dorsal striatum. Known as the main entry station for sensorimotor information to the basal ganglia circuitry.
Subthalamic nucleus – Almond-shaped brain nucleus located at the basis of the thalamus considered as a key structure in the basal ganglia circuitry. Neurons use glutamate as transmitter. Lesion of this nucleus alleviates Parkinson's disease motor symptoms.

Definition and History

The direct pathway is one of the two major tracts of the basal ganglia circuitry. It received its name because it consists of a single 'direct' projection from the striatum, known as the main basal ganglia input nucleus, to the internal globus pallidus (GPi) and substantia nigra pars reticulata (SNr), the two basal ganglia output nuclei. This system runs in parallel with the 'indirect pathway,' which conveys information from the striatum to the output nuclei, indirectly via the external globus pallidus (GPe) and the subthalamic nucleus (STN).

Striatal Direct Pathway Neurons

The striatum contains one main type of projection neurons which comprises ~90% of the total striatal neuronal population: the GABAergic medium spiny neurons (MSN). The dendrites of these neurons are covered with spines targeted by glutamatergic afferents from the cerebral cortex and thalamus. Dopaminergic inputs from the substantia nigra pars compacta (SNc), serotonergic afferents from the dorsal raphe, as well as GABAergic and cholinergic inputs from interneurons and MSN axon collaterals represent the bulk of other inputs that impinge upon striatal MSNs. The corticostriatal projection is by far the main source of information to striatal MSNs. This projection is topographically organized such that inputs from sensorimotor cortices terminate in the posterior putamen, projections from associative cortical areas innervate predominantly the caudate nucleus and the anterior putamen, and limbic information is conveyed to the ventral striatum.

Regardless of their location within the striatum, MSNs can be divided equally into two groups based on their distinct chemical phenotype and projection targets. Direct pathway (GPi/SNr-projecting) MSNs preferentially express D1 dopamine receptors and the neuropeptides substance P and dynorphin, whereas indirect pathway (GPe-projecting) MSNs preferentially express D2 dopamine receptors, adenosine A_{2A} receptors, and the neuropeptide enkephalin. Other subtle, though functionally important, differences exist in the physiology and morphology of direct and indirect pathway MSNs. Indirect pathway MSNs seem to be more responsive to cortical inputs than direct pathway MSNs, as shown by their immediate-early gene expression following microstimulation or pharmacological disinhibition of the motor cortex. Another difference is that striatal cholinergic interneurons often receive axon collaterals from direct, but not indirect pathway MSNs.

Segregation of Direct vs. Indirect Pathway Neurons

Despite clear phenotypic and hodologic differences, the degree of segregation between the two groups of striatal MSNs may not be as clear-cut as originally thought. The axonal projections of many direct pathway MSNs that arborize extensively in the GPi and SNr send axon collaterals to the GPe. The reverse also holds, that is, some indirect pathway MSNs that project preferentially to the GPe send axon collaterals to the GPi and SNr. The complete segregation of D1 and D2 dopamine receptors between direct and indirect pathway MSNs remains a subject of debate because a certain percentage of striatal projection neurons express mRNA for both receptor subtypes. Direct and indirect pathway MSNs communicate with each other via local axon collaterals in the striatum; the connections from D2- to D1-containing MSNs being more common than connections from D1- to D2-positive neurons.

Imbalanced Activity of Direct and Indirect Pathways in Parkinson's Disease

The concept of direct and indirect pathways has been the basis for significant development in our understanding of basal ganglia pathophysiology and the revival of surgical therapies for Parkinson's disease in the early 1990s. In patients with PD, there is a progressive degeneration of the dopaminergic projection from the SNc to the striatum. Because of the differential expression of dopamine receptors between direct and indirect pathway neurons, the loss of dopamine has an opposite functional effect on the activity of direct or indirect pathway neurons, creating an imbalance in the basal ganglia circuitry. Direct pathway MSN activity is decreased, while indirect pathway MSN activity is increased following striatal dopamine depletion. Together, these changes result in decreased GABAergic inhibition from the striatum and increased glutamatergic drive from the STN upon basal ganglia output nuclei. These changes increase the GABAergic tone from the GPi/SNr upon thalamocortical neurons and brainstem nuclei, known as the main recipient regions

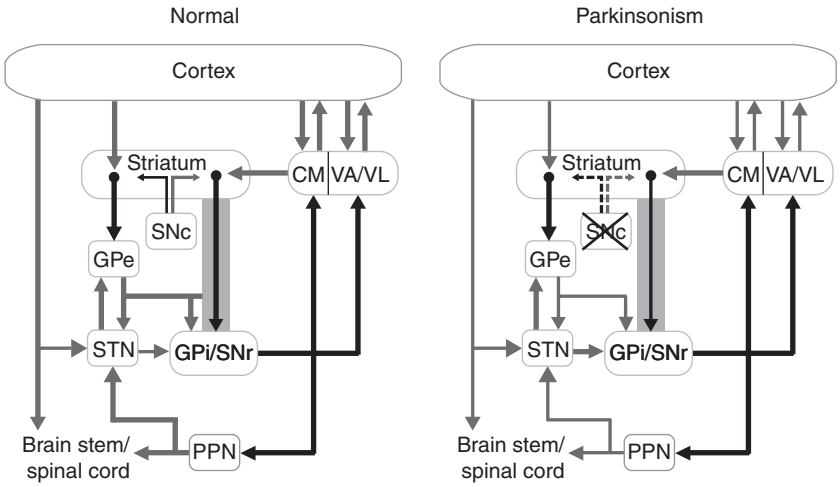

Figure 1 Schematic diagram of the basal ganglia under normal and parkinsonian conditions. Black arrows represent inhibitory projections, and gray arrows represent excitatory projections. In the parkinsonian condition, the weight of the arrows represents the level of neuronal activity relative to the normal state. The inhibitory striatofugal connection that makes up the direct pathway is shaded in gray. CM, centromedian thalamic nucleus; GPe, external globus pallidus; GPi, internal globus pallidus; PPN, pedunculopontine nucleus; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus; VA/VL, ventral anterior/ventral lateral thalamic nuclei. Adapted from Wichmann and DeLong (2003) Pathophysiology of Parkinson's disease: The MPTP primate model of the human disorder. *Annals of the New York Academy of Sciences* 991:199.

of basal ganglia outflow. The resulting decreased thalamocortical activity likely contributes to the cardinal motor symptoms of parkinsonism (**Figure 1**).

Morphological changes in direct and indirect pathway MSNs may also contribute to their pathological activity in parkinsonism. In human parkinsonians and animal models of PD, the depletion of striatal dopamine is accompanied by a significant loss of striatal spines, the main recipient of glutamatergic and dopaminergic inputs in the striatum. Although some authors have suggested that this loss of spines is selective for D2-containing neurons in rodents, these observations have not been confirmed in the nonhuman primate model of parkinsonism or patients with PD.

Direct Pathway Neurons and L-DOPA-induced Dyskinesia

The current pharmacological treatment for PD is based on dopamine replacement therapy using either dopamine precursors like levodopa or direct dopamine receptor agonists. However, such chronic therapy often results in the progressive development of involuntary movements known as dyskinesias. The supersensitivity of the D1 dopamine receptors and the aberrant activation of downstream ERK1/2 MAP kinase in direct pathway MSNs is considered as a potential substrate for the development of L-DOPA-induced dyskinesias. Another, less-studied receptor likely to be involved in the development of dyskinesia is the dopamine D3 receptor, which is co-expressed with D1 in direct pathway MSNs. Although it is expressed at low levels in animal models of parkinsonism, its expression is greatly increased in individuals with levodopa-induced dyskinesias. Not only does this receptor's expression mirror the development of dyskinesias, but D3 antagonists or partial agonists attenuate dyskinesias, further implicating the direct pathway in this neuropathic phenomenon.

Pathology of Direct and Indirect Pathway Neurons in Huntington's Disease

Huntington's disease (HD) is a genetic disorder in which a polyglutamine repeat is expanded in the N-terminal region of the huntingtin protein. This mutation causes protein aggregation and death of striatal MSNs (as well as cortical neurons), resulting in chorea, psychiatric disorders, cognitive decline, and eventually death. As is the case with Lewy bodies in Parkinson's disease; it is not clear whether the protein aggregation in HD actually causes neuronal death, or if it is a protective mechanism to prevent cell death. Although the cellular mechanisms underlying neuronal degeneration in HD are not well understood, different studies suggest a differential susceptibility of direct and indirect pathway MSNs.

Postmortem studies from HD brains showed that direct pathway neurons are less sensitive to degeneration than indirect pathway neurons. This preferential loss of the striatopallidal projection could create a situation opposite to that in PD, that is, an increased activity of the direct pathway relative to a decreased transmission

along the indirect pathway, which could possibly underlie the choreic and unwanted movements seen in HD. These findings corroborate recent data showing that dopamine can enhance activation of the proapoptotic JNK/c-Jun pathway and potentiate huntingtin aggregation in cultured striatal MSNs transfected with pathogenic huntingtin; an effect that can be blocked by D2, but not D1, dopamine receptor antagonists. On the other hand, dopamine and glutamate act synergistically to cause aberrant elevations in intracellular calcium levels, and thus, apoptosis in striatal MSNs; an effect blocked by D1, but not D2, receptor antagonists. Both mechanisms may contribute to striatal cell death in HD.

Dopa-decarboxylase Inhibitors

Paul M Carvey, Rush University Medical Center, Chicago, IL, USA

Glossary

Area under the curve – An indirect but standard measure of how long an active drug remains in serum or plasma after dosing. It is the area underneath a plot of concentration (*y* axis) versus time (*x* axis).

Biotransformation – Pharmacological term used to describe the metabolic and spontaneous conversion of a drug from its administered state, usually to an inactive state.

C_{max} – The highest concentration achieved in serum or plasma.

Formulation – All the components (drugs, inert filler, and active filler that may regulate the rate of release of a drug) that are used to make a pill.

$t_{1/2}$ or half life – The time it takes for one half of the drug to be eliminated from serum or plasma.

The advent of levodopa for the treatment of Parkinson's disease (PD) represented a significant step in the management of neurological disease. Its effect produced miraculous therapeutic results in many patients. Unfortunately, levodopa therapy was fraught with side effects and involved oral delivery of gram quantities of drug, making administration difficult for many PD patients. The primary side effects were nausea, vomiting, and epigastric distress as well as cardiovascular disturbances, including hypertension, orthostatic hypotension, and dysrhythmias (sinus tachycardia and atrial and ventricular extrasystoles). These side effects were primarily a result of peripheral conversion of administered levodopa to dopamine (DA). Because of the prevalence and severity of these side effects, levodopa was titrated up slowly delaying the effective therapeutic efficacy. However, even when therapeutic benefit was realized, gastrointestinal and cardiac side effects were often present, but tolerated.

Udenfriend and colleagues (1966) were the first to demonstrate that α-methyldopahydrazine (an aromatic amino acid decarboxylase (AAAD) inhibitor (AAADI)) increased catecholamine content in the brains of animals following levodopa treatment. The following year, Birkmayer is credited with the first coadministration of benserazide and levodopa to patients demonstrating increased efficacy and reduced side effects. Bartholini et al. is generally credited with the concept that AAADs worked because they predominantly inhibited AAAD in the periphery thereby making levodopa more available to brain. The reduction in peripheral side effects, the ease with which dosage could be escalated, and the enhancement of levodopa potency produced by the peripheral AAADIs led to a rapid adoption of their use in the management of PD, and today, levodopa is not prescribed in the absence of an AAADI.

Carbidopa and Benserazide

The two AAADIs in use today are carbidopa (L-α-hydrazino-α-methyl-β (3,4 dihydroxybenzene) propionic acid; MW 244.25) and benserazide (2′-(2,3,4-Trihydroxybenzyl)-DL-serinohydrazide; MW 293.71; **Figure 1**). Carbidopa was first formulated with levodopa as Sinemet by Merk Sharpe and Dohme, while benserazide with levodopa was called Modopar (Roche). The two AAADIs are structurally somewhat similar, although benserazide used clinically contains both the levo- and dextrorotary form, whereas carbidopa is exclusively levorotary. The utility of these drugs is in their peripheral inhibition of AAAD when combined with levodopa. Both the drugs are potent competitive inhibitors of AAAD in both the periphery and brain. However, carbidopa does not cross the blood brain barrier (BBB) under normal circumstances, whereas benserazide can be detected in brain following high-administered doses. At what dosages benserazide begins to enter brain is unknown. However, recent studies from my laboratory suggest that the BBB may not be intact in PD patients and therefore, even carbidopa may enter brain.

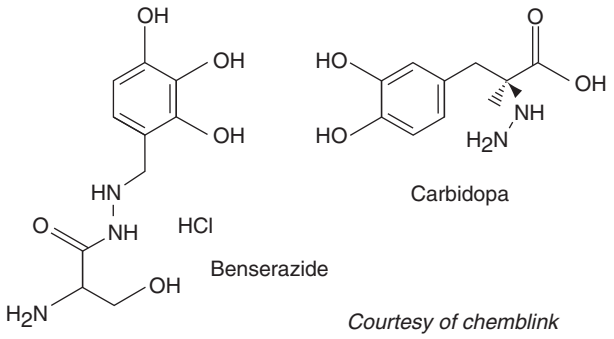

Figure 1 Structures of the two aromatic amino acid decarboxylase inhibitors used clinically.

Distribution of AAAD

Aromatic-L-amino acid decarboxylase (EC 4.1.1.28) is ubiquitously distributed throughout the body and brain where it decarboxylates aromatic amino acids for use in metabolism and protein synthesis. Several aromatic amino acids, including phenylalanine, histidine, tryptophan, and tyrosine, are taken in through the diet and subsequently biotransformed by enzymes, including AAAD, to substances needed by the body. AAAD is essential, although not normally rate limiting, for the conversion of DOPA to dopamine (DA; and also norepinephrine and epinephrine given their common anabolic pathways), 5-hydroxytryptamine (5HTP) to serotonin (5HT), and several trace amines (e.g., octopamine and phenylethylamine) in both the periphery and brain. The activity of AAAD is under transcriptional and posttranscriptional regulation and is upregulated by DA antagonists and downregulated by DA agonists and chronic levodopa. Splice variants exist for AAAD and may explain differential responses by some patients to AAADI treatment. Pyridoxyl-5-phosphate, the active form of pyridoxine (one of the vitamin B6 group), is a cofactor for AAAD.

AAAD is found in the cells lining the GI tract, the liver, pancreas, kidney, heart, and peripheral nerves. It is also found in the endothelial cells of blood vessels and in neurons and astrocytes within the CNS. Since AAAD is present in the GI wall, liver, and endothelial cells, the oral administration of levodopa is subject to a significant first pass effect. The presence of AAAD in endothelial cells that compose the BBB is particularly important, given levodopa's need to enter the brain for its anti-Parkinson's effect. The highest concentrations of AAAD are found in the kidney, followed by the liver and heart.

Tritiated distribution studies reveal that 40–70% of carbidopa and 66–74% of benserazide are absorbed from the gut. Both cross into placenta and breast milk. Both the AAADs undergo spontaneous biotransformation to substituted quinones in the GI tract. Peak plasma levels are generally realized within one hour for both inhibitors, although this is highly variable. Metabolic biotransformation involves side-chain degradation as well as glucuronide conjugation. The half-life for carbidopa is 2–3 h and somewhat less for benserazide (1.5–2.5 h). Approximately 30% of both carbidopa and benserazide are excreted unchanged primarily leaving only metabolites present in the urine after 6 h. Fecal excretion is more prevalent for carbidopa and its

metabolites than benserazide, although both are highly variable. Thirty-six percent of carbidopa is bound to serum proteins.

Efficacy of AAADIs

The coadministration of AAADIs together with levodopa produces greater absorption, reduced first-pass effect, and increased entry into brain. Central efficacy of levodopa is generally increased 4–5-fold in the presence of AAADIs. Although levodopa is absorbed from the gut via the large neutral amino acid facilitative transporter (LAT1), its availability for transport is dependent upon decarboxylation that occurs in the GI tract. By inhibiting AAAD, the AAADIs increase LAT1 substrate availability. Similarly, inhibition of AAAD in liver and the rest of the body increases the amount of levodopa available for transport across the BBB by LAT1 found in endothelial cells in the BBB. As a result, a significantly larger fraction of levodopa is available for entry into the brain in the presence of AAADIs. Since AAADIs at administered doses used clinically do not enter the brain in the presence of an intact BBB, levodopa is transported into brain where it can be decarboxylated to DA by AAAD present in neurons and astrocytes.

The AAADIs competitively inhibit AAAD in a dose-dependent fashion. Prior to the advent of AAADIs, inhibition of AAAD was achieved somewhat by depleting pyridoxine in the patient's diet, although the clinical benefit was always controversial. This approach is not needed if AAADIs are coadministered with levodopa. Both the AAADIs have longer plasma half-lives than levodopa, and as a result, accumulate over the day under the multiple daily dosing regimens generally used clinically. Initial administration of low doses of the combination formulation can result in inadequate AAAD inhibition resulting in peripheral side effects. This problem can be averted by prescribing a higher ratio of AAADI/levodopa in the combination formulation. Carbidopa is available as a monotherapy to supplement decarboxylase inhibition when patients exhibit peripheral side effects following combination therapy.

Toxicology

At dosages used clinically, AAADIs have no observable pharmacological actions in humans. Similarly, acute challenges in animals are extremely safe with no discernable changes in cardiovascular, renal, GI, or CNS function. Moreover, very few alterations are observed acutely even with extremely high doses (greater that 1000 mg/kg). Chronically, at extremely high doses, carbidopa reduces locomotor function slightly and can produce weight gain, while benserazide at chronic high doses was associated with fatty degeneration of the liver and skeletal changes. However, it is important to appreciate that the doses used in these studies were more than 100-fold higher than those used clinically.

Clinical Effects of AAADI on Levodopa

The primary objective for the use of AAADIs in combination with levodopa is to reduce peripheral side effects and increase central efficacy. This has been clearly and repeatedly demonstrated. Introduction of the combination formulation led to a significant reduction in the amounts of levodopa needed to produce anti-Parkinsonian effects (~4–5-fold reduction), providing significant benefit to patients whose swallowing capability was compromised by disease. Animal studies revealed that concomitant AAADI administration led to a ten-fold increase in brain DA, likely reflecting the significant reductions in first-pass effect, reduced biotransformation outside of the portal system, and inhibition of AAAD in the BBB. The reduced peripheral conversion of levodopa to DA in the periphery is also associated with significant reductions in nausea, vomiting, and epigastric distress. However, the addition of an AAADI to the treatment regimen must still be cautiously titrated since nausea and vomiting are still produced, albeit dose escalation can be achieved much more quickly because of the AAADI. Most importantly, AAADIs significantly attenuated the cardiovascular side effects associated with levodopa monotherapy, including tachycardia, hypertension, and arrhythmias. Interestingly, chronic treatment with levodopa monotherapy was well known to produce hypotension following an initial hypertensive phase that lasted for up to an hour. The addition of AAADIs dramatically attenuated the hypertensive effects, but had little effect on hypotension, suggesting that the later was centrally mediated.

When levodopa is combined with carbidopa or benserazide, the optimal ratios for therapeutic benefit (i.e., levodopa/AAADI) are 10:1 and 4:1, respectively. There will always be patients who require AAADI supplementation in which case carbidopa (Lodosyn) can be added to the regimen. Problems with inadequate AAADI are more prevalent early in therapy when lower doses of levodopa are required. Several studies have shown that daily levels of carbidopa greater than 75–160 mg failed to produce further AAAD inhibition (100 mg daily is the general rule of thumb). When only low levels of levodopa are required as part of the therapeutic regimen, the levels of AAADI may not be adequate for effective AAAD inhibition. As the disease progresses, however, the higher administered doses of levodopa are associated with larger daily dosages of carbidopa, and because of its longer half-life, the 100 mg daily target is more readily achieved. However, this is not necessarily true of benserazide, because it crosses the BBB as plasma levels get higher. The level at which this occurs

has not been firmly established, but doses as high as 400 mg daily have been used without untoward CNS effects.

Carbidopa's effect on the peripheral kinetics of levodopa have been highly studied. C_{max} for levodopa is increased and achieved more quickly translating into a larger area under the curve. In addition, the half-life for levodopa is increased significantly when carbidopa is coadministered. Similar findings have been observed with benserazide, although there is controversy as to whether the half-life is significantly extended. Regardless, both the AAADIs smooth the levodopa dose–response curve and reduce individual variation.

Extended Release Formulations

The advent of extended release formulations of levodopa/AAADIs has reduced dosage intervals, further improved the smoothing of the plasma curves, and extended the duration for which levodopa levels remain within the therapeutic window. The efficacy of the AAADIs within these formulations, as is true of all extended/delayed release formulations, is dependent upon dissolution rates within the GI tract, and individual patient variation can always contribute to poor patient response.

Combination Therapies with Catechol-O-methyl Transferase Inhibitors

The most recent addition to the levodopa formulation has been the addition of the catechol-*O*-methyl transferase (COMT) inhibitor entacapone to the levodopa/carbidopa formulation (Stalevo). When levodopa is administered with benserazide, entacapone can be added on as an adjunctive agent. In the presence of an AAADI, levodopa is driven through an otherwise trace metabolic pathway involving COMT. Because AAAD is ubiquitously distributed and has high activity for levodopa, most levodopa is biotransformed to DA. However, when an AAADI is coadministered, levodopa biotransformation to DA is inhibited leaving more levodopa substrate available for COMT, which converts levodopa to 3-*O*-methyldopa (3OMD). Numerous studies demonstrated that 3OMD accumulation can compete with levodopa for access to brain via competitive inhibition for the large neutral amino acid transporter although the therapeutic implications within the context of the number of large neutral amino acids taken in by diet are controversial. Regardless, the addition of a COMT inhibitor to the therapeutic regimen is well documented to further increase the availability of levodopa to the brain and to enhance C_{max} of levodopa, while smoothing plasma levels even more so than that seen with only the addition of an AAADI.

Dopamine

Paul M Carvey, Rush University Medical Center, Chicago, IL, USA

Glossary

Catechol-*O*-methyl transferase (COMT) – One of several enzymes that degrade catecholamines such as dopamine, epinephrine, and norepinephrine.
Monoamine-oxidase inhibitor (MAO) – Enzymes that catalyze the oxidation of monoamines, found bound to the outer membrane of mitochondria in most cell types in the body.
Neurotransmitter – Chemicals that relay, amplify, and modulate signals between a neuron and another cell. Neurotransmitters are packaged into synaptic vesicles that cluster beneath the membrane on the

presynaptic side of a synapse and are released into the synaptic cleft, where they bind to receptors in the membrane on the postsynaptic side of the synapse.
Parkinson's disease – Neurodegenerative disease of the brain characterized by degeneration of the nigrostriatal system, resulting in tremor, bradykinesia, rigidity, and postural reflex abnormalities.

Dopamine (DA) is a member of the small molecule neurotransmitter class of biogenic amines found primarily in the CNS, but also in the periphery. It is the most studied neurotransmitter (based on the number of Pubmed citations) reflecting its role in numerous CNS diseases and disorders. Thus, DA function is centrally involved in Parkinson's disease (PD), schizophrenia, attention deficit/hyperactivity disorder (AD/HD), Gilles de la Tourette's syndrome, Huntington's disease, prolactin secretion, emesis, the sense of smell, and drug dependence. Central DA likely also plays somewhat of a role in depression, obsessive/compulsive disorders, and learning. In the periphery, DA regulates pyloric sphincter tone and gastric motility, light–dark adaptation in the retina, vascular flow to the kidney, hypoxic drive in the carotid body, and autonomic and cardiac function. Dopamine is a highly conserved neurotransmitter and is found in numerous phyla, including worms, fruit flies, and snails.

DA Pathways

There are four major dopaminergic systems in the human brain (**Table 1**). The nigrostriatal pathway is by far the largest and accounts for 80% of the brain's DA. Thus, dopaminergic fibers course primarily from the substantia nigra pars compacta, and to a significantly lesser extent from the substantia nigra (SN) reticulata, via the medial forebrain bundle to the striatum (caudate and putamen). Lesser projections in this pathway innervate the globus pallidus. This pathway predominantly regulates motor activity. The mesolimbic pathway contains dopaminergic fibers coursing from DA cell bodies in the ventral tegmental area (VTA; located medial to the SN), and to a lesser extent from medial regions of the SN and retrorubral area, to the nucleus accumbens, anterior cingulate cortex, septum, hippocampus, amygdala, nucleus of the diagonal band, and anterior olfactory nucleus. These target structures are primarily limbic in nature and thus point to dopamine's involvement in limbic function. The third pathway is the mesocortical. It projects predominantly from the VTA to the anteromedial frontal, orbitofrontal, suprarhinal, and other cortical areas. This pathway regulates cognitive processing. The final pathway is the tuberoinfundibular/incertohypothalamic tract. Dopaminergic fibers from the periventricular and arcuate nuclei of the hypothalamus project into the median eminence of the hypothalamus where they release DA into the perivascular space, which then circulates to the lactotrophs in the anterior pituitary in a paracrine fashion to inhibit their secretion of prolactin. DA is thus prolactin inhibitory factor (PIF). Other fibers in the hypothalamus project to the anterior and periventricular hypothalamus as well as the septum and medial preoptic area where they may participate in the regulation of gonadotropin releasing hormone and corticotropin releasing hormone. Given that drugs affecting DA receptors currently lack regional/target specificity, pharmacotherapy designed to affect one system generally affects all of these systems, leading to unwanted effects.

DA Function

Dopamine is said to perform a 'gating' function. As is true of the other biogenic amines as well as acetylcholine, fibers

Table 1 Primary dopaminergic pathways in the brain

Pathway	*Area of origin*	*Target structures*	*Primary function*
Nigrostriatal	Substantia nigra in midbrain	Caudate and putamen (striatum)	Motor control
Mesolimbic	Ventral tegmental area, medial nigra and retro-rubral area	Nucleus accumbens, anterior cingulate cortex, septum, hippocampus, amygdala, nucleus of the diagonal band and anterior olfactory nucleus	Limbic regulation
Mesocortical	Ventral tegmental areas	Anteromedial frontal, orbitofrontal, suprarhinal and other cortical areas	Cognitive processing
Tuberoinfundibular/ incertohypothalamic tract	Periventricular and arcuate nuclei of the hypothalamus	Median eminence, the anterior and periventricular hypothalamus as well as the septum and medial preoptic area	Prolactin inhibitory factor and regulation of gonadotropin releasing hormone and corticotropin-releasing hormone (CRH)

from the bed nuclei for these small molecule neurotransmitters mostly bypass thalamic circuitry to affect the passage of electrical activity through their target structures. Thus, in the striatum DA probably affects the flow of electrical activity emanating from the glutaminergic corticostriate pathway to the globus pallidus, thalamus, and eventually the frontal cortex. This somatotopically highly organized parallel pathway is likely designed to progressively focus the excitation of upper motor neurons (corticospinal track) to facilitate only those motor units needed for an intended movement. I have always viewed dopamine as playing a center-surround function in the striatum enabling the selected group of glutaminergic pathways needed for an intended movement while inhibiting surrounding nonnecessary fibers to ensure appropriate movement; thus a gating function. Too little DA, as occurs in PD, precludes glutaminergic output, leading to hypokinesia; too much DA does not provide adequate center surround function, leading to the involvement of additional, unneeded nearby motor circuits in the movement, resulting in dyskinesias. A similar function may be assumed in the mesocortical pathway where too little DA leads to bradyphrenia while excess DA activity, as is thought to occur in schizophrenia, leads to disjointed thinking.

DA Biochemistry

First identified by Arvid Carlsson in 1952, DA is the end-product of synthesis from tyrosine (**Figure 1**). Tyrosine is a nonessential amino acid that is either taken up into the DA neuron from the diet or synthesized intraneuronally from the essential amino acid phenylalanine. The fact that tyrosine is synthesized from the large neutral amino acid phenylalanine is interesting, given that the use of levodopa in the management of PD utilizes the large neutral amino acid pump (LAT1) to gain access to circulation from the gut and to gain access to the brain from the vasculature. Thus, levodopa treatment, although it bypasses the tyrosine synthetic step, may inhibit the uptake of phenylalanine and thereby deprive dopaminergic and noradrenergic neurons of necessary amino acid precursor. Tyrosine is converted into dihydroxyphenylalanine (DOPA) by the rate-limiting enzyme tyrosine hydroxylase (TH) in the presence of the cofactor tetrahydrobiopterin, which is also required in the production of tyrosine from phenylalanine, as well as in the synthesis of serotonin and nitric oxide.

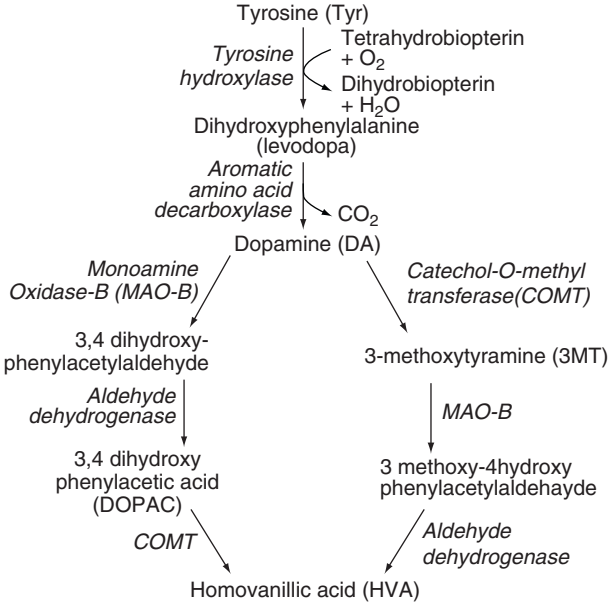

Figure 1 Dopamine synthesis and degradation pathways.

TH is a highly regulated enzyme. It is subject to classical end-product inhibition perhaps through competition between DA and tetrahydrobiopterin (BH_4) or another noncompetitive site. Thus, when free DA levels are high inside the DA neuron (the cytoplasmic or so-called mobile pool), synthesis is reduced. Since BH_4 is obligatory for TH activity, reduced availability of this cofactor can also reduce synthesis. BH_4 is the product of a three-step synthetic pathway in which GTP cyclohydrolase I is the rate-limiting enzyme. BH_4 subsequently binds to TH to increase its activity and BH_4's binding affinity (low or high) is affected by the phosphorylation status of TH. Increased neuronal firing leads to a reduced end-product inhibition by altering the phosphorylation status of TH, thus increasing the rate of hydroxylation (conversion of TH from a low to high affinity state for BH_4) and effectively enhancing the supply of DA for highly active neurons. The alterations in TH phosphorylation status are regulated through four sites on the enzyme that are activated by PKA, PKC, and Ca^{2+}-calmodulin-dependent kinase with the latter thought to be more active than PKA or PKC. Neuronal activity affects these phosphorylation reactions thereby affecting synthetic rate. Also, released DA acting through its presynaptic autoreceptor reduces TH through regulation of phosphorylation. These posttranscriptional mechanisms appear to be the primary regulators of TH activity and it is currently unknown whether transcriptional increases in mRNA for TH occur as they do in other catecholaminergic neurons. Several polymorphic forms of TH are known to exist leading to further variations in synthetic rate and phosphorylation capacity. Finally, it is widely believed and likely true that tyrosine availability to TH is rate limiting and near saturation under normal conditions. However, excessive or prolonged periods of DA neuron firing can lead to reduced levels of tyrosine such that the availability of this precursor then becomes rate limiting. Whether or not this is relevant to DA neurodegenerative diseases such as PD is unclear.

Once formed, DOPA is subsequently converted into DA by aromatic amino acid decarboxylase (AAAD), which is a ubiquitous enzyme found throughout the body and brain.

Because of the abundance of this enzyme in the stomach, GI track, liver, and vascular beds throughout the body, administered levodopa is extensively metabolized (first pass effect) dramatically reducing the amount of levodopa available to brain. AAAD requires pyridoxine (vitamin B6) as a cofactor. Prior to the advent of AAAD inhibitors, including carbidopa and benserazide, peripheral metabolism of levodopa could be reduced by depleting B6 (avoiding B6 rich foods and multivitamins), a therapeutic strategy that is no longer required. AAAD is far from being saturated under normal conditions and levels of DOPA are generally undetectable in the brain. This formulated the basis for the effectiveness of the so-called 'precursor load strategy,' where DA levels are effectively increased in the brain by administering its immediate precursor, levodopa. Although it is widely assumed that AAAD is not rate limiting in the production of DA, it does become rate limiting when high levels of levodopa are administered. Thus, levodopa's efficacy may exhibit a ceiling effect following very high doses or in the late stages of disease when significant losses of DA neurons reduce the pool of AAAD in the targeted DA neurons. Since polymorphism is known to occur in AAAD as well, the point at which there is a ceiling effect for levodopa conversion to DA will differ from one patient to another. Indeed, at one time saturation of AAAD was thought to contribute to the well known on–off effect observed in many later-stage PD patients.

DA is synthesized in the varicosities and end terminals of DA neurons as well as in the cell bodies (**Figure 2**). Since synthesis occurs in terminals, released DA and other neurotransmitters working through auto and hetero-receptors respectively, can influence the phosphorylation status of TH and the local synthetic rate of DA. Regardless, once synthesized, DA eventually collides, via Brownian motion, with the vesicular monoamine transporter (VMAT2) sites on synaptic vesicles and is transported into vesicles forming the so-called vesicular pool of DA. VMAT2 is a H^+-dependent antiporter and a member of the toxin extruding antiporter (TEXAN) gene family that confers antibiotic resistance in many bacteria. The acidic pH inside of vesicles is created by a V-type ATPase H^+ transporter creating an electrochemical gradient out of the vesicle that drives VMAT2. DA in exchange for two H^+ ions is transported into the vesicle where it binds to unknown sites inside of the vesicles sequestering it in the vesicular pool and effectively lowering its concentrations in the mobile pool. The latter point is critical to DA neuron function, since it has been proposed that high levels of mobile pool DA lead to overwhelming concentrations of reactive oxygen species (ROS) that affect the integrity of the DA neuron. Indeed, methamphetamine toxicity and α-synuclein mutations appear to affect vesicular transport function and lead to cell death. Additionally, DA has a pK_a of 8.45 at 37 °C that effectively ion traps DA inside of the vesicles. The result of this ion trapping, together with the binding of DA to proteins inside the vesicle, creates extremely high concentrations in the vesicular pool (10 000-fold relative to the mobile pool). Subsequent vesicular release of DA into the synaptic cleft (the so-called synaptic pool) is mediated by traditional Ca^{2+}-dependent release through exocytosis. Once released, DA is then free to interact with receptors on its target structures via bulk diffusion.

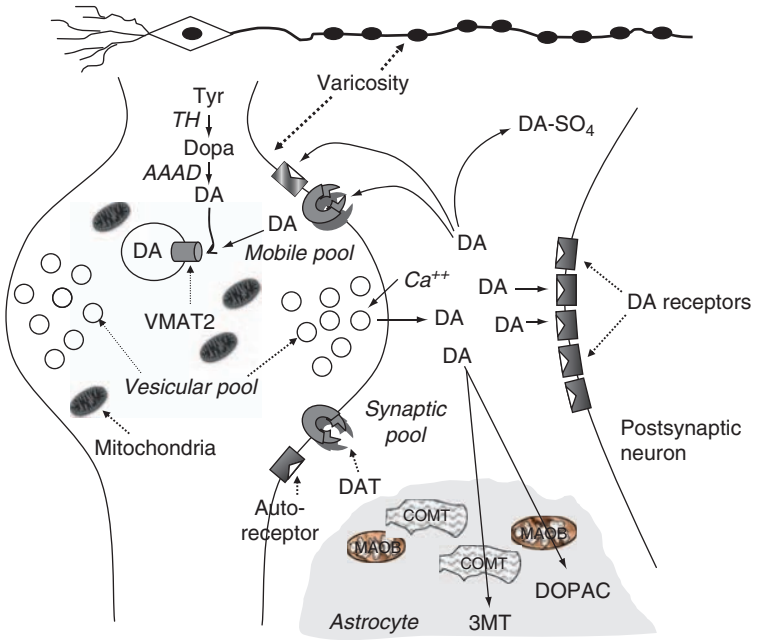

Figure 2 Depiction of the fates of dopamine (DA) as it is synthesized and distributed throughout the synaptic release phase.

Fate of Released DA

Once released into the synaptic pool, DA is free to diffuse and it will collide with postsynaptic DA receptors to produce is effects. Concentrations needed to meet the affinity needs of the target receptors are in the high-nanomolar and low-micromolar range; concentrations readily achieved in the synaptic pool as part of Ca^{2+}-dependent release. The vast majority of released DA (85–95%) is taken back up into the DA neuron via the dopamine transporter (DAT). DAT is located away from the synaptic zone consistent with the notion that only the DA diffusing away from the receptor fields is subject to reuptake.

DAT is a symporter carrying two molecules of Na^+ and one molecule of Cl^- into the neuron together with two molecules of DA. Once bound, DAT is translocated to the cytoplasmic side of the membrane releasing its DA into the mobile pool. Once back inside, the transporter releases its two molecules of DA where it can recollide with the DA binding sites on the DAT and can be transported back into the synaptic pool. This process continues until extracellular concentrations of DA are depleted effectively trapping the DAT on the external surface of the DA neuron membrane in preparation for the next synaptic volley. Psychostimulant drugs that have affinity for DAT and behave as ligands such as amphetamine and methylphenidate take advantage of this shuttling ability of the DAT. Thus, they bind to the DAT (have affinity) and are transported to the cytosolic side of the membrane (they are ligands), where mobile pool DA can then bind and can be transported back into the synaptic pool, producing the so-called Ca^{2+}-independent release. Psychostimulants like cocaine appear to bind to a regulatory site on the DAT and alter the affinity of DAT for DA effectively reducing reuptake. The gene for DAT has a variable number of tandem repeats (VNTR) associated with various basal levels of expression. In addition, both MAPK and PKC modulate the rate at which DA is transported.

Once DA is back in the mobile pool, it can bind to TH and produce feedback inhibition. Alternatively, it can collide with VMAT2 and can be resequestered into the vesicular pool effectively recycling DA. It is often believed that mobile pool DA is catabolized by monoamine oxidase type B (MAOB) located in the mitochondria of DA neurons. This is likely untrue. Although some DA cell bodies in the SN have been shown to contain MAOB, it is generally assumed that MAOA is primarily located in DA neurons. Thus, MAO primarily functions as a scavenging enzyme in terminals effectively catabolizing serotonin, norepinephrine, and other bioactive amines that may be inadvertently taken up by the terminal because they have some affinity and behave as ligands for the DAT. This scavenger function reduces the likelihood that false neurotransmitters will be taken into DA vesicles. This does not mean that DA is not catabolized. It simply means that the vast majority of its catabolism occurs outside the DA neuron.

Although the vast majority of DA is taken back up, DA is catabolized by catechol-O-methyl transferase (COMT) and MAOB. It is widely believed that COMT is expressed on target neurons and as such can catabolize DA directly at the target site in a fashion similar to that known to occur when acetylcholinesterase catabolizes ACh. Several studies have also observed soluble COMT in the brain. However, these two forms of COMT have a low affinity for DA. High-affinity COMT is found primarily in astrocytes and perhaps microglia. There are Na^+-dependent and Na^+-independent transport sites for biogenic amines on astrocytes. These apparently unsaturable uptake sites deliver DA into the cytosol of astrocytes, effectively sequestering it from the synaptic pool. Once inside, COMT transfers a methyl group from *S*-adenosyl-L-methionine to the catechol substrate in the presence of magnesium producing 3-methoxytyramine (3MT). COMT activity is genetically polymorphic, and individuals with the low-activity genotype have a thermolabile COMT protein that affects the efficacy of the COMT inhibitors tolcapone and entacapone. This genotype is less common in Asians than in Caucasians.

Once sequestered in astrocytes, DA can also be catabolized by MAOB located on the outer membrane of mitchondria in the cytoplasm of these cells. MAOB requires a flavin cofactor, flavin adenine dinucleotide (FAD), which binds to the cysteine residue of a pentapeptide sequence (Ser-Gly-Gly-Cys-Tyr). Monoamine oxidase catalyzes the oxidative deamination of DA. Oxygen is used to remove the amine group from DA resulting in the corresponding aldehyde 3,4-dihydroxyacetylaldehyde and ammonia. The resulting aldehyde is acted on by aldehyde dehydrogenase to produce DOPAC and then by COMT to produce homovanillic acid (HVA). Similarly, 3MT, the product of COMT acting on DA, is similarly acted on by MAOB and then aldehyde dehydrogenase to produce HVA. GT repeat sequences exist within MAOB, suggesting variations in its activity, although differences in the length of these repeats are not associated with the PD phenotype.

Since DA is catabolized outside of the DA neuron, the ratio of its metabolites to the parent neurotransmitter is widely used as an index of release. Referred to broadly as DA activity, the ratio of DOPAC/DA or HVA/DA has been widely shown to be associated with DA release status. Thus, increases in either of these two ratios are usually associated with loss of DA neurons. The term DA activity should not be confused, as it often is, with the term turnover, which more accurately reflects the ratio of tyrosine/DA and therefore reflects synthetic rate.

In addition to enzymatic degradation by COMT and MAOB, released DA can also be conjugated with sulfate or act on autoreceptors. DA sulfates have been isolated in low quantities from CSF. The sites of these conjugation reactions are unknown, although they probably occur ubiquitously as is true in the periphery. DA that is not taken up by astrocytes or the DAT can also bind to DA autoreceptors. These autoreceptors are, like the DAT, located well away from the active synaptic area, probably farther away from the active zones than the DAT field. This physical location ensures that only when synaptic pool DA concentration is excessive, will it diffuse to and bind to the autoreceptor. Binding to the autoreceptor not only will affect kinases to reduce TH activity, but also will reduce future DA release by interfering with Ca^{++}-dependent release mechanisms.

Dopamine Depletors and Movement Disorders

L C Shih and D Tarsy, Beth Israel Deaconess Medical Center, Boston, MA, USA

Glossary

Alpha-methyl-para-tyrosine – Inhibitor of tyrosine hydroxylase; a dopamine depletor not in clinical use but used extensively in research.
Dopamine depletor – A pharmacologic agent that decreases the amount of dopamine available for synaptic release by one of the two mechanisms: blocking of vesicular monoamine transporters or inhibition of production by tyrosine hydroxylase; sometimes used to treat extreme hypertension or hyperkinetic movement disorders.
Monoaminergic neurotransmitters – Neurotransmitters derived from amino acids; include norepinephrine, epinephrine, histamine, serotonin, and dopamine.
Reserpine – The prototype for the dopamine depletor class of drugs; a vesicular monoamine transporter inhibitor.
Tetrabenazine – A reversible vesicular monoamine transporter inhibitor; approved for use in Huntington's chorea.

Dopamine depletors are a class of pharmacologic agents that decrease the amount of dopamine available for synaptic release. Although commonly known to reduce dopamine availability in the synapse, these agents reduce other catecholamine levels as well, contributing in large part to their clinical indications. Dopamine depletors have been used for treatment of hyperkinetic movement disorders such as chorea, tardive dyskinesia, and Tourette syndrome, as well as for hyperadrenergic states such as severe hypertension and pheochromocytoma. They frequently have been used in experimental animal model studies on mechanisms of dopamine release, parkinsonism, and depression.

In dopamine-producing cells, two pools of intracellular dopamine can be identified. The cytosolic pool contains newly synthesized dopamine, while the vesicular pool contains stored dopamine. The two best known dopamine depleters are reserpine and tetrabenazine, both of which work by depleting the vesicular pool of dopamine. The mechanism of action of reserpine and tetrabenazine is to inhibit monoaminergic neurotransmitter storage by blocking vesicular monoamine transporters (VMAT) that normally store histamine, norepinephrine, serotonin, and dopamine in storage vesicles. Effects of tetrabenazine are largely confined to the central nervous system, while reserpine has effects on peripheral (VMAT1) and central (VMAT2) nerve terminals. Reserpine is also likely to be an irreversible inhibitor of VMAT. Because of numerous side effects associated with reserpine such as bradycardia, hypotension, and depression, its use in this area of clinical practice has been limited.

Reserpine, considered the prototype for this class of drugs, was isolated from the root of *Rauwolfia serpentina*,

also known as Indian snakeroot, a plant that was used for medicinal effects dating back to the sixteenth century. Its use in nervous system disorders was first reported in 1933 by Chopra for treating insomnia and hypochondriasis in India. In the 1950s, after its introduction to the western hemisphere, it was used for hypertension, psychosis, chorea related to Huntington's disease (HD), and later for tardive dyskinesia. It came into more widespread use in the western hemisphere after its isolation, identification, and synthesis, but significant side effects were noted including hypotension, depression, and weight gain. Importantly, though clinical use of reserpine diminished with time, the discovery of reserpine enabled several different lines of scientific inquiry, including the mechanisms of central nervous system dopamine storage and release and in generating animal models of parkinsonism.

Tetrabenazine was synthesized in 1956 in an effort to find a similar agent with a more tolerable side effect profile. In 1969, Dalby reported on tetrabenazine's benefit in a variety of hyperkinetic disorders including chorea, hemiballismus, dystonia, parkinsonian tremor, and intention tremor. Tetrabenazine's usefulness for hyperkinetic movement disorders was recognized by many, especially in light of the poor tolerability of reserpine. Though not available in the United States until 2008, it has been in widespread use for tardive dyskinesia, Tourette syndrome, and chorea.

Tetrabenazine, the most important of the dopamine depletors, is a selective and reversible VMAT2 inhibitor, which also exhibits preferential depletion of dopamine over other monoaminergic transmitters. It also has weak D2 receptor antagonist activity, which is thought to play only a minor role in producing its clinical benefits. Although much less commonly used chronically than antipsychotic drugs, tardive dyskinesia has not been reported after use of tetrabenazine, thereby making it a more attractive option than neuroleptics for treatment of hyperkinetic disorders. Tetrabenazine is a mainstay of treatment of persistent tardive dyskinesia after removal of neuroleptics as well as in Huntington's chorea. In a Huntington Study Group multicenter randomized controlled trial involving over 80 HD patients, tetrabenazine was shown to be safe and effective with only five reported adverse events (suicide by drowning, a complicated fall, restlessness/suicidal ideation, and breast cancer). Side effects of tetrabenazine include sedation, depression, akathisia, and parkinsonism that require close monitoring. Incidence of postural hypotension is probably lesser than that in reserpine. Patients with preexisting depression are more likely to experience worsening depression on this drug than patients without preexisting depression. However, 10–15% of patients may experience de novo depression while taking tetrabenazine. Effective doses of tetrabenazine range from 25 to 150 mg daily with recommended starting dose of 12.5 mg twice to three times daily. Tetrabenazine is extensively metabolized in the liver to intermediate compounds which also are similarly active in producing monoamine depletion.

In contrast to the mechanisms of action of reserpine and tetrabenazine, alpha-methyl-para-tyrosine (AMPT), also known as metyrosine, reduces the cytosolic pool by directly inhibiting tyrosine hydroxylase, which is the rate-limiting step in the conversion of tyrosine to levodopa and norepinephrine. Its discovery in the mid-1960s led to its use in treating pheochromocytoma, but its use in movement disorders was limited for unclear reasons. Several reports surfaced in the early 1980s regarding its benefit in chorea and tardive dyskinesia, especially as a potentiator of the action of other dopamine depleters such as reserpine and tetrabenazine. Rare cases of neuroleptic malignant syndrome were reported in conjunction with tetrabenazine, but by and large, severe adverse reactions were not seen with AMPT. Currently, it is only approved for use in pheochromocytoma by the US FDA, and its clinical use in neurological disorders is minimal to nonexistent.

Dopamine depletors have been used extensively in research. Because cocaine stimulates dopamine release, reserpine and AMPT have been tried unsuccessfully as potential therapeutic agents for cocaine dependence. AMPT has been used in neuroimaging and clinical studies of major depression. In patients with depression in remission, AMPT can cause return of depressive symptoms particularly in those patients chronically taking serotonergic and noradrenergic reuptake inhibitors. AMPT has also been used in conjunction with reserpine as a means for producing nearly complete dopamine depletion in functional imaging studies that evaluated dopaminergic radioligands. Tetrabenazine and its metabolites, methoxytetrabenazine and dihydrotetrabenazine, have also been used as investigational positron emission tomography radiotracer ligands. Because these agents bind to VMAT2, which is located on dopaminergic terminals in the striatum, it may serve as a biomarker of dopaminergic neuronal loss in PD.

Dopamine Dysregulation Syndrome

O Klepitskaya, University of Colorado at Denver Health Sciences Center, Aurora, CO, USA

Glossary

Akathisia – A syndrome characterized by unpleasant sensations of 'inner' restlessness that manifests itself by an inability to sit still or remain motionless. It can be a side effect of medications, mainly neuroleptic antipsychotics.
Anhedonia – An inability to experience pleasure.
Compulsive behavior – Behavior resulting from an irresistible urge to perform a certain act, regardless of the rationality of this act.
Dysphoria – A state of feeling unwell or unhappy; a feeling of emotional and mental discomfort and suffering from restlessness, malaise, depression, or anxiety.
Hedonistic homeostatic dysregulation syndrome – A neuropsychological behavioral disorder associated with substance misuse and addiction.
Hypersexuality – Excessive interest or involvement in sexual activity.
Pathological gambling – An urge to gamble despite harmful negative consequences or a desire to stop.
Punding – Activity characterized by a compulsive fascination with and performance of repetitive, mechanical tasks, such as assembling and disassembling, collecting, or sorting common household objects.
Substance abuse – Overindulgence in and dependence on a drug or other chemical leading to effects that are detrimental to the individual's physical and mental health, or the welfare of others.
Suicide – The intentional taking of one's own life.

Definition and History

Dopamine dysregulation syndrome (DDS) is a neuropsychological disorder in patients with Parkinson's disease (PD) associated with compulsive misuse of and addiction to dopamine replacement therapy (DRT). The model of maladaptive use of addictive medications, called hedonic homeostatic dysregulation (HHD), was first described in association with psychostimulant abuse, specifically cocaine. It was later recognized that similar behavioral problems can occur in patients with PD as a consequence of DRT. Although the name HHD was used in the first reports of this phenomenon in PD patients, recently the term DDS in relationship to compulsive and maladaptive use of DRT is more accepted.

Pathophysiology

Dopamine plays a key role in the mesocorticolimbic system connecting the basal ganglia, ventral striatum, nucleus accumbens, ventral tegmental area (VTA), and basal forebrain. This system controls many aspects of normal human behavior, such as feeding, motivation, and reward processing, as well as pathological behaviors such as substance abuse, gambling, overeating, hypersexuality, and other addictions and compulsions. Changes in dopamine neurotransmission within this system are responsible for positive reinforcement of substance abuse in the 'reward pathways.' Facilitation of dopamine transmission in this pathway is critical for acute reinforcing actions of cocaine, amphetamine, and nicotine. Multiple dopamine receptors, including D1, D2, and D3, have been implicated in this reinforcement. Recent pathological studies revealed an intriguing link between mechanisms of neurodegeneration in PD and in chronic cocaine abusers. α-Synuclein, a major component of Lewy bodies and possible pathological agent in PD, was found in increased levels in the midbrain and nigral dopamine neurons of cocaine abusers. It was postulated that overexpression of α-synuclein occurs as a protective response to increased dopamine turnover and oxidative stress caused by chronic cocaine use. There are also striking similarities in clinical effects of psychostimulant use and DRT. Cocaine can cause hyperkinetic movements, such as reversible chorea

and stereotypies; behavioral alterations, such as mood swings, paranoia, panic attacks, and psychosis; and withdrawal symptoms of depression and anxiety. All of these are well-known, dose-dependent side effects from DRT in PD patients. It was concluded that both neurobiological and clinical effects of psychostimulants are similar to those of dopamine, and therefore, the mechanism of dependence on DRT is analogous to that of stimulant dependence. In fact, PD patients with DDS fulfill the DSM-IV clinical criteria of American Psychiatric Association (APA) for substance abuse and dependence that include 'overwhelming involvement with the use of a drug' (compulsive use), loss of control over drug intake, and drug seeking. These patients demonstrate the classic 'spiraling distress–addiction cycle' with stages of binge intoxication (emotional well-being on DRT), preoccupation–anticipation (feeling of need for the next dose of DRT in anticipation of the upcoming emotional wearing off), negative effect of withdrawal (anxiety and depression described as 'non-motor mental off'), and back to binge intoxication that provides positive reinforcement. This cycle increases in amplitude with repeated experience leading to addiction. However, as most drug users do not become drug abusers, most of PD patients treated with DRT do not develop DDS. A number of social, psychiatric, psychological, and neurochemical factors can be involved in the failure of the self-regulation of the appropriate use of DRT.

Epidemiology and Risk Factors

DDS has been reported in ~4% of all PD patients. This number, however, is likely biased, because it is based on the reports from the subspecialty movement disorders clinics. Milder forms of DDS are under recognized and under reported in general practice. There is also some evidence that PD patients with DDS are over represented in certain PD populations. For example, among potential surgical candidates for deep brain stimulation (DBS), the incidence can be as high as 18%. About 80% of PD patients affected by DDS are men. Younger patients have a much higher risk of DDS than older patients. The average age of the disease onset for PD patients with DDS is about 43. It is yet to be determined whether the age of the disease onset or the age of the exposure to the DRT determines the susceptibility to DDS. On the one hand, patients with young-onset PD (YOPD) represent a different spectrum of the disease, often determined by genetic mutations, and might already have genetic predispositions for the development of DDS. For example, clinical features of PARK-7-linked autosomal recessive Parkinsonism, characterized by psychiatric, emotional disturbances, and obsessive-compulsive behavior, are similar to those of PD patients with DDS. On the other hand, age critically mediates vulnerability to addiction in general. Adolescents have much higher novelty seeking and risk acceptance personality traits that make them more likely to experiment with alcohol and drugs. Younger age of exposure to addictive drugs influences subsequent severity of substance abuse. It had been shown that younger age of the exposure to DRT independently increased the risk of development of DDS in PD patients.

There are certain personality traits that can predispose PD patients to the development of DDS. Novelty seeking is most strongly associated with DDS. PD patients with DDS scored much higher on impulsive sensation seeking rating than those without DDS. Significantly more PD patients with DDS have a past history of experimental drug use, compared with PD patients without DDS. History of alcohol abuse and dependence, as well as current level of alcohol intake is predictive for the development of DDS. Depression is another important predictor of DDS in PD. Although depression is a common symptom of PD, it is also a common comorbidity in drug abusers. PD patients with DDS report more severe off-period dysphoria, apathy, and anxiety. That prompts them to take more frequent and higher doses of DRT, often in excess of what is needed for their motor control, to avoid those unpleasant withdrawal symptoms. This, in turn, reinforces the positive emotional effect in the vicious cycle. As a result, the daily doses of DRT in PD patient with DDS are usually much higher than in patients in a similar stage of the disease without DDS.

To conclude, the typical-case scenario for DDS is a depressed male with YOPD and a history of alcohol and substance abuse or at least experimentation in the past, on very high doses of DRT.

Clinical Picture

Core clinical criterion of DDS is a pattern of pathological use of DRT in excess of what is required to alleviate motor impairments of PD despite disabling dyskinesias resulting in euphoric effect and behavioral disturbances affecting social and occupational functioning for more than 6 months in duration.

The term 'pathological use' of DRT in PD is difficult to define, because the patients need DRT for the improvement of motor symptoms. However, if the medications are taken to achieve emotional, not only motor, 'on' state despite severe complications with disabling dyskinesias, it should be considered pathological. The emotional and behavioral effects of medications in this situation can range from simple relief of withdrawal symptoms of anxiety, dysphoria, depression, irritability, apathy, and fatigue, perceived as 'mental off state,' to symptoms of intoxication with hypomania, mania, paranoia, and compulsive behaviors. These patients have an altered perception of 'on' state, which usually includes wild dyskinesias and emotional 'on.'

The preoccupation and anticipation involved in taking medication for this purpose negatively affects the patients' social and family life. Aggression, irritability, and an unwillingness to decrease doses despite severe consequences are typical of this condition. The decreasing of doses can indeed be very difficult because of severe negative withdrawal effects, and the attempts to do so have been proved to be unsuccessful on most occasions. Instead, due to the development of tolerance, the typical phenomenon of addiction, the patients tend to increase the doses over time on their own despite physician's advice. Medication hoarding becomes the major task. Unfortunately, because the symptoms of DDS are difficult to recognize immediately and because DRT is widely prescribed for controlling motor symptoms in PD, usually these patients do not have trouble to stock massive doses of levodopa. Any dopaminergic medications could potentially cause DDS. Rapid acting medications with shorter half life present much higher risks likely because of their pulsatile nonphysiological stimulation of dopamine receptors. Among them are rapid-release carbidopa/levodopa and apomorphine. The latter gives patients a subjective 'kick' or 'rush,' which some patients describe as being high, resembling the similar effect of psychostimulants. Therefore, subcutaneous infusions of apomorphine in high doses can potentially provoke this condition.

Behavioral disturbances escalate with escalating doses of medications. The patients become irritable, agitated, intolerant to critique, demanding, and hyperexcitable. Their thoughts become disorganized, they display poor judgment and frequent mood swings. Paranoia and frank psychosis can occur. Pathological compulsive behaviors are common, including, but not limited to, punding, hypersexuality, walkabouts, pathological shopping, gambling, overeating, excessive preoccupation with hobbies, and other activities. The consequences of these behaviors can be devastating. Many patients find themselves in financial crises more then once due to overspending on shopping and gambling. Many patients destroy their family relationships due to inappropriate sexual behavior, ranging from increased libido to prostitution, exhibitionism, and others. Some develop restlessness and akathisia that make them wander long distances without realizing it. Food cravings can become severe and uncontrollable. All of these, combined with physical limitations caused by dyskinesias, result in loss of families, friends, absence from work, social isolation, and subsequent worsening of depressive symptoms.

Management

Management of DDS is extremely difficult. Psychological help with psychotherapy is essential. Since this syndrome is a variant of substance abuse, a formal evaluation and treatment with psychiatrist are warranted. The goal should be to restrict DRT and dispense medications only under strict supervision of the physician and/or pharmacist in the amount needed only to control motor symptoms of PD. This task, however, is proven to be difficult, because dopaminergic medications are not considered to be drugs of abuse, and as a result, it is easy to get a prescription from another physician. Therefore, in severe cases, the medication reduction should be attempted in the hospital under strict supervision of both a neurologist and a psychiatrist. Severe manic and psychotic episodes should be treated with antipsychotics, such as clozapine, olanzapine, or quetiapine. After a decrease in doses of DRT, psychotic features can be rapidly replaced by the equally dangerous depressive state, often with suicidal ideations. During that period, the patient should be closely supervised by a psychiatrist. Antidepressants are usually needed for a longer period of time even after clinical resolution of depressive state.

Prognosis and Prevention

Prognosis of DDS is poor. Even appropriately treated DDS has a tendency to relapse. Unlike other substances of abuse, it is impossible to avoid DRT completely in PD patients, because they still need it to alleviate their motor impairments. Sooner or later, they tend to fall back into the vicious cycle of 'reward reinforcement' and lose control over their dopaminergic medication use.

To prevent relapse, the lowest doses of DRT needed for control of motor problems should be used, preferentially in the form of slow-release medication. Rapid-release medications, doses given 'as needed,' and specifically, boluses of subcutaneous apomorphine should be avoided. Ongoing psychotherapy should use positive reinforcement of appropriate behavior. Education of family and caregivers about the nature of this problem is important, as they are willing to provide more social support when they understand the medication-related nature of their loved one's problems.

In recent years, there has been more evidence that bilateral subthalamic nucleus deep brain stimulation (STN DBS) can improve or completely abolish the addiction to DRT. The mechanism of this effect is still controversial but likely consists of two parts. First, dramatic improvement of motor symptoms by STN DBS allows significant decrease and sometimes complete discontinuation of DRT in PD patients. This eliminates the nonphysiological pulsatile stimulation of dopamine receptors that is a major strategy in the treatment and prevention of DDS. Second, the direct effect of high-frequency STN stimulation on the dopaminergic reward-seeking pathways inhibits the neurochemical circuitry of positive

reinforcement in the mesocorticolimbic system. Animal data have shown that STN DBS reduces the rewarding effect of cocaine. That can explain why PD patients with DDS can tolerate rapid medication decrease and withdrawal after STN DBS without typical dysphoric symptoms or craving of dopamine. They no longer need that emotional 'kick' that they were getting from medication prior to surgery. This data, however, are still controversial, because STN DBS was shown to cause a variety of different effects on emotional state and behavior in PD. Some patients can develop depression, dysphoria with suicidal ideation in the postoperative state, while other patients exhibit quite opposite symptoms of hypomania and paranoia. Therefore, until we better understand the behavioral effects of DBS, the perioperative psychiatric and psychological care for patients with DDS should be very vigilant. A slow medication taper in the postoperative period helps to avoid anhedonia and depression and to decrease the risks of suicide. Antidepressants could be used during this period if needed. Nevertheless, STN DBS can be potentially curative for DDS and should be strongly considered early in the course of the disease for PD patients suffering from DDS and for those at risk of this disabling behavioral disorder with an otherwise-poor prognosis.

Dopamine Receptors

M Habibi, University of Illinois at Chicago, Chicago, IL, USA

Glossary

G protein – Cell membrane protein involved in the cellular signal transduction pathway.

Neurotransmitter – A chemical substance carrying signals or messages from one nerve cell to another nerve cell.

Nigrostriatal pathway – Dopaminergic pathway connecting substantia nigra to striatum.

Substantia nigra – An area located in the midbrain containing dopamine-producing neurons that project to striatum.

Transmembrane receptors – Integral membrane proteins spanning the entire thickness of the membrane.

Introduction

Dopamine is a neurotransmitter, which is synthesized from amino acid tyrosine and has a significant role in regulating a variety of physiological functions. It exerts its actions by binding to different dopamine receptors located throughout the peripheral and central nervous systems (CNS).

Classification and Structure

Dopamine receptors are the pharmacological targets of many drugs in treating several neurological, psychiatric, and cardiovascular disorders. Currently, five distinct dopamine receptors are known. These receptors have seven transmembrane domains connected by three intracellular and three extracellular loops, and belong to the

G-protein-coupled receptor superfamily. Based on their biochemical and structural properties, dopamine receptors are divided into two main groups. The D_1-like group includes the D_1 and D_5 receptors, whereas the D_2-like group consists of the D_2, D_3, and D_4 receptors. There are significant sequence similarities in the transmembrane domains between members of each group. D_1 and D_5 receptors share an overall homology of 80%, but are only 31% identical to the D_2-like receptors. Similarly, D_2 and D_3 receptors share a 75% homology, and, to a lesser degree, D_3 and D_4 receptors share a 54% homology in their transmembrane domains. All dopamine receptor subtypes have similar numbers of amino acids in their extracellular NH_2-terminal stretch and the three extracellular loops and a variable number of *N*-glycosylation sites. Dopamine receptors also have two cysteine residues in the second and third extracellular loops, which form a disulfide bridge stabilizing the receptor structure.

There are some differences between the D_1 and D_2 families. Unlike the D_2-like group, the D_1-like receptors have a much larger c-terminal tail extending into the cytoplasmic compartment which is rich in serine and threonine and has a cysteine residue anchoring the cytoplasmic tail to the membrane; they also have a shorter third cytoplasmic loop between transmembrane helices 5 and 6. The third cytoplasmic loop is responsible for the G-protein coupling, signal transmission, and activating different signaling pathways.

It is important to note that the D_2 receptor has two main isoforms, the long isoform, D_{2L}, and the short isoform, D_{2S}. The D_{2L} is different from D_{2S} by a 29 amino acid stretch in the third cytoplasmic loop, which does not affect ligand recognition but affects G-protein coupling and signal transmission.

The D_5 receptor has two related pseudogenes that code for incomplete, nonfunctional forms of the receptor. D_4 receptor has many variants that differ in the number of repeat amino acid units in the third cytoplasmic loop. $D_{4,4}$, $D_{4,7}$, and $D_{4,11}$ have 4, 7, and 11 repeats, respectively. The $D_{4,4}$ is the most common variant. In addition, several nonfunctional variants of D_3 receptor have been identified.

The binding site of dopamine and other agonists is predicted to be between transmembrane helices 3, 4, 5, and 6 with tight binding between helices 3 and 5, whereas the binding of the antagonists involves helices 2, 3, 4, 6, and 7 with tight binding between helices 3 and 6 and minimal contact with transmembrane helix 5.

Transduction Pathways

Activation of dopamine receptors modulates adenylyl cyclase activity. Stimulation of D_1-like receptors is excitatory. The short third cytoplasmic loop interacts with G-stimulatory (Gs) subunits of the G proteins, activating adenylyl cyclase. This results in an increase in intracellular concentration of the second messenger, cyclic AMP. On the contrary, D_2-like receptors interact with G-inhibitory (Gi) subunits and their stimulation inhibits the activity of adenylyl cyclase decreasing the formation of cAMP.

Cyclic AMP is an activator of protein kinase A (PKA) and stimulation or inhibition of cAMP results in modulation of PKA, which through phosphorylation of cytoplasmic, nuclear and membrane proteins can significantly affect the cellular regulation and physiology.

Other important transduction pathways and effector systems modulated by dopamine receptor activation include phospholipases, arachidonic acid, activity of the K^+ and Ca^{2+} ion channels, mitogen-activated protein (MAP) kinases, Na^+/H^+ exchanges, and Na^+–K^+-ATPase. Coupling to potassium and calcium channels is one of the signaling pathways by which dopamine receptors can affect cell excitability. With regards to K^+ channels, activation of D_1 receptor reduces K^+ conductance causing depolarization and enhancing excitability and cell firing. Conversely, D_2 receptor activation results in hyperpolarization of the membrane and reduction of firing rate. Similarly, modulation of Ca^{2+} channels via activation of D_1 receptor enhances excitability, while the activation of D_2 receptor reduces Ca^{2+} current and has the opposite effect.

Binding Affinities

The D_1 and D_2-like receptors show pharmacological differences based on variable affinity of certain agonists and antagonists. Dopamine binds the five receptors and, although no pharmacological differences have been identified between the D_1-like receptors, dopamine has 10 times higher affinity for the D_5 than the D_1 receptor. The affinity of other agonists for these two receptors is identical, while antagonists bind the D_1 receptor with a slightly higher affinity. Among the D_2-like receptors, no compound has been able to distinguish between the D_{2L} and D_{2S} isoforms. Although D_3 and D_4 receptors bind D_2 receptor ligands with high affinity, they can be distinguished by some agonists or antagonists based on their pharmacological characteristics. As an example, dopamine has 20 times higher affinity for the D_3 compared with the D_2 receptor and ropinirole binds D_3 receptor with higher affinity compared with D_2 and D_4 receptors. With respect to antagonists, haloperidol shows 10–20 times higher affinity for the D_2 receptor. The D_4 receptor is distinguished from the other two by its higher affinity for clozapine.

CNS Distribution

Dopamine receptors are widely distributed throughout the CNS, mediating the effects of dopamine on locomotion motivation, emotion, cognition, and endocrine system. The dopamine receptors are mainly located in the striatum, the limbic system, the brain cortex, and the infundibulum which form the three main dopaminergic pathways, the nigrostriatal, the mesocorticolimbic, and the tuberinfundibular.

The D_1 receptor is the most widespread receptor and its mRNA has been found in striatum, nucleus accumbens, and the olfactory tubercle. In addition, D_1 receptors have been detected in the limbic system, thalamus, and hypothalamus. The D_5 receptor expressed less compared with D_1, and its mRNA has been found in the cerebral cortex, lateral thalamus, striatum, hippocampus, and to a lesser degree in the substantia nigra, and medial thalamus.

The D_2 receptor has mainly been located in the striatum, nucleus accumbens, and olfactory tubercle. D_2 receptor mRNA is also present in the prefrontal cortex, amygdala, hypothalamus, hippocampus, and substantia nigra. The D_3 receptor has been found in the nucleus accumbens and the olfactory tubercle, and is poorly expressed in the dorsal striatum. In comparison to D_2 receptor, minimal expression of D_3 receptor has been detected in the substantia nigra, hippocampus, and ventral tegmental area. The D_4 receptor is highly expressed in frontal cortex, amygdala, hippocampus, hypothalamus, and mesencephalon.

Physiological Properties

Movement

Disturbances in the dopaminergic systems result in several neurological and neuropsychiatric disorders. Dopamine in the nigrostriatal pathway serves to generate voluntary movement. Destruction of the dopaminergic neurons of the substantia nigra is the pathological hallmark of Parkinson's disease, causing bradykinesia, akinesia, and muscular rigidity. The degree of forward movement is mainly controlled by the activation of D_1, D_2, and D_3 receptors in the ventral striatum. Activation of D_2 autoreceptors causes a decrease in dopamine release and decreases locomotion; on the other hand, activation of postsynaptic D_2 receptors slightly increases locomotion. It has now been confirmed that the simultaneous activation and synergistic interaction between the D_1 and D_2 receptors are essential for a D_2 agonist to exert its maximal effect on locomotion. As a result, the blockade of D_2 receptors by antipsychotic drugs can manifest motor dysfunctions similar to those in Parkinson's disease.

It is also important to note that activation of postsynaptic D_3 receptors in the nucleus accumbens can have an inhibitory effect on movement. Activation of these receptors by an agonist inhibits motor activity, whereas activation by an antagonist has the opposite effect.

The symptoms of restless leg syndrome (RLS) are more severe at night when dopamine level falls and is at its lowest amount. In addition, RLS symptoms improve with dopamine agonists, ropinirol, and premipaxole and worsen with dopamine antagonist such as neuroleptics. These observations indicate a relationship between dopaminergic system and RLS. In fact, positron emission tomography (PET) studies have suggested a reduction in D_2 receptor binding in the striatum of patients with RLS.

Reward, Motivation, and Cognition

The mesolimbocortical pathway is involved in cognition, reward, reinforcement, motivation, and emotional stability. An increase or decrease in dopamine activity in the mesolimbic pathway has been associated with different symptoms of schizophrenia. The increase in dopaminergic transmission causes a state of psychosis, resembling the positive symptoms of schizophrenia. D_2 receptor antagonists (i.e., neuroleptic drugs) treat these symptoms very effectively with little effect on the negative symptoms of the disease. A number of the patients treated with neuroleptics suffer from movement disorders or extrapyramidal side (EPS) effects. It is thought that the antipsychotic properties of neuroleptics derive from their action on the dopamine receptors in the mesolimbic system, while their EPS are from blocking the D_2 receptors in striatum.

The dopaminergic activity in the mesolimbic system also plays a significant role in reward and reinforcement. Drugs of abuse increase dopamine release in the mesolimbic system, whereas their withdrawal reduces dopaminergic transmission. Studies have shown that both D_1 and D_2 receptors are involved. Receptor antagonists attenuate this behavior while agonists enhance the reinforcement effects of these drugs.

Learning and Memory

The effect of dopamine on learning and memory has been studied extensively. Studies have reported a relationship between the activation of the D_1 receptor in the prefrontal cortex (PFC) and optimization of working memory. One study indicated that too much or too little stimulation of D_1 receptors in PFC impaired the working memory. A similar relationship between D_2 receptors in PFC and working memory has not been established. However, there is some evidence that stimulation of D_2 receptors in the hippocampus can improve memory functions and performance. Studies have also shown that the activation of hippocampal D_1 receptors may improve acquisition and retention of memory. The high expression of D5 receptors

in hippocampus indicates their potential role in mediating the effect of dopamine and other agonists in learning and memory; however, their role has not been shown to be as significant as D_2 receptors. Based on these findings, both D_1 receptors in the PFC and D_2 receptors in hippocampus can be considered pharmacological targets for cognitive impairments that are associated with debilitating disorders like Parkinson's disease and Alzheimer's disease. Unfortunately, currently, there are no medications available to target these receptors in these specific areas. Clinically, all available dopamine agonists tend to worsen the cognitive function in patients with Parkinson's disease and memory impairment.

Pituitary Gland and Prolactin

Tuberoinfundibular pathway is one of the major dopamine pathways in the brain originating from hypothalamus. The release of dopamine in this pathway regulates prolactin secretion by the pituitary gland. D_2 receptor and its isoforms, D_{2L} and $D_{2S,}$ are expressed in the anterior and intermediate lobes of the pituitary gland with D_{2L} isoform being more prominent. In addition, D_4 receptor and in particular, $D_{4,4}$ variant, has been found in the anterior pituitary. The major role of the D_2 receptor in the pituitary gland is to inhibit the synthesis and secretion of prolactin, while the physiological role of the $D_{4,4}$ variant in the pituitary gland is not known. Some antipsychotic drugs block dopamine receptors in this pathway causing hyperprolactinemia, while D_2 receptor agonists, such as bromocriptine, are shown to be very effective in normalizing elevated prolactin levels. Several studies also suggest that dopamine may play a role in regulating the release of thyroid stimulating hormone, follicle stimulating hormone, and luteinizing hormone from the anterior pituitary gland.

Migraine

The role of D_2 receptors in the treatment of migraine has been studied and reported. It has been hypothesized that migraine sufferers have a lower threshold for dopamine receptor activation. This is consistent with typical features of a migraine attack. Studies have shown that administration of a dopamine agonist such as apomorphine can induce a statistically significant higher rate of dopaminergic symptoms such as nausea and vomiting in migraine patients. It has been suggested that this is due to a chronic deficiency of dopamine release by the presynaptic neurons making the postsynaptic dopamine receptors hypersensitivite in these individuals. D_2 receptor antagonists, such as prochlorperazine and metoclopramide, have shown to acutely relieve several symptoms of a migraine attack.

Dopamine Transporter: Aging and Parkinson's Disease

C R Overk and E J Mufson, Rush University Medical Center, Chicago, IL, USA

Glossary

Cholinergic – Acetylcholine-based neurotransmission of neural impulses.
Dopamine (DA) – A monoamine catecholamine neurotransmitter and hormone.
Dopamine transporter (DAT) – A 12 transmembrane symporter protein that transports DA out of the synaptic cleft and into the presynaptic terminal.
1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) – A neurotoxin selective for substantia nigra DA neurons.
Single positron emission computerized tomography (SPECT) – 3-dimensional tomographic imaging system using gamma waves and radionucleotides.

Definition and History

Dopamine Transporter

Dopamine transporter (aka. dopamine active transporter; DAT) was first described by Iversen and colleagues in 1971 and cloned 20 years later by Giros and coworkers.

DAT, a 12 transmembrane-spanning protein, is a symporter coupled to Na^+/Cl^- encoded on chromosome 5 (5p15.3) and is ~64 kbp long containing 15 coding exons. The neurotransmitter DA is transported out of the synapse and into the neuron by DAT (**Figure 1**), which is found in the perisynaptic area of dopaminergic neurons. Select neuronal populations within the brain express DAT including the striatum (caudate and putamen), nucleus accumbens, globus pallidus, cingulate cortex, olfactory tubercle, amygdala, and the midbrain subgroups of the substantia nigra and ventral tegmental area.

Dopamine

Dopamine (DA), a monoamine catecholamine belonging to a class of compounds that function as both a neurotransmitter and a hormone (**Figure 2**), was first synthesized by George Barger and James Ewens in 1910 in the Wellcome laboratories in London.

The enzyme which converts levodopa (L-dopa) to DA, termed dopa decarboxylase, was discovered by Peter Holtz in 1938. Sir Henry Dale evaluated the biological actions of DA and found them to be similar to adrenaline and in 1952 suggested the name, DA, to replace the full chemical name 3,4-dihydroxyphenylethylamine. In 1957, scientists at the Hans Weil–Malherb's laboratory first demonstrated DA in the brain. Two years later, DA was localized in the striatum. DA is a neurotransmitter for several neural pathways including the nigrostriatal, mesolimbic (including the tegmental area, nucleus accumbens, ventral striatum, and amygdala) and mesocortical (ventral tegmental area to the medial prefrontal, cingulate, and entorhinal cortex) pathways. DA is also found in the tuberoinfundibular pathway coursing from the arcuate and periventricular nuclei of the hypothalamus to the pituitary and median eminence.

Pathogenesis/Pathophysiology

DAT and Parkinson-Like Syndrome

Although the biological action of DAT is to selectively transport DA into the presynaptic neuron, it can transport structural analogues of DA such as the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; **Figure 2**), which induces a Parkinson-like syndrome in humans, some nonhuman primates, and mice. MPTP selectively degenerates dopaminergic neurons in the substantia nigra *pars compacta* by metabolizing monoamine oxidase type B followed by spontaneous oxidation to 1-methyl-4-phenylpyridium (MPP^+), which is structurally similar to DA. DAT transports MPP^+ (**Figure 2**) into neurons at rates similar to DA uptake leading to DA cell toxicity.

Other DAT Transported Compounds

In addition to MPTP/MPP^+, two pyridine derivatives, 2-methyl-MPP^+ and *p*-amino-MPP^+, are also intraneuronally symported by DAT, although with less toxicity and selectivity than MPP^+. Environmental factors such as isoquinoline (**Figure 2**) and its derivatives are considered as dopaminergic neurotoxins, and play a role in the pathogenesis of a Parkinsonian-like syndrome. These compounds have a lower affinity and uptake velocity than MPP^+, which may limit toxicity in dopaminergic cells. β-Carbolines, heterocyclic molecules structurally related to MPTP/MPP^+ (**Figure 2**), use DAT to enter nondopaminergic

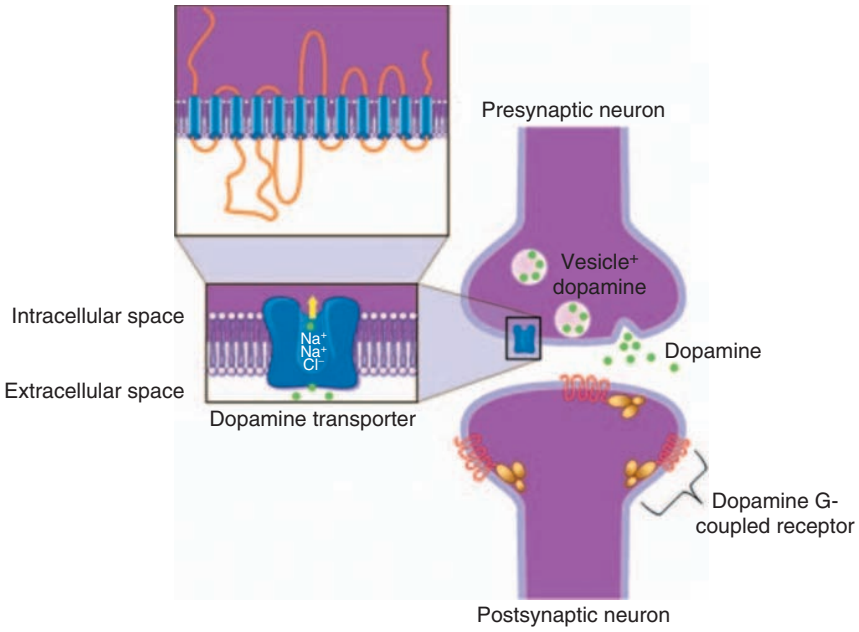

Figure 1 Structural diagram of DAT.

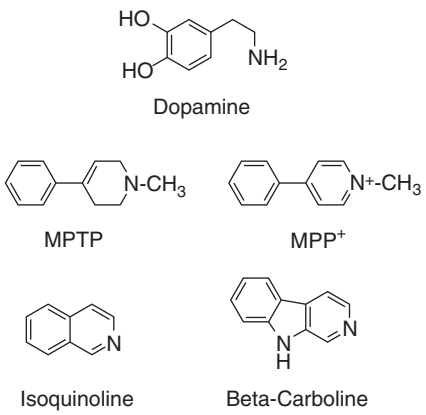

Figure 2 DAT transported compounds.

neurons such as cholinergic perikarya. The functional consequences of these molecules are poorly understood as is their involvement in Parkinson's disease (PD) and other movement disorders.

Epidemiology/Risk Factors

DAT Levels

The epidemiologic risk factors that affect the biochemistry of DAT remain ill defined. However, there is evidence suggesting that high levels of DAT play an important role in the selective vulnerability of substantia nigra dopaminergic neurons. On the other hand, a corresponding loss in DAT is associated with reduced transport of DA neurotoxins such as MPTP/MPP^+, resulting in less dopaminergic neuron loss over time. In this regard, animal models of DA cell death indicate that high levels of DAT lead to increased MPTP vulnerability whereas low DAT levels correlate with less MPTP toxicity.

Age

Age is a major risk factor for several neurological diseases including PD. Clinical pathological studies have reported a reduction in the number of neurons containing the protein and genetic signature for DAT within the substantia nigra beginning around the fifth decade of life. The structural and functional consequences of the reduction in DAT during normal aging are unknown. Since ~40% of human dopaminergic cells in the substantia nigra may be lost by 60 years of age, the remaining dopaminergic cells may attempt to maintain synaptic dopamine levels by decreasing DAT expression. Age-related reductions in neuronal DAT may be a protective mechanism aimed at slowing the detrimental effects of dopaminergic dysfunction.

Clinical Features and Diagnostic Criteria

Although it is well established that there is a threshold loss of ~70–80% of nigral DA neurons which correlates with the onset of the classic motor symptoms seen in patients with PD, the normal age-related loss of DAT containing nigral neurons does not result in a similar sequela of symptoms. Alterations in DAT activity

determined by single positron emission computerized tomography (SPECT) imaging are used as a diagnostic tool to differentiate PD from essential tremor and other overlapping syndromes. For example, a progressive loss in DAT striatal ligand uptake corresponding with PD severity is distinguished from essential tremor where there is normal striatal uptake.

Diagnostic Work-up/Tests

Parkinson's Disease

The clinical diagnosis for PD is generally straightforward; however, when incomplete or overlapping syndromes are presented, DAT imaging can improve diagnostic accuracy. Alzheimer's disease, essential tremor, vascular Parkinsonism and drug-induced Parkinsonism are examples of inconclusive parkinsonian features. SPECT–DAT allows imaging of striatal DA activity using different SPECT ligands ([^{99m}Tc]TRODAT, [^{123}I]β-CIT, [^{123}I]IPT, or [^{123}I] FP-CIT) that bind to the DAT. SPECT–DAT assists in differentiating between patients with frank PD and other movement disorders depending on differential DAT imaging. Positron emission tomography (PET) using radioligands is also used to evaluate DAT density in the striatum of humans. In fact, dopa-decarboxylase PET labeling was the gold standard for evaluating DA neurons in the substantia nigra prior to the advent of DAT tracers. Although PET has a higher resolution and provides better quantitative capacity than SPECT, the shorter half-life for the radiotracers and the higher cost per scan are caveats associated with the use of PET.

Dopaminergic Agonists in Parkinson's Disease

P A LeWitt, Wayne State University School of Medicine, Detroit, Michigan, USA

Glossary

Agonist – A neurochemical entity that acts at a receptor to stimulate a physiological response.

Dopamine – A naturally-occurring catecholamine active throughout the body in various neuronal and neuroendocrine roles. Dopamine is a neurotransmitter whose major deficiency in the striatum confers the symptomatology of Parkinson's disease.

Dopamine receptor – The structural and functional element of a neuron in a dopaminergic pathway at which dopamine acts. The dopamine receptor, which has several sub-types, is also subject to the influence of synthetic compounds that can act as either an agonists or antagonist.

Dopaminergic agonist – A compound with the neurochemical property of stimulating one or more classes of dopamine receptor.

Definition and History

Drugs that stimulate dopamine receptors in the striatum (putamen and caudate nucleus) have been a major direction of drug development for PD. Following the success of levodopa, an amino acid precursor of dopamine, researchers sought small molecules that could duplicate and, possibly, improve upon the effectiveness of levodopa at reversing parkinsonian signs and symptoms. Although these efforts yielded major advances in PD therapeutics, this class of drugs – *dopaminergic agonists* – has not replaced levodopa as the major therapy. Today, there is worldwide marketing of 12 dopaminergic agonists (DAs) with pharmacological actions resembling those of dopamine. DAs are extensively used for treating patients affected at all stages of PD. Their effectiveness as a primary management strategy for another movement disorder, restless leg syndrome (RLS), introduced them to an even larger group of patients.

The initial roles for DAs were as a substitute or as a means to augment the effectiveness of levodopa in PD. However, there has been evidence that their long-term use from the start can lower the risk of a PD patient to develop dyskinesias or motor fluctuations in association with levodopa. Furthermore, there is also an indication that DAs might be neuroprotective against PD progression. The consensus of most clinicians is that each of the available orally-administered DAs is quite similar in clinical effectiveness for PD and RLS. The major differences are found in their delivery and side-effect profiles. Despite more than two dozen prototypes of DAs that underwent clinical trials, major pharmacological improvements to either their potency or their selectivity of action (particularly to avoid adverse effects) have not been accomplished.

Table 1 The 29 dopaminergic agonists that are currently marketed or else have undergone clinical trials for Parkinson's disease

- ABT-431
- Aplindore (DAB-452)[a]
- Apomorphine[b]
- Bromocriptine [Parlodel][b,c]
- Cabergoline [Cabaser, Dostinex][b,c]
- CF 35–397[c]
- Ciladopa (AY27,110)
- CI 201–678[c]
- CQA 206–291 (and CQ 32–084)[c]
- CQP 201–403[c]
- CV 205–502[c]
- CY 208–243[c]
- α-Dihydroergocryptine [Almirid][b,c]
- FCE 23884[c]
- Lergotrile[c]
- Lisuride [Dopergin][b,c]
- Mesulergine (CU 32–085)[c]
- Naxagolide (PHNO; MK-458)
- Pardoprunox (SLV-308)[a]
- *N*-Propyl-aporphine
- Pergolide [Permax][c]

[c]Compounds with an ergot or ergolene structure.
Marketing brand names are listed in square brackets.

Dopaminergic Agonists for Parkinson's Disease

Listed in **Table 1** are all of the DAs that have undergone clinical trials for PD since 1974. Of these, 10 are currently marketed. Structures of some of the marketed DAs are shown in **Figure 1**. Currently, two DAs are engaged in clinical investigation (aplindore and pardoprunox). Of the DAs that were discontinued from development, the major issues have been inefficacy, side-effects or toxicity, or the lack of clear advantage over other drugs.

Besides levodopa, the first drug administered for PD with dopaminergic properties was apomorphine. In 1951, a small clinical trial was published showing that transient reversal of parkinsonian features was accomplished with subcutaneous injections of this drug. The prominent nausea and hypotension acutely caused by apomorphine limited any practical application as a therapy. Furthermore, there was no understanding at this time that nigrostriatal dopamine deficiency was the key pathophysiology in PD. Hence, apomorphine was ignored from further development as a PD therapy for almost 3 decades. The subsequent rediscovery of this drug capitalized on its requirement for subcutaneous administration, in order to achieve rapid and reliable reversal of PD symptomatology. Apomorphine is now used for "rescue" from immobile states. It also can be infused continuously in the subcutaneous space by means of a portable pump, thereby maintaining constancy in anti-parkinsonian actions. However, despite its anti-parkinsonian potency, the inconvenience and discomforts of subcutaneous injection have relegated apomorphine to a rarely-utilized therapeutic niche as compared to the orally-active DAs.

Bromocriptine: The First Oral Dopaminergic Agonist for Parkinson's Disease

Introduced in 1974, bromocriptine was the first oral DA used to treat PD. Bromocriptine is synthetically modified from a naturally-occurring ergot structure and shares a structural homology with the molecular structure of dopamine,

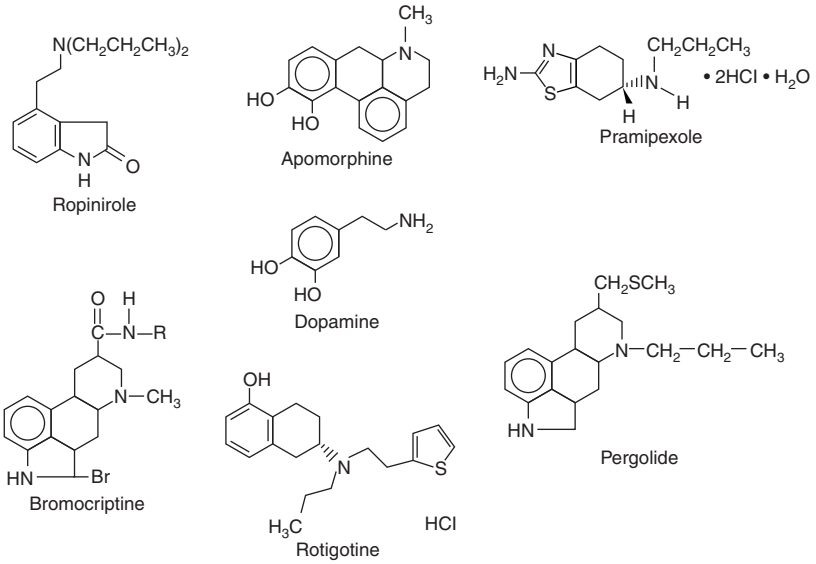

Figure 1 Dopaminergic agonists for Parkinson's disease.

as do virtually all of the marketed DAs (**Figure 1**). Bromocriptine was chosen for treating PD based on its dopaminergic properties that are also enacted on hypothalamic endocrine systems. Following initial clinical trials with bromocriptine, clinicians realized that this compound provided a possible substitute for levodopa that was not subject to its capricious absorption and metabolic pathways. In addition, many studies in PD subjects showed that the problems of advanced PD could be helped with this DA. Treating motor fluctuations and the opportunity for the lowering of LD dose (to lessen dyskinesias) were some of the clinical applications that bromocriptine offered to the patient with advanced PD. These properties are largely shared by the other marketed DAs, whose clinical differences are largely due to their side-effect profiles. Bromocriptine is still available but only infrequently used today.

Further Development in Dopaminergic Agonists: Dopamine Receptor Activity

In developing new DAs, the "ideal" receptor stimulation profile has not been definitively created. Early on, the predominant dopamine receptor population in the striatum was recognized to be a G-protein receptor not linked to adenylate cyclase. As additional classes of dopamine receptors were discovered, DAs in clinical use were found also to be quite potent at other dopamine receptors, termed D-3 and D-4. Relationships between the stimulation of these receptors and clinical outcomes (anti-parkinsonian effect and adverse effects) have not been clearly defined. Among marketed DAs, each differs in affinities at D-2, D-3, and D-4 receptors. The properties most closely linked to anti-bradykinetic effect in animal model studies were those of D-2 and D-3 agonism. However, these pharmacological differences do not seem to translate into altered profiles of clinical effectiveness.

One possible anti-parkinsonian target that has puzzled researchers is the adenylate cyclase-linked D-1 dopamine receptor. Experiments with animal models of Parkinsonism might suggest that stimulating the D-1 receptor should be avoided, since the mechanism for LD-induced dyskinesias seems to be mediated through this system. Among DAs used to treat PD, pergolide confers D-1 agonism while bromocriptine was a weak antagonist of the D-1 receptor. The relative similarity in clinical outcomes from these two drugs might suggest that the D-1 receptor played no role in anti-parkinsonian effects. However, one topic of interest has been whether a selective D-1 agonist might be effective for parkinsonian features without causing hallucinations or other undesired effects common with drugs acting at other classes of receptor. Two DAs, CY 208–243 and ABT-431, underwent limited testing in clinical trials and indicated that an anti-parkinsonian action could be achieved in the absence of stimulating D-2 receptors. (These drugs were not characterized with respect to the higher-order dopamine receptors such as D-3 and D-4). The limited clinical experience with each of these compounds did not allow answering the critical question of whether selective D-1 agonism would result in a better side-effect profile. Both D-1 agonists were discontinued after limited clinical trials because of their adverse effects.

Pharmacological Challenges with Dopaminergic Agonists: Adverse Effects

Managing side-effects of DAs is a major challenge for their use, especially at their initiation. Their adverse effects

can include nausea and vomiting, hypotension, sedation, confusion, hallucinations, and exacerbation of levodopa-induced dyskinesias). Fortunately, there are several medication strategies that can help to manage many of the adverse effects of DAs, including concomitant use of the anti-nausea compounds trimethobenzamide, domperidone, and clozapine, and other drugs that can counteract orthostatic hypotension. In addition, the principles of gradual introduction of these drugs and the development of tolerance permit DAs to be used successfully. Even regular use of apomorphine, a potent emetic, can be well tolerated with prior use of a DA.

The side-effect profile of DAs includes adverse reactions also encountered with the use of LD. At initiation of therapy, DAs are best titrated upward over several weeks in small steps to avoid problems. Dopaminergic side-effects previously experienced with LD, such as dyskinesias, can be exacerbated. A unique category of behavioral adverse reactions has been recognized with DAs. Termed *impulse control disorders*, these problems can develop in association with conventional DA dosage in PD (and RLS) patients with no prior propensity for uncontrolled gambling, hypersexuality, excessive participation in hobby activities, compulsive shopping or eating, or any of a number of similar behavioral alterations.

Another category of problems occurring with DAs was the discovery that they were associated with rare instances of fibrotic disorders. This was a known property of certain drugs with ergot structures like the anti-migraine drug methysergide, which had long been recognized to have the risk of causing retroperitoneal fibrosis. The first of the fibrotic disorders recognized to occur with bromocriptine was pleural thickening, intraparenchymal fibrosis, and effusion. This disorder led to severe pulmonary compromise in some instances, but appeared to remit gradually after discontinuation of the drug. Similar problems were recognized to occur after the introduction of pergolide. The ergot-related structure of these compounds and of others to follow was linked to this rare and seemingly idiosyncratic problem. The latest fibrosis-related problem to be recognized was that of cardiac valve thickening, sometimes requiring surgical treatment. Several reports linking this problem appeared in analysis of cases involving pergolide and cabergoline treatment. Though rare, these serious consequences have led to a reappraisal of the role for ergot-derivative DAs in PD therapy, especially since DAs without an ergot structure (like pramipexole and ropinirole) appeared to be equally effective as the ergot compounds. In the United States, pergolide has been withdrawn from the market because of its toxicity. Cabergoline has never been marketed in the United States for PD. In other countries, these compounds continue to be used, and so regular monitoring for the occurrence of pulmonary and cardiac valve fibrosis continues to be necessary.

Pharmacological Experience with Dopaminergic Agonists: Symptomatic Benefits

The initial experience with bromocriptine led to recognition of how effective DAs can be to enact major improvements in the various motor features of parkinsonism. Among several dozen studies, clinical observations indicated that tremor, rigidity, slowed movement, gait disorder, and postural disturbance could be helped, much as was accomplished by levodopa. In addition, the advanced PD patient often could be helped for problems not readily responsive to further increases of the levodopa regimen. The problem of regular wearing-off in the actions of levodopa can be helped by combining it with a longer-acting DA. Other clinical experience has shown PD patients with unpredictable "off" states and freezing of gait can be improved after addition of a DA regimen. Although the combination of DA with levodopa can lead to an increase of adverse effects, especially dyskinesias, it appears that DAs do not seem to exacerbate the problem as much as would an increased intake of levodopa. In fact, one strategy for managing patients with marked levodopa-induced dyskinesias was to substitute a DA against the prior regimen of levodopa.

As shown by the initial experience with bromocriptine and found subsequently with other DAs, one important application has been the treatment included early morning dystonia, especially if the drug was taken at bedtime. Adjunctive DA therapy also seems to lessen dystonic symptoms at other times of day as well. Combination of a DA with levodopa can be used as initial therapy to some advantage in avoiding various undesired outcomes occurring with levodopa alone. In several clinical trials carried out with bromocriptine, ropinirole, and pramipexole, initial treatment with a DA (even if combined at some point with levodopa) fared better than levodopa in risk for developing dyskinesias or motor fluctuations.

Several other parkinsonian disorders besides PD also have a dopaminergic deficiency, including progressive supranuclear palsy and multiple system atrophy (previously termed olivopontocerebellar atrophy, Shy–Drager syndrome, and striatonigral degeneration). Clinical trials investigating the possible effectiveness of DAs in these disorders did not find, in general, that DAs offered any relief of their parkinsonian features (as has been the experience with levodopa treatment). In typical PD, problems usually unresponsive to levodopa such as retropulsive imbalance and forward-flexed posture are also unlikely to improve with a DA. One study with pramipexole found that patients with resting tremor persisting during levodopa therapy did lessen after this DA was added.

Besides the ergot-derivative pergolide, the major DAs currently marketed on a worldwide basis are pramipexole and ropinirole. Both of these compounds with nonergot structures enact potent stimulation at D-2 and D-3

dopamine receptors but lack D-1 agonism. Each underwent extensive preclinical testing in animal models of parkinsonism that found they could act independently of levodopa in treating PD. This property was tested with each drug in a number of clinical trials. In addition to demonstration of their symptomatic efficacy as monotherapy and as adjunctive treatment with levodopa, other clinical trials investigated long-term outcomes of DA monotherapy and combined with levodopa, as compared to levodopa alone. Both ropinirole and pramipexole share with levodopa a similar profile of anti-parkinsonian actions. Added to levodopa in advanced PD with motor fluctuations and suboptimal response, various response measures have also demonstrated improvements and better quality of life from the DA, as compared to placebo treatment. The results of these studies have not, in general emphasized the improved features of one DA over another, although there haven't been randomized clinical trials comparing pramipexole to ropinirole. Earlier crossover studies comparing the anti-parkinsonian effectiveness of the DAs lisuride and pergolide to bromocriptine concluded that there was no overall difference.

Pharmacological Experience with Dopaminergic Agonists: Protective Benefits

As described above, DAs can be regarded as a therapeutic alternative to levodopa. Their increased expense and incidence of side-effects, as well as somewhat less symptomatic effectiveness, might seem to be reasons not to make use of DAs in early stages of PD. However, the demonstration of protective roles for various DAs has prompted consideration of their use in additional contexts.

Clinical trials exploring the risk for developing dyskinesias and motor fluctuations have been influential in charting an important role for DA therapy in PD. This role has arisen from hypotheses that the longer duration of action of DAs (based on their pharmacokinetic profiles) offers more continuous dopaminergic stimulation and, hence, less provocation of dyskinesias and motor fluctuations than shorter-acting levodopa preparations. This notion has been tested in two large scale studies involving randomizations between optimized regimens of levodopa and the DAs pramipexole and ropinirole (the CALM-PD and Ropinirole 056 studies, respectively). Both studies were carried out for several years and permitted a comparison between outcomes with levodopa alone and the DA (either as a monotherapy or with some supplemental levodopa, as needed). Subjects were followed with respect to clinical outcomes such as relief of Parkinsonism and the development of dyskinesias (and, in the case of the CALM-PD study with pramipexole, also for development of motor fluctuations). In both studies, monotherapy with the DAs was associated with less incidence of dyskinesia, even if levodopa needed to augment to the previous DA monotherapy regimen. After a few years of treatment, most subjects needed to supplement DA regimens with levodopa for optimal effect. Although the supplemental levodopa clearly increased the incidence of dyskinesias or motor fluctuations, risks for developing these chronic levodopa-related outcomes were diminished by the early use of the DA. These studies also provided the chance to compare symptomatic control of parkinsonism by the two randomized treatment options; benefits of the DAs appeared to be less than achieved by levodopa. Combining a DA with levodopa does permit a smaller daily dose of levodopa to be used, but this levodopa sparing effect may not be the entire story for improved outcomes. It is also possible that the more continuous dopaminergic stimulation with the combination regimens was the basis for the better results with respect to dyskinesias and motor fluctuations, although this question clearly needs further exploration.

Another protective dimension of DAs has to do with their possible actions as disease-modifying drugs. Neuroprotective actions of both ropinirole and pramipexole have been demonstrated in various in vitro models of neuronal degeneration induced by toxins or other experimental interventions. These results have been extrapolated to hypotheses that doses of DAs used in PD therapeutics might offer a PD patient not only symptomatic benefit but, possibly, slowing of disease progression. The two studies investigating this question compared regimens of pramipexole (a subset of patients enrolled in the CALM-PD study) or ropinirole (a trial termed REAL-PET) versus randomization to levodopa. In each instance, a surrogate marker of disease progression was the basis for interring neuroprotection. For the pramipexole study, it was change from baseline in presynaptic dopamine transport binding in the stratum with a single-photon emission computerized tomography ligand, beta-CIT (whose binding is proportional to the extent of nigrostriatal dopaminergic projections). The ropinirole trial used positron emission tomography scans of the striatum using ^{18}F-fluorodopa (a levodopa analogue), also providing a view of whether the continuing degeneration of dopaminergic nigrostriatal neuronal projections differed between the levodopa and DA regimens. In each instance, these surrogate markers of neuronal degeneration suggested that the DAs slowed disease progression compared to levodopa.

Although alternative views might be that levodopa might have accelerated disease progression (as judged by loss of dopaminergic presynaptic innervation in the striatum), or that the neuroimaging studies were merely artefactual, many neuroscientists have viewed these trials as confirmation of preclinical animal model data with the DAs. Further investigation of these intriguing findings is needed before firm conclusions are warranted as to a disease-modifying neuroprotective role of DAs in PD.

Furthermore, the question remains whether the apparent benefits of these drugs are linked to their DA properties or other pharmacological actions.

Delivery of Dopaminergic Agonists

The continuity of dopaminergic action appears to be critical for avoiding long-term and irreversible complications of LD treatment in PD. There is evidence from animal models of parkinsonism that intermittent pulsatile receptor stimulation with a DA can generate dyskinesias (much as short-acting LD does). In these experiments, the same drug administered in a more continuous manner avoids this outcome. These observations are in support of a therapeutic strategy for long-acting dopaminergic stimulation. The available oral drugs have plasma elimination half-lives in excess of that for a LD. It may be for this reason that DAs produce better results than LD on a long-term basis. However, other evidence from animal studies suggests that LD confers increased risk for dyskinesias independently of its short plasma elimination half-life.

The three major marketed DAs (ropinirole, pramipexole, and cabergoline) offer pharmacokinetic profiles useful for managing different problems in this disorder. In recent years, a transdermal DA was introduced with a 24-h effect. Rotigotine, a novel nonergot compound with a short clearance half-life, was formulated for maintaining constant dopaminergic stimulation. The product can be especially helpful for patients needing PD medication effect throughout the night or upon awakening. Otherwise, the effects of rotigotine are quite comparable to the other marketed DAs. A controlled-release preparation of ropinirole, introduced in 2008, also offers also a 24-h continuity of effect.

On the other side of the pharmacokinetic spectrum, injection of apomorphine provides a rapid dopaminergic effect. With the onset of the anti-parkinsonian effect typically occurring within 5 min after subcutaneous injection, apomorphine can rapidly and reliably rescue a PD patient from immobility associated with irregular effects of oral medications. Apomorphine is a potent DA with both D-1 and D-2 dopamine receptor effects. It has also been used for continuous subcutaneous infusion as a substitute for all other PD treatment. Continuous apomorphine delivery can be titrated to a dose that maintains an "on" state without triggering dyskinesias.

Dopaminergic Agonists: Role in Therapy

DAs have achieved a major role in the treatment armamentarium for PD, especially as a means for boosting the effectiveness of anti-parkinsonian control when levodopa effect is maximal. Their extended plasma clearance half-life is another factor contributing to their utility. As shown by a large number of studies, these drugs can provide sustained benefit for advanced PD. They may also help to avoid problems associated with long-term LD use and, possibly, progression of the disease itself. DAs are far from an ideal therapy: they are expensive and have a number of adverse effects associated with them, especially the relatively uncommon though potentially disabling behavioral disorders discussed above. Younger PD patients seem to be good candidates for the initial use of DAs, since LD exposure poses the risk for developing dyskinesias and motor fluctuations. Some clinicians are concerned that older PD patients are not likely to tolerate this class of medications at usual therapeutic doses, although there are many examples of elderly patients well managed on DAs. The still-unconfirmed findings of apparent neuroprotective actions are a reminder that drugs sometimes have additional actions beyond initial intentions that guided their development.

Drosophila Models of Parkinson's Disease

E Ziviani and A J Whitworth, University of Sheffield, Sheffield, UK

Glossary

Drosophila – *Drosophila melanogaster*, a common fruit fly.
GAL4/UAS – A widely used bipartite system that uses the induced expression of yeast transcription activator GAL4 to drive expression of a transgene adjacent to upstream activator sequences (UAS).
Mutagenesis – The process of inducing changes in the DNA, usually by chemicals or mobile DNA elements, to attenuate the function of a gene.
Parkinson disease (PD) – A neurodegenerative disorder leading to loss of motor skills, caused by the loss of dopaminergic neurons in the central nervous system.
RNAi – RNA interference, a mechanism by which endogenous gene transcripts are degraded following exposure to short, complementary sequences of double stranded RNA.

Definition and History

Drosophila melanogaster, commonly referred to as fruit flies reflecting their natural habitat on rotting fruit, belongs to the family *Drosophilidae*, which derives its name from the Greek *drosos* = dew and *philos* = loving. *Drosophila* is a widely used laboratory model organism, particularly in the fields of genetics and developmental biology. Recently, *Drosophila* has been used to study human disease mechanisms. The first *Drosophila* model of Parkinson disease (PD) was reported in 2000 with the generation of transgenic flies expressing normal and dominant mutant forms of α-synuclein. The first model of recessive forms of PD was reported in 2003 with the generation of loss-of-function mutations in the *Drosophila* homolog of *parkin*.

Why Use *Drosophila* Models?

Drosophila present a number of technical advantages over other common laboratory organisms. These include a short life cycle and generation time, taking only 10 days from fertilized egg to mature adult, a myriad of powerful molecular and genetic tools available, and a diverse and freely accessible public resource centers. One of the most powerful tools used in *Drosophila* is the GAL4/UAS system, which exploits the potent yeast transcription activator GAL4 to selectively drive the expression of a designated sequence adjacent to the upstream activator sequence (UAS). This system has been widely used in the investigation of gene function in vivo, since it offers a high degree of temporal and spatial controllability. Typically used to overexpress a gene of choice, this system has recently been adapted to induce gene-specific RNAi knockdown in vivo. To complement this, a wide array of classic genetic approaches is available to mutate the genome for gene-specific or random mutagenesis. It is relatively straightforward, rapid, and extremely cost-effective to generate 'knock out' models of a gene of interest by targeted mutagenesis.

Perhaps the most widely lauded advantage of *Drosophila* research is the ability to conduct large-scale genetic screens capable of identifying novel genes regulating a biological process of interest. This approach allows the identification of other genes that interact with a gene of interest through modification of a loss-of-function or overexpression phenotype. These flies are then mated to a mutagenized strain and the progeny screened for mutations that either suppress or enhance the phenotype. Identifying the genes that modify the mutant phenotype is an extremely powerful method for uncovering the biological basis of the pathology. It is largely for this reason that in recent years *Drosophila* has received significant attention as a powerful model organism with which to dissect the pathogenic mechanisms of human disease and even as a tool in the drug discovery pipeline.

The specific clinical and pathological details concerning idiopathic PD and other forms of Parkinsonism are elaborated in other articles of this Encyclopedia; however, we shall briefly iterate the salient points relevant to the context of modeling PD in *Drosophila* and its contribution to our understanding of the disorder. Briefly, the cardinal features of PD include degeneration of dopaminergic (DA) neurons, progressive locomotor deficits, and in many cases the presence of Lewy body inclusions. All of these features can be analyzed experimentally in *Drosophila*.

Much insight into the pathogenic mechanisms contributing to PD has been provided by the analysis of genes linked to relatively rare heritable forms. Mutations in a growing list of genes can give rise to dominant and recessive Parkinsonism, indicating aberrant toxic gain-of-function or loss-of-function, respectively, of those inherited cases. It is thought that similar pathogenic mechanisms may contribute to the more common sporadic form of PD. The genetic aberrations that cause heritable Parkinsonism can be mirrored using standard genetic approaches in *Drosophila*. For example, dominantly acting mutations in

Table 1 Major characteristics of the current *Drosophila* models of PD

Gene/ protein	*Mode of inheritance*	*Model type*	*DA neuron loss*	*Locomotor deficits*	*Other*	*Putative function*
SNCA/α-synuclein	Dominant	Transgenic	±	±	Lewy body-like aggregates	Synaptic plasticity?
Parkin	Recessive	Mutation	+	+	Mitochondrial dysfunction	E3 ubiquitin-protein ligase
DJ-1	Recessive	Mutation	− (+)	−	Oxidative stress sensitive	Oxidative stress sensor, chaperone
PINK1	Recessive	Mutation	−	+	Mitochondrial dysfunction	Mitochondrial kinase
Dardarin/ LRRK2	Dominant	Transgenic, mutation	±	++		Kinase
HtrA2/Omi	?	Mutation	−	+	Oxidative stress sensitive	Protease

α-synuclein and LRRK2 have been successfully modeled by generating transgenic lines that can express wild-type and pathogenic forms in a spatially and temporally controlled manner. Similarly, loss-of-function mutagenesis has been used to target the conserved genes for recessively inherited Parkinsonism *parkin*, *PINK1*, and *DJ-1*. The major characteristics of the various current models are summarized in **Table 1** and provided in further detail in the following section.

Summary of Model Characteristics

Although the *Drosophila* genome does not encode members of the synuclein family, models to study the pathogenic mechanisms of α-synuclein have been established. A number of independent transgenic lines expressing wild-type or pathogenic human α-synuclein have been shown to cause degeneration of DA neurons and locomotor deficits have been reported. It should be noted that not all experimenters have observed robust DA neuron degeneration but instead have reported a decreased DA neuron integrity. Protein aggregates with Lewy body-like characteristics have also been reported in this model, further strengthening the popular hypothesis that aberrant protein aggregation/degradation underlies α-synuclein pathogenesis. Consistent with these ideas, it has been reported that transgenic or chemical induction of molecular chaperones, such as heat shock proteins, is able to prevent some aspects of α-synuclein pathology in *Drosophila*.

Studies in other systems suggested that the toxicity of α-synuclein may be affected by posttranslational modifications such as phosphorylation. Compelling evidence using transgenic lines expressing phospho-mimic and phospho-defective forms of α-synuclein has demonstrated that phosphorylated α-synuclein may promote aggregation and toxicity.

Loss-of-function mutations in *parkin* cause age-related degeneration of DA neuron loss and locomotor deficits. They also show widespread mitochondrial disruption accompanying the degeneration of flight muscles and defects in spermatogenesis. Parkin mutants are also sensitive to chemicals that elevate oxidative stress or disrupt mitochondrial function. These observations support the view that a primary role of Parkin is to maintain mitochondrial integrity and protect against oxidative stress. Remarkably, these phenotypes are exactly recapitulated in loss-of-function *PINK1* mutants. In a ground-breaking study, a number of groups demonstrated using classic genetic analysis in *Drosophila* that parkin and PINK1 likely act in a common pathway, and epistasis analyses showed that parkin acts downstream of PINK1. This work in *Drosophila* was the first evidence that two genes linked to PD function in a common biological pathway. Another breakthrough came with the discovery that PINK1 and parkin genetically interact with components of the mitochondrial fission and fusion pathway. A number of studies in *Drosophila* models have now shown that the PINK1/parkin pathway likely regulates mitochondrial fission events, which have since been corroborated in mammalian systems. These findings provide a compelling lead toward the function of the PINK1/parkin pathway and its role in PD pathogenesis.

In contrast to the distinct overt phenotypes of *parkin* and *PINK1* mutants, mutations in *DJ-1* do not cause morphological or behavioral defects. Drosophila encodes two genes highly homologous to DJ-1, although the expression of one (DJ-1a) appears to be restricted to the male germline. Surprisingly, *DJ-1a/b* null mutations display no observable external abnormality and no degeneration of DA neurons; however, it has been shown that *DJ-1* mutants are strikingly sensitive to oxidative stress agents such as paraquat and rotenone. Indeed, a combination of biochemical and transgenic techniques has shown that posttranslational modification of DJ-1 upon oxidative stress is critical to DJ-1's protective role.

The most recent new *Drosophila* model of PD has been created using the common human $LRRK2^{G2019S}$ mutation.

This model recapitulates the cardinal features of progressive DA neurodegeneration and locomotor deficits; however, currently little more is known about the mechanism of LRRK2-mediated pathology. One intriguing recent report studying the sole *Drosophila* homolog has shown that one target of its kinase activity may be to 4E-BP, regulating protein translation and the induction of stress response programs.

Oxidative stress is a central theory in the pathogenesis of PD. *Drosophila* models have contributed to this idea by demonstrating that transgenic or pharmacological induction of antioxidant mechanisms is capable of mitigating toxic effects in nearly all models analyzed to date, including α-synuclein, parkin, PINK1, and DJ-1. Further work using these models to identify additional protective pathways will provide valuable insight into the pathogenic mechanisms of PD and highlight putative therapeutic avenues.

Drug-induced Movement Disorders

W J Weiner, University of Maryland School of Medicine, Baltimore, MD, USA

As drugs that affect central nervous system chemistry have only been in widespread use for the last 50–60 years, drug-induced movement disorders have not been long recognized. Akathisia, which is not a movement disorder but an inner feeling of restlessness and inability to sit still, was first described, in 1947, as a drug-induced state in association with the use of promethazine. The introduction of typical neuroleptics, which have a common dopamine receptor antagonism, made the clinical phenomenon of drug-induced akathisia apparent. Atypical antipsychotics have expanded the spectrum of drugs that induce akathisia.

Drug-induced parkinsonism was first described with the use of reserpine, a dopamine depleting agent. When traditional antipsychotics were introduced, drug-induced parkinsonism became a common clinical phenomenon. In the late 1950s and early 1960s, the first understanding of parkinsonism as it related to dopamine deficiency or dopamine blockade led to the momentous discovery that levodopa could alleviate the motor symptoms of Parkinson's disease. The successful introduction of large dosages of levodopa to treat Parkinson's disease in 1967 also included the description that athetoid movements were induced by levodopa in some of the patients. In 1969, additional reports about the early usage of levodopa in Parkinson's disease described that as many as 50% of the patients receiving levodopa developed dyskinesia. Levodopa became the treatment of choice for Parkinson's disease, and in subsequent years, many types of dyskinesia associated with the administration of levodopa have been described including wearing off dyskinesia, peak-dose dyskinesias, diphasic dyskinesias, and off-period dystonia. Most of the abnormal movements associated with the administration of levodopa are choreodystonic.

Tardive dyskinesia encompasses all of the delayed onset movement disorders associated with the use of dopamine receptor blocking agents. The movements seen in tardive dyskinesia can be choreoform or dystonic. Tardive dyskinesia was probably first described in 1957, 5 years after the introduction of chlorpromazine when a number of patients were reported who had been exposed to the drug for 2–8 weeks. These patients were elderly women who developed a lip-smacking dyskinetic movement. In subsequent years, isolated reports of choreodystonic movements and lingual facial buccal dyskinesia developing after the use of dopamine receptor blocking agents were published. Initially, the psychiatric community was reluctant to accept the notion that these movement disorders were secondary to the administration of neuroleptic agents. It was only in the late 1960s, when large-scale epidemiologic studies that demonstrated that these movements were associated with long-term neuroleptic treatment appeared, that the concept of tardive dyskinesia was accepted.

Pathophysiology

Most drug-induced movement disorders involve alterations in dopaminergic transmission. Drugs that are dopamine receptor antagonists such as the traditional neuroleptics – chlorpromazine and haloperidol – and the atypical neuroleptics – olanzapine, resperidone, and clozaril – as well as the antiemetic metaclopramide can all induce akathisia, acute dystonia, drug-induced parkinsonism, and tardive dyskinesia. The simplest and most long-standing theory of the pathophysiologic basis of these movements is that, dopamine receptor blockade induces supersensitivity of the dopamine receptors, which leads to abnormal movements. This concept was first published in 1970, based on the similarity between levodopa-induced dyskinesia in parkinsonism and tardive dyskinesia. The suggestion was made that chronic neuroleptic treatment produced supersensitivity of striatal dopamine receptors analogous to denervation-induced cholinergic supersensitivity seen in peripheral muscles. This concept has remained an important central construct in thinking about managing drug-induced movement disorders secondary to dopamine receptor blockade. However, there has been much criticism of this theory, and several important inconsistencies have been noted. In animal models of dopamine receptor antagonism-induced supersensitivity, the supersensitivity and the behavioral response occur quickly whereas tardive dyskinesia, in patients, usually takes months or years to develop. In addition, the movements of tardive dyskinesia can persist for years and sometimes be permanent whereas in the animal model, supersensitivity tends to dissipate quickly. It is also apparent that supersensitivity can be readily induced in the animal model whereas only a subset of patients develop a 'supersensitive' response, resulting in tardive dyskinesia. The supersensitivity dopamine receptor model is attractive and simple, but probably not the entire explanation.

Types of Drug-Induced Movement Disorders

The following drug-induced movement disorders will be described: acute dystonia, akathisia, drug-induced parkinsonism, and tardive dyskinesia. Drug-induced movement disorders can be divided into those movement disorders that are related to drugs which block or interfere with dopaminergic mechanisms and those which are dopaminergic agonists. Drug-induced movement disorders related to dopamine receptor antagonists occur in a temporal sequence from the earliest administration of the drug to more prolonged administration of the drug. The earliest drug-induced movement disorder is acute dystonia followed by akathisia, drug-induced parkinsonism, and, finally, tardive dyskinesia. Drugs which act as dopaminergic agonists or promote dopaminergic mechanisms including levodopa, methyphenidate, amphetamine, and cocaine induce choreo dystonic movement disorder after its prolonged use. However, cocaine and amphetamine can induce acute choreo dystonic disorders, but the most common agonist-induced movement disorder is levodopa-induced dyskinesia following months to years of dopaminergic administration for Parkinson's disease.

Drug-Induced Movement Disorders Related to Dopamine Receptor Antagonists

Akathisia

Akathisia is not a movement disorder but a subjective complaint of restlessness, often associated with the inability to keep still. Patients may complain of tension or abnormal limb sensations such as pulling or drawing feelings. The subjective inner sensation of restlessness often results in the patient performing a variety of motor movements in an attempt to relieve this sensation. Mildly affected patients may demonstrate little movement or can be seen physically tapping their toes or shifting in their chair. They may also move from one foot to another while standing and feel that they have to keep walking. Patients who are more severely affected may pace, run, rock, and, quite simply, be unable to sit still or even lie still for any period of time. The important point is that akathisia is not associated with any particular involuntary movement.

Differential diagnosis

The differential diagnosis of akathisia is not large. Other diagnoses to be considered in patients with this subjective sensation include agitation seen with psychiatric disorders, drug withdrawal states, and restless leg syndrome (RLS). Differentiating akathisia from agitation in a very disturbed patient can be difficult and may rely on a trial of increasing the neuroleptic dose. If an increase in the neuroleptic dose improves the psychosis and the restlessness, then it is probably more related to the psychiatric state. However, if increasing the neuroleptic increases the restlessness then the patient has akathisia. Opiate withdrawal can also result in restless, painful sensations in the legs and this is obviously diagnosed with the history of opiate ingestion. RLS can be difficult to distinguish, but in RLS, the abnormal sensation is usually limited to the legs and is particularly prominent at rest and often more so at night. It is quite useful that in RLS, movement alleviates the abnormal sensation.

Management

The most reliable therapy for akathisia includes neuroleptic dosage reduction or withdrawal if this is possible from a psychiatric standpoint. If this is not possible, a less potent neuroleptic or atypical neuroleptic could be

substituted, but this may not be possible from a psychiatric standpoint. There are reports that anticholinergics, antihistamines, and amantadine may improve restlessness. Benzodiazapines, β-blockers, and clonidine may be useful in treating akathisia.

Epidemiology

Akathisia can develop extremely rapidly after the initiation of neuroleptic treatment or it can develop after neurolpetic dosage is increased or a change is made from an atypical to a more potent traditional neuroleptic. The prevalence of akathisia varies widely in the literature depending on the potency and dosage of the drug examined. Prevalence estimates range from as low as 5% to as high as 75% with potent traditional neuroleptics such as haloperidol.

Pathophysiology

The underlying pathophysiology of akathisia is not known. It is known that akathisia seems to be related to reduced dopaminergic function either by receptor blockade or by dopamine depletion. There has been speculation that mesocortical dopaminergic mechanisms are involved.

Drug-Induced Acute Dystonia

Acute dystonic reactions, along with akathisia, are early drug-induced movement problems. Fifty percent of acute dystonic reactions occur within 48 h of beginning treatment with a neuroleptic, and 90% of acute dystonic reactions occur within 5 days of beginning the treatment. Acute dystonic reactions are associated not only with all antipsychotic drugs, but also with metaclopramide.

Epidemiology

The risk of acute drug-induced dystonia varies considerably depending on the age of the population studied, the potency and dosage of the drug administered, the route of administration, and any previous history of dystonic reactions. This movement disorder is much more likely to occur in younger individuals and is almost never seen after the age of 40. There does not seem to be a gender predilection for this reaction and there has been some discussion whether previous cocaine use is a risk factor. Patients who experienced a previous dystonic reaction seem to be at more risk.

Pathophysiology

The pathophysiology of acute dystonic reactions is obscure. It is related to dopaminergic mechanisms since this type of dramatic reaction is only seen with drugs that interfere with dopaminergic mechanisms. However, very little is known about why one patient develops an acute dystonic reaction and another does not when both are exposed to the same potent drug.

Clinical features

Acute dystonic reactions consist of a wide variety of prolonged or short-lived muscle spasms that result in typical dystonic abnormal postures and movements. Involvement of the eyes, face, throat, and neck are the most frequent manifestations. Oculogyric crisis in which the eyes are forced upward and lateral can be associated with head and neck dystonic postures. Acute dystonic reactions may encompass blepharospasm, grimacing, forceful jaw opening, tongue protrusion, and glossopharyngeal contractions. Torticollis, scoliosis, and trunk flexion are also possible. If the movement and postures are severe enough, there may be considerable pain. Younger children tend to have more generalized dystonic posturing particularly of the extremities and trunk.

Management and treatment

If the offending drug is withheld, the movement disorder will resolve spontaneously. However, the movements are distressing and can be disabling and acute treatment is warranted despite the self-limited nature of the condition. Almost all acute dystonic reactions will respond rapidly to parenteral injection of an anticholinergic or antihistaminic drug such as benztropine, procyclidine, or diphenhydramine. A single intramuscular dose of benztropine 1–2 mg or diphenhydramine 25–50 mg will usually resolve the episode within 15–20 min, but must be followed by an oral anticholinergic for at least a few days. Parenteral diazepam may be equally effective in relieving the movements; however, parenteral diazepam will usually sedate the patient and possibly cause respiratory depression. Acute laryngeal spasm, which is potentially a life-threatening condition, should be treated with intravenous benzodiazepam or benztropine. If no response is obtained within 30 min, the dosage of medication can be repeated.

After the resolution of the acute dystonic episode, most movement disorder experts will continue to administer benztropine or trihexyphenidyl in low dose for 4–7 days. This is done to prevent the reoccurrence of acute dystonia.

Drug-Induced Parkinsonism

Epidemiology

Drug-induced parkinsonism is a clinically distinct syndrome consisting of resting tremor, cogwheel rigidity, bradykinesia, and gait impairment. It is not clinically distinguishable from Parkinson's disease. There are some caveats with regard to the previous statement, which will be discussed in 'clinical course.' Risk factors for the development of drug-induced parkinsonism are uncertain and the literature has many contradictory reports. These risk factors have variously been listed in the past as including female gender, being elderly, administration of high potency and high dosages of neuroleptics. Other risk factors that have been examined include prior brain

damage, hereditary factors such as a family history of Parkinson's disease, and cognitive impairment. The most commonly accepted risk factors for the development of drug-induced parkinsonism remain female gender and the potency and dosage of the drug administered. Even with these risk factors, however, many patients taking high-dose potent neuroleptics do not develop drug-induced parkinsonism. Further, the time course for the development of drug-induced parkinsonism can vary considerably. Occasionally, patients develop severe parkinsonism after only a few days of a small-to-moderate dose of a neuroleptic administration and on other occasions, it may take months for the parkinsonism to develop. It is important to follow patients with drug-induced parkinsonism even after neuroleptics or dopamine depleting drugs are stopped, because reports exist demonstrating the evolution of Parkinson's disease, both clinically and pathologically, years after the development of transient and reversible drug induced parkinsonism. This observation suggests that patients who develop drug-induced parkinsonism may have subclinical Parkinson's disease and the drug exposure has served as a 'drug challenge' to unveil a disorder that may only develop spontaneously years later.

Pathophysiology

The pathophysiology of drug-induced parkinsonism when precipitated by typical or atypical neuroleptics seems straight forward with dopamine receptor antagonism resulting in parkinsonism. However, many patients receiving traditional or atypical neuroleptics at high dosage do not develop drug-induced parkinsonism. Obviously, more than simple dopamine receptor antagonism is involved. However, interference with dopaminergic mechanisms is the best explanation for this phenomenon. It is also consistent with the observation that drugs that deplete central nervous system dopamine, such as reserpine, also induce parkinsonism.

Parkinsonism can also be induced by medications which are not traditional or atypical neuroleptics; for example, Lithium. Lithium, more commonly, causes a symmetric postural and kinetic tremor. However, it has been reported to induce hypokinesia, akathisia, rigidity, and a resting tremor. Another nonneuroleptic which induces parkinsonism through mechanisms unknown is valproic acid, which is a standard anticonvulsant. Valproic acid does not affect dopamine receptors. Certain calcium channel blockers, particularly cinnarizine and flunaraizine, not available in the United States, also induce parkinsonism. However, these particular calcium channel blockers may influence calcium-mediated neurotransmitter release, and thus might decrease the amount of dopamine available. It has been reported that SSRIs (selective serotonin reuptake inhibitors) can induce parkinsonism. However, in my experience, this is a very rare phenomenon. More often than not, these cases involve misdiagnosis.

Clinical features

Parkinsonism induced by neuroleptic drugs can mimic all of the features seen in Parkinson's disease. Bradykinesia is particularly common in a drug-induced state with a paucity of tremor. Since the basic clinical features of drug-induced parkinsonism can appear exactly the same as Parkinson's disease, it is important to recognize certain historical and additional clinical features that can be helpful in differentiating drug-induced parkinsonism from Parkinson's disease. Historically, drug-induced parkinsonism is seen in persons taking one of the medications known to cause this problem. In addition, the onset from normal motor behavior to moderate parkinsonism is usually of a subacute nature occurring over weeks to months instead of the slow insidious progression over years seen in Parkinson's disease. In addition, drug-induced parkinsonism is almost always symmetric in presentation whereas Parkinson's disease almost invariably starts in a unilateral fashion, and over a period of years spreads to the opposite side.

Management and treatment

The management and treatment of drug-induced parkinsonism involves understanding the reason the patient is taking the causative drug. The ideal approach from a neurological standpoint is to discontinue the agent inducing parkinsonism. Even if this is possible, it may take weeks to months for the parkinsonism to resolve. In the event that the patient's psychiatric state requires continued administration of a neuroleptic, changing the dose to a less potent neuroleptic might prove beneficial, in terms of the motor phenomenon, to the patient. However, this can result in an increase in the psychiatric problem. Depending on the clinical manifestations of the parkinsonism, anticholinergics, amantadine, and levodopa can be employed to treat drug-induced parkinsonism with varying degrees of success.

Drug-induced parkinsonism requires pharmacological treatment only when the patient is markedly symptomatic from the parkinsonism. Treatment should be continually reevaluated since it will not be needed for long periods.

Tardive Dyskinesia

Epidemiology

The epidemiology of tardive dyskinesia has been both controversial and confusing. Tardive dyskinesia is defined as any delayed onset movement disorder induced by a dopamine receptor antagonist (neuroleptics and antiemetics). The definition of what constitutes tardive dyskinesia has been made difficult because many of the abnormal movements recognized as part of the tardive dyskinesia spectrum were described in schizophrenic patients long before the introduction of neuroleptic agents. A wide variety of stereotyped mannerisms,

agitated behaviors, and other motor disorders have been seen in psychotic patients. It is true that the mannerisms seen in psychosis that resemble tardive dyskinesia are usually more complex, highly ritualistic, and may have symbolic significance to the patient. When formal epidemiologic studies were first reported to study tardive dyskinesia there were methodological problems, including a paucity of proper prospective studies using matched untreated controls, clinical definitions were not often given, accepted rating scales were not employed, and documentation of treatment schedules were not recorded. Nonetheless, despite all of these initial problems, it became clear that the administration of certain categories of medications, particularly the dopamine receptor antagonists, can result in a wide range of abnormal choreodystonic movements. Estimates of the prevalence of tardive dyskinesia range from 1% to 60% of patients. Standard neuroleptic therapy results in tardive dyskinesia in ~20% of patients. The average yearly rate of developing tardive dyskinesia is ~5% per year for the first several years with accumulative 5-year incidence of 20–25%. A wide variety of risk factors have been identified including age, psychiatric diagnoses, gender, pre-existing organic brain damage, diabetes, potency and dosage of neuroleptics administered, and the question of whether medication-free periods also enhance the risk of developing tardive dyskinesia. However, many of the risk factors have been controversial or at least inconsistently reported. Patients who were psychiatrically normal can develop tardive dyskinesia. The most consistent risk factors seem to be age and type of medication administered. There has been increased interest in the use of the so called atypical neuroleptics as a way of reducing the risk and incidence of tardive dyskinesia. There have been multiple studies indicating that atypical neuroleptics seem to have a lower risk of inducing tardive dyskinesia, but the caveat is that this lower risk has led to the more wide spread use of the atypical neuroleptics and the end result may be that more patients develop tardive dyskinesia because more are exposed.

Pathophysiology

Dopaminergic mechanisms seem to be heavily involved in the development of tardive dyskinesia. It has been proposed that the chronic administration of neuroleptics results in a chronic blockade of striatal dopamine receptor sites and that this chronic blockade ultimately induces alterations in the sensitivity and numbers of dopamine receptors. Clinical data that support this notion include the exacerbation of tardive dyskinesia with dopaminergic medications, suppression of tardive dyskinesia with dopaminergic antagonist, and enhancement of the movements with anticholinergics. In addition, the study of atypical antipsychotics has demonstrated that those with the lowest risk for extrapyramidal side effects are those atypical neuroleptics that do not chronically bind to dopamine receptors. Clozapine is an example of such an atypical neuroleptic. The dopaminergic supersensitivity model remains essential when thinking about tardive dyskinesia; however, it is probably simplistic and not the only mechanism. Other neuro transmitters have been investigated regarding their role in tardive dyskinesia. The role of GABA has been investigated and it has been proposed that release of GABA from the external globus pallidus neurons innervating the subthalamic nucleus could result in decreased outflow from the globus pallidus and result in abnormal movements. Finally, there has been some discussion that an additional pathophysiologic mechanism might be direct neurotoxicity of neuroleptic medications. It has been hypothesized that the blockade of dopamine receptors results in increased dopamine turnover which results in the formation of increased free radicals, which damage those neurons.

Clinical features

Choreodystonic movements which characterize tardive dyskinesia are usually seen in the context of a chronically administered neuroleptic without a change in dosage. The most common clinical setting in which the movement disorder emerges is after the dosage is lowered or discontinued entirely. The movements may also emerge when a more potent neuroleptic is substituted with a less potent neuroleptic. Involuntary movements usually begin after as little as 3 months of neuroleptic exposure although, more often than not, exposure has been much more prolonged. In very rare instances, tardive dyskinesia may begin with a shorter course of neuroleptic therapy.

The most common movement, buccolingual facial dyskinesia can look like chewing or biting movements, teeth clenching, or lateral side-to-side movements of the jaw. Lip involvement can result in pouting, pursing, or sucking movements which often times have an audible component. If the movements are severe enough, it may ulcerate the tongue or grind down the teeth. Excessive eye blinking, blephrospasm, and grimacing of the lower jaw may also be seen. Neck, trunk, and axial muscles can be involved resulting in locking or thrusting movements. The diaphragm can be involved resulting in respiratory dyskinesias which often are experienced by the patient as a feeling of shortness of breath. Limb movements in this clinical setting may be choreoform, athetotic, or ballistic, and are often more stereotypic than those seen in other choreoform disorders such as Huntington's disease. The intensity of the movement is mild to quite severe with resulting disability.

Management and treatment

The movements of tardive dyskinesia often remit and dissipate entirely with time. However, it may take years for the movements to disappear entirely and some portion of patients with tardive dyskinesia develops a permanent

movement disorder. Since tardive dyskinesia is an iatrogenic disorder, prevention is better than treatment. There are some straight forward management steps that help to prevent the development of tardive dyskinesia. Most importantly, the number of subjects at risk should be limited and this implies that typical and atypical neuroleptics as well as antiemetics should be administered only with definite therapeutic goals in mind and in appropriate clinical situations. The neuroleptics are for the treatment of severe psychiatric disorders including psychosis and severe bipolar problems and are not for the treatment of mild anxiety, restlessness, insomnia, and other minor psychiatric disturbances. Neuroleptic dosage should be limited and guided by therapeutic response. In patients who have developed tardive dyskinesia, the best possible course of therapy is to discontinue the offending agent if that is possible from a medical and psychiatric standpoint. If that is not possible from a psychiatric standpoint, then switching to a less potent atypical neuroleptic might prove useful. Drugs which deplete the brain of dopamine such as reserpine or tetrabenazine can also used to reduce the choreodystonic movements seen in tardive dyskinesia. Typical potent neuroleptics can be administered to reduce the movements in tardive dyskinesia, but this places the treating physician in the position of using the etiologic agent to treat the complications of that agent. This is obviously not a smart move unless movements are so severe that they are causing severe disability or are life-threatening.

Additional therapeutic attempts to treat tardive dyskinesia have included use of dopamine agonists such as levodopa or dopamine receptor agonists such as bromocriptine with the idea of 'downregulating' dopaminergic hypersensitivity. There is not much support in the literature for this approach. A variety of GABA agonist drugs including valproic acid, diazepam, clonazepam, and baclofen have been used, but all have been disappointing. There are reports in the literature of high dosage Vitamin E being effective, but this is not thought to be a very useful approach.

Drug-Induced Movement Disorders Related to Dopamine Receptor Agonists

Levodopa-Induced Dyskinesias

In contrast to drug-induced disorders that are seen with dopamine receptor antagonists or dopamine depleting agents, levodopa or dopamine agonist-induced dyskinesias develop in Parkinson's disease patient treated with drugs that augment dopaminergic pharmacology. These dyskinesias are abnormal involuntary movements usually of a choreo dystonic nature. Extremities, lingual facial buccal regions, neck, trunk, and, occasionally, thoracic and abdominal musculature may be involved. Although these movements occur with dopamine agonists as well as levodopa, they are classically referred to as 'levodopa-induced dyskinesias' because they were originally described with this drug and are more frequently encountered with levodopa therapy than dopamine agonist treatment.

Epidemiology

Levodopa-induced dyskinesias only occur in the context of the treatment of Parkinson's disease or other neurodegenerative disorders involving the dopaminergic system. The chronic administration of levodopa in high dosage in patients with a normal central nervous system will not induce abnormal movements. Levodopa-induced dyskinesias begin after 2–3 years of levodopa treatment and become progressive and more prevalent until ~50% of patients exhibit some form of levodopa-induced dyskinesias after treatment for 5 years. Levodopa-induced dyskinesias can range from very mild adventicial movements, which are of no concern to the patient or family, to more severe choreo dystonic movements, which can interfere with the activities of daily living including dressing, eating, and walking. Most patients with Parkinson's disease prefer to have a degree of levodopa-induced dyskinesias rather than being more parkinsonian. Balance between inducing dyskinesias or alleviating the motor symptomotology of Parkinson's disease is the art of pharmacologic therapy for these patients. The interplay between dyskinesias and the alleviation of motor symptoms has also been at the heart of controversy regarding whether to begin therapy with levodopa or dopamine receptor agonists in the initial treatment of Parkinson's disease. Another potential risk factor for the development of levodopa-induced dyskinesias includes young age of onset of Parkinson's disease. There is a widely held perception from clinical practice and the literature that, younger patients seem to be more prone to the development of levodopa-induced dyskinesias. It is also true that patients with more long-standing and severe parkinsonism who have not been treated with levodopa are more likely to develop levodopa-induced dyskinesias in a shorter period of time.

Pathophysiology

The pathophysiology of levodopa-induced dyskinesia is not entirely understood. The most simplistic approach to explain these movements is that dopamine receptors become supersensitive because of the loss of the dopaminergic input from the substantia nigra which occurs in Parkinson's disease. However, levodopa-induced dyskinesias rarely, if ever, occur with the initial dose of levodopa. Chronic administration of levodopa is required to bring out the dyskinesias, thus it cannot simply be that the receptors are supersensitive. Other potential mechanisms

to explain dyskinesia is a shift in dose response to levodopa, alterations in dopamine receptor subtypes, and the possible influence of the temporal pattern of drug administration. A number of other neurotransmitter systems may also be involved in the pathophysiology of dyskinesias, including drugs that affect the glutamate receptors, serotonergic system or the opiate system, and the GABA system.

Clinical features

In addition to the abnormal movements of a choreo dystonic nature, levodopa-induced dyskinesias can include myoclonus, dystonia, ballism, and stereotyped movements. There are different temporal patterns of levodopa-induced dyskinesia with the most common being 'peak-dose' dyskinesia which occurs when the beneficial effects of levodopa on the motor symptoms of Parkinson's disease are most apparent. Diphasic dyskinesia occurs just as levodopa begins to take effect and as it is wearing off. Off-period dystonia is the occurrence of dystonic postures when the patient is off and the levodopa antiparkinsonian effect is at its lowest efficacy. A new type of dyskinesia was described recently as a result of clinical research trials involving embryonic mid-brain fetal transplants into Parkinson's patients. This type of dyskinesia has been called 'run away dyskinesia.' This is a typical choreo dystonic movement which is unrelated to the dosing cycle. In some patients who developed run away dyskinesia, levodopa was discontinued and the dyskinesia persisted.

Management and treatment

Although it is important to determine the pattern of dyskinesia to plan effective management, the best overall strategy is simply to understand that levodopa-induced dyskinesias are more properly referred to as dopaminergic-induced dyskinesias. All of the drugs used to alleviate the motor symptoms of Parkinson's disease have a positive and promoting effect on the dopaminergic system in one way or another, and in order to alleviate levodopa-induced dyskinesias, antiparkinsonian drug dosage must be slowly decreased until the patient reaches a point of improvement in the dyskinesias to a manageable level or when the motor stigmata of Parkinson's disease begins to be a burden. When that point is reached, other pharmacologic therapy directed specifically at the dyskinesia, such as amantadine, may be introduced. The best plan in terms of reducing antiparkinsonian medications in a patient with troublesome dyskinesias is to slowly decrease and eliminate drugs which are having the least beneficial effect in terms of the management of the Parkinson's disease. Typically, this means decreasing and stopping drugs in more or less the following order, anticholinergics, MAO (monoamine oxide inhibitors), COMT (catechol-*O*-methyl transferase inhibitors) dopamine agonists, and, finally, levodopa. Patients can always be assured that dyskinesia can be controlled; however, the problem in controlling the dykinesia is that the parkinsonism will worsen. It is also true that if pharmacologic therapy fails, or the dyskinesias are severe enough, deep brain stimulation surgery with the target being either the STN (subthalamic nucleus) or GPI (globus pallidus interna) is quite effective in alleviating dyskinesias.

Miscellaneous Drugs Which Can Induce Movement Disorders

Anticonvulsant medication has been reported to induce various movement disorders. In fact, if one considers cerebellar syndromes as a 'movement disorder' then phenytoin, phenobarbital, primodone, and carbamazepine can cause a kinetic tremor as well as asterixis and myoclonic jerks. Valproic acid can induce a postural and kinetic tremor. This tremor has even been reported at rest. The severity of the tremor is usually mild, but can be severe. Valproic-induced tremors are often quite amenable to treatment with β-blockers.

A less often, anticonvulsant-induced movement disorders are phenytoin-and, more rarely, carbamazepine-induced choreo dystonic movements. The majority of patients with these types of dyskinesias usually demonstrate other evidence of toxicity such as cerebellar features or elevated plasma drug level. However, there is some evidence that pre-existing cerebral pathology predisposes patients to the development of phenytoin-induced or carbamazepine-induced dyskinesias.

Phenytoin has also been reported to induce parkinsonism; however, valproic acid has emerged as the most common anticonvulsant to induce parkinsonism. In the clinical setting of the subacute onset of symmetric parkinsonism, a careful search of the patient's history for the administration of anticonvulsants is always important.

Occasionally, anticholinergic, antihistaminic, antianxiety, oral contraceptive, antihypertensive, and cardiac drugs have been reported to be associated with tremor, myoclonus and parkinsonism, and chorea. In addition, stimulants such as amphetamine and cocaine have also been reported to induce choreo dystonic movements on rare occasions.

Dysarthria

E Q Wang, Rush University Medical Center, Chicago, IL, USA

Glossary

Altered Auditory Feedback (AAF) – A collective term for delayed auditory feedback (DAF), frequency-altered feedback (FAF), and masking noise, or a combination of the three.
Dysarthria – A group of speech disorders that are due to lesions in either the peripheral or central nervous system.
Festinating speech – A type of speech characterized by increasingly fast and accelerated speaking rate with diminished volume and significantly reduced speech intelligibility. It is commonly observed in patients with advanced PD and Parkinsonism such as PSP or MSA. Patients with festinating speech often experience festinating gait and freezing of gait.
Lee Silverman Voice Treatment (LSVT/LOUD) – An evidence-based treatment method for hypophonia and hypokinetic dysarthria experienced by 89% of patients with IPD. Its single treatment target is loudness with high intensity in its delivery mode and sensory retraining.
Speech intelligibility – The amount of speech that can be understood by listeners who speak the same language.

Definition and History

Speech problems experienced by persons with Parkinson's disease (PD) were first described in a case in 1817 by James Parkinson in his famous book '*An Essay on the Shaking Palsy*'. The patient, the Count de Lordat, who suffered from a fall three and half years earlier prior to the visit, was still able to walk alone with a cane with great difficulty but had limited range of motion of his upper limbs. He could not control his saliva, drooling continuously. He had great trouble swallowing liquids and could no longer swallow solids. Although his mind was sound and he was able to attend and understand conversations, 'What words he still could utter were monosyllables, and these came out, after much struggle, in a violent expiration, and with such a low voice and indistinct articulation, as hardly to be understood but by those who were constantly with him.' Speech impairments such as this were termed as dysarthria. It comes from the Greek prefix dys and the Greek root arthroun, while 'dys' means 'bad or abnormal' and 'arthroun' means 'to speak clearly.'

In their influential studies of the dysarthrias published in 1969, Darley, Aronson and Brown used correlation matrices to demonstrate for the first time that cooccurrence of deviant speech dimensions observed could be delineated into different types of dysarthria. They further defined that 'Dysarthria is a collective name for a group of speech disorders resulting from disturbances in muscular control over the speech mechanism due to damage of the central or peripheral nervous system. It designates problems in oral communication due to paralysis, weakness, or incoordination of the speech musculature. It differentiates such problems from disorders of higher centers related to the faulty programming of movements and sequences of movements (apraxia of speech) and to the inefficient processing of linguistic units (aphasia).'

Epidemiology/Risk Factors

Epidemiology as Related to Different Etiologies

Different underlying neurological disturbances are associated with different types of dysarthria. However, speech intelligibility is inevitably reduced in all. The dysarthria classification was proposed in 1969 on the basis of lesion sites. There are six single types of dysarthria: flaccid dysarthria, spastic dysarthria, ataxic dysarthria, hypokinetic dysarthria, hyperkinetic dysarthria, and unilateral upper motor neuron dysarthria, in addition to the category of mixed dysarthria, which encompasses all possible combinations of the six single types.

Dysarthria accounts for 54% of all acquired neurologic communicative disorders. The prevalence of dysarthria in movement disorders is high. Hypokinetic dysarthria is the dysarthria of idiopathic PD and atypical Parkinsonism, while hyperkinetic dysarthria is associated with involuntary movements as in Huntington's disease (HD). Eighty-nine percent of patients with idiopathic Parkinson's disease (IPD) have hypokinetic dysarthria. Mixed hypokinetic–hyperkinetic dysarthria is commonly associated with IPD, once patients develop on–off medication-related motor fluctuations and dyskinesias. In patients with atypical Parkinsonism such as progressive supranuclear palsy (PSP) and multiple system atrophy (MSA), speech impairment may be the first motor sign to appear. In PSP, dysarthria occurs in 48–88% of patients, while in MSA, in 34–100%, depending on the disease progression. Hypokinetic dysarthria is seldom the only type of dysarthria observed in atypical Parkinsonism. Mixed hypokinetic-spastic dysarthrias are most commonly associated with PSP, while mixed hypokinetic-ataxic-spastic dysarthrias mostly seen in MSA. Hyperkinetic dysarthria occurs when purposeful speech movement is interrupted by involuntary movements. Although it is identified as a single type of dysarthria, there are shared features yet remarkable differences in its actual speech characteristics, depending on where and how the involuntary movements interfere with speech movements. Any involuntary movements that involve muscle groups in the trunk, head, and neck area will likely cause hyperkinetic dysarthria. Hyperkinetic dysarthria is commonly associated with chorea in HD, palatopharyngolaryngeal myoclonus, tics in Tourette's syndrome (TS), dystonia involving head and neck muscles (cervical dystonia, laryngeal dystonia, and oromandibular dystonia), Essential tremor (ET), hemifacial spasm, tardive dyskinesias, and medication-induced dyskinesias.

Risk Factors

In idiopathic PD, the most important risk factors for developing dysarthria are progression of the disease, disease severity level, and 'on–off' motor fluctuations. In atypical Parkinsonism, the most important risk factors are presence of dysphagia, gait disturbances, and premorbid speech impairment. In movement disorders associated with hyperkinetic dysarthria, the risk factors involve muscle groups in the trunk, head, and neck area, and the extent, frequency, and intensity of the involuntary movements, as well as disease duration and progression.

Clinical Features/Diagnostic Criteria

Characterization

The main characteristic of any type of dysarthria is the reduction of speech intelligibility. The severity of hypokinetic dysarthria in PD is task dependent. The speech intelligibility is worse with spontaneous speech than with automatic speech such as counting, recitation, and reading when the content of speech is provided. In more advanced PD, the mixed hypokinetic–hyperkinetic dysarthria is medication related. The hypokinetic component is worse during 'off' time, while the hyperkinetic component is worse during 'on' time because of increased dyskinesias.

Salient Speech Features

Speech characteristics vary among different types of dysarthria. Salient speech features of hypokinetic dysarthria in IPD progress from early symptoms such as reduced loudness, monotone, monopitch, reduced pitch, and breathy and hoarse voice quality, to relatively later symptoms such as variable rate, short rushes of speech, hesitations, disfluency similar to stuttering, palilalia which is speech produced with significantly accelerated speaking rate with diminished volume, and significantly decreased articulatory accuracies. Hyperkinetic dysarthria associated with involuntary movements is characterized by unpredictable articulatory breakdowns and loudness and pitch variability. Dysarthria associated with cervical dystonia often manifests itself as spasmodic dysphonia. The salient speech features are strained and strangled vocal quality and frequent vocal arrests. Some patients may resolve to use whispering voice. Other types of dysarthria commonly associated with movement disorders are spastic dysarthria and ataxic dysarthria. Spastic dysarthria presents with strained–strangled vocal quality, low pitch, hypernasality, slow but regular speaking rate, and effortful speech. Ataxic dysarthria presents timing-related irregular articulatory breakdowns and variable pitch, loudness, and speaking rate.

Diagnosis of Dysarthria

Certified and licensed speech-language pathologists (SLP) are trained to diagnose dysarthria, using a combination of perceptual and instrumental tests to evaluate respiration, phonation, articulation, resonance, and prosody. A typical evaluation has the following components:

an in-depth medical history, a complete oral motor examination, and speech testing. On the basis of the findings, the SLP will be able to differentially diagnose the type or types of dysarthrias.

Pathophysiology

The precise pathophysiology underlying dysarthria in IPD, atypical Parkinsonism and other movement disorders is unclear. Rigidity and bradykinesia may be partially responsible for hypokinetic dysarthria, while for hyperkinetic dysarthria, the involuntary movements. Strained and strangled vocal quality and slow but regular articulatory movement patterns are consistent with increased spasticity in the muscles in spastic dysarthria. Irregular articulatory breakdowns and irregular loudness and pitch of ataxic dysarthria are consistent with dysfunction of the cerebellum.

Management

Medication

Hypokinetic dysarthria of IPD may appear early or late in the disease progression. The response to dopaminergic stimulation in speech is mixed. Drug-induced orofacial and respiratory dyskinesias interfere with speech movements resulting in mixed hypokinetic–hyperkinetic dysarthria in IPD.

Deep Brain Stimulation

Bilateral deep brain stimulation (DBS) of the subthalamic nucleus (STN) has gained increased acceptance, because it substantially reduces dyskinesias and fluctuations and improves the cardinal features of IPD. STN DBS does not improve speech; rather, one of its common adverse effects is worsened speech intelligibility. Speech deterioration may be from two sources: the progression of the disease itself and long-term stimulation-related changes. It has been suggested that the contact site and stimulation intensity may be partly responsible for the worsening speech.

Speech Therapy

Speech therapy that has demonstrated clear efficacy is Lee Silverman Voice Treatment (LSVT/LOUD), an intensive treatment program for treating hypophonia and hypokinetic dysarthria in patients with IPD, targeting a single treatment target of loudness with high intensity in its delivery mode and sensory retraining. It works best when the main symptoms are soft and breathy voice. More advanced symptoms such as inability to initiate speech, frequent hesitations, and palilalia have been reportedly controlled by altered auditory feedback (AAF) provided by a wearable device.

Prognosis

Dysarthria in patients with IPD or other movement disorders will worsen as the underlying disease progresses. Early onset of severe speech deficits such as palilalia in PD may indicate atypical Parkinsonism such as PSP or MSA especially when dysphagia and gait disturbances are present.

Glossary

Basal ganglia – The basal ganglia are neurons nuclei located at the brain base, comprising the substantia nigra, the striatum, the internal and external segments of the globus pallidus, and the subthalamic nucleus (STN) ganglia and playing a key role in the control of motor behavior through their in- and outputs.
Continuous dopaminergic stimulation – The mode of administration (pulsatile versus continuous) of dopaminergic antiparkinsonian medications seems crucial in the development of LIDs. Normal endogenous striatal dopamine receptor stimulation is supposed to be phasic and tonic at the level of a synapse, with a relatively stable continuous baseline release. Short acting drugs (such as levodopa) induce an abnormal pulsatile stimulation that disturbs the striatal relay of the motor system. Exposing an increasingly denervated striatum to pulsatile dopaminergic stimulation might then induce dyskinesia.
Deep brain stimulation – Chronic high frequency stimulation mimics the effects of ablative neurosurgery. This stimulation is obtained by means of an electrode with four contacts implanted into the target area and connected to a programmable stimulator under the chest wall.
Diphasic dyskinesias or 'onset- and end-of-dose-dyskinesias' – Diphasic dyskinesias correlate respectively with the rising and falling phases of levodopa plasma levels, can involve stereotypical rapid alternating movements, as well as unusual ballistic kicking or dystonia and tend to affect the legs predominantly.
Dyskinesias – Dyskinesias are abnormal involuntary hyperkinetic movements commonly observed in patients with PD chronically treated with levodopa (levodopa induced dyskinesias (LIDs)) and rarely with dopaminergic agonists.
Off dystonia – Off dystonia is painful dystonic posturing affecting the limbs particularly the legs and feet, occurring at the end of action of levodopa in levodopa-treated parkinsonian patients.
Peak-dose dyskinesias – Peak dose dyskinesias are the most common LIDs. They occur at the time of the peak concentration or peak benefit of the dose of levodopa when parkinsonian symptoms are improved. Typically, peak-dose dyskinesias involve the upper limbs more than the legs, trunk, or head and have a choreic phenotype.

Definition and History

The word 'dyskinesia' is derived from the Greek roots 'dys' (difficult, abnormal) and 'kinesis' (movement) to indicate abnormal, involuntary movements that can be associated with many neurological disorders. Here we will discuss levodopa-induced dyskinesias (LIDs) in Parkinson's disease (PD).

Treatment of PD with the dopamine precursor drug, levodopa, is initially remarkably effective. However, this 'honeymoon' period gradually vanishes with chronic levodopa exposure and disease progression, and many patients experience levodopa-induced motor complications within a few years. Such motor complications are of two main types: motor fluctuations in response to medication and to dyskinesias. LIDs are abnormal involuntary hyperkinetic movements commonly observed in patients with PD chronically treated with levodopa. Historically, LIDs were reported by Cotzias and colleagues in 1969 shortly after these authors described the dramatic antiparkinsonian efficacy of levodopa. LID is a historically honored term, but it includes dyskinesia induced with any form of dopaminergic drug therapy. For example, dopamine agonists likewise can induce the same types of dyskinesia, but because these problems are more frequently encountered with levodopa therapy than other dopaminergic drug classes, the term LID and the link to levodopa remain commonly used.

Clinical Manifestations of Dyskinesia

Different forms of LIDs are usually separated according to their phenomenology and their relationship with levodopa intake. These two classifications often overlap, so that the type of dyskinesia is usually distinctive depending on its temporal relationship to levodopa dosing. Further, multiple forms of dyskinesia can occur in the same patient. In spite of the prototypic types of dyskinesia, many patients have mixed forms, suggesting that the various LIDs are probably part of a clinical and pathophysiological continuum (**Figure 1**).

Phenomenology

LIDs are typically a mixture of chorea, ballism, and dystonia or more rarely myoclonus. LIDs have been reported to start frequently in the foot, ipsilateral to the side most affected by PD with inversion of the foot and ankle. This finding is consistent with early loss of dopaminergic innervation of the dorsolateral striatum, corresponding somatotopically to the foot area. In spite of this typical pattern, LIDs can affect any other part of the body (limbs, cervical, lingual–facial–buccal and/or even thoracic, respiratory, abdominal, or ocular musculature). Choreiform movements in the limbs, head, neck, and trunk are most common, but dystonic posturing in the limbs and craniocervical dystonia are not rare. Enhanced tremor, restlessness, and akathisia also occur in levodopa-treated patients. Although it is unclear whether these symptoms are drug-induced or part of advanced parkinsonism, they are not typically considered LIDs. The diagnosis of LIDs is therefore generally easy in most patients, but these last cases sometimes pose difficult differential diagnosis issues in a given patient, with consequent management problems. In such cases, careful direct examination of the

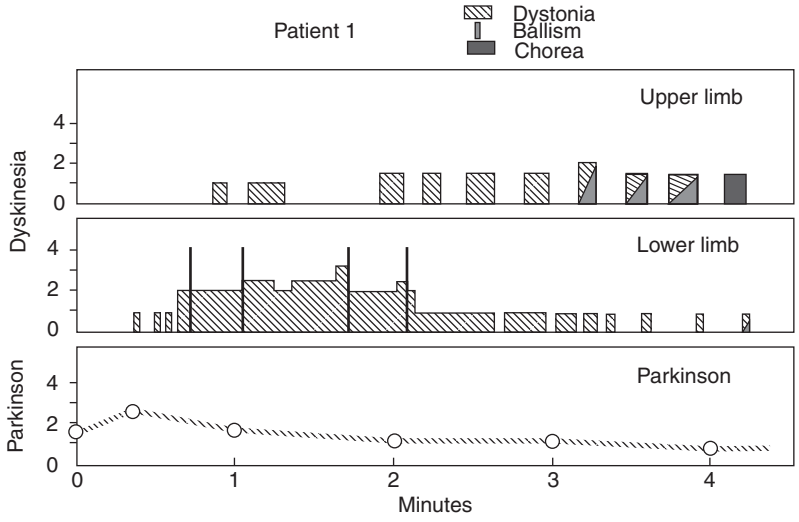

Figure 1 Phenomenology (dystonia, ballism, chorea) and topography (upper limb, lower limb) of LIDs in a patient with PD during the first 5 min of onset of 'on' (while the patient is switching from 'off' to 'on' after previous levodopa intake). Notice that LIDs are first occurring in the lower limb, as dystonic and ballic abnormal movements, then progressively spreading to the upper limb, becoming of the choreic type. Reproduced from Marconi et al. (1994) Levodopa-induced dyskinesias in Parkinson's disease phenomenology and pathophysiology. *Movement Disorder*.

patient over the cycle of 'off' (when levodopa-induced antiparkinson effects have waned) and 'on' (when levodopa-induced antiparkinson effects are present) conditions is helpful. LIDs markedly fluctuate in the same patient, depending on environmental/psychological factors and timing regarding levodopa intake (see later text). Stress and emotion can dramatically worsen LIDs, as it is the case for most hyperkinetic involuntary abnormal movements. Therefore, when examining a patient, mental calculation is commonly used as a facilitator to increase LIDs intensity as opposed to the resting condition in a quiet environment.

Relationship with Levodopa Dose

LIDs are also classified on the basis of their occurrence with regard to levodopa intake and such temporal classification allows the delineation of three main types of LIDs: 'peak-dose dyskinesias,' 'off-period dystonia,' and 'diphasic dyskinesias.' These three types of LIDs sometimes occur in the same patient at different moments. To document these patterns, it is sometimes helpful to perform an acute levodopa challenge in a given patient. In this case, the patient takes a typical dose of levodopa in the physician's office and stays there until the time of the next levodopa dose. This allows the physician to observe the entire cycle of the clinical response and the temporal changes in the spectrum of abnormal movements. This observation has practical importance, because different forms of dyskinesia are treated with different pharmacological strategies (**Figure 2**).

Peak-dose dyskinesias

These are the most common LIDs occurring at the time of the peak concentration or peak benefit of the levodopa dose, but they may also occur throughout the duration of the on-period (square-wave dyskinesias). Peak-dose dyskinesias usually consist of stereotypic, choreic, or ballistic movements involving the head, trunk, and limbs, and occasionally, the respiratory muscles. Typically, peak-dose dyskinesias involve the upper limbs more than the legs, trunk, or head, and have a choreic phenotype. They tend to be less disabling and less painful than diphasic-dyskinesia or off-dystonia. In some patients, however, peak-dose dyskinesias may evolve into athetosis and dystonia, thereby inducing significant social and/or functional disability as well as pain.

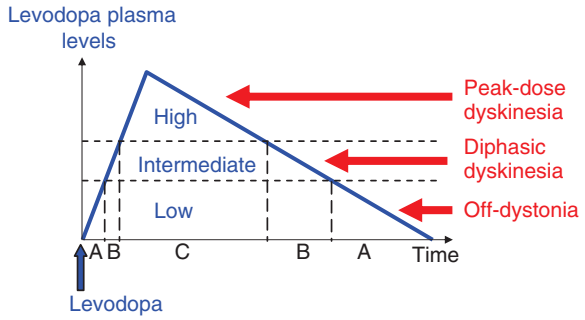

Figure 2 Schematic representation of the occurrence of different types of LIDs according to the temporal response to levodopa administration in a patient with PD. Notice that off-dystonia is observed when levodopa plasma levels are low and the patient is 'off' (a); diphasic dyskinesias are observed when levodopa plasma levels raise up or fall down to intermediate levels, and the patient is not completely 'on' nor fully 'off' (b); peak-dose dyskinesia are observed when levodopa plasma levels are at their maximum, above a threshold that turns the patient fully 'on' (c).

Off-period dystonia

The role of levodopa in such dyskinesias is debated, since they can occur in untreated PD patients. However, they also occur as a wearing-off phenomenon in levodopa-treated patients. They tend to affect the limbs, particularly the legs and feet of the more affected side. Patients typically experience a painful fixed dystonic posture (e.g., ankle intorsion with toe flexion or extension), especially early in the morning (early morning dystonia). Off-dystonia is frequently troublesome because of painful sensations and functional impairment.

Diphasic dyskinesia

This type of LIDs is also known as 'onset- and end-of-dose-dyskinesias.' They correlate respectively with the rising and falling phases of levodopa plasma levels, rather than the peak or nadir. They occur in ~15–20% of patients, which tend to affect the legs predominantly and can involve stereotypical rapid alternating movements, as well as unusual ballistic kicking or dystonia. In some patients, a mixture of dyskinesia and parkinsonian signs occurs concurrently, because the patient is in between 'on' and 'off' phases. Such LIDs can be very disabling, especially those inducing large ballistic movements of the limbs. It is sometimes difficult to recognize diphasic dyskinesias and separate them from peak-dose dyskinesias. This is especially true in the afternoon, when it is difficult to assess if a poor postprandial absorption of levodopa has led to low/intermediate plasma levels of levodopa, or on the contrary if levodopa has accumulated over the day, leading to very high plasma levels.

Rating Scales for Dyskinesias

An ideal scale for dyskinesia would score the phenomenology, severity, and impact on activities of daily living of the abnormal movements, and obviously be short and easy to use. Current rating scales do not fulfill these criteria. A unified dyskinesia rating scale combining elements of the AIMS and Rush scale along with a patient questionnaire has recently been introduced. The abnormal involuntary movements scale (AIMS) has been used to assess LIDs,

but it was originally developed for tardive dyskinesia and thus places predominant emphasis on lingual–facial–buccal movements. The UPDRS-IV scores global disability and duration of LIDs, along with the presence or absence of early morning dystonia and painful dyskinesia, but provides no information on anatomical distribution. The rush dyskinesias scale (or Goetz scale) introduces the objective assessment of dyskinesias during activities of daily living and focuses on disability from dyskinesias. LIDs can also be rated using diaries fulfilled during several consecutive days by the patient himself (possibly with the help of a caregiver) every 30 min over the waking hours. It is sometimes difficult to train the patient (and caregiver) to adequately rate his/her abnormal movements, separating, for example, tremor from LIDs and separating various types of LIDs. Patients can also be asked to rate whether they are 'on' with or without 'troublesome' or 'nontroublesome' LIDs, thus separating 'good on' from 'bad on.' Various instrumental techniques such as accelerometers have also been proposed to quantitatively assess LIDs. Their use remains exploratory and experimental until better validation is available.

Evolution and Impact of LIDs

Over the years of PD, the duration and severity of LIDs generally tend to progressively worsen in a given patient. The impact of LIDs on patients' health-related quality of life remains a matter of controversy, because it can markedly vary from one patient to another, depending on many factors including age, familial, professional, social and cultural environment, duration and intensity of LIDs, type of LIDs, severity of accompanying motor and nonmotor parkinsonian symptoms.

For most patients in the early stages of PD, LIDs are mild and nontroublesome, with minimal impact on daily quality of life. They are frequently unnoticed by the patients themselves and more embarrassing for the relatives and caregivers. Commonly, when asked, dyskinetic patients see LIDs as a kind of a 'marker' of their 'on' stage, a condition much more enjoyable for them than the 'off' episodes.

Conversely, in more advanced PD, LIDs frequently become troublesome and disabling. Severe LIDs can impair motor function and activities of daily living such as eating, washing, or walking, to a point that patients give up doing such tasks during the moments of the day they are dyskinetic. LIDs can also be socially embarrassing irrespective of their intensity, and this embarrassment depends largely on personal, familial, social, and cultural environments. Such embarrassment is a stress for patients, and because stress aggravates dyskinesia, patients experience a 'vicious' circle of increasing impairment. LIDs can also be painful, especially off-dystonia, to a point that affects the quality of life. Finally, peak-doses of LIDs often limit the use of levodopa, as their duration, if not their intensity, is worsened by higher doses of levodopa. Such dose-limiting effects can preclude the use of adequate doses of levodopa to optimally controlled parkinsonian symptoms, with consequent further impairment of the patients' quality of life.

Epidemiology and Risk Factors

LIDs have been reported to occur in 30–80% of levodopa-treated PD patients. In a community-based population study published by Schrag and colleagues in 2000, LIDs were present in 28% of PD patients with a mean time of 6.7 years from PD symptom onset to the development of LIDs. The variability of prevalence figures reported in the literature is mainly related to differences in the method of ascertainment of the presence of dyskinesias (self-assessment diary, objective measurement, use of activation procedures), and to differences in studied populations (community-based or hospital-based).

On an average, incidence of LIDs is estimated to be ~10% per year. Again, percentages can vary significantly from one trial to another, according to definitions and methods. The only prospective, placebo-controlled study assessing the effects of levodopa in early PD (ELLDOPA study, 2004) was conducted by Fahn and colleagues who reported LIDs in up to 16.5% of patients after only 6 months of levodopa therapy. This high incidence finding suggests that LIDs probably occur earlier than previously thought, although they probably go unnoticed at this stage by most patients and doctors. With the widespread use of dopamine agonists as initial monotherapy, the overall treatment exposure to levodopa may be decreasing, especially in the first several years of treatment. Early exposure to dopamine agonists as the primary treatment of parkinsonism is associated with a lower incidence of dyskinesia than when levodopa is the primary treatment (see below).

LIDs are much more common in PD than in patients with atypical parkinsonism. This observation suggests that pathophysiology of LIDs are likely to involve alterations in the level of postsynaptic dopamine receptors, since such receptors are relatively preserved in PD as opposed to atypical parkinsonian syndromes where the neuronal degenerative process involves the postsynaptic striatal neurons. However, dystonic facial LIDs can be observed in patients with multiple system atrophy and progressive supranuclear palsy.

The development of dyskinesia has been associated with several risk factors such as

- The age of the onset of PD: this is one of the most important risk factors for dyskinesias, and almost all patients with early onset of the disease develop dyskinesias whereas they are less frequent in patients with late onset of PD.

- PD severity: patients who have severe parkinsonian features at the onset of levodopa therapy develop more rapid and more severe LIDs than those who are less severely affected at the time of levodopa treatment. This is probably due to the severity of the underlying dopaminergic denervation at the time of first exposure and is in line with the observation that nonparkinsonian patients who are treated for many years with high doses of levodopa for other reason do not develop LIDs.
- Duration of the levodopa treatment: after 5 years of levodopa therapy, ~40% of patients experience LIDs, while nearly 90% do so after more than 10 years of treatment.
- Daily dosage of levodopa: LIDs are significantly more common in PD patients treated with high doses of levodopa compared to those exposed to low doses for the same period. In the ELLDOPA study, LIDs were reported after 6 months of levodopa therapy in 3.3%, 2.3%, and 16.5% of patients with early PD randomized respectively to 150 mg, 300 mg, or 600 mg day^{-1}.
- Use of levodopa versus dopamine agonists: several randomized controlled trials comparing the incidence of LIDs in patients with early PD randomized to levodopa therapy or a dopamine agonist (bromocriptine, cabergoline, pergolide, pramipexole, ropinirole) consistently demonstrated that the risk of developing LIDs was substantially less on agonist, at least as long as it was maintained as a monotherapy without levodopa. A genetic predisposition for the development of LIDs has not been established yet, although some positive gene polymorphism associations have been reported in a few small pharmacogenetic studies.

Pathophysiology of Dyskinesias

The mechanisms leading to the development of LIDs remain poorly understood. They are believed to be the consequence of complex alterations of the motor network circuitry of the basal ganglia. Animals with nigro-striatal dopaminergic denervation (6-hydroxy-dopamine (OHDA)-lesioned rat or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-intoxicated monkey) undergoing chronic levodopa therapy develop LIDs and are useful experimental models to provide new insights into the molecular, physiological, and pharmacological mechanisms generating LIDs. Studies of human brain tissues have also permitted a better, although partial insight into such mechanisms. A challenge in interpreting these studies is to determine if the observed changes are the cause or the consequence of the abnormal movements.

Briefly, LIDs are considered to be the result of the combination of several factors. First, there is loss of the dopamine striatal input caused by the degeneration of the nigrostriatal pathway. This loss induces alterations of synaptic connectivity within the striatum. Second, antiparkinsonian drugs, such as levodopa, imperfectly mimic normal transmission when used to compensate for the loss of endogenous striatal dopamine inputs. This artificial dopaminergic stimulation on an abnormal dopamine-depleted system generates inappropriate molecular postsynaptic messages, in turn leading to an abnormal neuronal cell signaling. As a consequence, researchers hypothesize that abnormal neuronal motor network activity is induced leading to abnormal motor programs and generation of abnormal movements such as LIDs. Interestingly, several of these changes are long-lasting and are known as the 'priming' phenomenon. Priming is possibly related to some kind of long-term molecular plasticity, as dopaminergic input to the striatum controls important processes such as long-term potentiation (LTP) and long-term depression (LTD) that are responsible for the maintenance of motor memory. Once 'primed,' it is not clear if this phenomenon is completely or only partially reversible, and to which extent 'depriming' strategies could switch the system back to normal.

Importance of Striatal Dopamine Depletion in the Genesis of LIDs

The importance of the extent of nigral dopaminergic cell loss is well documented by several experimental observations. As in humans, monkeys with normal dopaminergic nigrostriatal systems do not develop LIDs, unless they are treated with extremely large doses of levodopa. The rate of onset of dyskinesia is correlated with the extent of the dopaminergic lesion: animals with partial dopaminergic lesions hardly develop LIDs while those with severe dopaminergic depletion (>90%) develop marked LIDs within few days. Therefore, dopamine striatal denervation is an important facilitating factor for the development and expression of LIDs.

'Dopaminergic Continuous Stimulation' Theory

The mode of administration (pulsatile versus continuous) of dopaminergic antiparkinsonian medications seems crucial in the development of LIDs. Briefly, the dopaminergic continuous stimulation (CDS) theory considers that short acting drugs (such as levodopa with its 90 min elimination half-life and its erratic gastro–intestinal absorption responsible for peaks and troughs in plasma levels) induce an abnormal pulsatile stimulation that disturbs the striatal relay of the motor system. Normal endogenous striatal dopamine receptor stimulation is supposed to be both phasic and tonic at the level of a synapse, with a relatively stable continuous baseline release. Phasic dopamine release might occur preferentially within the synapse, while tonic release might be extrasynaptic. In the *early stages* of PD, levodopa might be stored in surviving dopaminergic

terminals in the striatum and released gradually in a relatively preserved physiological manner. However, as terminals are progressively lost with the disease progression, levodopa cerebral effects become more closely dependent on plasma levels of levodopa. Exposing an increasingly denervated striatum to pulsatile dopaminergic stimulation might then induce dyskinesia. This concept is supported by several experiments conducted in levodopa-naïve MPTP-intoxicated monkeys. Dopamine agonists with longer elimination half-life than levodopa (bromocriptine, ropinirole) induce significantly less LIDs than levodopa. One could argue that pharmacodynamic differences might also play a role, including differential effects of levodopa and agonists on dopaminergic receptor subtypes (D1- or D2-like) or on nondopaminergic (noradrenergic or serotonergic) receptors. However, conflicting or inconsistent pharmacodynamic explanations have generally been reported. Moreover, the importance of the mode of administration of the drug is supported by the fact that (1) combining entacapone, a catechol-*O*-methyl transferase (COMT) inhibitor that prolongs levodopa elimination half-life, with levodopa therapy induces fewer LIDs than levodopa alone, and (2) a short acting dopamine agonist like 4-propyl-9-hydroxynaphthoxazine (PHNO) can induce dyskinesias by itself when administered in a discontinuous pulsatile manner.

Changes Induced by Pulsatile Dopamine Stimulation in the Corticobasal Ganglia Circuitry

Such an irregular and disorganized dopamine response within the striatum is supposed to induce in turn an abnormal function of the cortico–subcortical neuronal networks that generate motor programs within the basal ganglia.

Healthy basal ganglia

The basal ganglia plays a key role in the control of motor behavior. They comprise the *substantia nigra*, *striatum*, *internal and external segments of the globus pallidus* (GPi and GPe, respectively), and *subthalamic nucleus* (STN) (**Figure 3**)

- The major inputs into the basal ganglia are:
  - the dopaminergic nigrostriatal pathway (#1, **Figure 3**)
  - the glutamatergic corticostriatal pathway (#4, **Figure 3**)

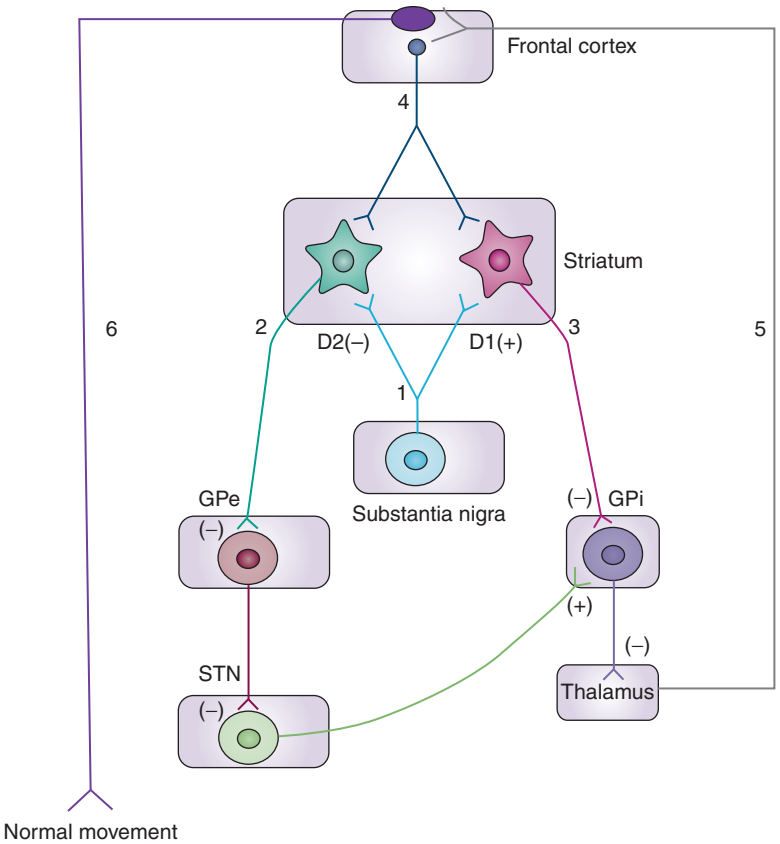

Figure 3 Schematic of normal basal ganglia (D1(+): dopamine D1 excitatory receptors; D2(–): Dopamine D2 inhibitory receptors; GPe: globus pallidus external segment; GPi: globus pallidus internal segment; STN: Subthalamic nucleus; (–): GABAergic inhibitory input; (+): glutamatergic excitatory input). Adapted from Jenner P (2008a), with permission from Nature Publishing Group.

- There are classically two major striatal outputs: the direct and indirect pathways composed of GABAergic inhibitory medium spiny neurons.
  - The neurons of the direct output pathway (#3, **Figure 3**) have *D1 dopamine excitatory receptors* on their cell bodies (D1(+), **Figure 3**). They project to the *GPi*.
- The neurons of the indirect output pathway (#2, **Figure 3**) have *D2 dopamine inhibitory receptors* on their cell bodies (D2(−), **Figure 3**). They project *to the GPe*, where they synapse with more GABAergic projection neurons. In turn, these neurons project *to the STN* and form synapses with the glutamatergic excitatory neurons that provide output to the GPi which sends in turn GABAergic inhibitory projections to the thalamus.
- The GPi therefore receives inhibitory inputs from the direct pathway and excitatory inputs from the indirect pathways. Normally, dopamine exerts inhibitory control over the indirect pathway, and by contrast, it exerts an excitatory effect on the direct output pathway. The balance between the direct and indirect pathways is thought to be responsible for a normal motor output of the system toward the thalamic nuclei that close the motor cortico–subcortical loop via thalamocortical projections (#5, **Figure 3**) and relay the message back to the frontal motor cortex for a normal efferent motor program (#6, **Figure 3**).

This classical view of the basal ganglia organization is overly simplistic and can be challenged in many ways. For example, axons projecting from the striatum are known to send collaterals to virtually every basal ganglia target, which is not in line with this 'sequential' schematic.

Changes in basal ganglia circuitry caused by striatal dopamine depletion (Figure 4)

In PD, degeneration of substantia nigra neurons causes loss of dopaminergic input to the striatum. This loss of dopaminergic input is supposed to provoke an imbalance in the activity of the direct and indirect striatal output pathways.

- Dopamine denervation increases the activity in the indirect pathway (loss of physiological dopamine inhibition). The GABAergic projection from the GPe to the STN becomes underactive as a consequence of this increased inhibitory GABAergic input. The STN glutamatergic neurons become in turn overactive, leading to increased activity of the inhibitory GABAergic neurons in the GPi that project to the thalamus.

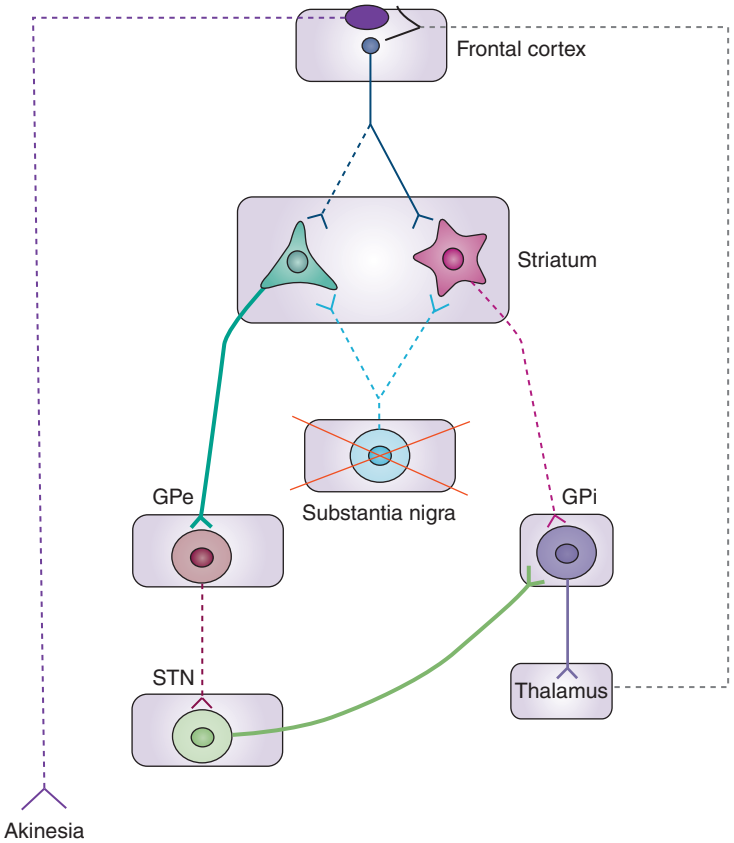

Figure 4 Schematic of changes occurring within the basal ganglia motor circuitry in Parkinson's disease. Adapted from Jenner P (2008a), with permission from Nature Publishing Group.

This decreases thalamic neuronal firing and alters input to the premotor cortex.

- Activity in the direct pathway decreases following the loss of dopamine physiological excitatory effects. This contributes to the increased activity of the GABAergic neurons that project to the thalamus with further increase in functional thalamic inhibition.

An abnormal motor program characterized by reduced voluntary movement (akinesia) is the final result of these changes in the basal ganglia output.

Changes in basal ganglia circuitry associated with LIDs in PD (Figure 5)

- The genesis of dyskinesia is generally explained by changes in the *direct and indirect output pathways* that are the opposite of those following dopamine depletion.
- It is suggested that D1 and D2 receptors are overstimulated by levodopa, leading to *underactivity of the indirect output pathway* and *overactivity of the direct output pathway*. This in turn leads to *decreased GABAergic input to the thalamus* and *increased firing of thalamic neurons toward the motor cortex*, resulting in involuntary movement.

It is easy to provide observations that illustrate the limits of this model. As an example, an upregulation of striatal dopamine receptors is expected as a result of *denervation supersensitivity* while a subsequent downregulation is expected after chronic dopaminergic treatment. However, there is a lack of any substantial detectable change in dopamine receptors in humans and in animals. Studies evaluating the involvement of the direct and indirect output pathways by their markers in animal models also show that many other different transmitters, including the opioid system, A2A adenosine, cannabinoid, noradrenergic, serotoninergic, and histaminergic receptors are modified in LIDs models. They probably play an important role, although yet poorly understood. This may serve as a useful basis for the development of future nondopaminergic antidyskinetic medications.

Corticostriatal Connectivity and the Role of Glutamate Transmission (Figure 6)

Cortical areas send dense glutamatergic innervation to the striatum (#3, **Figure 6**). The dopaminergic control within the striatum is supposed to integrate the glutamatergic

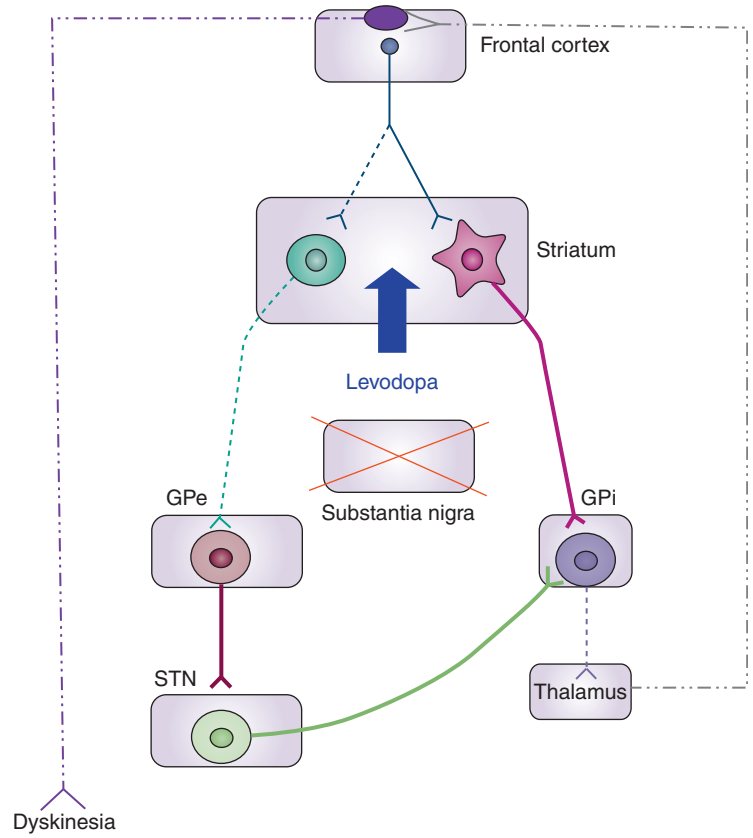

Figure 5 Schematic of alterations of the functioning of the basal ganglia motor circuitry in parkinsonian patients with levodopa-induced dyskinesias. Adapted from Jenner P (2008a), with permission from Nature Publishing Group.

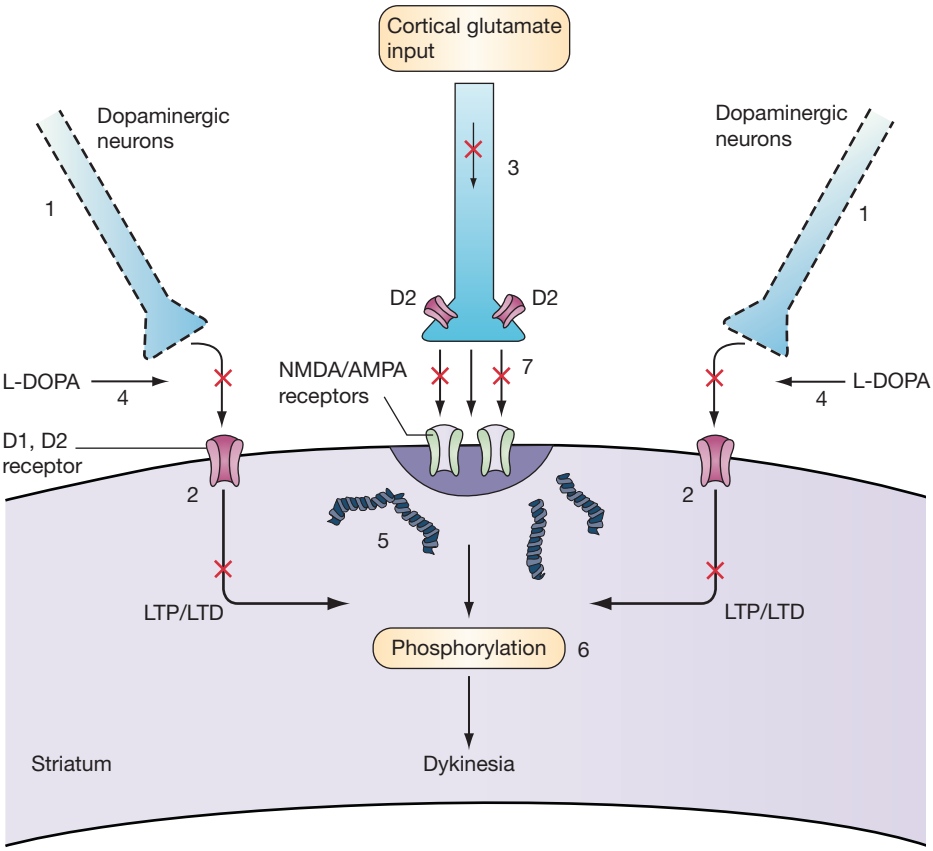

Figure 6 Altered transmission in the striatum that leads to dyskinesia expression. Adapted from Jenner P (2008a), with permission from Nature Publishing Group.

corticostriatal input with the GABAergic striatal output. The loss of striatal dopamine innervation in PD suppresses this dopamine-dependant integration. Morphologically, following the loss of striatal dopaminergic input, the medium spiny neurons lose the spines on which the glutamate receptors that receive input from the cortex are located. As the disease progresses, glutamatergic receptors might change in number and distribution, as a result of spine loss and changes in scaffold proteins (#5, **Figure 6**) which are important in fixing them in position to other glutamate and dopamine receptors on the spines. Moreover, important processes (such as state of phosphorylation) that are known to control glutamate receptor function are impaired by dopamine denervation and levodopa pulsatile stimulation. (#6, **Figure 6**). Taken together, these changes alter the consequences of glutamate activity (#7, **Figure 6**). As a consequence, the global effects of glutamate are modified, inducing abnormal intracellular signaling cascades with abnormal final striatal output and inappropriate motor programs. The striatal glutamatergic system thus appears to play a central role, with evidence of an abnormal NMDA-receptor- and AMPA-receptor-mediated responsiveness to glutamatergic corticostriatal input. This is supported by the fact that the NMDA glutamate antagonist amantadine reduces LIDs in parkinsonian monkeys and in PD patients.

Pharmacological Management to Prevent Dyskinesia

LIDs occur at an average annual rate of 10% when patients with early PD are started on levodopa therapy. In this context, it is pertinent to assess if the use of alternative medications as first line treatment may change the picture. This effect could be due to an indirect 'sparing' effect on levodopa use and/or to a more specific impact on underlying mechanisms, such as CDS.

Levodopa and COMT Inhibitors

According to the continuous dopaminergic stimulation hypothesis, prolonging the levodopa response with controlled-release (CR) formulations or early combination with a COMT inhibitor should induce less LIDs. Unfortunately, in contrast with expectations, two large randomized clinical trials (RCTs) showed that the early use of CR levodopa induced the same amount of LIDs than standard levodopa. Though an ongoing RCT aims at comparing the rate of LIDs between levodopa alone or in combination with entacapone (known as the STRIDE-PD study), this last strategy cannot be recommended for everyday practice as long as no clinical evidence is yet available.

Dopamine Agonists

There is consistent clinical evidence from several 2–5-year RCTs that the early use of a dopamine agonist, such as ropinirole or pramipexole, reduces the risk of emergence of LIDs as compared with levodopa first line treatment. The incidence of dyskinesias is nearly nil as long as the patient can be maintained on agonist monotherapy. The incidence goes up, however, once levodopa is added to the agonist. The latter is necessary in most patients after a few years of follow-up in order to keep adequate control of parkinsonian signs. The impact of this strategy on the prevalence of late disabling LIDs and on long-term health-related quality of life remains controversial. Moreover, there are other issues than LIDs to consider when starting a patient on an agonist early, since agonists can induce other troublesome adverse reactions such as daytime somnolence, hallucinations, and impulse control disorders.

Other Agents

The impact of an early treatment with monoamine oxidase Type B inhibitors (MAO-BIs), selegiline, or rasagiline, on the subsequent emergence of LIDs is not clearly understood. Selegiline may actually increase the risk of LIDs. No good level of evidence is available for anticholinergics or amantadine. The absence of information on amantadine is a serious scientific lacuna because the antiglutamate effects of amantadine could theoretically reduce the risk of subsequent development of LIDs.

Management Strategies to Reduce Dyskinesias

In some cases, no specific treatment of LIDs may be required especially when LIDs are mild and not troublesome to the patient. In other cases, LIDs require treatment because they are socially or functionally disabling or because they limit levodopa doses and thus compromise optimal control of parkinsonism. If LIDs deserve therapeutic management, it is then crucial to recognize their clinical pattern since off-period dystonia, diphasic dyskinesias, and peak-dose dyskinesia are not to be managed in the same manner.

Peak-Dose Dyskinesias

These dyskinesias are the most frequent LIDs. They can be managed using two different approaches (pharmacological or surgical), based on two different mechanisms each: indirect (levodopa dose reduction) and direct (specific antidyskinetic effects).

Adjustment of antiparkinsonian medications to reduce levodopa daily dose

This approach is often disappointing because of the risk of consequent worsening of parkinsonism, but several strategies can be tried:

- *Levodopa adjustments*: Manipulation of levodopa dosage (lower doses administered more frequently) may occasionally be helpful.
- *Dopamine agonist addition or adjustments:* The addition of a dopamine agonist, if the patient is not already receiving this class of drug, may permit a *reduction in levodopa dose* without worsening of Parkinsonism. If the addition of the agonist worsens the dyskinesias, a down-titration of levodopa dose can be tried. However, even patients who experience initial benefit can rarely be satisfactorily controlled in the long term. Substituting levodopa with high doses of a dopamine agonist has been reported, but at the risk of neuropsychiatric side effects.

Addition of a drug with direct antidyskinetic properties

- *Amantadine*: This is the most useful symptomatic antidyskinetic medication presently available. It is believed to work via NMDA receptors blockade. Amantadine added to levodopa improved antidyskinesia without worsening parkinsonism in placebo-controlled RCTs. High doses ($>200\,mg\,day^{-1}$) are more efficacious than lower ones, but less well tolerated because of cognitive side effects. Long-term benefit remains controversial.
- *Other drugs*: Clozapine is an atypical antipsychotic medication with poorly known mechanism of action (dopamine D1, D2, D4, and 5HT2 receptor antagonist and 5HT1A receptor agonist). It improves dyskinesia in one placebo-controlled RCT, but it can induce severe agranulocytosis, which prevents recommending it as a standard antidyskinesic treatment. A reduction in LIDs has been reported with low doses of other atypical antipsychotics (risperidone, olanzapine, quetiapine), but this cannot be recommended for common practice since even low doses can worsen parkinsonism. Non-dopaminergic drugs like sarizotan (5HT1A agonist), talampanel (glutamate AMPA antagonist), fipamezole (alpha2 agonist), and others have been reported to reduce dyskinesias in levodopa-primed MPTP-intoxicated primates, but such preclinical data remain exploratory and deserve clinical confirmation.

Use of continuous infusion therapies

- *Continuous subcutaneous infusion of apomorphine* (programmable pump usually during waking hours) was reported to control disabling motor complications, including dyskinesia in small open-label series of advanced PD patients. This effect is explained by the

more continuous delivery of dopamine stimulation and the concomitant reduction in levodopa daily dose. A limiting side effect is the occurrence of localized skin reactions.

- *Continuous intraintestinal infusion of levodopa.*

A water-soluble system for delivering continuous intrajejunal levodopa (Duodopa) has shown to be effective in controlling motor fluctuations without worsening dyskinesias in small open-label studies. This requires a surgical procedure to implant a permanent intraintestinal catheter.

Surgical approaches

Both ablative and deep brain stimulation (DBS) procedures are currently available to treat levodopa-associated motor complications that cannot be satisfactorily controlled with medical therapies. These techniques are based on the evidence indicating that the globus pallidus pars interna (GPi) and subthalamic nucleus (STN) are *overactive i*n PD. This overactivity is reversed by lesion or high frequency stimulation. Interestingly, while the *classic model* predicted that pallidotomy would worsen dyskinesia, these procedures produced a dramatic amelioration of dyskinesia, probably as a result of interference with abnormal firing patterns in basal ganglia output neurons.

- *Ablative procedures* (unilateral pallidotomy): Several controlled studies confirmed the efficacy of unilateral pallidotomy in improving dyskinesia. Benefits are long standing. Antidyskinetic benefits have been reported with lesions placed in an anteromedial location, a more ventral location, or anywhere in the posteroventral GPi. Ablative procedures are associated with a risk of *hemorrhage, infarction, and infection* (common to all stereotactic operations). Bilateral procedures are not recommended because they are associated with further risks, including *speech, swallowing, and cognitive problems*. With the development of DBS, ablative lesions are now more rarely performed.
- *Deep brain stimulation*: Chronic high-frequency 'deep brain' stimulation (DBS) mimics the effects of ablative neurosurgery. In this procedure, a stimulating electrode with four contacts is implanted into the target area and connected to a programmable stimulator with a long-life battery placed under the skin of the chest wall. The stimulator parameters (voltage, frequency, and pulse width) are gradually adjusted to reach the maximum benefits with the minimum side effects.

Several studies have confirmed that pallidal DBS is associated with a marked reduction in contralateral dyskinesia in addition to improvements in 'off'-periods. The duration of benefit is variable. Improvement in parkinsonian signs and dyskinesia may result from direct effects on two different anatomofunctional systems within the pallidum. The stimulation of the most ventral contact is effective on dyskinesia but may worsen akinesia and block the antiparkinsonian effect of levodopa. In contrast, stimulation through the most dorsal contact is most effective against akinesia but may induce dyskinesia.

Subthalamic nucleus (STN) DBS is efficacious to treat dyskinesia in advanced PD patients. It significantly improves motor function, dyskinesia, and quality of life compared with best medical management. Dyskinesia improvement is mainly explained by the concomitant reduction in levodopa daily dose. Long-term studies demonstrate the stability of this therapy.

Candidates for DBS are patients with typical PD, who are levodopa responsive but have troublesome motor complications that cannot be satisfactorily controlled with medical therapies and who do not have cognitive impairment.

DBS is expensive and associated with potentially serious side effects including those related to the *surgical procedure* (hemorrhage, infarction, infection), the *hardware* (lead breaks, lead displacement, ulceration, local infection), and *stimulation* (dysarthria, oculomotor disturbances, emotional problems, and cognitive impairment). In addition, the battery has a finite life and must be periodically replaced.

Off-Period Dystonia

Dystonia can improve with the same therapeutic strategies that reduce motor fluctuations and off periods: increasing levodopa dosage, increasing the frequency of dosing, combining a dopamine agonist (including apomorphine subcutaneous injections) to levodopa, adding a COMT-inhibitor or a MAO-B inhibitor. Injections of botulinum toxin may help alleviate prolonged painful foot dystonia.

Diphasic Dyskinesias

These dyskinesias are the most difficult to manage. Greater doses of levodopa may help, but generally at the cost of more severe peak-dose dyskinesias. Adjusting and modifying time and doses of antiparkinsonian medications are often disappointing. Subcutaneous apomorphine or intraduodenal levodopa may help, although the level of evidence to support the efficacy of these strategies is low. DBS of the subthalamic nucleus is an option in severe cases.

In summary, from a practical clinical perspective, the early use of a dopamine agonist rather than levodopa can be considered as initial treatment of PD in order to postpone the subsequent emergence of dyskinesia, especially in patients with early disease onset, as they are at greater risk for dyskinesia than older patients. Once present, and if disabling, dyskinesia should initially be managed by levodopa doses adjustment combined with

dopamine agonists. Usually this strategy is only transiently efficacious. Then, amantadine can be added for its antidyskinetic effects. If dyskinesia remains disabling in spite of such pharmacological adjustments, functional surgery is then indicated, especially STN DBS. For patients who cannot be operated, subcutaneous infusion of apomorphine or intraintestinal infusion of levodopa is to be considered.

Dyskinesias: Animal Models

A Richter and S E Sander, Institute of Pharmacology and Toxicology, Berlin, Germany

Glossary

Channelopathies – Disorders related to dysfunctional ion channels.
Face validity – Phenomenological similarities between an animal model and the disorder in patients.
Long-term potentiation – Form of synaptic plasticity in which coincident activity of pre- and postsynaptic elements leads to a long-lasting facilitation of neuronal transmission.
Neuroleptics – Antipsychotic drugs with an antidopaminergic activity.

Definition and History

Dyskinesias are abnormal involuntary movements, including dystonic, athetotic, and choreic movements, which are heterogeneous with respect to etiology, triggers, and affected body parts. The First, descriptions of dyskinesias experimentally induced by drugs or neurolesions in animals can be found in the early 1970s. Furthermore, several mutant rodents have been reported to exhibit permanent dystonic symptoms. Animal models of dystonia and Huntington's disease are described elsewhere. Since the term dyskinesia is preferred for (1) hereditary paroxysmal dystonic and choreathetotic movements and

(2) drug-induced abnormal movements, this chapter focuses on a well-established genetic rodent model of paroxysmal dyskinesias and throughout drug-induced animal models on levodopa-induced dyskinesias (LIDs) in rats.

Genetic Animal Models of Paroxysmal Dyskinesias

Paroxysmal dyskinesias are a group of episodic movement disorders. Four major types of paroxysmal dyskinesias are differentiated by the precipitating and exacerbating factors: paroxysmal nonkinesigenic dyskinesia (induced by stress and caffeine; see below), paroxysmal kinesigenic dyskinesia (induced by sudden movements), exertion-induced dyskinesia, and hypnogenic paroxysmal dyskinesia. These episodic disorders have been suggested to be related to ion channelopathies, but the underlying mechanisms are unknown and are probably heterogeneous in various forms of dyskinesias. Clearly defined animal models of paroxysmal dyskinesias are restricted to the genetically dystonic hamster.

The *dt*^{sz} Mutant Hamster

In the *dt*^{sz} mutant hamster, an inbred line of Syrian hamsters, attacks of generalized dyskinesias occur in response to mild stress and, sometimes, also spontaneously. The vitality is normal in mutant hamsters, probably because of the paroxysmal nature of the movement disorder, and the age-dependent time-course of dystonia (see below) contributes to an unaltered fertility. These hereditary motor impairments, which are transmitted by an autosomal recessive gene, were initially misdiagnosed as epilepsy. Therefore, the original gene symbol was *sz* (for seizures). However, more detailed investigations (e.g., electroencephalography) revealed that the attacks are not epileptic seizures, but show the characteristics of paroxysmal nonkinesiogenic dystonic choreoathetosis (PDC) in humans. Since dystonia is the predominant symptom, the *dt*^{sz} mutant is also regarded as a model of (paroxysmal) dystonia. The responsible gene has not yet been identified, but the myofibrillogenesis regulator-1 (MR-1) gene, known as a causative gene for human PDC, could be excluded as the culprit in mutant hamsters.

In mutant hamsters, the severity of dyskinesia (determined by a score-system) is age-dependent with a maximum at an age of 30–40 days of life and with a complete remission of the stress-induced movement disorder at about 10 weeks. Nevertheless, paroxysmal dystonia in mutant hamsters is obviously not really transient because relapses of dystonia occur in females during late pregnancy and the prodystonic drugs lamotrigine and riluzole can provoke severe attacks in over 10-week-old male and female hamsters.

Among the drugs tested in *dt*^{sz} hamsters, pronounced beneficial effects were observed after acute treatments with various GABA-potentiating drugs, antidopaminergic compounds, and K_v7 potassium channel openers, while drugs which disturb GABAergic inhibition or which increase the dopaminergic activity worsened PDC. A dramatic aggravation of dystonia in mutant hamsters was provoked by the sodium channel blockers, lamotrigine and riluzole.

Pharmacological examinations in mutant hamsters are important to find more effective therapeutics and are also very helpful for interpretations of neurochemical findings. By neurochemical examinations, most changes were detected in the striatum and ventral thalamic nuclei of *dt*^{sz} hamsters. There is strong evidence that disturbed GABAergic inhibition and enhanced dopaminergic activity are critically involved. Measurements of levels of dopamine and its metabolites in tissue homogenates, examinations of tyrosine hydroxylase and of dopamine transporters did not disclose any abnormalities. As indicated by an unaltered density of nigral dopaminergic neurons, the dopaminergic system seems to be intact, but autoradiographic analyses have shown a lower dopamine D_1 and D_2 receptor binding in the dorsal striatum. This can be interpreted as a receptor downregulation, that is, as a consequence of an enhanced dopamine release, microdialysis in freely moving *dt*^{sz} hamsters revealed increased extracellular dopamine levels during dystonic episodes. In fact, striatal microinjections of the dopamine D_2 receptor agonist, quinpirole, significantly worsened the symptoms, while combined microinjections of D_1 and D_2 receptor antagonists exerted striking beneficial effects. However, the striatal dopaminergic overactivity could be secondary to impaired GABAergic inhibition. Reduced GABA levels, a decreased expression of the GABA-synthesizing enzyme, and changes in the density of benzodiazepine binding in the striatum, determined in mutant hamsters at the age of most marked severity of paroxysmal dystonia, but not in older animals after the remission of stress-induced dyskinesia, are in line with pharmacological observations. Systemic and intrastriatal injections of GABA-potentiating drugs, such as the $GABA_A$-receptor agonist muscimol, improved dyskinesia in the hamster model. These findings can be explained by a deficit of striatal aspiny GABAergic interneurons, found in *dt*^{sz} hamsters at an age of most marked expression of dyskinesia but not in older hamsters after spontaneous remission of PDC. The retarded development of striatal GABAergic interneurons possibly represents the primary defect in this animal model. As shown by recent studies, the density of striatal projection neurons seems to be unaltered in mutant hamsters.

The marked age-dependent deficit of striatal inhibitory interneurons is in line with electrophysiological findings in *dt*^{sz} hamsters. This structural defect obviously

leads, by disinhibition of striatal projection neurons, to an abnormal basal ganglia output. Thus, single unit recordings revealed a significantly increased basal activity of striatal GABAergic projection neurons in dt^{sz} hamsters, while the firing rate of entopeduncular GABAergic neurons was significantly decreased. Furthermore, the firing patterns were found to be more irregular in the entopeduncular nucleus (globus pallidus internus in primates). In line with an age-dependent normalization of the density of striatal GABAergic interneurons, the neuronal striato-entopeduncular activity reached normal levels in older dt^{sz} hamsters, that is, after remission of stress-induced dystonia. Deep brain stimulations of the entopeduncular nucleus improved dystonia in mutant hamsters, substantiating the importance of an abnormal basal ganglia output. In the globus pallidus (globus pallidus externus in primates), the neuronal activity only tended to be increased (+40%), but a wide range in the activity may indicate also an involvement of the indirect striato-pallidal pathway. In view of the paroxysmal nature of dyskinesia in dt^{sz} hamsters, the permanent deficit of striatal GABAergic interneurons, resulting in an enhanced striato-entopeduncular activity, seems not to cause motor disturbances by itself. However, this structural defect may lead to a disinhibition of stress-induced dopamine release in the striatum and thereby to the manifestation of a dystonic attack.

Drug-Induced Dyskinesias

Drug-induced dyskinesias are a severe problem in the chronic treatment of various diseases. The most common types of drug-induced dyskinesias are tardive dyskinesias, which can be caused by the treatment with neuroleptics, and LIDs as a side effect in the therapy of Parkinson's disease (PD). Although there have been excessive efforts in the last decades to develop new therapeutics for the treatment of PD, there is a lack of effective drugs with tolerable acute or chronic side effects. Animal models have been shown to give valuable insights into the pathophysiology of LID and represent a useful tool in the preclinical research. LID is only inducible in parkinsonian organisms. To generate animal models of PD, toxins can be administered either systemically (e.g., 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) or rotenone) or intracerebral, like 6-hydroxydopamine (6-OHDA). Probably, most popular is the induction of LID in MPTP-treated primates, but in respect to animal welfare and economic considerations, murine animal models of LID gain in importance. The unilaterally 6-OHDA-lesioned rat provides an excellent reproducibility and good face validity.

LID in the 6-OHDA-Lesioned Rat

LID in 6-OHDA-lesioned rats mimics the symptoms of peak-dose dyskinesias. In this most common type of LID, dyskinetic movements correspond to high concentrations of dopamine agonists in the brain, leading to an overactivation of postsynaptic dopamine receptors.

For generating hemi-parkinsonian rats, 6-OHDA is usually injected unilaterally into the substantia nigra or into the medial forebrain bundle. Additional application of the toxin into the striatum amplifies the depletion of striatal dopamine. Intracerebral injection of 6-OHDA induces degeneration of monoamine neurons, in general, but the selectivity for dopaminergic neurons can be increased by inhibitors of monoamine transporters, like desipramine, administered prior to the operation. The success of unilateral dopaminergic denervation can be detected by quantifying the rotational behavior after the application of dopaminergic drugs. Direct agonists of dopamine receptors like apomorphine provoke contralateral rotations to the lesion, caused by a hypersensitivity of dopamine receptors of the lesioned side. Drugs like amphetamine induce ipsilateral rotations, as only the intact side releases dopamine to stimulate dopamine receptors. The stepping or the cylinder tests also unmask lateral behavior, which reflects the parkinsonian symptoms, bradykinsia or akinesia, caused by the unilateral dopamine depletion. Chronic administration of levodopa (in addition with a decarboxylase inhibitor) induces LID. These involuntary choreoathetotic movements can affect orofascial muscles ('orolingual' dyskinesias), the limb (especially, the forelimb), and the whole body axis ('axial' dyskinesias) and appear contralateral to the lesioned side. An increased contralateral rotation ('locomotive' dyskinesia) can be induced by various dopaminergic drugs and should be distinguished from the three other subtypes of LID. According to Lundblad and coworkers, the severity of each subtype can be rated by a score system from 0 to 4: 0, absent; 1, present during less than half of the observation time (occasional); 2, present during more than half of the observation time (frequent); 3, continuous but interruptible by external stimuli; 4, continuous and not suppressible by external stimuli. Interestingly, the severity of dyskinesia is not predictable by the extent of dopaminergic depletion or levodopa dose.

In compliance with parkinsonian patients, D_2 receptor antagonists and the antiglutamatergic compound amantadine attenuated dyskinesia in the rat model of LID. Nevertheless, the therapeutic benefit of these drugs is only limited as D_2 receptor antagonists worsen parkinsonian symptoms and the glutamate receptor antagonist amantadine is only moderately effective, has side effects, and its efficacy declines over time. Although the combined administration of serotonergic drugs showed pronounced beneficial effects in the rat model of LID, there are contradicting reports to their antidyskinetic potency in patients. Recently, K_v7 channel openers proved to attenuate dyskinesias in 6-OHDA-lesioned rats, possibly pointing to a new therapeutical target in this disease.

Besides the preclinical drug research, neurochemical and electrophysiological studies give further insights into the pathophysiology of LID. It is known that the depletion of dopamine caused by degeneration of midbrain dopaminergic neurons results in an increased responsiveness of striatal GABAergic projection neurons to activation of dopaminergic receptors. During chronic levodopa treatment, when an intermittent increase of extracellular dopamine levels exists, this hyperresponsiveness gains in importance. Furthermore, serotonergic neurons have been shown to be able to convert levodopa to dopamine. However, in contrast to dopaminergic neurons, they lack of a feedback control for the release of dopamine. This could contribute to LID by causing unphysiological high levels of extracellular dopamine after administration of levodopa. Lundblad et al. propose an involvement of several different types of nerve fibres in the conversion of levodopa to dopamine. Otherwise, combined administration of serotonergic drugs, which reduce the release of synaptic vesicles containing serotonin and which convert dopamine by stimulating presynaptic autoreceptors had antidyskinetic potency in the rat model of LID (see above). There is also evidence for an implication of an altered corticostriatal glutamatergic neurotransmission. Picconi and coworkers demonstrated a loss of depotentiation in corticostriatal synapses in dyskinetic rats, consisting of an inability to downregulate long-term potentiation upon low-frequency stimulation of the corticostriatal pathway. This is in line with studies which revealed an enhanced striatal glutamate release in the rat model of LID.

These pathophysiological conditions probably lead to an increased activity of striatal GABAergic projection neurons. Especially, neurons of the 'direct pathway,' which express D_1 receptors, seem to be affected. These neurons show marked molecular changes in LID, including an upregulation of several GABA-related genes. An increased activity of these neurons presumably contributes to a reduced firing rate of neurons of the basal ganglia output structure, as shown in previous studies, which finally results in a disinhibition of the glutamatergic thalamocortical transmission.

Conclusions

Although the etiology of dyskinesias is different in the here described animal models, there seem to be common mechanisms in the pathophysiology. Striatal dysfunctions, leading to an abnormal basal ganglia output, are critically involved in the *dt*^{rz} mutant hamster as well as in LIDs in the rat model. This is in line with the current hypothesis on the pathophysiology in dyskinetic patients. Progress in the identification and in the understanding of shared mechanisms may be promising to find new therapeutic strategies in larger subpopulations of dyskinetic patients. The above described animal models can contribute to find new targets and are suitable for preclinical drug research.

Dysphagia

E Q Wang, Rush University, Chicago, IL, USA

Glossary

Aspiration – Occurs when food or liquid enters into the airway below the true vocal folds.
Dysphagia – Difficulty in moving food from mouth to stomach.
Fiberoptic endoscopic evaluation of swallowing (FEES) – Is an instrumental assessment tool that allows direct visualization of the pharyngeal and laryngeal structures and their performance before and after the swallow.
Laryngeal penetration – Occurs when food or liquid enters the vestibule or entrance of the airway to any level but not below the superior surface of the true vocal folds.
Videofluoroscopic swallowing study (VFSS) – Is an instrumental assessment tool to determine the nature and extent of an oropharyngeal swallowing disorder. The studies are captured using fluoroscopy in video or digitized format.

Definition and History

Dysphagia is defined as the disordered movement of the bolus from mouth to stomach due to abnormalities in the structures critical to swallowing or in their movements. It comes from the Greek prefix *dys* meaning 'difficulty' or 'disordered' and *phagia* meaning 'to eat.'

The field that studies dysphagia and its treatment is relatively new. The field was in its infancy from the 1970s to the 1980s. The information regarding normal swallow physiology and abnormal swallow pathophysiology has been growing exponentially since the 1990s. The literature on dysphagia falls into three categories: on physiology of normal swallowing; on changes in physiology of swallowing as a result of a variety of medical conditions; and on methodologies for screening, diagnosis, and management of patients with dysphagia.

Pathophysiology

Swallowing, as a complex process, is divided into four stages: oral preparatory, oral, pharyngeal, and esophageal. The *oral preparatory stage* is highly volitional and characterized by chewing and mixing the bolus with saliva. The *oral stage* is characterized by the final formation of the bolus into a shape and posterior movement of that bolus through the faucial pillars and into the pharynx to trigger the pharyngeal stage of swallowing. In the *pharyngeal stage*, the bolus is moved through the pharynx and rostral esophagus. This striated muscle section of the esophagus is called the upper esophageal sphincter (UES). The *esophageal stage* involves movement of the bolus through the esophagus into the stomach. Dysphagia occurs when one or more of the four swallowing phases are impaired due to an underlying neurological condition such as PD or HD. The symptoms of dysphagia vary in different movement disorders at each of the swallowing stages. These differences may reflect the underlying etiology. For example, patients with PD often show a typical tongue movement pattern characterized by a repetitive upward and backward movement of the central portion of the tongue known as 'tongue pumping,' which may last 10 s or more before a full swallow can be initiated. The 'tongue pumping' movement pattern is similar to the festinating gait in PD, that is, many repeated attempts are made before a successful initiation of an intended movement. This may result from the dysfunction of the BG in its role in executing a planned movement sequence in a timely manner. In both Parkinson's disease and Huntington's disease, proprioceptive sensory deficits have been suggested to contribute to decreased sensitivity to aspiration. Other underlying movement disorders with frequent and significant dysphagia include cervical dystonia, oromandibular dystonia,

multisystem atrophy (MSA), progressive supranuclear palsy (PSP), and corticobasal ganglionic degeneration (CBGD), and tardive dyskinesia.

Epidemiology/Risk Factors

Epidemiology as Related to Different Etiologies

Dysphagia or swallowing disorders occur in nearly 100% of people with idiopathic Parkinson's disease (IPD) and Huntington's disease (HD), usually in relatively more advanced stage. In contrast, in atypical Parkinsonism such as MSA, PSP, and CBGD, dysphagia occurs earlier and is more severe in the course of the disease.

Risk Factors

In idiopathic PD, the most important risk factors for developing dysphagia are progression of the disease, disease severity level, and 'on–off' motor fluctuations. In atypical Parkinsonism, the most important risk factors are early signs of dysphagia, dysarthria, and gait disturbances. In all movement disorders, changes in swallowing muscle function and coordination could lead to dysphagia.

Clinical Features/Diagnostic Criteria

Dysphagia can occur at any or a combination of the four stages and it is a serious threat to one's health because of the risk of aspiration pneumonia, malnutrition, dehydration, weight loss, and airway obstruction.

Warning Signs Associated with Dysphagia and Aspiration Risk

Decreased alertness
- heavy sedation from medication
- playing with food
- taking too large or repeated bites without attempting to chew or swallow
- talking or emotional liability during attempts to swallow

Change in approach to food
- avoiding eating in front of others
- avoiding foods of specific consistency
- prolonged meal time; frequent use of liquid to 'wash-down' food
- moving head or neck in certain ways to try to get food down

Impaired functions associated with dysphagia and aspiration
- involuntary tongue movements or head movements that interfere with swallowing
- wet, hoarse voice, extremely breathy voice
- limited mouth opening due to increased spasticity
- drooling or oral spillage, pooling, and pocketing of food in mouth
- coughing and choking upon swallowing
- constant throat clearing during or immediately after meals

Patient complaints and observation
- "It is hard to swallow"
- "It feels like something is stuck in my throat"
- "My taste is changing"
- "It hurts when I swallow"
- "Food or drink comes out of my nose when I eat or drink"
- "It takes too long to eat"
- "I have trouble breathing when I eat or right after I eat"

Diagnosis of Dysphagia

Certified and licensed speech-language pathologists (SLP) are trained to diagnose dysphagia. The following testing procedures are routinely used for diagnosing dysphagia: (1) clinical swallowing study, also called as bedside swallowing study if the test is done in inpatient setting in a hospital; (2) the videofluoroscopic swallowing study (VFSS), also referred to as modified barium swallow (MBS), typically done in a hospital setting because the procedure requires both an SLP and radiologist; (3) the fiberoptic endoscopic evaluation of swallowing (FEES) is an instrumental assessment tool allowing direct visualization of the pharyngeal and laryngeal structures and their performance before and after the swallow. It may require the presence of an otolaryngologist in some states.

Management

Medication

There is limited evidence that medication used to treat PD may be beneficial to the swallowing function. On the other hand, drug-induced orofacial and respiratory dyskinesias can interfere with the swallowing process, which may result in oropharyngeal and/or pharyngeal dysphagia.

Deep Brain Stimulation

Bilateral deep brain stimulation (DBS) of the subthalamic nucleus (STN) has mixed results on swallowing. Currently, it is unclear about the exact effect of STN DBS on the swallowing function.

Dysphagia Management

Treatments for swallowing can be divided into compensatory and rehabilitative approaches. Compensatory techniques are aimed at an immediate effect on safety and adequacy of nutrition and hydration. They are applied

when a person is receiving rehabilitation but needs instant help for safe eating, or when a person cannot be expected to complete or profit from rehabilitative efforts. There are three broad categories of compensatory techniques. They are *change in the posture*, *change in the food and/or liquid consistency*, and *change in the approach to eating*. For example, a *postural adjustment such as chin tuck* is often used when a patient has penetration or aspiration due to a delayed swallowing initiation or poor airway protection. The rehabilitative techniques are of two basic types: *they aim to change the underlying pathophysiology such as weakness or reduced endurance and to increase skill*. For example, the Mendelsohn maneuver is used to enhance the anterior hyolaryngeal movement to increase the duration and extent of UES opening during swallow.

Prognosis

Dysphagia in patients with IPD or other movement disorders will worsen as the underlying disease progresses. Early onset of severe swallowing deficits usually indicates poor prognosis.

Dystonia

C Comella, Rush University Medical Center, Chicago, IL, USA

Glossary

Blepharospasm – Focal dystonia involving the periocular muscles.

Cervical dystonia – A focal dystonia of the neck also called spasmodic torticollis.

Dystonia – A neurological disorder marked by the presence of involuntary, sustained muscle contractions causing abnormal postures.

Generalized dystonia – Dystonia involving at least one leg, the trunk, and one other body area.

Geste antagoniste – A touch or sensory maneuver that reduces or abolishes the dystonic symptoms.
Occupational dystonia – A dystonia that occurs only during a specific activity, such as writer's cramp or musicians dystonia.

Definition

Dystonia is a neurological syndrome with sustained muscle contractions that result in twisting and repetitive movements or abnormal postures. The sustained movements of dystonia may have overlying spasms that resemble tremor but can be distinguished from essential tremor by the directional quality of the movement. Dystonia is a dynamic disorder that changes in severity depending on activity and posture. An example of this is writer's cramp, a dystonia that involves the hand and arm, which is present only during the action of writing but not apparent during any other activity. Another characteristic feature of dystonia is the sensory trick. The sensory trick (or geste antagoniste) is a touch or sensory maneuver that reduces or abolishes the dystonic symptoms. It occurs in approximately 60% of patients. These tricks may be effective in some patients if imagined but not performed physically.

Dystonia is categorized in several ways. Categorization by body distribution separates dystonia into focal (involving a single body area), segmental (involving contiguous body areas), and generalized (involving at least one leg, the trunk, and another body area). Less common body distributions include multifocal (two or more noncontiguous body areas involved) and hemidystonia (involvement of one side of the body). Categorization of dystonia by age of onset divides dystonia into young onset (age of onset less than 26 years) and adult onset (age of onset greater than 26 years). The third categorization is by etiology, which is broadly separated into primary and secondary dystonia (**Table 1**).

The body region at onset and age of onset are important clinical clues when assessing dystonia. Young-onset dystonia most often begins with symptoms in the limbs, with the leg most frequently involved at onset. Dystonia that begins in childhood spreads to other body areas to become generalized dystonia in over 50% of patients. In contrast, adult-onset dystonia most frequently begins in the neck, arm, or face and tends to remain focal or may spread to become segmental but not generalized in most adult patients. Hence, a child with onset in the neck or face or an adult with onset in the leg or an adult who develops generalized dystonia would be atypical and indicate the need for further evaluation for an underlying cause.

Table 1 Classification of dystonia

Age of onset	Young onset: $\leq$26 years
	Adult onset: $>$26 years
Body distribution	Focal: single body region
	Segmental: contiguous body regions
	Generalized: both legs and at least one other body region
	Multifocal: noncontiguous body regions
	Hemidystonia: involving one half of the body
Etiology	Primary:
	Dystonia is only sign; may be sporadic or inherited
	Secondary:
	Dystonia occurring associated with a defined etiology or associated with other neurological abnormalities

The third method of dystonia classification is by etiology (**Table 2**). This classification scheme has undergone modification as new etiologic and genetic forms of dystonia have been described. The two broad categories in this classification include primary and secondary dystonia. Patients with primary dystonia present with signs related solely to dystonia and have no additional neurologic, laboratory, or imaging abnormalities. If dystonia is associated with muscle weakness, spasticity, ataxia, ocular motility abnormalities, retinal abnormalities, cognitive impairment, or seizures, then it is categorized as a secondary dystonia. In primary dystonia, the onset and progression of symptoms are gradual and without fixed postures unless contractures from longstanding dystonia occur. Secondary dystonia arises from an underlying condition. Examples include perinatal asphyxia or exposure to dopamine receptor antagonist drugs prior to development of dystonia. The presence of other neurological abnormalities may provide the clue to the cause of the dystonia.

Pathogenesis

There are no consistent neuropathological findings in primary dystonia. The lack of cell degeneration suggests that primary dystonia is a dynamic disorder, arising from abnormal cell function. The anatomic localization and specific neurotransmitter defects of dystonia have also been elusive. The first clue that dystonia is a disorder of the basal ganglia came from studies of hemidystonia in which lesions of the contralateral basal ganglia were associated with ipsilateral dystonia.

Recent neuroimaging studies with positron emission tomography and functional magnetic resonance imaging have shown that dystonia is associated with abnormal

activity in multiple regions of the brain, including motor cortex, supplementary motor areas, cerebellum, and basal ganglia. Abnormalities in blink reflex recovery and exteroceptive reflexes suggest a loss of central inhibitory mechanisms. Extensive electrophysiologic data in combination with functional imaging have suggested that the pathophysiology of dystonia, in particular the task-specific dystonias may arise to form a decrease of inhibition, an increase of plasticity or an impairment in sensory function.

Direct microelectrode recordings obtained in dystonia patients during electrode implantation for deep brain stimulation have shown alterations in mean discharge rates, somatosensory responsiveness, and altered patterns of neuronal activity in the globus pallidus. These recordings have given rise to new constructs for diagrams of the basal ganglia and its involvement in dystonia, in which the modulating influences within the basal ganglia change with activity, reflecting the movement-dependent nature of dystonia.

The underlying neurochemistry of dystonia is not known. Indirectly, abnormalities of dopaminergic activity in the basal ganglia are suggested by extrapolation from observations that dopamine receptor antagonism can cause acute and chronic dystonic symptoms (e.g., oculogyric crisis and tardive dystonia) and that dystonia is often associated with Parkinson's disease, a disorder with marked dopamine depletion. The occurrence of dopa-responsive dystonia further implicates a role for dopamine in the pathogenesis of dystonia. Response to anticholinergic agents implicates cholinergic mechanisms.

Epidemiology and Genetics

Investigations into the incidence and prevalence of dystonia are complicated by the difficulties in the ascertainment of affected individuals. The most cited prevalence figures are derived from a study conducted in the late 1980s in Rochester Minnesota, in which the prevalence of generalized dystonia was 34 per million population and the prevalence of focal dystonia was 295 per million, with cervical dystonia being the most frequent. However, subsequent epidemiological studies have shown a wide range in prevalence that may arise from differing methodologies of case identification, and the demographic and ethnic composition of the population assessed. In all studies, focal dystonia is more frequent, being estimated to be approximately ten times more frequent than generalized dystonia. Prevalence figures, however, have ranged from 6 to 732 persons per 1 000 000 population. In the absence of a reliable and validated screening tool that can be applied practically in large populations, underdiagnosis and misdiagnosis of dystonia are likely major confounds. In one study of familial dystonia, half the cases were not diagnosed. Recent efforts have been

directed toward development of diagnostic criteria and a reliable practical screening instrument that can be applied to large population studies.

There have been many recent advances in the area of dystonia genetics (**Table 3**), with identification of new genetic loci, increased understanding of genotype–phenotype interactions, and investigations into the role of the mutant gene products. DYTI dystonia is autosomal dominant but penetrance is reduced approximately 30–40%. The DYT1 gene accounts for about 90% of limb early-onset dystonia in the Ashkenazi population. In the non-Jewish population, however, only 40–65% of early-onset primary dystonia cases carry the gene. The DYT1 gene has a 3-base pair (GAG) deletion at 9q34, giving rise to mutated torsin A.

Torsin A is a member of the AAA+ superfamily and is present in all multicellular organisms. Wild-type torsin A colocalizes with cytoplasmic membrane structures and may be associated particularly with the endoplasmic reticulum. Recent studies of mutant torsin A have shown that it may be redistributed to other membrane structures, and demonstrates perinuclear staining, with the formation of distinct globular inclusions that contain vesicular monoamine transporter 2 (VMAT2).

Myoclonus-dystonia is a movement disorder characterized by alcohol-sensitive myoclonic jerks primarily affecting the arms and axial muscles combined with variable features of dystonia. Myoclonus-dystonia typically begins in the second decade and occurs equally in men and women. The dystonia may be mild, involving neck or limbs, and may occur in both in body areas affected by dystonia and affected areas. This form of dystonia may improve dramatically after alcohol intake. Myoclonus-dystonia is an autosomal dominant disorder with reduced penetrance.

Table 3 Genetic forms of dystonia

Locus	*Designation*	*Mode of inheritance*	*Clinical features*	*Chromosome, gene product and mutation*
DYT 1	Early-onset dystonia	AD	Typically begins in childhood; onset in limb often with progression to generalized dystonia	9q34; GAG deletion in DYT1 gene causes abnormality in ATP-binding protein, torsin A
DYT2	Autosomal recessive dystonia in Gypsies	AR	Childhood onset, generalized or segmental	Unknown chromosome, gene product
DYT3	Dystonia-parkinsonism 'Lubag'	X-linked recessive	Segmental or generalized dystonia with parkinsonism; predominantly in males from Panay island in Philippines	Xq13.1; unknown gene product
DYT4	Whispering dysphonia	AD	Whispering dysphonia; described in Australian family	Unknown chromosomal location, gene product
DYT5	Dopa-responsive dystonia/parkinsonism	AD	Dystonia with or without parkinsonism; dramatic response to levodopa	14q22: GCH1 locus; mutations in GTP cyclohydrolase I gene
	Segawa syndrome	AR	Dystonia with or without parkinsonism; diurnal variation, with worst symptoms in evening; marked response to levodopa	11p15.5; mutations in the tyrosine hydroxylase gene
DYT6	Adolescent-onset dystonia of mixed type; mennonite families	AD	Mostly segmental dystonia; mixed limb, cervical, cranial	8p; THAP1 gene
DYT7	Adult-onset focal dystonia; German family	AD	Adult onset with cervical dystonia, limb dystonia, dysphonia, or blepharospasm	18p
DYT8	Paroxysmal nonkinesigenic dyskinesia	AD	Episodes of dystonia/choreoathetosis not precipitated by exercise or activity	2q, myofibrillogenesis regualtro (MR-1)
DYT9	Paroxysmal choreoathetosis with episodic spasticity and ataxia	AD	Episodes of dystonia, diplopia, paresthesias with spastic paraplegia between attacks	1p Gene, product unknown
DYT10	Paroxysmal kinesigenic choreoathetosis	AD	Episodic choreoathetosis and dystonia brought on by exercise/activity	16p-q; gene, product unknown
DYT11	Myoclonus-dystonia	AD	Myoclonic jerks associated with variable features of dystonia; very alcohol responsive	7q; epsilon-sarcoglycan gene (SGCE)
DYT12	Rapid-onset dystonia-parkinsonism	AD	Onset of dystonia and parkinsonism over days to months	19q; Na/K ATPase alpha 3
DYT13	Multifocal and segmental dystonia	AD	Early-adult-onset segmental dystonia with cervical, cranial, and arm dystonia	1p; unknown gene product
DYT15	Myoclonus-dystonia	AD	Myclonus and dystonia	18p; unknown

AD = autosomal dominant; AR = autosomal recessive; ATP = adenosine triphosphate.
Bressman S (2007) Genetics of dystonia: An overview. *Parkinsonism and Related Disorders* 13: S347–S355.

Several loci for myoclonus-dystonia have been identified, one on chromosome 7q21, which harbors the gene for ε-sarcoglycan (SGCE), and another on chromosome 18p11. Other loci have been identified in two families, including a missense change in the D2 dopamine receptor (DRD2) gene on 11q23 and a novel 18-bp deletion mutation in the DYT1 gene on 9q34, indicating genetic heterogeneity for myoclonus-dystonia.

Dopa-responsive dystonia (DRD) manifests primarily as dystonia with onset in early childhood. Parkinsonism, including rigidity and bradykinesia, may develop during the course of untreated disease or be present at onset. Often, children with DRD are initially misdiagnosed as having a primary dystonia or cerebral palsy. The hallmark of this disorder is a marked, sustained response to levodopa. In the initial description of DRD, Segawa and colleagues reported a diurnal fluctuation in symptoms, such that symptoms worsened over the course of a day and improved following sleep. The diurnal fluctuation of symptoms may not be present in all patients with DRD. The most frequent form of DRD is autosomal dominant with a mutation in the gene for guanosine triphosphate (GTP) cyclohydrolase I. GTP cyclohydrolase I is involved in the biosynthesis of tetrahydrobiopterin, which is a cofactor for tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of dopamine. It is also a cofactor for phenylalanine and tryptophan hydroxylase. Numerous mutations of the GTP cyclohydrolase I gene and mutations in can cause DRD, making gene testing difficult. Diagnostic testing that has been suggested includes assessing tetrahydrobiopterin and neopterin in the cerebrospinal fluid and a phenylalanine-loading test. In the clinical setting, the marked benefit of dystonia to a trial of levodopa slowly increased to doses of 600–1000 mg day^{-1} is usually the most useful for diagnosis although this does not differentiate from juvenile onset parkinsonism. In DRD, levodopa, usually at small doses, produces a marked sustained benefit, with virtual elimination of symptoms. DRD may be misdiagnosed as cerebral palsy.

Other genetic forms of dystonia combine features of dystonia with parkinsonism. Rapid-onset dystonia-parkinsonism is an autosomal dominant disorder in which symptoms of dystonia and parkinsonism with prominent dysarthria and dysphagia evolve over a period of hours to weeks. Onset occurs in adolescence and early adulthood. Despite reduced cerebrospinal homovanillic acid levels, this syndrome responds poorly to dopaminergic agents. Linkage to chromosome 19q13 has been found and six missense mutations in the gene for the Na+/K+-ATPase alpha3 subunit (ATP1A3) have been described. Genetic testing for the ATP1A3 gene is recommended when abrupt onset, rostrocaudal gradient and prominent bulbar findings are present.

Lubag is an X-linked dystonia-parkinsonism causing progressive dystonia, often accompanied by parkinsonism. This disorder affects Filipino males in their fifth decade Philippines. Women are also affected, with a recent study showing that in women, the clinical course is much more benign. Prominent pathologic findings include pronounced atrophy of the caudate and putamen. The disorder is poorly responsive to medication and patients usually survive with the disease for only about 10–12 years. Genetic studies have located the affected gene to Xq13.1.

The genetics of adult-onset, focal, and segmental dystonia has been more difficult to delineate. Many cases are likely to be hereditary. The DYT1 gene has been largely excluded as a cause in this form of dystonia. A gene locus has been described for several subgroups. Large Mennonite families with adult-onset, autosomal dominant, cranial-cervical dystonia have been described. The gene locus in these families is localized to chromosome 8 (DYT6).

Three additional genetic forms of focal and/or segmental dystonia have been described (DYT4, DYT7, DYT13). Cohort analysis suggests an autosomal dominant inheritance with variable penetrance. Although these families are rare, additional gene loci will be identified in the future.

Clinical Features

Early-onset dystonia typically begins in the lower body, affecting one leg. The initial symptoms are typically a posturing of the foot that is first noticed during more strenuous activities, such as running. Over time, the posturing will occur with less activity, being apparent during walking or standing. Subsequently, the dystonia occurs with minimal activation, and may be present at rest. In early-onset dystonia, approximately 50–90% of children will experience a spread of dystonia to other body areas, including the other leg, torso, arms, and upper body. Focal, young-onset dystonia tends to spread to become generalized dystonia usually within 5 years of onset. In primary dystonia, cognition and intellectual abilities remain intact despite the presence of significant movement abnormalities. Early-onset dystonia that begins in late childhood and adolescence may initially present in the arm and have less likelihood of subsequent spread to generalized dystonia.

In contrast to early-onset, late-onset primary dystonia often begins in the upper body, usually in the arm, neck, or face. Although symptoms may worsen in the area of involvement or spread to contiguous body regions (segmental dystonia), rarely does adult-onset dystonia become generalized. However, regional spread to contiguous body areas can occur, and is most frequently described with blepharospasm. In adults, the onset of leg dystonia is infrequent but can occur not associated with DYT1. Onset of generalized or hemidystonia in an adult is infrequent and warrants further investigation.

Late-onset focal dystonia may involve different body areas. Blepharospasm is a focal dystonia involving the

periocular muscles. Clinical manifestations include increased blinking and spasms of involuntary eye closure. Symptoms are bilateral but may be asymmetric. Typically, patients with blepharospasm complain of increased spasms under conditions of bright light or stress (such as driving a car in traffic). Pain is infrequently associated with blepharospasm, although patients may observe a feeling of irritation in the eyes as one of the first symptoms. Blepharospasm may be mild and not interfere with function, or it may cause significant disability through interference with vision as a result of the eye closure. Blepharospasm may be associated with dystonia of the lower face and/or jaw (Meige's syndrome or Brueghel's syndrome).

Cervical dystonia (CD) affects the muscles of the neck and shoulders. It may appear as horizontal turning of the head (torticollis), lateral flexion of the neck (laterocollis), forward flexion of the head (anterocollis), or posterior extension of the head (retrocollis). Some patients may have overlying dystonic spasms that resemble tremor, but are distinguished from tremor by the directional quality of the movement. Approximately half of patients with CD will complain of pain associated with the dystonia.

Arm dystonia is manifested as a posturing of the hand and/or arm. Overlying dystonic spasms may occur and resemble essential tremor. However, in contrast to essential tremor, dystonia is often unilateral, and triggered by specific activities, such as writing or typing. Dystonia of the arm and hand is often not present at rest and may be variably present with arms outstretched. Occupational or task-specific dystonia is only manifested during particular activities. Writer's cramp is the most common form. This focal dystonia is elicited by the act of writing, appearing as an involuntary flexion, extension and/or rotation of the fingers, wrist and less frequently the elbow and shoulder. The act of writing becomes effortful, and handwriting changes, becoming illegible in some patients. Other types of task-specific dystonia include typist dystonia, golfer's dystonia (yips), and musician's dystonia.

Oromandibular dystonia (OMD) and facial dystonia are characterized by involuntary movements involving masticatory, lingual, and pharyngeal muscles. OMD can be manifested as jaw clenching, jaw opening, jaw deviation, and tongue protrusion. It is often found in combination with dystonia of adjacent body regions, including blepharospasm and cervical dystonia. Symptoms can result in difficulty speaking and swallowing and may be cosmetically disfiguring. Occupational facial dystonia may manifest as embouchure dystonia, a dystonia of the lips, jaw, or tongue that affects musicians only during the act of playing their instruments, and is absent during other activities such as eating or speaking.

Spasmodic dysphonia is a focal dystonia involving the laryngeal muscles. The most common type of spasmodic dysphonia is the adductor type, with apposition of the vocal cords only during the action of vocalization. This causes voice breaks and a strained pattern of vocalization. Abductor spasmodic dysphonia is characterized by an abduction of the vocal cords during vocalization, resulting in a voice that is whispering and breathy. Vocal tremor arises from rhythmic movements of the vocal cords and produces an oscillation of vocal patterns.

Differential Diagnosis and Diagnostic Work Up

Dystonia is diagnosed based on its clinical features. Primary dystonia is separated from secondary dystonia by the absence of additional neurological abnormalities and the lack of possible acquired cause (**Table 4**). Laboratory testing in primary dystonia is of minimal usefulness but essential in the evaluation of secondary dystonia, or dystonia with atypical features. In primary dystonia, there are no abnormalities on MRI or computerized tomography scans. In secondary dystonia, the MRI findings vary with the etiology. In patients with early-onset dystonia (<26 years of age) or late onset but with an affected relative with early-onset dystonia, DYT1 gene testing is indicated with appropriate genetic counseling. Currently, testing for other genetic loci is not available for clinical use.

The assessment of secondary dystonia is extensive. Laboratory evaluations and brain imaging should be obtained and appropriately directed.

Management

The treatment of dystonia is symptomatic. No curative therapies are available. Treatment options include oral medications, chemodenervation, and surgical management. Oral medications have not been extensively studied

Table 4 Clinical features distinguishing primary dystonia

Presence of:
• Sustained involuntary movement, sometimes overlying spasms
• Consistent directional quality
• Involves same body region(s)
• Enhanced or produced by activity of involved area
• Varies with change in activity or posture
• Sensory tricks may reduce symptoms (*geste antagoniste*)
Absence of:
• Weakness
• Amyotrophy
• Spasticity
• Ataxia
• Ocular abnormalities
Abnormal eye movements
Retinal changes
• Cognitive impairment
• Seizures

in controlled trials. Many drugs have been reported to be of some benefit in a number of patients with dystonia. However, the therapeutic window for oral agents is narrow, with drug side effects frequently limiting achievement of adequate clinical benefit. Examples of oral agents useful for the treatment of dystonia are listed in **Table 5**.

Anticholinergic drugs, usually in high doses, have been of benefit in focal and generalized dystonia, as shown in one of the few controlled studies of treatments for dystonia. Peripheral side effects, such as dry mouth, blurred vision, and urinary retention, may be reversed using a peripheral cholinesterase inhibitor (glycopyrrolate). The central side effects, including memory loss and sedation, are dose limiting. Anticholinergic treatment is initiated at small doses, with a gradual dose escalation until acceptable improvement or unacceptable side effects occur. Discontinuation of anticholinergic agents should be gradual, as withdrawal effects may occur.

Carbidopa/levodopa is dramatically beneficial in DRD, in which small doses of levodopa may virtually eliminate dystonic symptoms for an indefinite period of time. In other forms of dystonia, the response rate with levodopa is approximately 15%. Dopamine receptor antagonists, although beneficial in some patients, are not used because of the possibility of tardive dyskinesia, a disorder that may be disabling and irreversible.

Tetrabenazine combines monoaminergic depletion and dopamine antagonist effects and has recently been approved

Table 5 Oral Medications useful for the treatment of dystonia

Pharmacologic agent	*Efficacy and comment*	*Side effects*
Dopamine agonists Carbidopa/Levodopa (Sinemet®)	Dramatic response in the dopa-responsive form of dystonia; effective in 10–15% of patients; more rapid upward titration possible	Nausea (especially at initiation of therapy); may worsen dystonia; rapid discontinuation possible
Anticholinergic/antihistaminic Trihexyphenidyl (Artane®) Benztropine (Cogentin®) Procyclidine (Kemadrin®) Diphenhydramine (Benadryl®) Ethopropazine (Parsidol®)	Effective in approximately 40% of patients; benefit limited by side effects; requires slow upward titration	Dry mouth (may lead to dental caries); blurred vision; exacerbation of acute-angle glaucoma; urinary retention; memory problems; sedation; confusion; hallucinations; heat intolerance
Baclofen (Lioresal®)	Effective in approximately 20% of patients; high doses tolerated in children; benefits limited by side effects; intrathecal baclofen minimally successful; *withdrawal effects on sudden discontinuation*	Nausea; sedation; dysphoria; muscle weakness (in those with spasticity associated)
Clonazepam (Klonopin®)	Effective in approximately 15% of patients; possibility for addiction; *withdrawal effects on sudden discontinuation*	Sedation; depression; confusion; dependence
Muscle relaxants Tizanidine Cyclobenzaprine	Limited benefit in some patients; side effects frequent	Sedation; dysphoria
Anticonvulsant medications Carbamazepine Gabapentin	Benefit in less than 10% of patients	Ataxia; sedation
Dopamine-depleting agents Tetrabenazine Reserpine	Tetrabenazine is not available in the United States; available from Europe/Canada; requires a very slow upward titration (4 weeks between dose increases)	Depression; dysphoria; parkinsonism
Dopamine antagonists	Effective in up to 25% of patients; clozapine requires weekly blood counts and may cause life threatening agranulocytosis	The possibility of tardive dyskinesia and the other adverse effects from this class of medications severely limits usefulness; not recommended for dystonia

in the United States for Huntington's disease. Tetrabenazine has been found to be beneficial in a variety of hyperkinetic movement disorders, including dystonia. Side effects, however, are frequent and include sedation, parkinsonism, depression, akathisia, nervousness, and insomnia.

Clonazepam is a benzodiazepine reported in uncontrolled studies to improve symptoms of dystonia in approximately one fifth of patients at doses ranging from 1.5 to 12.0 mg day^{-1}. Adverse effects from clonazepam include sedation, depression, confusion, and dependence.

Baclofen, a presynaptic γ-aminobutyric acid B receptor agonist, may be very effective at high doses in children with generalized dystonia, and less beneficial for treatment of focal dystonia because side effects, including nausea and sedation, may be intolerable. While administration of intrathecal baclofen allows for regionally elevated spinal fluid levels thereby reducing the occurrence of central side effects, it has yet to be established as an effective treatment for dystonia not associated with spasticity.

Botulinum toxin (BoNT) is a potent neurotoxin produced by clostridium botulinum that causes regional muscle weakness through its action as a zinc endopeptidase, cleaving specific proteins involved in vesicular fusion. Disruption of these fusion proteins interferes with the release of acetylcholine at the neuromuscular junction, resulting in localized muscle weakness. Although now applied to a variety of neurological and nonneurological disorders, BoNT has been used extensively for a variety of dystonias for over 20 years. Two serotypes, BoNT A and BoNT B are used commercially. Both are approved in the United States for treatment of cervical dystonia and BoNT A is approved for blepharospasm. BoNT treatment benefits from 50% to 85% of patients with these dystonias. It is also viewed as the treatment of choice for spasmodic dysphonia, limb dystonia and oromandibular dystonia. Adverse events are frequent and attributable to excessive weakness in injected muscles or diffusion into nearby muscles. These side effects are typically mild and transient. From 5% to 20% of patients receiving repeated large injections (greater than 300 units) of BoNT develop clinical resistance to the toxin. The availability of alternate serotypes provides options when resistance occurs.

Surgical treatment of dystonia is reserved for patients with severe dystonia who fail drug and chemodenervation treatments. Bilateral thalamotomy was used in the 1960s and 1970s for generalized dystonia, but complications from the procedure, including hemiparesis, spasticity, ataxia, dysphagia, and dysarthria were serious complications. Subsequently, deep brain microelectrode stimulation of the globus pallidus has been shown to dramatically improve symptoms of primary dystonia. The US Food and Drug Administration approved DBS for use in dystonia at centers with approved surgical protocols. Over the past year, DBS has been evaluated in open label and controlled studies for generalized dystonia and cervical dystonia. Other targets for DBS in dystonia include the subthalamic nucleus. DBS has not been as consistently effective for treatment of secondary dystonia, although several recent case reports indicate improvement in for some secondary cases including pantothenate kinase-associated neurodegeneration. A recent study indicates that accurate localization of stimulating electrodes in the area of the intercommissural plane provides for optimal outcome in generalized dystonia, and specific targets in the globus pallidus should be targeted for dystonia in specific body regions, reflecting the somatotopic organization of that structure.

Prognosis

Primary dystonia is usually a life-long disorder that may fluctuate in severity. Although remissions have been observed in up to 20% of patients, there is usually a recurrence of symptoms. In childhood-onset dystonia, especially with onset in the leg there is often spread of dystonia to involve other body areas, and over half will go on to develop generalized dystonia. In adult onset dystonia, symptoms tend to involve the face, neck and arm. These symptoms rarely spread to generalized dystonia. Although primary dystonia is not a life-threatening disorder, the symptoms may cause significant disability and impaired quality of life.

Dystonia in Amish-Mennonite and Mennonite Families

R Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Overview and History

The history of the Amish and the Mennonite populations spans four centuries and three continents. Due to persecution and religious differences, it is a story of migrations and splitting of groups. Dating the time of a founder mutation is helpful in determining which groups of Amish and Mennonites are at risk for certain disorders, as the oldest founder mutations may be represented in all groups and the more recent founders mutations will only be present in certain groups.

Begun in sixteenth century Europe, Amish-Mennonites and Mennonites were often persecuted, and migrated within and out of Europe to escape persecution. This often produced insular communities, and marriage was usually among individuals within the particular religious community. It is debated whether Anabaptism rose in separate places simultaneously or descended from one larger group; however, geographic clustering of two large groups, the Dutch and Swiss, were clear. Prior to the twentieth century, intermarriage between these two groups was uncommon.

Dutch/Northern German/Prussian/Russian

Menno Simons joined the Anabaptist movement in Holland around 1535, and followers of this group, called Mennonites, were primarily in Holland and Northern Germany. Some migrated from Holland directly to Pennsylvania in the late 1600s. Old Order Mennonites split from the Mennonite Church in the United States and Canada during 1870–1900 and, divisions in Indiana/Ohio, Ontario, Lancaster, PA, and Virginia arose.

Many Dutch Mennonites who remained in Holland migrated around this time to Prussia. Beginning in 1788–1789, some migrated further to Russia, and then from the 1870s to 1920s, moved again to midwestern and western Canada (especially southern Manitoba, and also Alberta) and the midwestern United States (Nebraska, Kansas). Later, waves of emigrants went to South America, particularly Paraguay. Hence, mutations that may have arisen after the migration to Pennsylvania in the 1600s might be seen only in the descendants of the Russian Mennonites. Descendants of both groups never practiced the Amish religion, thus were never Amish. However, other Russian Mennonites migrated to Ontario in the Kitchener–Walterloo areas, where some Swiss Amish-Mennonites had previously settled, thus leading to some mixing in the twentieth century.

Swiss/Alsatian/South German

Jakob Amman (hence Amish) led an Anabaptist movement in Switzerland in the 1690s. Both Old Order Amish (referred to here as Amish) and Amish-Mennonites descended from these groups. Descendants started migrating to the Alsace region in the late 1690s and eventually to southern Germany, and in the eighteenth century to Pennsylvania. In the beginning of the nineteenth century, there was another migration from Alsace-Lorraine and Bavaria to Ontario, Ohio, Indiana, and Illinois.

Because of high birth rates in the Amish communities, where contraception is not practiced and there are low infant mortality rates, the number of Amish has grown from ~3700 in 1900 to 231 000 in 2008. Therefore the likelihood that a common founder would be detected in the population is high. The adherence to stricter societal norms including not using electricity separates the Amish from Amish-Mennonites. However, even among groups who were originally Amish, many descendants no longer

consider themselves Amish, rather they are Mennonite, as splits among the Amish communities, led to different societal practices. This is the background in which the original DYT6 family was described as 'Mennonite.' Although they self-reported to researchers that they were of Mennonite background, it is not of the Dutch Mennonite described above, but rather of a Swiss Amish-Mennonite background, and to make this distinction, subsequent publications on DYT6 have labeled these families as 'Amish-Mennonites.'

Prior to the twentieth century intermarriage between those of Dutch and Swiss backgrounds was uncommon, so that individuals of Mennonite background differed genetically from those of Amish-Mennonite background, and founder mutations have been observed in one group but not the other.

Approach to Dystonia in the Amish-Mennonites and Mennonites

While the mixed phenotype primary torsion dystonia due to THAP1 mutations in the DYT6 gene has become synonymous with Amish-Mennonite dystonia, other etiologies of dystonia have been demonstrated in the Amish-Mennonites and Mennonites. Clinical patterns for the most part, guide a determination of the type of dystonia between families, although overlap may be present.

As in other forms of dystonia, determination of whether the dystonia is primary or secondary, that is, whether there are other neurologic features other than tremor, imaging abnormalities or a metabolic defect is key to classification.

Among Amish-Mennonites and Mennonites, three types of primary dystonia have been described.

DYT6 Dystonia

This type is characterized by early or adult onset primary dystonia which usually involves the arm or leg, and often has prominent cranial-cervical dystonia.

The DYT6 locus was first mapped in two Amish-Mennonite families who were not known to be related, although they shared a common haplotype and common genealogic ancestors were subsequently demonstrated. Together with additional members from these families as well as a third family, the gene region was narrowed, and the DYT6 gene, THAP1 was identified. THAP1 is a nuclear proapoptotic factor, whose causal relation to dystonia is not yet known. An exon 2 missense 5 bp insertion/3 bp deletion mutation which leads to premature termination of the THAP1 protein is responsible in the Amish-Mennonites. DYT6 is inherited in an autosomal dominant pattern with reduced penetrance of ~60%. Although more women than men are affected, no gender related penetrance is noted. Other DYT6 mutations have since been identified in other ethnic groups, and further research will demonstrate whether there is a genotypic heterogeneity even among Amish-Mennonites and Mennonites, as would be anticipated by their varied genetic backgrounds.

DYT6 was described as mixed, as it shared features with DYT1, early onset dystonia, the particularly arm involvement and early onset, as well as features with adult onset dystonia, the prominent cranial and cervical involvement, which is infrequently seen in DYT1, but is not a major feature of DYT1. Mean age of onset in the three Amish-Mennonite families was 16 years with a range of 5–38 and more than half of the cases starting before 16 years. Arm was the most frequent site of onset (approximately half), and dystonia eventually involved the arm in almost all. Other sites at onset included cranial muscles and neck, but leg was rare (4%). This is in contradistinction to DYT1 where leg onset is frequent. Speech involvement was a prominent feature in half of the affected individuals, and cranial and neck dystonia were present in 80%. While the leg became involved in over 50%, the severity of leg dystonia was much less than DYT1, which more commonly leads to difficulty ambulation.

DYT1 Dystonia

As noted, above, the affected sites and the severity of sites may distinguish DYT6 dystonia from DYT1. Therefore the DYT1 diagnosis made in a man of Amish-Mennonite background, who had childhood onset dystonia with prominent bilateral leg, trunk dystonia which impaired walking, as well as bilateral arm and mild neck dystonia and no cranial dystonia or speech involvement was diagnosed with DYT1 dystonia, was not surprising. However, in this man of Amish-Mennonite background, the DYT1 mutation was not a founder, rather, it was determined to be a de novo mutation, as a small proportion of DYT1 mutations are. Thus, DYT1 dystonia should be considered in individuals of Mennonite and Amish-Mennonite background, but this consideration should be driven by the clinical picture.

Non-DYT6, Non-DYT1 Primary Dystonia

Two Amish-Mennonite families with dystonia have also been described who have neither DYT6 nor DYT1 mutations. These families have prominent cervical dystonia, and older average age of onset than DYT6. Characteristic features of cranial dystonia and early onset were lacking, suggesting that the phenotype was different from both DYT6 and DYT1. The type of dystonia seen in these families is more suggestive of focal cervical dystonia, one of the most common forms of dystonia. The hope is that these families may also lend insight into other genetic etiologies of this type of primary dystonia.

Secondary Dystonia

Dystonia may also be accompanied by other neurologic symptoms and signs, and this falls into the rubric of secondary dystonias. All of these disorders are autosomal recessive. These include (but are not limited to):

- Pantothenate kinase-associated neurodegeneration (PKAN), which has two founder mutations in the Amish. MRI is notable for iron accumulation leading to the 'eye of the tiger' sign. Clinical features also include optic atrophy, pigmentary retinopathy, spasticity, and progressive dementia.
- Ataxia-telangiectasia, which is observed in both the Amish-Mennonites and the Dutch-Russian Mennonites, and is a disorder of DNA repair associated with low or missing ataxia-telangiectasia mutated protein. It is usually associated with early childhood onset ataxia, chorea, oculomotor apraxia, neuropathy, and conjuctival telangiectasias although in cases of variant ataxia-telangiectasia, ataxia, oculomotor abnormalities or telangiectasias may be mild or absent.
- Glutaric acidemia type 1 is a disorder due to deficiency of glutaryl-coA-hydrogenase. It is of increased frequency in the Amish. It often presents with acute encephalopathy with subsequent dystonia and chorea, but may present as macrocephaly and subdural hematomas.
- Homocystinuria, due to an Amish founder mutation in methyltetrahydrofolate reductase is associated with growth deficiency, microcephaly, developmental delay, mental retardation, spasticity, weakness, and seizures.

Hence, while DYT6 dystonia is often known as Amish-Mennonite dystonia, the differential for dystonia in the Amish-Mennonites and Mennonites is broad, and should be guided by the history, examination, and clinical features.

Dystonia, Drug-induced (Acute)

A Rajput, University of Saskatchewan, Saskatoon, SK, Canada

Glossary

Acute dystonic reaction – Often affects the face and neck musculature, with a sense of pain, discomfort, or tightness. Almost all occur within 5 days of medication change, usually a D2 dopamine receptor blocking agent. Younger persons are more susceptible. Treatment with anticholinergic and antihistamine medication causes prompt resolution.
Drug-induced movement disorders – Includes parkinsonism, dystonia, tardive dyskinesias, and akathisia. Most though not all are due to dopamine-blocking medication. Some appear early (acute), while others delay (tardive). Treatment and prognosis are variable depending on the condition. More than one drug-induced movement disorder may be present at a time.
Dystonia – Involuntary twisting and turning movements caused by coactivation of agonist and antagonist muscles. The position may be fixed, affected by movements, and associated with jerky

irregular tremor. Dystonia is due to dysfunction of the basal ganglia. There are many different causes of dystonia.
Neuroleptic – Literally, 'that which grips the nerve.' These medications block the dopamine receptors, and are effective in treating psychosis (and are often called 'antipsychotics'). Neuroleptic medications blocking the D2 dopamine receptors may cause drug-induced movement disorders, including acute dystonic reactions.

Definition and History

An acute dystonic reaction consists of cocontraction of agonist and antagonist muscles temporally related to either introduction of a new medication or increase in dosage. Acute dystonic reactions linked to neuroleptics were first noted in the late 1950s. About half of acute dystonic reactions occur within the first 48 h and nearly 90% within 5 days of medication change. The presentation is often marked, though milder cases may not present for a few days. The most common medications associated with acute dystonic reactions are neuroleptics with D2 dopamine receptor blocking properties.

Pathogenesis and Pathophysiology

There are two competing theories for acute dystonic reactions. According to the 'mismatch' hypothesis, increased dopaminergic input occurs acutely after treatment with dopamine D2 receptor blocking agents. D2 autoreceptor stimulation inhibits neurotransmitter synthesis and release. Blockade of the D2 receptors would be expected to produce increased striatal dopamine release in the short term. Acute dystonic reactions tend to occur when plasma levels fall after a single antipsychotic dose which supports this theory. Also, acute dystonic reactions are rare in the elderly. Striatal dopamine D2 receptor density decreases with age, 'protecting' the elderly from transient hyperdopaminergic states.

The more generally accepted theory is that acute dystonic reactions result from a hypodopaminergic state induced by dopamine D2 receptor blockade. Potent D2 receptor blockers are more likely to cause this than weaker blocking agents; presynaptic dopamine depleters can produce acute dystonia, and dopamine agonists may exert an antidystonic effect.

Interestingly, one study reported diurnal variation in acute dystonia with more than 80% occurring between noon and 11 p.m. This variation could not be accounted for sleep, fatigue, or time since last dose.

Rarely, nondopaminergic medications, particularly the selective serotonin reuptake inhibitors (SSRIs), have been linked to acute dystonic reactions. While the antihistamine diphenhydramine (Benadryl) provides prompt relief (see section Management), an acute dystonic reaction has been reported in a child with the antihistamine cetirizine, a medication approved by the Food and Drug Administration for treating allergic disorders in children younger than 5 years of age.

The author suggests reading the chapter by Mazurek and Rosebush (see Further Reading) for further details.

Epidemiology and Risk Factors

The incidence of acute dystonic reactions among patients taking antipsychotics varies widely. Earlier studies tended to quote lower risks. Using pooled data from nine studies of patients not on prophylactic anticholinergics, almost 15% developed dystonia regardless of the antipsychotic agent used compared to over 50% of patients receiving high-potency antipsychotics. The risk of an acute dystonic reaction in patients treated with conventional neuroleptics for first-onset psychosis is reported to be between 34 and 60%. A reasonable overall estimate based on the available information is 20–40%.

No particular psychiatric illness predisposes one to develop an acute dystonic reaction.

Acute dystonic reactions are most common in children and young adults, with the frequency declining with age. While it has been generally reported that males are more prone to developing acute dystonia, this is not the universal opinion. Young males tend to be treated more often with antipsychotic agents than young females, which may account for this perceived bias. In prospective follow-up of their own patients, Mazurek and Rosebush report rates of $<10\%$ in males and $<20\%$ in females above the age of 40 years.

Medications that are potent D2 receptor blockers (such as haloperidol) are more prone to producing an acute dystonic reaction. Lower potency D2 receptor blocking agents are less prone, perhaps because some have prominent anticholinergic activity as well. High dose and parenteral administration also increase the risk.

The incidence of drug-induced acute dystonia requiring treatment was similar in a prospective study of neuroleptic-naïve patients comparing oral haloperidol (34%) with oral risperidone (26%) (a high potency second generation 'atypical' antipsychotic).

Risk factors reported for developing an acute dystonic reaction include male gender, potency of D2 blockade, young age, high dose, and parenteral administration.

Cocaine use increases the risk of an acute dystonic reaction more than fourfold. Cocaine may trigger an

acute dystonic reaction in the absence of dopaminergic blocking agents.

HIV infection more than doubles the risk of developing an acute dystonic reaction, likely because the basal ganglia tend to be vulnerable to HIV infection.

Clinical Features and Diagnostic Criteria

Acute dystonic reactions most commonly affect the neck, followed by the cranial musculature including the jaw, throat, and tongue (including actual tongue swelling). Movements at the neck are typically rotational (torticollis) or extensional (retrocollis), though flexion (anterocollis) is also seen. Sensation of pain, tightness, or pulling almost always accompanies acute dystonia. Cranial dystonia includes eye blinking or closure (blepharospasm), facial grimacing, jaw clenching (trismus), and jaw opening. Acute dystonic reactions may involve the limbs and occasionally the trunk. Backward arching of the trunk (opisthotonus) may be mistaken for a psychogenic movement disorder. Some report that lower limb involvement is uncommon (though it is more common in younger persons). Upper limb involvement includes wrist flexion with extension of the index finger and flexion of the other fingers.

Laryngeal dystonia is an uncommon but potentially fatal presentation as it may progress to laryngospasm.

Oculogyric crisis occurs in ~10% cases, often with retrocollis and/or torticollis accompanying the tonic upward (and often lateral) deviation of the eyes. Patients may have difficulty speaking and, in rare cases, dystonia of the vocal cords causes respiratory distress. Oculogyric crisis was first noted in cases of acute encephalitis lethargica seen in the early twentieth century. There may be associated feelings of depression, fear, or anxiety which improve with treatment.

Dystonic movements and posturing may last up to 30 min, waxing and waning, before gradually resolving. Younger patients are more prone to have generalized dystonic reactions, while in older patients, the dystonia is usually restricted to the cervical musculature.

Differential Diagnosis

Conditions that could be mistaken for acute dystonia include tonic seizures or painful tonic spasms of Multiple sclerosis (MS). Tonic seizures are usually brief, lasting for a few seconds to a minute or two, and are associated with altered consciousness and EEG changes. Painful tonic spasms of MS most often affect the lower limbs. Paroxysmal nonkinesiogenic chorea may have dystonic features; the kinesiogenic form is brief and should not cause sustained postures. Hypocalcemia or hypomagnesemia may produce carpopedal spasm. Acute laryngospasm in a case of neuroleptic-induced laryngeal dystonia has been mistaken for an anaphylactic reaction.

Dystonia is commonly diagnosed as a psychogenic movement disorder by persons who have not seen dystonia. This is particularly a concern in a population at risk who already have a psychiatric diagnosis requiring neuroleptic treatment.

The role of medications may go unnoticed by those unfamiliar with acute dystonic reactions. The most serious problem is laryngospasm. Acute drug-induced dystonia should be considered in those with dyspnea and stridorous voice with normal pulmonary exam and investigations; this is the key for primary care and emergency room physicians.

With the appropriate history of drug exposure, no particular investigations are needed. Often general labs including calcium and a toxicology screen (specifically cocaine) are tested in young adults.

Management

Mild acute dystonic reactions may improve after simply withholding medications.

Prompt treatment with the anticholinergic benztropine (Cogentin) 1–2 mg i.m. or i.v. and the antihistamine diphenhydramine (Benadryl) 25–50 mg results in resolution within 20 min. Sometimes diazepam (Valium) 5–10 mg i.m. or i.v. or lorazepam (Ativan) 1–2 mg i.m. or i.v. is used for similar effect. Usually benztropine 1–2 mg bid (oral) for up to 7 days is prescribed to prevent recurrence.

While prophylactic oral anticholinergics (such as benztropine, biperiden, and trihexyphenidyl) reduce the risk of an acute dystonic reaction, the routine use of these agents is controversial. An elderly person at low risk of an acute dystonic reaction and at definite risk of adverse effects from anticholinergics (confusion, constipation, urinary retention, blurred vision) should likely not be treated, while a young male patient treated with a high potency D2 receptor blocking agent may warrant prophylactic anticholinergics at least initially. For patients isolated because of agitation, anticholinergic prophylaxis is recommended to reduce the risk of potentially fatal laryngospasm.

It is essential that the causal medication be documented so that the patient is not rechallenged in the future. Physicians should also be aware that an acute dystonic reaction may occur with similar medications.

Prognosis

A full and prompt recovery is expected with treatment. An acute dystonic reaction increases the risk of recurrence. In one prospective study of patients who had an acute

dystonic reaction, 51/89 (57%) had at least one more reaction while in the hospital. Recurrent episodes tended to be more widespread.

Dystonia, Secondary

P Greene, Columbia University Medical Center, New York, NY, USA

Glossary

Athetosis – Writhing limb movements, sometimes accompanied by rapid, flicking movements (chorea). A common setting for choreoathetosis is kernicterus or other causes of birth injury. Since many of the children with athetosis in this setting go on to develop dystonia, it has been suggested that athetosis is a form of mobile dystonia.

Deep brain stimulation – A surgical procedure wherein a high-frequency current is delivered to a small area of the brain using an implanted electrode. The full effects of this stimulation on the brain are not completely understood.

Dystonia – A symptom consisting of sustained involuntary muscle contractions usually resulting in abnormal postures, sometimes accompanied by tremor or jerking.

Parkinsonism – A syndrome with many or all of the signs and symptoms of Parkinson's disease (PD), but the underlying pathophysiology is presumed to differ from the typical degeneration of the substantia nigra seen in PD. Sometimes called Parkinson-plus syndromes, these diseases almost always have pathological abnormalities not seen in PD and usually involve cell loss in the substantia nigra, although usually without the Lewy bodies characteristic of PD.

Psychogenic – A controversial term applied to symptoms that are believed to be an unconscious adaptation to psychological stress. This usually implies the absence of detectable physical or biochemical dysfunction in the brain; recently, however, evidence has emerged that such symptoms may be accompanied by measurable metabolic changes in the brain.

Tardive – Signifies delayed. When applied to movement disorders caused by centrally acting drugs that block the dopamine D2 receptor, this initially is referred to the appearance of involuntary movements only after prolonged exposure to the blocking agent. Most neurologists now use the word to signify persistence of the involuntary movements even if the blocking agent is discontinued.

Secondary Dystonia

In the past, secondary dystonia referred to the symptom dystonia in the setting of another identified neurological disease, and primary dystonia referred to a condition of unknown cause in which dystonia was the only symptom. This distinction is breaking down. We now know that most cases of primary dystonia in childhood and some adult cases are genetic in origin. There are currently blood tests for a few of these genetic diseases, and we hope someday to have tests for all of them. There are several conditions in which dystonia is combined with a single other neurological symptom: parkinsonism (dopa-responsive dystonia, rapid

onset dystonia-parkinsonism) or myoclonus (myoclonus-dystonia syndrome), and some have proposed a third category of 'dystonia plus' for these diseases. However, these distinctions seem increasingly arbitrary. (For example, some cases of primary dystonia also have a superimposed tremor, which might reasonably put them in the category of dystonia-plus.) Although most patients with dystonia have the symptom during the entire waking day, there are rare patients in whom the dystonia is present in discrete episodes generally called paroxysmal dystonia.

There are many causes of secondary dystonia. I have divided the causes into degenerative diseases, with dead or dying brain cells, and nondegenerative diseases. The nondegenerative diseases include tardive dystonia and acute dystonic reactions (caused by exposure to the centrally acting dopamine receptor blocking medications), psychogenic dystonia, dystonic tics, dystonia triggered by peripheral injury, and others.

There are a large and growing number of known causes for degenerative dystonia, most of them are rare. These can be divided into nongenetic and genetic causes. The nongenetic causes include dystonia after birth injury (static encephalopathy), delayed onset dystonia after birth injury, head trauma, cerebrovascular disease, CNS tumors in the basal ganglia, demyelinating diseases (multiple sclerosis, central pontine myelinolysis, etc.), Parkinson's disease (PD), and nongenetic Parkinson's plus syndromes, multiple toxins, and infections. Patients with these conditions may have stable dystonia after a brain insult, but sometimes, as in the case of dystonia after birth injury, the onset of dystonia may be delayed after the insult, and the dystonia may progress long after the injury is over.

There are many inherited degenerative diseases, which can cause dystonia. Almost all of these are rare, and they are usually associated with other neurological signs and symptoms in addition to dystonia. Autosomal dominant diseases include dominant forms of juvenile parkinsonism, Huntington's disease (HD), some of the dominant spinocerebellar atrophies, neuroferritinopathy, and others. Autosomal recessive diseases include Wilson's disease, neurodegeneration with brain iron accumulation (NBIA) (including Hallervorden–Spatz Disease, or PKAN), Niemann pick type C, glutaric aciduria (GA), ceroid lipofuscinosis, and many others. There are other genetic inheritance patterns that have been identified for diseases causing dystonia: X-linked recessive (Lubag, a dystonia/parkinsonism syndrome found almost exclusively on the island of Panay in the Philippines, and deafness-dystonia syndrome, a mitochondrial disease) and maternal inheritance (mitochondrial cytopathies such as Leigh's syndrome, mitochondrial encephalopathy with ragged red fibers or MERRF, Leber's optic neuropathy, and others).

Why make the distinction between primary and secondary dystonia? First, in order to determine what diagnostic tests to perform. There are far too many rare causes of dystonia to test for all possible diseases in every patient. With the possible exception of MRI of the brain, the distinction between primary and secondary dystonia is initially clinical. Second, the most important therapeutic decision is whether to treat the symptom dystonia or whether there is also an underlying disease that requires treatment.

What are some of the clinical features distinguishing primary and secondary dystonias? If there are family members affected with primary dystonia, it is more likely (but not certain) that the patient has primary dystonia. In many primary dystonias, the involuntary movement appears only during action, sometimes with a specific action (task specific dystonia) such as writing, talking, playing a musical instrument, typing, or certain types of sports maneuvers (e.g., a golf swing). The presence of sensory tricks usually indicates a primary dystonia. Sensory tricks are movements that a patient can make to relieve symptoms of his/her dystonia. They are often effective when the disease is mild and sometimes lost as it becomes more severe. However, tardive dystonia and dystonia related to birth injury are two secondary dystonias in which onset with action and sensory tricks are common.

Similarly, there are some features which are characteristic of the secondary dystonia. As noted above, other neurological abnormalities are the rule in most of the degenerative dystonia syndromes, including parkinsonism, dementia, ataxia, corticospinal tract dysfunction, neuropathy, myoclonus, abnormal extraocular movements, or an abnormal fundus. Hemidystonia often, but not always, indicates a basal ganglia lesion in the contralateral hemisphere. Fixed dystonia at or shortly after onset of the disease is highly suggestive of secondary dystonia. Early speech disturbance, excluding laryngeal dystonia, also suggests a secondary dystonia. Give-way weakness, change in dystonia with suggestion, and other incongruous findings may indicate a psychogenic cause for dystonia. In addition, primary dystonia from most causes involves parts of the body at characteristic times, so that dystonia of the legs starting in adult life is rarely due to primary dystonia.

The most common setting for dystonia in our center and most large movement disorders centers is PD or 'Parkinson plus' syndromes. The most common non-Parkinson-related secondary dystonias at our center are tardive dystonia, 19% of our secondary population; dystonia after hypoxic/ischemic injury, 12%; and psychogenic dystonia in 6%. This article briefly discusses the most common causes for dystonia and some of the less common but significant or interesting causes of dystonia.

Parkinsonism

Dystonia can be present before treatment in idiopathic PD, especially in young onset patients and in most

parkinson syndromes (especially cortical-basal ganglionic degeneration). The dystonia may be painful or painless, and it may only be present with action initially. In young patients with PD, hemidystonia (dystonia limited to one side of the body) may be more prominent at the onset than rigidity and bradykinesia, and such patients sometimes undergo testing for the causes of dystonia until the underlying parkinsonism becomes apparent. In very young patients, the symptoms and response to treatment of juvenile parkinsonism and dopa-responsive dystonia may be identical at the onset, leaving some doubt as to the correct diagnosis. Fluorodopa PET is normal in dopa-responsive dystonia and shows reduced signal in juvenile parkinsonism. The treatment of dystonia in the setting of PD is complex. In PD, levodopa may help the dystonia, worsen the dystonia, or have no effect. In the young, other medications for dystonia such as anticholinergics and baclofen, may help. Deep brain stimulation (DBS) (usually of the globus pallidus) sometimes helps dystonia in PD. Patients with Parkinson plus syndromes and dystonia usually have fixed dystonia that does not respond to medication. Botulinum toxin (BTX) injections usually do not improve function in that setting, but may relieve pain from muscle spasm. Rarely, focal dystonia such as blepharospasm or spasmodic dysphonia may precede Parkinson symptoms in a young patient. This may be coincidence, but it is hard to be sure.

Treatment, especially treatment with levodopa, may produce dystonia in patients with parkinsonism of all ages. Two patterns have been identified: peak dose dystonia which occurs when the blood (and presumably brain) levels are at a peak, and dystonia which occurs shortly after taking medication and as the medication effects wear off (dyskinesia-improved-dyskinesia or DID pattern). The DID dystonia is often painful. Any strategy which reduces fluctuations in the levodopa levels may help these forms of drug induced dystonia. Finally, dystonia may occur during the time when the medicine is not working ('off' state). A typical example is the painful toe cramping in the early morning in patients who have not taken medicine since the previous evening. Reducing off periods helps this type of dystonia.

Pallidal, and possibly subthalamic nucleus, DBS can help all these forms of dystonia. The use of BTX is usually limited when widespread muscles are involved. In patients with blepharospasm, torticollis, or pain from localized muscle spasm, the injections can be helpful.

Acute Dystonic Reaction

Acute dystonic reactions happen almost exclusively shortly after exposure to the centrally acting dopamine receptor blocking agents and usually resolve within hours to days of stopping the agents. The risk of developing this reaction seems to be higher in more potent blockers of the dopamine D2 receptor and decreases with increasing age of the patient. These reactions usually improve with anticholinergics or antihistamines.

Tardive Dystonia

Tardive syndromes are persistent movement disorders starting during or after exposure to centrally acting dopamine receptor blocking agents. The tardive syndromes include tardive dyskinesias, tardive dystonia, and tardive akathisia, although most patients have combinations of these symptoms. Less common syndromes include tics, myoclonus, tardive oculogyria, and possibly tremor and other movement types. Tardive dyskinesias are more common in older patients, whereas tardive dystonia is more common in younger patients. The prevalence of tardive dystonia has been estimated at 1.5–2% in most studies, although one VA study of young patients found a prevalence of 21%. There have been many estimates of the prevalence of idiopathic dystonia, with the largest being ~0.03%. Therefore, dystonia is ~50 times more common in the neuroleptic treated population than in the population at large. As with other tardive syndromes, there are occasionally spontaneous remissions in tardive dystonia when the dopamine receptor blocker is stopped. In the series from Columbia, which is a referral based series, we estimated the remission rate at 12% after 5 years. This is in contrast to an estimated remission of over 30% in patients with pure tardive dyskinesias.

The distribution of symptoms is somewhat different in tardive dystonia than idiopathic dystonia. Jaw, trunk, and legs are more likely to be effected in adults with tardive dystonia than primary dystonia. Blepharospasm (eyelid dystonia) is more common in young adults with tardive dystonia than in young adults with primary dystonia. Although tardive dystonia can be indistinguishable from primary dystonia, many patients with tardive dystonia have very rapid dystonic jerks, often with truncal or neck extension and intorsion of both arms, occasionally resulting in flailing movements when proximal muscles are involved. Unlike most patients with primary dystonia, the movements sometimes improve with walking and worsen with lying down. The only diagnostic test at present for tardive dystonia is the presence of other tardive movements and the history of exposure to dopamine receptor blocking agents. Patients will sometimes forget exposure to such drugs, and obtaining pharmacy records and hospital records is sometimes helpful. It is also important to remember that several antinausea agents (such as metoclopramide and prochlorperazine) are dopamine receptor blockers. Similarly, the tricyclic agent amoxapine is also a dopamine receptor blocker and has been associated with the development of tardive dystonia. Some cigarette smoking cessation programs include dopamine receptor blockers, and patients in hospitals may receive dopamine receptor blockers without their knowledge for behavior control.

The treatment for tardive dystonia and tardive syndromes in general are complex. Briefly, any drug that produces Parkinsonism as a side effect may help tardive dystonia. Treatment with most dopamine receptor blockers may suppress symptoms but worsen the underlying disease. Dopamine depleters such as reserpine and tetrabenazine often help the symptoms but have substantial side effects and are often not tolerated in optimal doses. Anticholinergics are sometimes effective. BTX is effective for focal symptoms as with all other causes of dystonia. Pallidotomy and now pallidal DBS seem to be effective for tardive dystonia, especially for retrocollis and truncal hyperextension.

Postischemic Dystonia

Dystonia after birth injury occurs in two settings. Children with early evidence of motor and intellection developmental delay may have early chorea or athetosis (writhing postures) which convert to dystonia later. In addition, there is a syndrome in which children survive birth injury without stigma but develop pure dystonia later in childhood. This dystonia may worsen for decades. The MRI in these cases is often normal or shows only generalized atrophy. The phenomenology of dystonia after ischemic stroke or hemorrhage in adult life divides into two groups: fixed postures (sometimes with pain) and posturing with superimposed tremor or writhing movements. The kinetic form of dystonia after ischemic injury usually involves lesions of the thalamus. The pain may be a combination of central (thalamic) pain and peripheral pain from muscle spasm. Surprisingly, dystonia arising after ischemic injury early in life may improve with the same medicines that treat primary dystonia, but postischemic dystonia arising in adult life is very difficult to treat. Pain arising from muscle spasm responds to BTX injections. The efficacy of pallidal DBS in postischemic, adult onset dystonia is not clear.

Psychogenic Dystonia

Psychogenic movements arise from a psychological disorder rather than from identified brain dysfunction. Recently, PET studies indicate that there are physiological changes in the brain corresponding to psychogenic movements. It is possible that in the future, we will consider psychogenic disorder as a biochemical disorder of the brain similar to depression, bipolar disorder, obsessive–compulsive disorder, and schizophrenia. For now, it is important to diagnose psychogenic dystonia and distinguish it from dystonia that is produced voluntarily (malingering). Many physicians are reluctant to make a diagnosis of psychogenic dystonia because of the stigma associated with the psychiatric disease ('give the patient the benefit of the doubt'). I believe, it is no worse to mistakenly diagnose psychogenic dystonia than it is to mistakenly diagnose organic dystonia. Both deprive patients of appropriate counseling and therapy. Psychogenic dystonia is a serious disease that destroys quality of life and can end in death by suicide. It is at least as treatable as most other forms of secondary dystonia. Management of psychogenic dystonia involves cooperation of several disciplines: the neurologist has primary responsibility for making the diagnosis; the psychiatrist and possibly the physical therapist have primary responsibility for making specific psychiatric diagnoses and treatment. Unusual features suggesting psychogenic dystonia include shuddering, unusual tremors or speech, elaborated startle, complex head shaking, deliberate slowness of gait, rapid and unpredictable change of direction, and unpredictable change in direction of dystonic tremor. Nonphysiologic features include give-way weakness, complex ataxia without falling, nonphysiologic numbness or anesthesia, and change in movements with suggestion or placebo. Inconsistent features include fluctuating weakness, disappearance with distraction, and fluctuating pressure (the more you resist the dystonia, the more forceful the contractions). Inconsistent course includes abrupt onset and disappearance for brief periods of time. When considering this diagnosis, be humble, but do not be timid.

There is no formula for the successful treatment of psychogenic dystonia. Some reasonable principles include: (1) destigmatize the diagnosis: we tell the patients that stress causes biochemical changes in the brain that can produce many symptoms such as ulcers and involuntary movements, (2) it is helpful to engage patients as partners in the effort to improve: set achievable daily goals, (3) we have relied primarily on individual psychotherapy with family therapy when needed, and (4) we do not use medications for dystonia, but do use antidepressants, antianxiety medications, hypnosis, and ECT when appropriate. It is essential to convince the patient that you believe they have a serious problem.

Wilson's Disease

Wilson's disease is rare: the prevalence is estimated at ~1 in 30 000, compared to the estimated prevalence of primary dystonia of 0.03% or 9 in 30 000. However, Wilson's disease is a treatable disease, especially when diagnosed early, and it is one of the few causes of secondary dystonia in which dystonia may seem to be the only symptom. In fact, personality change and psychiatric symptoms (sometimes subtle) usually precede motor symptoms. In addition, cranial parkinsonism is often present, with open mouth, drooling, and impaired postural reflexes, even when dystonia or tremor dominate. The presentation of Wilson's disease generally depends on age: hemolytic anemia and renal disease in infants, dystonia in children, and tremor in young adults, although a wide variety of

movement disorders have been seen in Wilson's disease, making the diagnosis difficult. The gene for Wilson's disease has been identified as a copper-transporting ATPase, but the large number of mutations makes genetic screening difficult. When the possibility of Wilson's disease is considered, screening for low serum ceruloplasmin will detect ~95% of cases, detection of Kaiser–Fleischer rings in the cornea will detect almost all cases with neurological symptoms, but liver biopsy with copper staining is the test of last resort. Copper chelation and liver transplant when necessary are the treatments for Wilson's disease. Treatment is complicated because many patients will worsen (sometimes permanently) at the onset of treatment. A new agent, tetrathiomolybdate may have less initial worsening than other agents, but this is currently under study. Treatment of dystonia is necessary only in severe cases, since treatment of the disease will ameliorate symptoms in mild to moderate cases. Successful treatment of dystonia with medications and pallidal DBS has been reported in a small number of cases.

Mitochondrial Syndromes

Many mitochondrial syndromes can occasionally produce a syndrome dominated by dystonia, including MERRF, Leber's hereditary optic neuropathy, infantile bilateral striatal necrosis, deafness-dystonia syndrome, and Leigh's syndrome. As with all mitochondrial cytopathies, these can arise from mutations in the mitochondrial genes (e.g., *MERRF*, Leber's disease), nuclear genes (deafness dystonia syndrome), or both (e.g., Leigh's syndrome). Perhaps the most common dystonic mitochondrial syndrome is Leigh's syndrome (oxidative phosphorylation defects), caused by mutations in both mitochondrial genes (pyruvate dehydrogenase complex, cytochrome oxidase) and nuclear genes (for elements of the respiratory chain complex). Leigh's syndrome can also result from CoQ10 deficiency. The syndrome is defined by the pathology, which includes necrosis, vascular proliferation, and spongiosis (resembling Wernicke's disease) in the brainstem, striatum, thalamus, dentate, substantia nigra, white matter, and optic nerves bilaterally. The presentation depends on the age at onset. Dystonia is common in the early childhood presentation that may produce ataxia, motor and intellectual regression, axial hypotonia, dystonia and/or chorea, respiratory dysrhythmia, ocular palsies, optic atrophy, and peripheral neuropathy. The symptoms often worsen during concurrent illness. Leigh's syndrome can be suspected when there is a multisystem disorder, including combinations of the above neurological deficits and an MRI with increased T2 signal in the basal ganglia, brainstem, dentate nucleus, and white matter. Once Leigh's syndrome is suspected, diagnosis can be confirmed if there are defects of the cytochrome oxidase system in muscle biopsy or any of the known mutations. Many attempts at treating these conditions have produced little success. CoQ10, idebenone, thiamine, riboflavin, biotin, vit E, succinate, creatine, and carnitine have produced minimal, if any, benefit. Efforts are underway to discover effective treatments, including introduction of wild-type genes and selective inhibition of mutant genes. There is little data on the symptomatic treatment of dystonia in mitochondrial cytopathy. The few patients we have treated have not done well. BTX should reduce painful muscle spasm. The effectiveness of pallidal DBS in mitochondrial disease is not known.

Glutaric Aciduria Type 1 (GA1)

The mitochondrial enzyme glutaryl-CoA dehydrogenase is necessary for the metabolism of lysine/tryptophan and hydroxylysine. Absence of the enzyme (usually autosomal recessive) results in mitochondrial dysfunction and production of the toxins glutaric acid and 3-OH-glutaric acid. Thus, GA1 is a mitochondrial cytopathy plus. The disease usually starts in the first year of life, occasionally later, as an acute encephalopathy with dystonia or chorea triggered by intercurrent illness. The pathological basis is striatal necrosis. Most children have only one or two such episodes, although there probably is some gradual worsening in the absence of crises. Occasionally, there is gradual progression without crises. Dystonia is often the overwhelming symptom: spasms of retrocollis and truncal arching can be extreme but alternate with periods of extreme axial hypotonia. Other signs include spasticity, chorea, hypoglycemia, acidosis, seizures, and ataxia, but intelligence is often relatively preserved. About 75% of infants with GA1 have macrocephaly from birth or infancy. Serum and urine GA are usually elevated, but there are low GA excretors. Glutaryl carnitine is always elevated in the urine. The MRI findings are suggestive of the diagnosis: bilateral increased T2 signal in putamen > caudate < globus pallidus, bilateral increased T2 signal in anterior and posterior white matter, generalized atrophy especially pretemporal ('bat wing' dilatation of the Sylvian fissures), and sometimes increased signal in corpus callosum, dentate, medial lemniscus, substantia nigra bilaterally. Dietary lysine restriction (reduced production of GA) and carnitine supplementation (detoxifies some of the toxic metabolites) may prevent neurologic disease in asymptomatic patients, but it is not clear if this helps symptomatic patients. The dystonia may be helped by anticholinergics, baclofen, and possibly pallidal DBS.

Neurodegeneration with Brain Iron Accumulation

There are several forms of NBIA. Probably the most common is autosomal recessive disease associated with mutations in the *PANK2* gene for pantothenate kinase

necessary for regulation of the Co-A synthesis, formerly known as Hallervorden–Spatz disease. Most patients with mutations in this gene have decreased signal in the globus pallidus surrounding a small area of increased signal, or 'eye of the tiger.' Others have decreased signal without the 'eye.' At this time, there appears to be a spectrum of presentations of this form of NBIA depending on the age at onset. Patients with symptoms in the first decade of life have severe dystonia, loss of ambulation, mental retardation, often optic atrophy, or retinitis pigmentosa. Children presenting later have less severe dystonia with preserved gait and intelligence, parkinsonism, tics, behavior disorders, and only occasional optic atrophy. The dystonia in NBIA may respond to medical therapy with anticholinergics, baclofen, BTX injections, and pallidal DBS, but the proportion of patients responding to treatment is not known. Less is known at this time about the treatment of the Parkinson features.

X-linked Dystonia-Parkinsonism (Lubag Disease)

Lubag disease is an X-linked recessive condition found almost exclusively in men from the island of Panay, Phillipines. There is occasionally a milder form in women who carry a single mutation. Young onset patients start with dystonia but usually develop parkinsonism later in life. Old onset patients may have exclusively parkinsonism. The dystonia of Lubag may improve with anticholinergics, clonazepam, zolpidem, or BTX injections. The parkinsonism seems particularly resistant to the treatment.

Huntington's Disease

Many adults with HD will develop some dystonic posturing as the disease progresses. Often this does not require treatment, although some patients have symptomatic blepharospasm. Juvenile HD results from a large repeat length, especially over 60 CAG repeats and is usually inherited from the father. Patients with juvenile HD may have significant generalized dystonia, and dystonia may dominate the picture. There is little data about the treatment of the dystonia.

Paroxysmal Dystonia

Paroxysmal dystonia is used to describe the syndromes in which dystonia (and sometimes other involuntary movements such as chorea) occurs in discrete episodes, while movement symptoms are absent at other times. These disorders have been categorized either by duration of the attacks or by precipitating factors. The two most common are paroxysmal kinesigenic dyskinesia (PKD – usually triggered by sudden movement and lasting at most several minutes) and paroxysmal nonkinesigenic dyskinesia (PNKD – not triggered by movement and lasting from many minutes to many hours). Both of these syndromes can be inherited, but both also have secondary forms. PKD has been reported after a large number of insults, most commonly multiple sclerosis and ischemic/traumatic brain injury. Similarly, PNKD also occurs in multiple sclerosis, after birth injury and many other causes. Psychogenic PNKD is very common. The dystonia of PKD may be unilateral, bilateral, or alternate sides. All the involuntary movements in idiopathic PKD (and many cases of secondary PKD) improve markedly with anticonvulsants. The dystonia of PNKD is usually accompanied by other movement types and is very difficult to treat. Some of the genetic forms respond to benzodiazepines, but there has been no consistent medication response in the various forms of secondary PNKD.

Dystonia, Task-specific

M Ann Thenganatt and S J Frucht, Columbia University Medical Center, New York, NY, USA

Glossary

Dystonia – Hyperkinetic movement disorder characterized by repetitive, involuntary, twisting movements typically producing sustained postures.
Embouchure dystonia – A dystonia that affects the muscles of the face, tongue, or jaw used to control the speed and force of air flow into the mouthpiece of a woodwind or brass instrument.
Focal, task-specific dystonia – Hyperkinetic movement disorder characterized by repetitive, involuntary, twisting movements typically producing sustained postures triggered by a specific task.
Focal, task-specific dystonia of musicians' hands – Dystonia triggered by playing a musical instrument with one's hands.
Writer's cramp – Dystonia triggered by the task of writing.

Definition and History

Dystonia is a hyperkinetic movement disorder characterized by repetitive, involuntary, twisting movements typically producing sustained postures. When the movement is triggered by a specific task, it is referred to as focal, task-specific dystonia (FTSD). This phenomenon was first described as early as 1830 when Charles Bell described cases of writer's cramp affecting the clerical staff of the British Civil Service. By the late 1800s, Gowers, among others, had described FTSD affecting the hands of musicians (FTSDmh). Historically, some referred to these movements as 'occupational neuroses,' and many thought there was a significant psychiatric etiology.

Pathogenesis/Pathophysiology

The underlying pathophysiology of dystonia is incompletely understood. Dystonia is caused by the simultaneous contraction of agonist and antagonist muscles. Lack of reciprocal inhibition of antagonist muscles contributes to this cocontraction, with dysfunction either at cortical or spinal levels. When task-specific dystonia spreads to related skills, there is a decrease in 'surround inhibition' as a result of faulty cortical inhibitory connections. In addition to motor dysfunction, there are abnormalities of sensory perception and representation. While primary sensory modalities are normal in these patients, there are disturbances in stereognosis. Interestingly, abnormalities in sensory discrimination have been demonstrated bilaterally in patients with lateralized focal dystonia. Furthermore, in animal studies, repetitive stereotyped movements have been associated with disorganization of the sensory cortex and an increase in size of cortical sensory receptive fields. Studies have also demonstrated an increase in neuronal plasticity resulting in excessive corticospinal excitability and decreased cortical inhibition. Structurally, imaging techniques have demonstrated abnormalities in subcortical and cortical structures. Studies have demonstrated an increase in putaminal volume by 10% as well as an increase in size of the primary sensory cortex.

Epidemiology/Risk Factors

FTSD is a diagnosis of young adults, affecting both sexes. Writer's cramp commonly presents in the third to fifth decades and earlier reports described a male predominance. With changes in the workforce over the years, writer's cramp no longer has a predilection for males. The epidemiology of writer's cramp was studied in Rochester, Minnesota between 1950 and 1982 and found to have a prevalence rate of 69 per million people. An underlying cause is rarely found; only about 5–10% of patients identify local trauma as a possible precipitant. Despite earlier claims that writer's cramp was a psychogenic illness, formal studies have failed to reveal a higher incidence of psychopathology in patients with this disorder. Approximately 5% of patients identify family members with similar symptoms, and some studies have suggested autosomal dominant inheritance with incomplete penetrance.

FTSDmh occurs at a mean age of 35.7 years and has a significant male predominance (80%). Up to 1 out of 200 musicians may be affected during their musical career, and as many as 8–14% of patients evaluated at performing arts medical centers receive this diagnosis. The type of hand dystonia that develops in musicians is dependent on the technical demands specific to the instrument. Some patients report a recent increase in practice time, a focus on a particularly challenging musical piece, or a change in musical technique immediately before developing dystonia. However, similar to writer's cramp, FTSDmh

develops insidiously and has no clear precipitant. While most patients with FTSDmh deny a family history of dystonia, careful examination of relatives has demonstrated an increased incidence of dystonia. One recent study of FTSDmh described three families in which family members were afflicted with focal dystonia, mainly writer's cramp.

Embouchure dystonia is another FTSD with a male predominance. The embouchure is the pattern of muscles of the face, tongue, and jaw used to control the speed and force of air flow into the mouthpiece of a woodwind or brass instrument. Risk factors, such as preceding trauma and dental work, are uncommon. The presence of writer's cramp in several of these patients also suggests a genetic contribution. Like FTSDmh, environmental influences are significant in embouchure dystonia with phenotype depending on the instrument.

Clinical Features and Diagnostic Criteria

FTSD is seen with skilled, over-learned tasks. This phenomenon has been described with various tasks and occupations, including writing, playing sports (golf, darts), operating a machine (typing, computer mouse, telegraph), or playing a musical instrument. It usually develops gradually over weeks to months and rarely has a precipitating event. Patients often develop a sensory trick (geste antagoniste) that provides relief from the dystonic movement. This may involve applying pressure to a critical area or change in position or grip.

Writer's cramp has been divided into three distinct types: simple, progressive, and dystonic. In simple writer's cramp, dystonia is limited to the task of writing. Progressive writer's cramp involves the spread of dystonia to other hand activities, and dystonic writer's cramp patients experience impairment in writing and similar manual tasks from onset. Abnormal postures commonly involve the fingers, wrist, and elbow. Dystonia may begin with difficulty in picking up a pen and declares itself shortly after starting to write. Patients have an excessively tight grip that may cause the pen to slip out of the hand. A classic posture is an exaggerated flexion of the wrist, thumb, and fingers and hyperextension of the distal interphalangeal joint of the index finger. Ulnar deviation at the wrist and elevation of the elbow may also occur. Patients may describe their symptoms as an ache, as clumsiness, or as a lack of motor control. Rather than pain, patients may describe muscle tension. Paresthesias can develop over time, as dystonic postures lead to compression neuropathies. Patients commonly describe fatigue and worsening of dystonia with persistent writing, requiring them to take breaks. Sudden jerks of the hand are common, resulting in random pen strokes across the paper. Tremor occurs in one-third of patients and is usually unilateral. Patients acquire compensatory maneuvers such as holding the pen vertically between the index and middle fingers or with a closed fist. Some may need to stabilize their writing hand with the assistance of the unaffected limb. Interestingly, some patients may still be able to write on a chalkboard, using more proximal muscles. Others have found ease in writing with a pen that has a thicker point. Approximately one-third of patients will resort to learning to write with their opposite hand because of the deterioration in their penmanship. While writing with the contralateral hand, these patients may produce dystonic movements with the primarily affected hand. These movements have been referred to as 'mirror movements.' Unfortunately, about 25% of patients will develop dystonia of their contralateral hand, although it may take years to manifest.

Patients with FTSDmh describe a loss of flexibility and automaticity, which motivates them to increase rehearsal time. This strategy, however, only exacerbates the problem. The hand that performs the more complicated task is predisposed to developing dystonia. Thus, the right hand is affected among pianists and plucked string players, while the left hand is predominantly affected in bowed string players and flutists. Both hands are equally affected in woodwind, percussion, and brass players. Dystonia usually begins in one finger, usually the third finger, and eventually spreads to adjacent digits. The ulnar aspect of the hand is disproportionately affected, perhaps due to the greater technical demands placed on this part of the hand. Biomechanical constraints may increase the risk of injury when the wrist is ulnarly deviated. The dystonic phenotype that develops is dependent on the instrument. Flexion dystonia is common in pianists, violinists, and guitarists, and isolated extension of the third finger is common in woodwind players. Once the phenotype is established in a given patient, it rarely varies, even if the patient takes a hiatus from playing their instrument. This raises the possibility that an abnormal, dystonic sensorimotor network somehow becomes selected and entrained. Certain triggers may be identified such as ascending-versus-descending scales in a specific key. Again, pain is uncommon and should raise the suspicion of an alternative diagnosis.

Patients with embouchure dystonia begin experiencing symptoms decades after learning to play their instrument. These patients describe a loss of embouchure control, loss of clarity of articulation, and involuntary movements of the lips, jaw, or tongue. Once again, frank pain is uncommon; however, patients may complain of vague oral discomfort. Various phenotypes of embouchure dystonia have been described, including tremor, lip pulling, lip lock, jaw dystonia, tongue dystonia, and Meige. The tremor is fast, involves the upper and lower lids, and is audible and visible. Lip-pulling refers to lateral or forward movement of the upper or lower lips. Lip lock describes the clamping together of the lips, triggered as the patient begins to play and thus either delays or cuts off the sound.

Jaw dystonia refers to involuntary jaw closure or lateral movements of the mandible when playing. Tongue dystonia refers to incoordination of the tongue, particularly during passages requiring tongue activation. Meige is involuntary movement of the upper and lower face triggered by playing an instrument. The different dystonic movements usually begin and remain limited to a specific pitch range. Gradually, the symptoms may spread to neighboring pitches. A specific musical style such as sustained legato or staccato can also be a specific trigger for dystonia. Certain trends have been observed in musicians according to musical instrument. Tremor and lip pulling is more common in high-register brass instruments such as trumpet and French horn. Lip lock dystonia tends to occur in patients who play low-register brass instruments such as trombone and tuba. Jaw and tongue dystonia is more commonly seen in musicians playing woodwind instruments. About 5% of patients with embouchure dystonia have writer's cramp, which presents years prior. Embouchure dystonia spreads to other oral tasks in about 15% of cases. It is more common for jaw, tongue, and Meige phenotypes to spread to other oral tasks such as speaking, chewing, or drinking. Once the spread has occurred, the dystonia is likely to persist even if patients stop playing their instrument.

Differential Diagnosis

Dystonia can be distinguished from other hyperkinetic movement disorders based on clinical examination. Task-specificity and sensory tricks are unique to dystonia. Abnormal postures can occur with musculoskeletal or peripheral nerve disorders and dystonia can be distinguished from these processes based on signs and symptoms such as pain, paresthesias, and muscles weakness. Focal dystonias, such as writer's cramp, may also be the initial presentation of a progressive neurological disease such as Parkinson's disease, multiple sclerosis, spinal muscular atrophy, or spinocerebellar degeneration.

Diagnostic Workup/Tests

The diagnostic evaluation of adults who present with focal dystonia should begin with a careful history and physical examination. A history of task-specificity and sensory tricks is classic for FTSD. Review of all medications (prescription and nonprescription) should search for a history of possible exposure to dopamine receptor blocking agents. For musician's dystonia, particular attention should be paid to the motor examination, with careful testing of all intrinsic and extrinsic hand muscles. Sensory deficits in ulnar, median or C6, C7, or C8 distributions are not uncommon in musicians and should be specifically addressed. Typically, cutaneous sensation is normal, but there are problems with stereognosis. When the history is classic for FTSD and there are no other abnormalities on the neurological examination, imaging of the brain or spine is unnecessary. An EMG can demonstrate cocontraction of agonist and antagonist muscles, with prolonged bursts of activity and overflow into other muscle groups. With a classic history of dystonia and otherwise unremarkable physical examination, EMG is unnecessary to make a diagnosis of task-specific dystonia; however, this neurophysiologic test should be pursued if there is a concern for a peripheral nerve injury based on neurological examination.

Management

Treating patients with focal dystonia may involve oral pharmacological agents, botulinum toxin injection, assist devices and compensatory techniques, rehabilitation, and surgical procedures. The goals of therapy may be directed toward decreasing the intensity of symptoms, developing ways to compensate for dystonia, and changing neuronal function. Until the genetic and environmental triggers are better understood, prevention remains the preferred goal.

Oral medications are available for the management of dystonia, but the data supporting the use of these agents for focal task-specific dystonia are limited. Trihexyphenidyl and tetrabenazine are two drugs that have been studied in randomized controlled trials and shown to be effective. A major limitation to oral medications is the side effect profile and thus these agents are not the mainstay of treatment.

Implementing assist devices or modifying technique are strategies to adapt to task-specific dystonias. Patients with writer's cramp may attempt to alter their grip, use a pen with a wider diameter, or use a uniquely designed writing device that allows one to take advantage of more proximal muscles. For musicians with hand dystonia, altering technique or adding appendages to the instrument may be helpful. For example, woodwind players who have difficulty with the extension of the middle finger may benefit from changing the placement of the instrument's keys or adding appendages to key levers. In 2001, Priori employed a more radical solution, splinting and immobilizing the hand of affected musicians for 6 weeks and then retraining the hand once the splint was removed. While preliminary results with patients with early dystonia were encouraging, subsequent trials involving patients with more established dystonia have not replicated these findings. Most patients with embouchure dystonia attempt to compensate by using other muscle groups or techniques to produce the desired result.

This strategy has been more successful in patients with the tremor type of embouchure dystonia.

The approval and introduction of botulinum toxin injection in the United States in the late 1980s revolutionized the treatment of focal dystonia, particularly blepharospasm, torticollis, and spasmodic dysphonia. Botulinum toxin injection was then used to treat writer's cramp and FTSDmh, with hand weakness being the most common side effect. Injections are performed under EMG guidance, and they usually need to be repeated every 3–4 months as the toxin's effect wears off. Initial reports suggested that many FTSDmh patients initially benefited from injections, but they discontinued the injections after a year or two due to inadequate efficacy or lack of functional improvement. More recent studies, however, have shown that many musicians with focal dystonia benefit significantly from expertly administered injections. Patients should understand that the injections provide symptomatic relief, not a cure.

Several treatment approaches attempt to reset or retrain the abnormal somatotopic cortical map in the affected hand in focal dystonia. Byl proposed a learning-based sensorimotor retraining strategy that was comprehensive, including improved posture, aerobic fitness, and specific retraining of sensorimotor function. Another approach, sensory motor tuning, involves constraining fingers adjacent to the dystonic finger triggering the dystonia. This strategy employs a series of daily exercises to retrain the affected fingers. While interesting, success has been variable. Other similar treatments have been used, including teaching affected patients to read Braille. The nature of the intervention may matter less than the fact that an intervention is performed that targets and requires attention, progressive learning, reinforcement, and sensorimotor integration.

A more invasive approach has been used in Japan, where botulinum toxin injection is not available. Taira performed thalamotomy of the nucleus ventrooralis of the thalamus contralateral to the affected hand in FTSDmh and writer's cramp with surprisingly good results. Other patients have been successfully treated with deep brain stimulation of the thalamic nucleus ventrooralis and ventralis intermedius nucleus. These treatment options need to be investigated further in clinical trials.

Prognosis

Spontaneous remission in FTSD is rare. There is a five percent remission rate in writer's cramp and even then, recurrence is common. Despite symptomatic therapy, the degree of improvement in musician's dystonia is usually inadequate for an individual to continue with their performing career. Patients with embouchure dystonia, particularly the jaw and tongue phenotype, should be advised of the risk of spread to other activities such as chewing or speaking that may remain permanently. It is critical for the treating physician to offer emotional support to musicians who face this diagnosis, as they may experience significant depression and anxiety during the process of diagnosis and treatment.

Dystonia, Traumatic

B I Karp, National Institutes of Health, Bethesda, MD, USA

Glossary

CRPS (complex regional pain syndrome) – A syndrome consisting of pain, autonomic dysfunction, and skin changes in a traumatized body area.
Hemidystonia – Dystonia involving both upper and lower extremities on the same side of the body.
Torticolls – A form of cervical dystonia with head rotation.

Definition and History

Dystonia following peripheral injury or head trauma was first reported in the 1970s to 1980s, although head turning associated with atlantoaxial dislocation (Grisel syndrome) had been described much earlier. It is now clear that dystonia can follow trauma to the head or body, but the association between the antecedent trauma and the subsequent dystonia remains a matter of controversy. A causal relationship between trauma and dystonia has been questioned because trauma is common while dystonia is not, and because case reports and retrospective studies are influenced by recall bias and lack of clear diagnostic criteria. However, the preponderance of evidence supports trauma causing or precipitating dystonia in some patients. Dystonia associated with head trauma will be discussed below separately from dystonia associated with peripheral injury.

Dystonia and Head Trauma

Dystonia can develop following a variety of cerebral insults including head trauma. It is most commonly associated with damage involving the basal ganglia, especially the putamen, but has also been reported with damage to the thalamus, the cerebellum, the brainstem, or their connections. The antecedent head trauma need not be severe. However, movement disorders including dystonia may be less likely with mild or moderate trauma and the latency between the trauma and dystonia onset may be longer for those with severe compared to those with milder head trauma. Dystonia may be more likely to develop in those who sustain trauma at a young age.

Head trauma is an uncommon cause of dystonia and dystonia is not the most common movement disorder following head trauma. Although 13–66% of survivors of head trauma have at least one movement disorder, the most common type is tremor. Dystonia may be present in about 18%, often accompanied by tremor or another movement disorder. The dystonia is transient in about 50% of trauma survivors, resolving within 1–12 months of the accident.

Dystonia associated with head trauma often develops secondary to brain injury sufficient to cause hemiplegia, and usually occurs in the previously hemiplegic limbs even after weakness has improved or resolved, leading to hemidystonia. Hemidystonia with involvement of upper and lower limb on one side is rarely seen with idiopathic dystonia. However, post-head trauma dystonia can also be focal, bilateral, multifocal, or generalized and can progress or spread from the original site of onset. Dystonia in the setting of brain trauma may be accompanied by neurologic deficits such as spasticity, rigidity, weakness, or hyperreflexia which are not seen in primary idiopathic dystonia. While dystonia after head trauma can resemble idiopathic dystonia clinically, it may be less likely to be action specific.

Dystonia usually develops months to years after the head trauma rather than acutely, although it has been proposed that an initial hemiplegia may mask the presence of dystonia. The delay in onset of dystonia following head trauma and the spread to areas beyond the hemiplegic limbs make it likely that dystonia does not result directly from trauma, but rather arises from remodeling associated with recovery from brain injury. Aberrant cerebral plasticity, sprouting, and remyelination have been postulated to result in dystonia, especially in patients who have a putative genetic predisposition.

Dystonia and Peripheral Trauma

A causal relationship between peripheral trauma and dystonia is even more controversial. Dystonia has been reported not only following severe injury from a wide variety of causes, but also with mild trauma such as soft tissue sprains, overuse, immobilization, casting, minor dental procedures or from electrical injury. The likelihood of developing dystonia following peripheral injury is impossible determine, especially if 'injury' is defined to include everyday sprains and common medical procedures. Five to twenty-one percent of patients with dystonia report trauma

in the preceding year. Sixty-eight percent of patients with fixed dystonia reported by Schrag gave a history of peripheral trauma within the preceding year.

Jankovic et al. proposed criteria that would limit the diagnosis of peripheral trauma-induced movement disorders arbitrarily to those arising within a year of the injury, in order to minimize the inclusion of subjects whose movement disorder was unrelated to trauma. Additionally, the injury must have been severe enough to cause local symptoms persisting for at least 2 weeks or requiring medical attention within 2 weeks, and the movement disorder had to arise in an area anatomically related to the site of injury. The diagnosis was further supported if no other cause for movement disorder could be identified, if features atypical of an idiopathic movement disorder were present, and if there was a poor response to medication. While these criteria may be helpful in defining a select cohort whose movement disorder is most likely related to trauma, many reported subjects with posttraumatic dystonia do not meet these criteria, often because of a delay in the onset of dystonia beyond 1 year.

Certain aspects of the dystonia have been proposed that may serve to differentiate peripheral trauma-associated dystonia from idiopathic dystonia. In particular, peripheral posttraumatic dystonia may be characterized by fixed postures or tonic rather than phasic muscle contraction, less task specificity, the absence of an effective geste antagoniste, higher likelihood of pain, lack of improvement after sleep or persistence during sleep, poorer response to treatment, including botulinum toxin injection, a more rapid rate of progression and, perhaps, a younger age of onset. Even if peripheral trauma initially or prominently affects the traumatized area, the dystonia can subsequently spread to become bilateral, multifocal, or generalized. Focal posttraumatic dystonia can be characterized by the body area affected.

Posttraumatic Cervical Dystonia

Local injury to the neck and shoulders, from automobile accidents with whiplash, lifting heavy objects, falling, blunt force, and repetitive strain have been implicated in 5–21% of cases of cervical dystonia (CD). An interval from injury to the onset of CD as short as hours and as long as 3 years have been reported. It may be difficult to differentiate posttraumatic dystonia from nondystonic abnormalities of neck posture such as those associated with occipital condyle fracture, atlantoaxial subluxation, spinal cord tumors, muscle inflammation, or fibrosis. Laterocollis (head tilting) is the most common pattern, followed by torticollis (head turning to one side), both of which may be accompanied by shoulder elevation and prominent neck muscle hypertrophy. Anterocollis and retrocollis are reported less frequently. Isolated neck or shoulder muscle hypertrophy may be variants of focal posttraumatic CD.

Tarsy compared those developing CD within 1 month of an injury to those whose dystonia presented 3 months to 1 year after injury and to a cohort without any antecedent trauma. Those with acute onset of dystonia developed pain, spasm and a fixed posture within days of the injury, along with shoulder elevation and muscle hypertrophy. Dystonia in the acute-onset patients also did not respond to sensory tricks, activating movements or botulinum toxin. Several patients with acute posttraumatic dystonia had complex repetitive discharges on electromyography. Interestingly, those with later-onset posttraumatic CD did not differ in any of these parameters from those with idiopathic CD. Tarsy therefore proposed that acute-onset posttraumatic CD might be a different disorder from late posttraumatic dystonia and idiopathic CD and might, in fact, be nondystonic.

In patients receiving botulinum toxin injections with CD arising within 1 year of head or neck trauma compared to a control population of patients with idiopathic CD, Samii found nonsignificant lower age of onset and more frequent pain in those with trauma, but no differences in the incidence of spontaneous remission, direction of head deviation, presence of an effective geste antagoniste, presence of tremor or response to botulinum toxin injection.

Posttraumatic CD may be more common in women even though trauma is more common in men. A psychogenic etiology for posttraumatic CD, as well as other posttraumatic dystonias, might be considered in those with the sudden onset within minutes to weeks of fixed painful spasmodic torticollis with rapid progression to fixed postures after minor trauma, especially if other nonphysiological symptoms like give-way weakness and nonanatomic sensory loss are present, as well as in those with pending litigation related to the injury.

Posttraumatic Craniofacial Dystonia

Cranial dystonias including blepharospasm, oromandibular dystonia (OMD), Meige syndrome (OMD with blepharospasm) and orofacial dystonia have been reported to follow eye disease or irritation, face and head surgery, facial trauma and dental procedures. Twelve percent of patients reported by Grandas had eye disease such as infection, trauma, or surgery within the year preceding the onset of blepharospasm and 17% of patients reported by Sankhla sustained trauma within the year before with OMD onset. There was no correlation between the severity of the trauma and the subsequent severity of the dystonia. After onset, more than half of the patients had spread to other cranial or cervical muscles. The patients reported by Sankhla did not differ significantly from

OMD patients without a history of a trauma precipitant in age at dystonia onset, the presence of pain, the effectiveness of sensory tricks, response to botulinum toxin, or a history of tremor. However, the nontraumatic cohort more frequently had spread of the dystonia, coexistent writer's cramp or spasmodic dysphonia and a family history of dystonia. Schrag similarly found, in eight cases of craniofacial dystonia arising within days to weeks of dental procedures, that posture was often fixed, pain was prominent and gestes were ineffective. A relationship between head or facial trauma and subsequent cranial dystonia, however, is not supported by all studies. Martino found the same self-reported incidence of head and maxillofacial trauma preceding hemifacial spasm as in patients with craniofacial dystonia.

Posttraumatic Limb and Segmental Dystonia

Upper limb, lower limb, and segmental dystonia have been reported following peripheral trauma. 28% of subjects with lower limb dystonia reported by McKeon sustained a distal or proximal (back, pelvis, or gluteal) injury to the affected extremity within 1 week of injury in half of the subjects and between 4 and 13 months in the others. Dystonia was accompanied by pain and 80% had a fixed dystonic posture. The dystonia was severe enough to interfere with walking in 30%.

Ten percent of patients with writer's cramp report previous trauma to the affected hand. Excessive repetitive use of a hand, as in musicians who practice many hours a day for years, could represent mild, chronic trauma and has long been considered a precipitant of focal hand dystonia. Posttraumatic focal hand dystonia may arise with trauma to the limb or neck. Its association with complex regional pain syndrome (CRPS; previously reflex sympathetic dystrophy) deserves particular mention. CRPS is characterized by persistent pain out of proportion to the precipitating event, autonomic dysregulation and trophic skin changes that follow trauma. In both CRPS and peripheral trauma-induced dystonia, the antecedent trauma may be trivial. Dystonia and CRPS may each follow soft tissue injury or limb immobilization as with casting. Movement disorders are present in up to 65% of patients with CRPS. Dystonia is the most common movement disorder in CRPS, present in 14–90% of those with movement disorders associated with CRPS, often in combination with tremor or myoclonus. In patients with CRPS, the dystonia typically takes the form of flexion of the fingers and wrist if the upper extremity is affected and inversion and plantar flexion of the foot with clawing of the toes if the lower extremity is affected. The dystonia in patients with CRPS can spread proximally, can become bilateral and can generalize. Patients with posttraumatic CRPS and dystonia tend to be younger than those with CRPS without dystonia. The onset of the dystonia may be abrupt or gradual, the dystonia may be sensitive to tactile or auditory stimuli, and may be fixed or mobile. In patients with dystonia and CRPS reported by van Rijn, the median interval between the onset of CRPS and dystonia was 61 days; however, about 25% of patients developed dystonia within 1 week and 3% more than 5 years after the development of other CRPS symptoms. Rarely, the dystonia presents before other CRPS symptoms affecting the same limb.

Pathophysiology

While a peripheral explanation might suffice for dystonia confined to the area of injury, only a central mechanism can explain the progression of dystonia to body areas other than that injured. It has been proposed that peripheral trauma leads to alterations in sensory feedback and sensitization of peripheral nociceptors, and subsequently to changes in spinal cord circuits eventually resulting in central sensitization and remodeling at cortical and subcortical levels.

As with head trauma, peripheral trauma is common but subsequent dystonia is not. It has been hypothesized that an underlying genetic predisposition may predispose patients to the development of dystonia following peripheral trauma. Bressman et al. failed to find the DYT1 gene in four patients with posttraumatic dystonia or other secondary dystonias. A genetic predisposition, however, is supported by reports of trauma precipitating or significantly worsening dystonic symptoms in patients with familial idiopathic generalized dystonia. It is also supported by the physiologic study of Bohlhalter. In this study, a patient with foot dystonia following an ankle injury, her brother with craniocervical dystonia and an unaffected sister all had abnormalities in motor cortical excitability assessed with transcranial magnetic stimulation similar to those previously reported in patients with idiopathic dystonia.

Treatment and Prognosis

The treatment of dystonia following either head or peripheral trauma is symptomatic and often ineffective. Typical medications used for idiopathic dystonia, including anticholinergic medications, baclofen, and benzodiazepines can be tried as well as physical and rehabilitation therapies. Early in the course of CRPS, intrathecal baclofen may provide relief of both pain and dystonia. Botulinum toxin helps some patients but may be less effective than in idiopathic dystonia. Stereotactic neurosurgery, such as pallidotomy or thalmatomy offer relief to some

patients but may be less effective in posttraumatic and other secondary dystonias than in idiopathic dystonia. Preliminary reports suggest that deep brain stimulation may be as effective as ablative surgery.

Dystonia: Animal Models

E J Hess and H A Jinnah, Emory University School of Medicine, Atlanta, GA USA

Glossary

Glutamic acid decarboxylase – The enzyme that catalyzes the conversion of glutamate to GABA.
Knockin mouse – A mouse that has had genetic information, such as a specific disease-causing mutation, inserted into the gene of interest.
Knockout mouse – A genetically engineered mouse in which a specific gene has been inactivated.
Transgenic mouse – A mouse that carries a foreign gene that is randomly inserted in the genome.
Voltage-gated calcium channel – Ion channels that open and conduct calcium upon membrane depolarization.

Definition and History

Dystonia is a movement disorder characterized by excessive and, sometimes, sustained muscle contractions. The abnormal contractions and resulting twisting movements and postures may arise as a result of brain injury or occur as a sporadic or inherited disorder. Dystonia is classified by the distribution of the affected muscle groups. Generalized dystonia is characterized by involvement of muscles throughout the body. Focal or segmental forms of the disorder involve a small number of muscles, such as those of the hand in writer's cramp or of the upper face in blepharospasm. Dystonia has no clear neuropathological signature. Most cases are not a degenerative disorder, and no single neural pathway is yet implicated in the disorder. In fact, functional imaging studies

generally implicate several brain regions including cerebellum, cortex, brainstem, and basal ganglia. Because our understanding of the etiology and pathophysiology of dystonia is limited, animal models are essential for understanding this systems level disorder. One of the first animal models of dystonia, the dystonia musculorum mouse mutant, was described in the early 1970s, and many models have been developed since. These models are used to facilitate the identification of anatomical, physiological, or biochemical processes involved in the expression of the motor syndrome. Some of the most commonly studied animal models of both generalized and focal dystonia are described.

Models of Generalized Dystonia

Genetic Models of Generalized Dystonia

$Ca_v2.1$ calcium channel mouse mutants

Mice bearing mutations within the *Cacna1a* gene, which encodes Cav2.1 (P/Q-type) calcium channels, are models of dystonia; dystonia is a prominent feature of the *tottering*, *rocker*, *leaner*, and *Cacna1a knockout mice*. Tottering mice exhibit paroxysmal generalized dystonia. Attacks of generalized dystonia last for 30–40 min and are experimentally induced by stress, caffeine, or ethanol. Tottering mice carry a point mutation in the *Cacna1a* gene that results in a reduction in Cav2.1 calcium current density. No gross neuropathological abnormalities are identified in the tottering mouse brain. During a dystonic attack, neuronal activation is observed throughout the olivocerebellar circuit, and lesions of the cerebellum alleviate the dystonia suggesting that the cerebellum is necessary for the expression of dystonia in *tottering* mice.

Leaner mice and *Cacna1a* knockout mice exhibit severe chronic generalized dystonia. Dystonia develops at ~2–3 weeks of life. This debilitating dystonia causes death, indirectly by interfering with feeding in weanlings. The motor dysfunction in these mutants is more severe dystonia in the knockout mice than in leaner mice. The leaner mutation causes a gross disruption in the channel protein, resulting from a G to A point mutation of a splice donor site near the 3′ end of the gene. The mutation produces aberrantly spliced mRNA species that causes a reduction in open-probability of the channels and an overall reduction in P/Q-type calcium current density. Prominent degeneration of cerebellar granule and Purkinje cells, particularly in the anterior cerebellum, is observed in both leaner mice and the null mutants.

Dystonia musculorum mice

Dystonia musculorum mice exhibit generalized dystonia caused by a mutation in the Bpag1 gene, which encodes a cytoskeletal linker protein. The mutation causes loss of neuronal cytoskeletal organization, axonal swelling, and abnormal axonal transport. Neuropathological studies reveal lesions of sensory nerves and dorsal root ganglia, cerebellum, and red nucleus plus degeneration of muscle spindles. Additionally, myelination is abnormal in both the peripheral and central nervous system. The precise mechanisms underlying the motor dysfunction are unknown.

dt^{sz} hamster

The *dystonic* (*dt^{sz}*) hamster exhibits generalized paroxysmal dystonia. Attacks of dystonia are stress induced and last for hours. The attacks begin after the second week of life, peak in severity between the fourth and sixth week, and disappear after eight weeks of age. The phenotype is caused by a recessive mutation, but the gene defect is unknown. The dystonia correlates with overactivity of striatal projection neurons and reduced basal ganglia output. Irregular patterns of electrical activity are observed within caudate, putamen, and globus pallidus, which may result from significant increases in corticostriatal and striatopallidal excitability. The overactivity is associated with a marked reduction in the number of striatal GABAergic interneurons, and an increase in striatal dopamine overflow during a dystonic attack, implicating the basal ganglia as the source of dystonic attacks.

dt rat

The chronic generalized dystonia exhibited by the dystonic (*dt*) rat is caused by a recessively inherited mutation in *Atcay*, the gene encoding caytaxin. Dystonia is observed starting 10 days after birth and becomes increasingly severe with age. Viability is compromised since animals have difficult eating and drinking. Neither gross neuroanatomical abnormalities nor neurodegeneration is apparent. Neurochemical abnormalities in cerebellum, include an increase in GABA synthesis and concentration in Purkinje cells, but a reduction in glutamic acid decarboxylase activity and GABA receptor density in the deep cerebellar nuclei. *dt* rat Purkinje neurons exhibit reduced complex spiking and abnormal patterns of simple spike bursting. Neurons within the deep cerebellar nuclei exhibit increased rhythmic bursting, with the most severe changes in activity observed in older animals with advanced dystonia. It is likely that both physiological and biochemical abnormalities result from abnormal Purkinje cell innervation by climbing fiber afferents from the inferior olive. Removal of the cerebellum or lesions of the deep cerebellar nuclei alleviate the dystonia in *dt* rats, further implicating the cerebellum in the disorder.

Genetically engineered models of dystonia

The focus of genetically engineered mouse models of generalized dystonia has been *DYT1* dystonia, a primary dystonia caused by an in-frame 3 base pair deletion of GAG in the *TOR1A* gene, which encodes the torsinA

protein. The dominant mutation exhibits partial penetrance and exerts its effects through mechanisms that are not fully understood. Both transgenic and knockin/out lines of mice carry the *DTY1* mutation. Transgenic mice overexpress a copy of the mutant gene along with normal endogenous gene. Several different promoters were used to drive expression of mutant torsinA in transgenic mice, including the mammalian neuron-specific enolase promoter, the human cytomegalovirus promoter, and the mammalian prion protein promoter. Perinuclear inclusions, blebbing of the nuclear membrane and torsinA-containing aggregates are observed in the brainstem of some, but not all transgenic lines. Dopaminergic dysfunction is also observed in many lines. Striatal dopamine concentrations are generally normal, but dopamine turnover and release are reduced. Striatal D2 dopamine receptor-mediated N-type calcium channel inhibition and GABAergic signaling are also altered. Although each line exhibits some motor abnormality, none has a motor disorder resembling human dystonia. It is important to note that transgenic lines overexpressing normal torsinA also exhibit abnormalities similar to those observed in the mutant torsinA transgenic lines including changes in motor behavior and perinuclear inclusions. Therefore, some abnormalities in the transgenics may reflect the consequence of overexpression or ectopic expression, rather than the consequence of mutant torsinA expression per se.

Mice homozygous for the Tor1A null mutation and knockin mice homozygous for the *DYT1* GAG deletion in the *Tor1A* gene die perinatally and exhibit abnormalities of the nuclear membrane. Gross brain histology of both heterozygous knockin and knockout mice is relatively normal but protein aggregates are observed in brainstem neurons. Heterozygous knockin mice are somewhat hyperactive and impaired on the beam-walking test without overt dystonia.

There are also genetically engineered mouse models of disorders in which dystonia is frequently observed, such as Lesch–Nyhan disease, Parkinson disease, and Wilson disease. Like DYT1, the models are a mix of transgenic, knockin and knockout mice, but few carry precise human mutations as knockins. None of these models exhibit dystonia with the exception of α-synuclein transgenic mice. This may be due to intrinsic differences in neural circuits between man and mouse or simply the lack of models expressing exact genocopies of the human disorders.

Drug-Induced Models of Generalized Dystonia

Generalized dystonia may be induced in otherwise normal animals using a variety of drugs. Drug-induced models are useful in defining defects common to many forms of dystonia, similar to the manner in which drug-induced animal models of Parkinson disease have elucidated the pathophysiology underlying that disorder.

Kainic acid-induced dystonia

Low doses of the excitatory glutamate receptor agonist kainic acid microinjected into the mouse cerebellum produce generalized dystonia. Dystonia peaks 30–40 min after injection and mice return to baseline motor activity 2 h after injection. The severity of the dystonia is dose dependent. Kainate-induced dystonia in normal mice is associated with neuronal activation within cerebellum, deep cerebellar nuclei, red nuclei, and other cerebellar relay nuclei; it is not associated with neuronal cell death. Non-N-methyl-D-aspartic acid (NMDA) glutamatergic antagonists injected into the cerebellum do not cause dystonia but block kainate-induced dystonia demonstrating that non-NMDA receptor activation, not simply a distortion of glutamatergic signaling, is necessary to induce dystonia. Microinjection of kainate into basal ganglia does not induce motor dysfunction, nor does kainate induce dystonia when injected into the cerebella of mice lacking Purkinje cells, indicating that output from cerebellum is necessary for expression of the dystonia.

3-Nitropropionic acid intoxification

In humans, ingestion of sugarcane tainted with the *Arthrinium* fungus causes a movement disorder that includes dystonia and chorea accompanied by lesions within striatum and globus pallidus. The contaminating toxin, 3-nitropropionic acid (3-NPA) induces similar motor dysfunction in mice, rats, and nonhuman primates. This model has been difficult to work with in rodents because 3-NPA is highly toxic and causes death in at least one-third of mice. In surviving mice, lesions occur in the dorsolateral striatum and cell loss is observed in the globus pallidus and substantia nigra pars reticulata and compacta. Loss of striatal projection neurons and increases in striatal dopamine are observed in both rodents and nonhuman primates after 3-NPA intoxification, suggesting a reduction in striatonigral inhibition. Thus, 3-NPA-induced striatal lesions predict dysfunctional basal ganglia output as the cause of dystonia.

Dystonia caused by L-type calcium channel activation

Low doses of systemically administered Bay K 8644, an L-type calcium channel agonist, cause slowing of movements with occasional momentary abnormal limb positions. Higher doses cause abnormal severe flexion of the trunk with flexion of the head toward the abdomen, which often causes the mouse to fall. Activity returns to baseline after ~120 min. With EMG, significant increases are observed in resting muscle activity and movement-related phasic bursting is prolonged and of high amplitude. A similar motor syndrome is evoked by intracerebral injection of Bay K 8644, demonstrating a central effect of the drug. Additionally, systemic administration of FPL 64176,

another L-type calcium channel agonist induces a similar syndrome. L-type calcium channel antagonists, such as nimodipine and nitrendipine, block the syndrome. Neuronal activation after Bay K 8644 challenge is apparent in the striatum, cortex, hippocampus, locus coeruleus, and cerebellum. The broad distribution of activation suggests that Bay K 8644 may induce dystonia through several different motor regions.

Models of Focal Dystonia

Genetic Models of Focal Dystonia

Rocker mice

Rocker mice carry a point mutation in the *Cacna1a* gene that results in a modest reduction in Cav2.1 calcium current density. Like the Cacna1a mouse mutant tottering, rocker mice exhibit paroxysmal dystonia. Attacks of dystonia are often limited to a single limb or segmental and occur only in female mice. Few obvious neuropathological abnormalities are observed in the rocker mouse brain with the exception of abnormal Purkinje cell dendritic arbors.

Lethargic mice

Lethargic mice carry a point mutation in the *cachb4* gene, which encodes the beta auxiliary subunit of voltage-gated calcium channels. Lethargic mice exhibit brief attacks of paroxysmal dystonia induced by short periods of exercise. Attacks of dystonia may be focal, segmental, or generalized. Surgical removal of the cerebellum eliminates the paroxysmal dystonia demonstrating that the cerebellum is necessary for the paroxysmal dystonia.

Induced Models of Focal Dystonia

Blepharospasm in rat

Blepharospasm is a focal dystonia of the upper face characterized by exaggerated involuntary blinking caused by spasms of the orbicularis oculi muscle. The rat model of blepharospasm was developed based on the hypothesis that dystonia results from a combination of abnormal sensory input plus basal ganglia dysfunction. To implement this two-hit model, a partial lesion of the facial nerve to reduce orbicularis oculi innervation was combined with a small unilateral 6-hydroxydopamine lesion of the substantia nigra pars compacta to induce mild dopamine depletion. Both insults alone produce small increases in trigeminal reflex blink excitability. In combination, the lesions cause increased blinking and spasms of lid closure, resembling blepharospasm in humans. Lid spasms persist even after reinnervation of the orbicularis oculis muscle suggesting long lasting and irreversible modifications to central processes mediating blink responses.

Hand dystonia in owl monkey

Most hand dystonias are task specific and may occur in response to excessive and repetitive movement. Abnormal hand representation in the somatosensory cortex is associated with the disorder. To mimic the conditions of task-specific overuse, owl monkeys were trained to squeeze a handgrip with as many as 3000 rapid opening and closing cycles daily for up to 25 weeks. Performance declined in several monkeys due to the emergence of abnormal movements resembling hand dystonia. After training, hand receptive field size in somatosensory cortex was strikingly enlarged, similar to observations in humans that develop task-specific dystonias following overuse. It is unclear whether the changes in receptive fields are a cause or an effect of the dystonia. This model has not been widely studied. Dystonia induced through this repetitive movement paradigm has been observed only in four owl monkeys and others have not yet replicated the model.

Summary

Animal models of both generalized and focal dystonia have been developed in numerous species and are critical tools for understanding the mechanisms underlying dystonia in humans. These models have been used to elucidate novel disease mechanisms and pathophysiology and should prove useful for identifying novel therapeutics.

Dystonic Storm

B I Karp, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD, USA

Glossary

CRPS (complex regional pain syndrome) – A syndrome consisting of pain, autonomic dysfunction, and skin changes in a traumatized body area.
Neuroleptic malignant syndrome – Life-threatening syndrome including fever, muscle rigidity, and autonomic instability usually associated with the use of neuroleptic medication.
Rhabdomyolysis – Muscle breakdown.

Introduction

Dystonic storm (status dystonicus) (DS) is used to describe episodes of acute or subacute severe generalized dystonia accompanied by fever and rhabdomyolysis in those with preexisting dystonic syndromes. Often refractory to medical management, DS can be life-threatening.

History and Epidemiology

Jankovic and Penn first described DS, in 1982, in a child with idiopathic torsion dystonia who had several exacerbations of dystonic spasms, high fever, and myoglobinuria leading to acute renal failure. Various medications, including Sinemet, baclofen, and tetrabenazine, were only transiently effective. The child ultimately improved following bilateral thalamotomy.

DS is rare, with only single cases and small series reported. DS affects subjects with underlying dystonic disorders – both primary dystonias, such as DYT1-positive and DYT1-negative primary torsion dystonia, and secondary dystonias, including posttraumatic dystonia, dystonia associated with cerebral palsy, Wilson's disease, pantothenate kinase-associated neurodegeneration (PKAN), complex regional pain syndrome, and neuroacanthocytosis. DS may be more common in males and in those with childhood-onset dystonic disorders. Although most commonly seen in those with generalized dystonia, it has been reported rarely in patients with focal or segmental dystonia.

Signs and Symptoms

The most prominent and disabling symptoms of DS are continuous, severe dystonic muscle contractions. The onset may be heralded by intermittent, less-severe attacks, or exacerbations of the underlying dystonia over days, weeks, or months before more abrupt progression to the characteristic widespread, continuous spasms, which are extremely painful. Dystonia may be accompanied by other abnormal movements, including tremor, myoclonus, or chorea. Severe spasm affecting the upper airway, including the larynx, leads to upper airway compromise with stridor, aspiration, dysphagia, and anarthria. Spasm of the respiratory muscles contributes to respiratory insufficiency so that intubation and mechanical ventilation are often necessary. The intensity of uncontrolled muscle activity also causes high fever, dehydration, acidosis, and rhabdomyolysis with an elevated creatine kinase level and myoglobinuria, which can subsequently cause acute renal failure.

Episodes of DS can last days to years. Intervals between episodes as short as hours and as long as years have been reported. A precipitant, such as respiratory or urinary tract infection, can be identified before many episodes. Some episodes were reported to begin shortly upon the initiation of medications, including clonazepam or zinc sulfate or D-penicillamine for Wilson's disease. In other patients, a decrease in dose or withdrawal of medications, such as intrathecal baclofen, lithium, or tetrabenazine, seems to initiate a spell.

The differential diagnosis of DS includes neuroleptic malignant syndrome and malignant hyperthermia, which are differentiated by the medical history and the background of occurrence in those with preexisting dystonia.

Management

Urgent management of DS includes protection of the airway, maintenance of ventilation, and correction of metabolic abnormalities, along with control of the muscle spasms and the associated pain. Admission to the intensive care unit is usually advisable.

The first line of care includes close hemodynamic and metabolic monitoring. Antipyretics, hydration, cooling blankets, and correction of acidosis may all be required. Dialysis may be used to prevent renal damage from myoglobinuria. Patients with DS often require sedation and may require mechanical ventilation. Sedation lessens the severe spasms thereby decreasing muscle breakdown and preventing rhabdomyolysis, as well as allowing adequate ventilation. The choice of sedating agent and muscle relaxant may not be important. Midazolam, propofol, thiopental, and lorazepam are commonly used, although it has been suggested that midazolam which has a direct action on spinal cord circuitry may be especially effective. Once started, intubation and ventilation may be required for a prolonged period. Among 12 DS patients reported by Manji, intubation was required for a mean of 52 days, but as long as 300 days. Sedation should be lifted periodically to determine if DS spasms have subsided.

Specific treatment for the dystonic spasms often begins with increases in the dosages of medications the patient is already on. A wide range of medications have been reported as possibly helpful for DS, including neuroleptics (haloperidol, chlorpromazine, pimozide, sulpiride, clozapine, risperidone), tetrabenazine, anticholinergics (trihexyphenidyl/benzhexol), acetazolamide, antispasmodics (dantrolene, baclofen), anticonvulsants (phenytoin, carbamezepine, valproic acid), and L-dopa. High doses may be required; neuroleptics are often pushed to the point of parkinsonism. Marsden et al. proposed initial treatment with high doses of an anticholinergic followed by the addition of tetrabenazine and pimozide, if needed. Several reported patients benefited significantly from intrathecal baclofen. Unfortunately, antidystonic medications are often ineffective or only partly effective. Some medications that appear to be working initially quickly lose benefit requiring higher doses or additional medications.

A number of neurosurgical procedures appear to be able to halt DS. Pallidotomy and thalamotomy have both been successful in a number of patients. Deep brain stimulation (DBS) may prove to be equally efficacious.

Prognosis

The long-term outcome varies widely. No prognostic factors have been identified that allow one to predict which subjects will have a good outcome. Following an episode of DS, many patients recover completely and return to their baseline level of dystonia. Some are permanently worse and some patients die, often of intercurrent infection associated with prolonged hospitalization and intubation. With surgery, pallidotomy, thalamotomy, or DBS, there are now reports of patients improving beyond their pre-DS condition.

Glossary

Dystonia – Sustained muscle contractions of agonist and antagonist muscles causing involuntary repetitive movements or abnormal postures, which are usually directional in nature.
Expression – Describes the type and severity of disease (e.g., DYT1 dystonia has variable expressivity, such that one carrier may manifest with severe generalized disease and be unable to walk, and another may have only mild non-debilitating writer's cramp).
Generalized dystonia – Dystonia involving both legs or the leg and the trunk and at least one other body region.
Geste antagoniste – Specific sensory modality (e.g., touching) used by a patient suffering from dystonia to lessen the abnormal posture or repetitive movements (also called sensory trick).
Null point – Position in which a dystonic contraction disappears, may be helpful in discriminating dystonic tremor from other types of tremor.
Penetrance – The rate at which a gene carrier develops disease (e.g., ~30% of DYT1 carriers will develop dystonia).
Primary dystonia – Dystonia is the only neurologic feature on examination (with the exception of tremor), there are no laboratory or imaging data to suggest an acquired or degenerative cause, there is no response to levodopa and there is no history to suggest an environmental or pharmacologic cause.

Definition and History

Dystonia is an involuntary hyperkinetic movement disorder characterized by sustained twisting and posturing movements which are usually directional in nature. It involves agonist and antagonist muscle contraction. Dystonia can be classified according to the body part(s) involved, the age of onset, or the etiology (see **Figure 1**). The term primary dystonia is used when dystonia is the only movement disorder (with the exception of tremor) and there is no secondary etiology. Secondary dystonia, on the other hand, is used when dystonia is associated with other movement disorder(s) and/or is due to an exogenous cause, such as dopamine receptor blocking medications or stroke or when structural changes are noted on imaging. The primary dystonias can be further classified according to the age of onset: *early* (age of onset <26 years, this is often due to mutations in DYT1), *late* (age of onset >26 years, most genetic etiologies are not known), and *mixed* (early and late onset within families (typically DYT6 and DYT13)).

DYT1 dystonia is the prototype of primary torsion dystonia. It is also called dystonia musculorum deformans 1, early-onset torsion dystonia, idiopathic torsion dystonia and Oppenheim dystonia. It is an early-onset dystonia, with patients almost always presenting before the age of 26 years with involvement of an arm or leg. DYT1 classically progresses to multifocal or generalized dystonia, but some DYT1 carriers will have dystonia that remains focal, with only brachial involvement, for example.

Although there is some debate regarding the first report of dystonia, the clearest description of primary dystonia was written by Hermann Oppenheim in 1911, who reported four children with features of abnormal muscle tone, includingtwisting postures with muscle spasms which affect the trunk and limbs, and described their 'dromedary gait' with flexion and twisting of the trunk. Labelled 'dystonia musculorum deformans,' these cases most likely represent DYT1 dystonia. DYT1 was incorrectly assumed to be an autosomal recessive disorder due to infrequent parent child transmission, but work by Zeman and coworkers demonstrated that the transmission was autosomal dominant with reduced penetrance. His work also led to better characterization of the DYT1 phenotype and an understanding that the condition was of increased frequency in Ashkenazi Jews. Linkage to chromosome 9q34 was reported in a French-Canadian family. In 1997, ~80 years after the first description this condition, the DYT1 gene, which encodes the protein torsin A was cloned by Ozelius and colleagues. It is important to note that while DYT1 is the major etiology of early-onset dystonia in the Ashkenazi Jews, DYT1 dystonia is not limited to French-Canadians and Ashkenazim, and has been reported in populations around the world, including other Caucasian, Asian and African populations.

Pathogenesis/Pathophysiology

Mutations in the DYT1 gene on chromosome 9q34 are responsible for DYT1 dystonia. This mutation consists of a three base pair (GAG) deletion in the hydroxy terminus

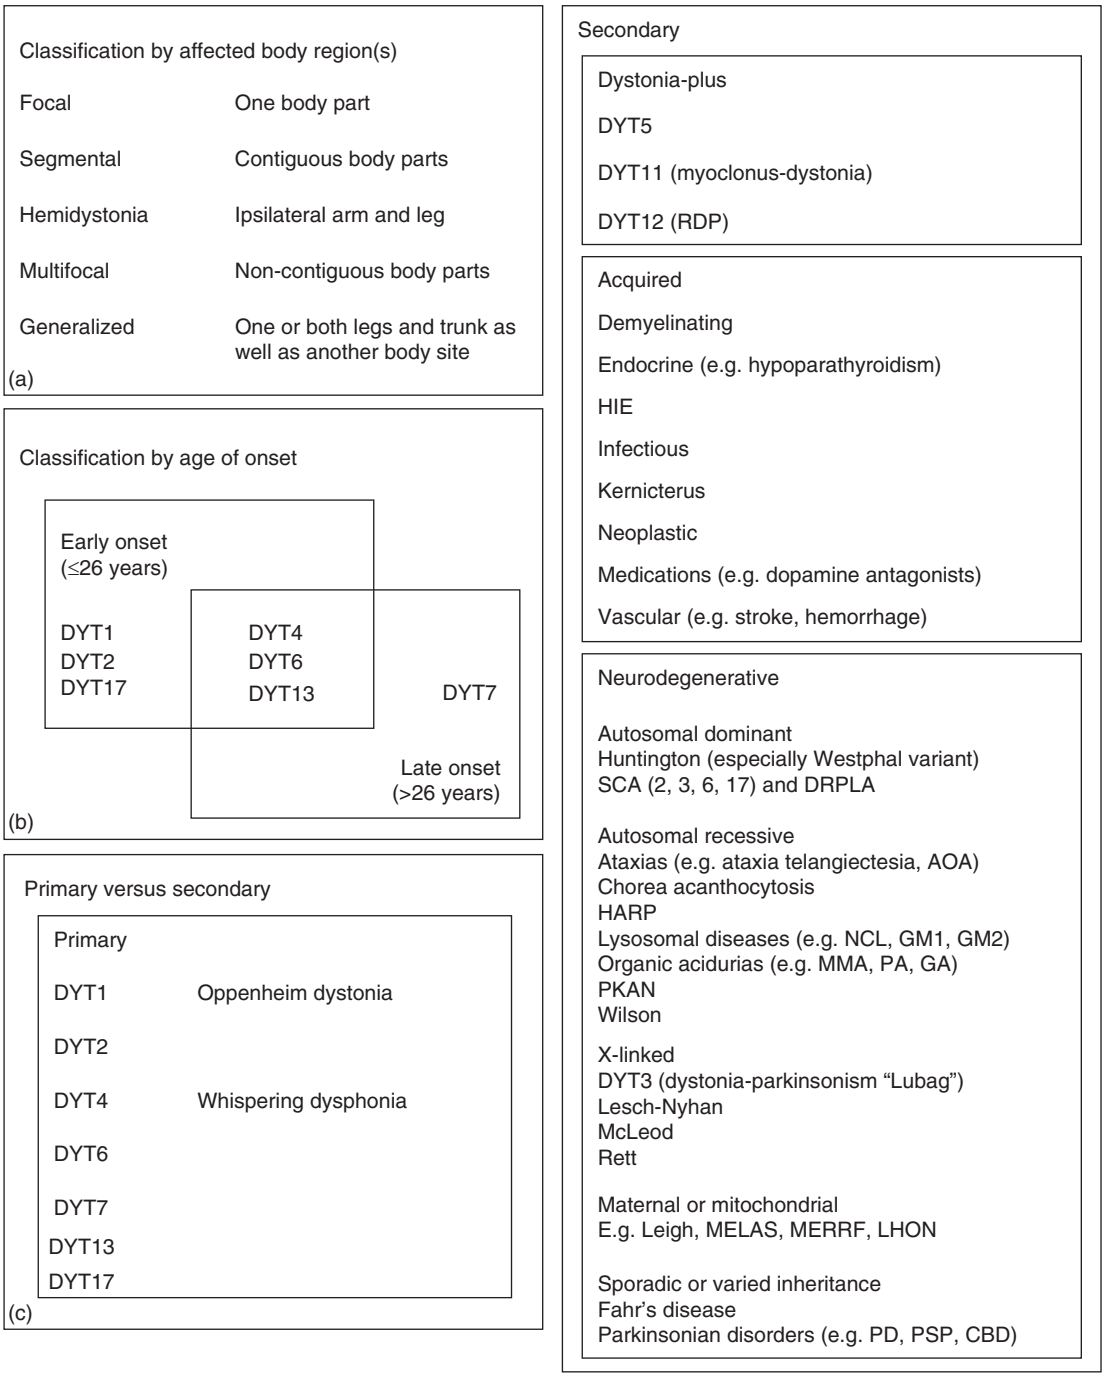

Figure 1 Dystonia classification. AOA: ataxia with oculo-motor apraxia; CBD: corticobasal degeneration; DRPLA: dentatorubral pallidoluysian atrophy; GA: glutaric aciduria; HIE: hypoxic ischemic encephalopathy; LHON: Leber hereditary optic neuropathy; MELAS: mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MERRF: myocclonic epilepsy associated with ragged red fibers; MMA: methylmalonic aciduria; NCL: neuronal ceroid lipofuscinosis; PA: proprionic aciduria; PD: parkinson's disease; PKAN: panthotenate kinase associated neurodegeneration; PSP: progressive supranuclear palsy; RDP: rapid-onset dystonia parkinsonism; SCA: spinocerebellar ataxia.

of the gene resulting in the loss of a pair of glutamic acid residues in the C-terminal region of the protein. The same mutation is present in virtually all patients, regardless of their ethnicity.

DYT1 dystonia is transmitted in an autosomal dominant fashion with reduced penetrance (30–40%), and varied expression. Reduced penetrance is most likely due to a combination of genetic and environmental causes. Thus far,

only one uncommon genetic change is known to decrease penetrance of DYT1. This change is a polymorphism in the coding sequence in *cis* with the DYT1 deletion which has been shown to be associated with markedly reduced penetrance. DYT1 dystonia also has variable expression, even within families. In the same sibship, one sibling may have a severe generalized dystonia requiring a wheelchair for mobility while another may never seek medical attention because of an isolated writer's cramp.

The DYT1 gene encodes for the protein torsin A. This protein is widely expressed in the human brain and has been found to have a greater expression in the neurons of the striatum, substantia nigra pars compacta, thalamus, hippocampus, cortex, and cerebellum (in Purkinje cells). The role of this protein is not yet fully understood: it is a member of the AAA + superfamily of heat shock and regulatory proteins, which are known to be important in protein folding and regulation. Both in vitro and in vivo studies suggest that torsin A is involved in protein trafficking, fusion of vesicles with the presynaptic membrane, movements of organelles, cytoskeletal dynamics, and protein folding.

Torsin A has been localized to the small vesicles of the presynaptic terminals in adult striatum. This may suggest that the protein also has a role in dopaminergic modulation. Torsin A may be important for dopaminergic transmission – in a neuropathological study, patients with DYT1 dystonia had larger appearing nigral dopaminergic neurons than normal. Moreover, another postmortem study revealed that both dopamine and homovanillic acid levels are decreased in the striatum of affected patients. Finally, torsin A has also been shown to be present with α-synuclein in Lewy bodies and ubiquitin positive perinuclear inclusions were found in the periaqueductal grey matter as well as in the reticular formation. Despite all of these elements suggesting that dopamine may play an important role in the pathogenesis of DYT1 dystonia, the significance of this role remains uncertain. An argument against the dopaminergic hypothesis is that patients with DYT1 dystonia do not have parkinsonian sign or symptoms, and the response to dopaminergic therapies is not marked.

Epidemiology/Risk Factors

DYT1 dystonia is the most common form of early-onset primary dystonia. Early-onset dystonia is caused by DYT1 dystonia in 80–90% of Ashkenazi Jews and in ~50% (30–60%) of non-Jewish patients. DYT1 is more prevalent among Ashkenazi Jews (1/3000 to 1/9000) compared to non-Jewish individuals (1/9000 to 1/27 000). The increased prevalence of the disease in Ashkenazi Jews is thought to result from a founder mutation that was postulated to have appeared in Lithuania or Byelorussia, ~350 years ago. De novo mutations have been reported in patients in varying ethnic backgrounds but their rate is unknown.

The most important risk factor for the development of DYT1 dystonia is being a carrier of the known gene mutation. It has been postulated that both environmental and genetic factors may be important for the development of the disease, but to date only the histadine polymorphism in *cis* with the GAG deletion has been clearly demonstrated to reduce the risk of developing the disease.

Clinical Features and Diagnostic Criteria

The diagnostic criteria for primary dystonia include: (1) dystonia is the only abnormality (exception: postural or/and kinetic tremor), (2) no evidence of an acquired or degenerative cause (by laboratory or imaging data), (3) lack of a marked and sustained response to levodopa, and (4) no identifiable environmental or pharmacological cause such as past or current use of neuroleptics or antiemetics (e.g., metochlopramide). DYT1 patients all meet these criteria. There may be a partial response to levodopa in some, but the improvement is not as dramatic or sustained as occurs in dopa-responsive dystonia (DRD).

As noted, while there is phenotypic heterogeneity in DYT1 dystonia, there are also classic clinical features. In 90% of cases dystonia starts in the arm or leg, and almost always one or more limbs become affected, with 95% of cases have at least one affected arm. In half of the cases, there is generalization with both legs or one leg and the trunk becoming affected. Trunk and cervical muscles may become involved in approximately one-quarter to one-third of the cases. While it is unusual to start in the cranial muscles, spread to these muscles occurs in up to 15–20% of cases. Also as noted, early age of onset is a major feature of DYT1, with average age of onset at 12.5 years. The reported ages of onset are quite variable, ranging from 3 to 64 years, but most cases with onset before the age of 21 and almost all before the age of 26. Earlier age of onset of dystonia is associated with a more severe phenotype. It is rare for adult onset focal dystonia to be attributed to a DYT1 mutation.

As the only definitive method of diagnosing DYT1 dystonia is through genetic testing. Guidelines for genetic testing suggest consideration of testing in individuals with onset of primary dystonia <26 years old, individuals with an older onset if there is a family history of early-onset dystonia or if writer's cramp is a prominent feature. Genetic counseling should be sought in combination with testing. If genetic testing is not available in a case of young-onset dystonia an empiric trial of L-dopa should be considered to evaluate the possibility of DRD (see below).

Several features lead the clinician away from the diagnosis of DYT1 dystonia: age of onset after the age of 40 years, focal or segmental craniocervical dystonia (including spasmodic torticollis or cervical dystonia,

spasmodic dysphonia, blepharospasm, oromandibular dystonia), dramatic and sustained improvement with levodopa, abnormal brain imaging, additional abnormal findings on examination (e.g., parkinsonism), and a history suggesting acquired cause (e.g., perinatal asphyxia, remote or current use of neuroleptics).

Because the disease is inherited in an autosomal dominant manner with incomplete penetrance, no family history may be apparent, especially in small families. Further, because there is tremendous phenotypic variability, family members may not realize that severe dystonia and very mild writer's cramp, for example, are both expressions of the same condition.

Differential Diagnosis

The differential diagnosis for DYT1 dystonia includes other forms of primary dystonia; including the mixed age of onset (DYT6, DYT13) and late age of onset (DYT7). DYT5 or DRD, which is also an early-onset dystonia with onset in a limb (usually the leg) which frequently spreads to generalized dystonia, may be confused with DYT1. Diurnal fluctuations are characteristic of DRD, but are not always seen, whereas they are uncommon in DYT1 dystonia. Parkinsonian features as well as a spastic gait and hyperreflexia may also be seen in DRD, but are not present in DYT1. Treatment of these two conditions is different; DRD patients typically respond dramatically to low doses of levodopa, while DYT1 patients may have a mild but not a dramatic and sustained response. If genetic testing for DYT1 is not readily available, or the test is negative, a levodopa trial should be undertaken. Because there may be some partial response to L-dopa in DYT1 dystonia, some clinicians may choose to continue the medication even if DRD is excluded by the lack of a marked and sustained response. **Table 1** summarizes the principal characteristics of the primary dystonias and dystonia-plus syndromes, according to their inheritance.

Among the secondary causes of dystonia, hereditary neurodegenerative conditions should also be considered in the differential diagnosis, especially Wilson's disease, as it is a highly treatable, but otherwise degenerative disorder. Wilson's disease typically presents with liver disease in the pediatric population, especially before the age of 12 years. The neurological and psychiatric presentations are more typical of adolescent and adult patients. When suggested by the clinical impression, testing for other diseases (e.g., Lesch–Nyhan syndrome, pantothenate kinase associated neurodegeneration (PKAN)), should be performed. However, this group of diseases typically involve other neurological symptoms or signs in addition to dystonia.

Dystonia may result from acquired injuries to the basal ganglia. In the pediatric population this is typically from a perinatal hypoxic–ischemic insult. Dystonia is also seen in patients with Kernicterus. In these later two conditions, even though the insult occurs in the neonatal period, it is typically only in early to mid childhood that the patients develop dystonia, often accompanied by choreoathetosis. Other acquired conditions may lead to dystonia include basal ganglia stroke, hemorrhage, tumor, and exposures to medications such as neuroleptics.

Other types of hyperkinetic movement disorders are part of the differential diagnosis; the most important being essential tremor. As previously mentioned, tremor may be a clinical feature of DYT1 dystonia and could resemble the postural and kinetic tremor of essential tremor. The presence of a tremor, especially if there is a positive family history suggesting an autosomal dominant mode of transmission, may lead to an erroneous diagnosis of essential tremor. A few characteristics of the tremor may help the clinician to differentiate these two entities: in the case of a dystonic tremor, the tremor is typically irregular both in amplitude and frequency, it has a directional nature, there may be a null point and the patient may use a sensory trick (geste antagoniste) to reduce the intensity of the tremor. In the case of an essential tremor, all of the above mentioned characteristics are absent. The other hyperkinetic movement disorders are tics, chorea, and myoclonus. They are less often mistaken for dystonia. Certain tics may have dystonic features (dystonic tics), but the association with an urge, the ability to temporarily suppress, the lack of predictability and ability to reproduce them with specific actions all help in differentiating them from dystonia. Chorea, on the other hand is primary distinguished from dystonia by its random quality, its dance-like pattern and its unpredictability. Myoclonus is very rarely confused with dystonia because of its rapid, shock-like jerks, although there is an overlap syndrome of myoclonus-dystonia, and patients with primary dystonia may have superimposed myoclonic jerks. These are typically, although not always, longer than 100 ms.

Dystonic movements may also be the presentation of a psychogenic movement disorder. Clinical features which support a psychogenic movement disorder are distractibility, inconsistent movement(s), and entrainment, in the case of a tremor. Abrupt onset, association with a trigger (e.g., stressful event), history of psychiatric condition(s), multiple unexplained medical complaints, and la 'belle indifference' may also be present in a psychogenic movement disorder. These may be present in primary dystonia as well, however. Further certain interesting characteristics of a physiologic dystonia can be falsely interpreted as psychogenic despite that they are known features of dystonia: movement specific dystonia (e.g., dystonia of the foot present when walking forward and not backward), presence of a sensory trick and of a null point in case of a dystonic tremor. Moreover, it should be kept in mind that these two

Table 1 Inherited primary dystonia: primary dystonia syndromes and dystonia-plus syndromes

Type	*Epidemiology*	*Age of onset*	*Clinical features*	*Gene/ Chromosome/Protein*
Autosomal dominant primary dystonia				
DYT 1 Dystonia musculorum deformans; Oppenheim's dystonia	Most common primary dystonia; 50% of EO dystonia in non-Jews; 90% in Ashkenazi Jews	Usually childhood Mean age = 12.5 years	Limb onset (typically LE), evolution to generalized or multifocal dystonia	TOR1A/9/Torsin A
DYT 4 Whispering dysphonia	Single large Australian family	13–37 years	Laryngeal and cervical dystonia	Unknown
DYT 6	Mennonite families	Mean age = 18.9 years	Focal or segmental, craniocervical involvement, possible evolution to generalized dystonia	THAP1/8/THAP1
DYT 7	Single German family	Adult	Focal (cervical, laryngeal, limb, blepharospam), postural tremor	Unknown/18/Unknown
DYT 13 Multifocal and segmental dystonia	Single Italian family	Mixed Mean = 15.6 years	Semental dystonia with cranio-cervical, upper extremity dystonia	Unknown/1/Unknown
Autosomal recessive primary dystonia				
DYT 2		Childhood onset	Generalized or segmental	Unknown
DYT 17	Single Lebanese family	Adolescence to early adulthood	Initially cervical dystonia, evolution to segmental or generalized dystonia	Unknown/20/ Unknown
X-linked recessive primary dystonia				
DYT 3 Dystonia-parkinsonism 'Lubag'	Predominantly males from Panay Island in Philippines	4th or 5th decades	Segmental or generalized dystonia with parkinsonism	DYT3/TAF X (gene is multiple transcript system)
Dystonia-plus syndromes				
DYT 5 DRD/ parkinsonism Segawa	F > M	Childhood Mean = 6 years Earlier, often in infancy	Foot dystonia, diurnal fluctuation, +/− parkinsonism, dramatic response to levodopa	(Autosomal Dominant) GH1/14/GTPCH1 (Autosomal Recessive) TH/11/Tyrosine hydroxylase
DYT 11 Myoclonus dystonia		Childhood to adolescence	Myoclonic jerks with variable features of dystonia; very EtOH responsive	SGCE/7/ε-sarcoglycan
DYT 12 Rapid-onset dystonia-parkinsonism	Very rare	From childhood to adulthood	Abrupt onset of dystonia (predominantly of bulbar muscles) and parkinsonism	ATP1A3/19/Na/K-transporting ATPase α-3 chain

EO, early onset; EtOH, ethanol; F, female; LE, lower extremities; M, male.

entities are not mutually exclusive and there may be elaboration in a patient with primary dystonia.

Diagnostic Work-up/Tests

As for any other etiology of dystonia, a detailed family history and detailed medical history, inquiring about past and current use of medications especially dopamine blocking agents (which may have been prescribed for psychosis, depression, anxiety, sleep, or as anti-emetics).

The diagnosis of DYT1 dystonia is made by molecular genetic testing for the only mutation known to cause this condition: the GAG deletion in the TOR1A gene. Such testing is available through some academic laboratories and commercially. Counseling regarding risk to family members and the meaning of a negative test, particularly that it does not mean that the dystonia is not genetic, should be performed in all cases. This should be done by a trained genetics counselor or physician. Physicians are encouraged to refer patients to genetics counselors as there are many implications both for the individual and the family.

Structural imaging of the brain, preferably an MRI, should be considered to exclude secondary etiologies. Testing for Wilson's disease should be performed in all patients presenting with dystonia before the age of 50 years or regardless of the age of the patient, even more so if there are suspicious associated clinical features (liver disease, psychiatric symptoms, dysarthria, etc.). This evaluation should include serum ceruloplasmin (falsely negative in ~5% of cases), ophthalmology consultation with slit lamp exam to assess for Kaiser–Fleisher rings (present in almost all patients with neurological symptoms and/or signs), and a 24-h urine collection for copper may be considered.

A levodopa trial for possible DRD is strongly recommended in early-onset patients, patients with a progressive 'cerebral palsy' phenotype, and those with a family history of dystonia and/or parkinsonism. Even in older patients, this diagnosis should be kept in mind and a therapeutic trial of levodopa should be considered in patients with diurnal fluctuations.

Complementary investigations depend on the clinical findings and are performed when indicated. For example, a metabolic work-up should be performed in a child with dystonia and episodes of metabolic decompensations in order to rule out or in, among other diseases, organic aciduria (e.g., methylmalonic aciduria, proprionic aciduria).

Management

As noted, in patients with suspected DYT1 dystonia as well as in any young patient with dystonia, a levodopa trial should be considered. Patients with DRD will improve dramatically with a low dose of levodopa, usually within a few weeks.

The mainstay of treatment of generalized dystonia not due to DRD (e.g., DYT1 dystonia and non-DYT1 primary dystonia) consists primarily of oral medications, although more recently surgical intervention is being started earlier. Anticholinergic medications, especially trihexyphenidyl, benzodiazepines, and lioresal are effective in treating dystonia. Double-blind studies are limited, however, with trihexyphenidyl constituting the best studied. In the pediatric population trihexyphenidyl may be well tolerated, even at high doses. The primary trihexyphenidyl trial used doses up to 30 mg/day, although higher doses are frequently used in children. In adults, the side effect profile may limit the dose and cause intolerable side effects before any benefit occurs. The dose of anticholinergic agents are titrated up until efficacy or until undesirable side effects occur, typically short-term memory loss, sedation, confusion, hallucinations, dry mouth, urinary retention, and constipation. While the peripheral anticholinergic side effects may improve with the addition of a peripheral procholinergic such as pyridostigmine, if cognitive side effects are primary, then the medication usually is decreased or discontinued.

Benzodiazepines, and especially clonazepam, are used in the treatment of dystonia, typically in combination with trihexyphenidyl, and with or without lioresal. The doses are increased gradually until efficacy is achieved. The principal side effect is drowsiness, although behavioral changes may also be prominent. Lioresal is also frequently used in the treatment of DYT1 dystonia, often in combination with trihexyphenidyl with or without clonazepam. The doses are increased until efficacy is obtained, undesirable side effects appear or the maximum recommended doses are achieved. The main side effects of this medication are sedation, confusion and drowsiness. If baclofen is not tolerated or ineffective, the dose should be tapered as sudden discontinuation can cause severe reactions, including seizures. If oral baclofen is effective but side effects are limiting the dosage used, it is possible to administer baclofen intrathecally, although this is usually reserved for patients with mixed spasticity and dystonia, as occurs in cerebral palsy. However, this mode of treatment is seldom used for primary dystonia, because patients with DYT1 dystonia respond so well to deep brain stimulation (DBS) of the globus pallidus interna.

Botulinum toxin injections are the treatment of choice for most focal dystonia. In the case of generalized dystonia, botulinum toxin may be used in certain problematic muscles if oral medications fail or produce a suboptimal response.

DBS is a relatively new treatment modality for movement disorders, and it is debated how early in the course of disease individuals should receive DBS. For dystonia, DBS electrodes are implanted in the globus pallidus internal segment bilaterally, and programming of the continuous electrical stimulation of these structures is done to optimize the response. DBS is been used in different type of movement disorders including Parkinson's disease, dystonia, tremor, and more recently tics (Tourette's syndrome). The region implanted and stimulated is different from one disease to another. Because of the possible serious although infrequent (1–2%) side effects (infection, stroke, intracranial hemorrhage, including fatal hemorrhage), this treatment modality is usually reserved for patients who failed medical therapy. DBS has been shown to be very effective in patients suffering from DYT1 dystonia, although a recent study suggests that the response for primary dystonia is excellent even among non-DYT1 individuals.

Supportive treatment is also of importance, including physiotherapy, exercises programs, psychological support for the patient and family. Genetic counseling is also suggested. The later is often challenging because of the low penetrance of this condition. Even though the risk of carrying the mutated gene is 50% for the patient's relatives (parents, siblings, offsprings), as much as 60–70% of

carriers will not develop the condition. In rare instances, a de novo mutation will be responsible of a patient's disease and in this particular case, only the patient's offsprings are at risk to carry the mutated gene and to possibly develop the disease. The variable expressivity of this disease adds further complexity to the genetic counseling; an asymptomatic patient may have a child with severe generalized dystonia and a patient with symptomatic generalized dystonia may have a completely asymptomatic child carrying the mutated gene. In the same line of thought, genetic testing for asymptomatic individuals with a family history of DYT1 dystonia remains a difficult dilemma because there is no presymptomatic treatment available. It is well accepted that genetic testing of an asymptomatic adult individual can be performed after a counseling session, but genetic testing for an asymptomatic child (younger than 18 years) is not recommended. Finally, prenatal diagnostic testing and preimplantation diagnostic testing is available.

Prognosis

DYT1 dystonia has a different evolution depending on the initial affected body part. In most patients presenting with dystonia of a leg, there is typically an evolution to a generalized dystonia over several months to years. On the other hand, in patients presenting with dystonia of an upper extremity, the progression is more variable and only about 50% evolve to a generalized dystonia. The rare patients presenting with dystonia of the neck or cranial muscles have also a variable progression. In general, 60–70% of patients with DYT1 dystonia progress to a generalized or a multifocal dystonia. Approximately 20% of DYT1 dystonia patients remain with a focal dystonia; and these are usually those who presented with writer's cramp. Finally, life expectancy in DYT1 dystonia is normal unless complications occur.

DYT2, Autosomal Recessive Generalized Dystonia

M San Luciano and R Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Glossary

Germinal mosaicism – It is a special form of mosaicism, where some gametes (sperm cells or oocytes) of the same individual carry a specific mutation but the rest do not. The cause is usually a mutation that occurred in an early stem cell that gave rise to all or part of the gonadal tissue. Germinal mosaicism can result in some children who are gene carriers not being affected even for a dominant disease with complete penetrance.

Pseudodominance – When an autosomal recessive condition appears in subsequent

generations, and so therefore appears to follow an autosomal dominant pattern. This usually occurs in inbred populations where there is a high frequency of an autosomal recessive founder mutation.

Definition and History

Since the 1960s there is accumulating evidence that most familial primary generalized dystonias are inherited in an autosomal dominant fashion with decreased penetrance and variable expression.

The occurrence of autosomal recessively inherited primary generalized dystonia has been and still is a matter of debate. The denomination DYT2 is reserved now for those families with suspected autosomal recessive inheritance with primary dystonia syndromes. So far, only a few cases have been described. Unfortunately, follow up data and examination of other first degree relatives, brain imaging, levodopa trial, and exclusion of the now known loci for primary dystonias and other disorders are lacking in many reports. This is important, in view of the history of DYT1, in which an autosomal dominant gene with decreased penetrance and variable expression including very mild 'formes frustres' of the disease, was mistakenly described as autosomal recessive for years.

A comprehensive review by Eldridge of the torsion dystonias from 1970 made the distinction between autosomal recessive and dominant inheritance on the basis of clinical observations in large families. Eldridge proposed that the recessive form would affect patients of Jewish ancestry and affected parents or offspring in Jewish families were explained by pseudodominance. Studies of families in the United Kingdom also supported this hypothesis. However, in the following years, studies from Israel showed that familial cases had affected relatives in other generations and there were too many affected relatives without a significant increase in parental consanguinity to support such autosomal recessive inheritance. Inheritance appeared dominant with decreased penetrance and for the first time, a founder effect was suggested to account for the increase prevalence among Ashkenazi Jews. Linkage analysis assigned DYT1 to chromosome 9q32–q34. The mutated gene (*DYT1*) and the affected protein (torsinA) were identified in 1997. So far, linkage analysis and in some cases gene identification have been described for other primary dystonias, most of them inherited in autosomal dominant fashion (DYT6, DYT7, DYT13). Only one dystonia gene inherited in autosomal recessive fashion has been identified to date, the gene coding for tyrosine hydroxylase that causes dopa-responsive dystonia. However this is a dystonia-plus syndrome rather than primary dystonia, as parkinsonism, hyperreflexia and impaired cognition may be present.

The reported cases in the literature of presumed autosomal recessive primary idiopathic torsion dystonia will be reviewed here. The described cases in Ashkenazi Jews prior to linkage analysis of DYT1 were excluded.

Pathogenesis and Pathophysiology/ Clinical Features and Diagnostic Criteria

Gimenez-Roldan reported in 1976 and 1988 a total of nine cases of childhood onset dystonia, from four families of Spanish Gypsy ancestry. Three of the families had known parental consanguinity and parents and other relatives were unaffected. Most patients had lower limb onset with rapid progression to a wheelchair-bound condition without other neurological features and normal cognition. Almost all patients evolved to have cranial involvement, and many had unintelligible speech by late adolescence. All cases had normal copper studies and unremarkable pneumoencephalograms. One family was however atypical, with predominantly orofacial involvement and postural and action myoclonus of the upper extremities, which while it could represent primary dystonia, most likely had myoclonus-dystonia (see DYT11 and 15 chapters).

A family described by Santangelo in 1934 is often cited as the first report of autosomal recessive inheritance of primary torsion dystonia. Three out of five children from first cousin consanguineous parents of Italian Catholic descent were affected with generalized dystonia in childhood. However, in detail review of Santagelo's cases, the three affected members also had mental retardation, cranial nerve abnormalities, especially oculomotor disturbances including oculogyric crisis, raising the question of another etiology rather than primary dystonia.

A report from Mexico in 1984 describes three out of five affected siblings of unaffected unrelated non-Jewish parents who developed in childhood limb onset dystonia that evolved to generalized dystonia. Despite normal intelligence, central facial paresis, ptosis, supranuclear gaze palsy, and hyperreflexia were present. Liver function tests and CT scan of brain were normal in the affected members. The patients were then lost to follow up. While sometimes cited as consistent with DYT2, the additional features discount the diagnosis of primary dystonia. In another family containing three affected sibs from South Africa, the diagnosis of primary dystonia is questionable in at least one subject who had hemilateral pyramidal signs after bacterial meningoencephalitis as an infant. Other sibling had intermittent blepharospasm and lateral ocular deviation in addition to generalized dystonia. These individuals were

tested only for serum copper and ceruloplasmin levels. There was no known parental consanguinity although the family was part of an isolated inbred community.

The most recent and better documented cases include a Sephardic Jewish kindred from Iran and pair of siblings of Chaldean Babylonian descent from Northern Iraq. Kahn et al. described the three affected children from first cousin parents with normal birth histories and developmental milestones, who had onset of lower limb and trunk dystonia in childhood that spread to involve craniofacial, bulbar, and cervical muscles. They were of normal intelligence and no other neurological manifestations were described. They had a comprehensive work up that included copper and other metabolic studies, cerebral imaging, and genetic testing for DYT1, screening for epsilon-sarcoglycan mutations, spinocerebellar ataxias (SCA) 2,3,6,7; dentatorubral-pallidoluysian atrophy (DRPLA) and mitochondrial point mutations. There was no significant response to alcohol or levodopa.

Moretti et al. described a brother and sister born to consanguineous parents of Chaldean Babylonian Iraqi descent. The dystonia began in the leg and spread to involve all extremities and the trunk years and was unresponsive to levodopa. Copper studies, plasma amino acids and urine organic acids, brain imaging and blood cell lysosomal enzyme panel were normal and they did not posses the DYT1 mutation. Partial response was obtained with baclofen and benzodiazepines.

Differential Diagnosis/Diagnostic Work-up and Tests

Thus in summary, the families who meet the clinical phenotype of primary torsion dystonia include some of the Spanish gypsy families, the Sephardic Iranian and the Chaldean Iraqi sib pairs. Only the latter two families had extensive genetic testing. While the inheritance pattern suggests autosomal recessive disease, dominant inheritance with reduced penetrance, new mutations and germinal mosaicism cannot be excluded. Determining that these conditions are truly autosomal recessive will only be possible when the specific genes have been identified.

The most frequent etiology for dystonia inherited in an autosomal recessive manner is dystonia due to metabolic causes. In these cases, dystonia is not usually the sole feature and other neurologic features are often present. In all cases of childhood onset dystonia, structural etiologies must be ruled out with brain imaging. Detailed birth, developmental history, and physical examination should guide other biochemical studies such as serum amino acids and urine organic acids. All cases suspected to have a primary dystonic disorder should undergo a levodopa trial (and potentially cerebrospinal fluid (CSF) measurements of catecholamine and tetrahydrobiopterin levels) to exclude dopa-responsive dystonia. Genetic testing is available for both GCH1 and tyrosine hydroxylase mutations, although at this time, mutations are not identified in all families. Serum copper, ceruloplasmin levels and neuroophthalmological evaluation to assess for Wilson disease should be performed also in all patients with early onset dystonia of unknown etiology, especially if the pedigree suggests autosomal recessive inheritance. Testing for the GAG deletion of *DYT1* gene is advised even if the pedigree suggests recessive inheritance.

Management/Prognosis

There is ongoing debate on the existence or homogeneity of autosomal recessive primary torsion dystonia, and clearly, more data and larger families in which linkage analysis can be performed are needed. Most primary generalized dystonias are dominantly inherited; it is to date unclear if of the few, when confirmed, recessively inherited primary dystonias represent the same single disease in all reports, phenocopies or other known conditions including dominantly inherited primary dystonias, or rare different conditions.

In view of this confusion, it is prudent to treat these patients as having primary torsion dystonia with the available arsenal of antispasmodic agents, including a levodopa trial, and consideration of oral agents including anticholinergics, lioresal, and benzodiazepines. Chemodenervation and deep brain stimulation surgery may be considered in certain refractory cases.

DYT3, X-linked Dystonia-parkinsonism (Lubag)

V G H Evidente, Mayo Clinic, Scottsdale, AZ, USA

Definition and History

X-linked dystonia-parkinsonism (XDP) or 'Lubag' afflicts primarily adult Filipino men, and rarely women. It was first described in the 1970s and is believed to have originated ancestrally in the Philippine island of Panay through a founder mutation some 50 meiotic generations ago (1–2000 years ago). In the local dialect, 'Lubag' describes intermittent twisting or posturing, whereas 'Wa-eg' and 'Sud-sud' refer to sustained postures and shuffling gait respectively.

Pathogenesis/Pathophysiology

Genetics

The gene locus (DYT3) was narrowed to a 350-kb candidate region at Xq13 between markers DXS559 and DXS6673E3′. The segregating XDP haplotype consists of the following allele sizes: 200 at DXS7117; 136 or 138 at DXS6673E3′; 150 at ZNF261; 292 at DXS10017; 140 at DXS10018; 240 at DXS559, and 114 at DXS1124.

In 2003, Nolte and Müller reported that the disease gene in Lubag was a multiple transcript system (MTS) within the XDP critical region, and is composed of several of the 38 known TAF1 (TATA-box binding protein-associated factor 1) exons and an additional 5 of the then-unknown exons that lie 3′ of TAF1 exon 38. They described five disease-specific single-nucleotide changes (DSCs), specifically DSC 1, 2, 3, 10, and 12, as well as a 48-bp deletion within this MTS unique to XDP.

Using genomic sequencing analysis followed by expression analysis of XDP brain tissues, Makino et al. recently reported a disease-specific short interspersed nuclear element, variable number of tandem repeats, and Alu composite (SVA) retrotransposon insertion in an intron of the TAF1 gene, with significantly reduced expression of TAF1 and the dopamine receptor D2 (DDR2) gene in the caudate nucleus of XDP patients.

Whether an abnormal protein gene product results from the mutation in DYT3/TAF1 is unknown. Nolte and Müller hypothesized that the DYT3-specific sequence changes could contribute to the disease by influencing splicing of transcripts. Makino et al. suggested that the SVA retrotransposon insertion into the TAF1 gene may cause XDP by altering expression of TAF1 isoforms (including the neuron-specific TA14–391), possibly through DNA methylation alterations. The decreased expression of the TA14–391 isoform (and possibly other TAF1 isoforms) in XDP brains may result in transcriptional dysregulation of many neuronal genes, including DRD2.

Neuropathology

The earliest neuropathological report in one Lubag patient with dystonia-parkinsonism described neuronal loss and multifocal mosaic pattern of astrocytosis in the caudate and lateral putamen. We later confirmed the

mosaic pattern of striatal gliosis, but further noted that the gliotic patches showed dorsal to ventral, rostral to caudal, and medial to lateral gradients. The caudate was more affected than the putamen, and the caudate head was more affected than the tail. The patchy areas of striatal gliosis were not associated with microglial activation. With synaptic immunostaining, we observed that the patchy areas of gliosis corresponded with the areas of poor synaptophysin staining, suggesting that the patchy gliosis represents synaptic loss rather than neuronal loss.

Goto et al. in 2005 elegantly described their neuropathological findings on 7 XDP patients. Postmortem analyses of the basal ganglia based on striatal compartments (i.e., the striosomes and the matrix compartment) showed that in the XDP neostriatum, the striosomes are severely depleted while the matrix component is relatively spared. Thus, they proposed that the disproportionate involvement of the neostriatum striosomal compartments and their efferent projections may be responsible for dystonia in XDP.

Epidemiology and Risk Factors

More than 500 cases of Lubag have been described in literature. The prevalence is 5.24 out of 100 000 in the Panay Islands, with the highest rate of 18.9 out of 100 000 in the province of Capiz. The prevalence in the Philippine general population is estimated at 0.34 out of 100 000. The male to female ratio is 99:1. The range of age at onset is 12–64 years (mean = 39.48 years). In women, the age of onset is older (mean = 52 years; range = 26–75 years). The time from onset of dystonia to generalization ranges from 1 to 23 years (mean = 3.8 years). A family history is positive in only 94% of cases.

Clinical Features and Diagnostic Criteria

Initial Symptoms

Traditionally, based on clinical history, the presenting symptom was thought to be consistently dystonia. On longitudinal follow-up of our cohort of genetically confirmed XDP carriers, the initial presenting sign is almost universally parkinsonism. Breakdown of rapid alternating limb movements can often be appreciated on careful neurological examination in early symptomatic (or soon to be symptomatic) XDP carriers.

Tremor

Tremor, either at rest or action, can be seen in the early stages or develop later in the disease. An asymmetric limb 3–6 Hz rest tremor can be observed similar to Parkinson's disease (PD). Some patients may also have a coarse, relatively symmetric upper limb or head tremor similar to essential tremor (ET). Thus, Lubag can be misdiagnosed as PD or ET. The tremor can also involve the trunk, craniofacial region (lips, jaw, or mimetic muscles), and larynx.

Parkinsonism

Lubag patients may present predominantly with one or more parkinsonian features, including rest tremor, bradykinesia, rigidity, or postural instability. Shuffling gait, in the absence of lower limb dystonia, can be quite severe. Some patients may remain with pure parkinsonism and no dystonia for many years. In some, the dystonia develops very late in the course, and is usually focal or segmental. Some patients with parkinsonism may be levodopa responsive. The parkinsonism often persists till death, though overshadowed by dystonia.

Dystonia

The dystonia develops focally, most commonly in the jaw, neck, trunk, limbs, eyes, and larynx in that order. Individuals who have dystonia progressing to a segmental or multifocal distribution within the first couple of years usually have a more rapid course. The most characteristic dystonia in male Lubag patients is jaw dystonia, more commonly jaw-opening than jaw-closing dystonia (**Figure 1**). Neck dystonia often develops, with retrocollis being more common than torticollis, laterocollis, or anterocollis. The retrocollis can be severe along with trunk hyperextension (**Figure 2**). Tongue dystonia may develop, manifesting as either involuntary tongue protrusion or limitation in voluntary tongue protrusion (**Figure 3**). Pharyngeal dystonia (with dysphagia) usually affects those with orolingual dystonia, and may lead to significant weight loss, aspiration pneumonia, or early death. Laryngeal dystonia with stridor can also lead

Figure 3 Male Lubag patient with severe tongue protrusion dystonia, drooling, and dysarthria.

to sudden death. Patients may present with vocalizations during inspiration or expiration. Sensory tricks are often observed, particularly those with cervical dystonia, blepharospasm, or jaw dystonia (**Figure 4**).

Other Phenotypes

Lubag can also present with pure tremor (similar to ET), chorea, athetosis, or myoclonus. The chorea usually involves the distal upper limbs with some athetosis. The chorea can also be seen with the generalized phasic dystonic movements. Action myoclonus can be present in the limbs or even the craniofacial region. The myoclonus may appear like a jerky tremor.

Phenotype in Women

Female XDP carriers are mostly asymptomatic. Rarely, women may present with focal dystonia of the neck or limb, which is nonprogressive and nondisabling. The other

phenotypes in women include chorea, focal tremor, or parkinsonism. The parkinsonism is usually mild, nonprogressive, and nondisabling. Rarely, severe levodopa-responsive parkinsonism can be observed.

Differential Diagnosis

With a clear-cut X-linked recessive pattern of transmission in a symptomatic Filipino adult male with parkinsonism-dystonia, and maternal roots from the Philippine Island of Panay, the diagnosis is almost certainly Lubag or XDP. However, some patients may have an atypical course, or may not have identifiable relatives with similar symptoms, or may have no traceable maternal roots from the Panay Islands. It is the latter set of patients that may be confused with PD, Parkinson's-plus syndrome, ET, or idiopathic dystonia.

Diagnostic Work-up/Tests

Laboratory Testing

No metabolic abnormalities occur in Lubag patients. A serum thyroid stimulating hormone (TSH) level may be reasonable to test for to rule out superimposed hypothyroidism. Serum or urine toxicologic studies are unnecessary since such have been completely normal in XDP patients.

Brain Imaging

We performed brain CT/MRI on 20 symptomatic genetically confirmed Lubag patients with parkinsonism plus varying severity of dystonia. None were deemed to have any significant striatal or brainstem atrophy, while some had age-appropriate generalized atrophy or some incidental ischemic white matter changes or scattered lacunes (due to vascular risk factors). In one patient, increased signal on T2-weighted images was seen at the outer rim of the putamen.

Fluorodeoxyglucose (FDG) positron emission tomography (PET) findings in three male XDP patients with dystonia-parkinsonism consisted of selective reduction in striatal glucose metabolism, but normal $\{^{18}F\}$ fluorodopa uptake, suggesting that the extrapyramidal manifestations are metabolically localized postsynaptically to the striatum. In a separate report, $\{^{18}F\}$ fluorodopa PET in an affected male with dystonia-parkinsonism showed reduced striatal uptake, consistent with presynaptic nigrostriatal involvement. We performed FDG-PET scans on 6 men with genetically confirmed XDP; four were symptomatic (2 had parkinsonism, and 2 had generalized dystonia-parkinsonism). The cranial PET scans showed nonvisualized bilateral putamina in all 4 symptomatic patients, and normal results in the 2 asymptomatic carriers. Brain CT/MRI revealed mild generalized atrophy in 3 of the 4 symptomatic patients, and normal results in 1 of 4. Thus, symptomatic Lubag patients may have putaminal abnormalities on FDG-PET scans even in early or mild disease despite normal brain CT/MRI.

We also performed single-photon emission computed tomography (SPECT) using $\{^{123}I\}\beta$-CIT (measures dopamine transporter density) in a male Lubag patient with generalized dystonia and levodopa-responsive parkinsonism. The SPECT scan showed reduced uptake in the putamen bilaterally similar to PD, but more symmetric and less pronounced.

Fluoropropyl-carbomethoxy-iodophenyl-nortropane (FP-CIT) SPECT scan in another male patient with multifocal dystonia and levodopa-responsive marked parkinsonism showed moderate decrease of putaminal dopamine transporter activity, thus suggesting a presynaptic nigral abnormality. This was further corroborated by evidence of hyperechogenic signals in both substantia nigrae on transcranial parenchymal sonography. The same patient also had on ^{123}I-iodobenzamide (IBZM)-SPECT scan decreased dopamine D2 receptor expression in both striata, suggestive of a dopamine postsynaptic defect.
