Thus, by functional imaging, Lubag patients may have postsynaptic striatal involvement, or presynaptic nigrostriatal involvement. The first group may represent the majority of XDP patients with pure dystonia or combined dystonia-parkinsonism from the early stages, that are not levodopa responsive. The second group may represent the rarer patients with pure parkinsonism (with dystonia setting in late in the course), that appear to be more levodopa responsive.

Neurophysiology

We performed electromyography (EMG), somatosensory evoked potential studies, electroencephalography (EEG), blink reflex studies, and brainstem evoked potential studies on 10 symptomatic male Lubag patients with dystonia-parkinsonism. No abnormalities were noted. Surface EMG–EEG polygraphy was also performed. Those with a resting tremor had the same frequency of tremor (3–6 Hz) commonly seen in PD. Rarely, a slow 1–3-Hz distal limb tremor can be observed (myorrhythmia). The action/postural tremor in Lubag patients may range in frequency from 3 to 12 Hz. Two patients with myoclonus presented with brief EMG bursts (50 ms or less) that on back-averaging were time-locked to a premovement EEG surface-positive cortical potential localized to the somatosensory cortex, thus supporting the cortical origin of the myoclonus.

Olfactory Testing

We administered a culturally corrected University of Pennsylvania Smell Identification Test (ccUPSIT) consisting of 25 odor items to 20 symptomatic males with XDP and 20 control subjects matched by sex, age, educational background, smoking history, and geographical origin. The mean ccUPSIT score of Lubag patients (18 ± 3.19) was statistically lower ($p = 0.003$) than controls (20.5 ± 3.02). The small scores did not correlate with phenotype, severity of dystonia, or duration of disease. Nine of 20 Lubag patients (45%) had ccUPSIT scores below the mean, with the lowest score being 11. Our findings suggest that olfactory dysfunction may occur in Lubag patients even early in the disease.

Management

Pharmacologic Treatment of Dystonia

The most common symptom requiring treatment in Lubag patients is dystonia. When the dystonia is focal/segmental, anticholinergic agents (trihexyphenidyl or biperiden) plus benzodiazepines (particularly clonazepem) may be effective. Once the dystonia is multifocal or generalized, even polypharmacy offers only partial relief. In Lubag patients, zolpidem appears to have a robust effect on dystonia (some experience near 100% improvement of dystonia for a few hours) and a modest effect on parkinsonism. The effect may last 6–8 h per 10-mg dose in the first few weeks. Subsequently, the duration becomes progressively shorter, bottoming out at 2–3 h (corresponding to its 2.5 h elimination half-life).

Neuroleptics, particularly haloperidol, are often prescribed because of the relatively cheap cost and easy availability. However, its benefits in more advanced dystonia remains dubious, as it may lead to the extrapyramidal side effects. Risperidone seems less effective than haloperidol in controlling dystonic symptoms. Of the atypical neuroleptics, clozapine has the greatest potential to be effective. However, its use is limited by its potential to cause aplastic anemia. Tetrabenazine can improve dystonia in Lubag. Other drugs with inconsistent effects on in Lubag include gabapentin, topiramate, baclofen, and tizanidine. Botulinum toxin injections have benefited focal dystonia, particularly cervical dystonia, blepharospasm, tongue dystonia, and jaw dystonia. It can, however, worsen swallowing. Muscle afferent blocking injections using ethanol and lidocaine are much cheaper than botulinum toxin, and have been attempted in Lubag patients with cervical dystonia. They only offer very short clinical benefits (1–2 weeks), and are associated with undesirable side effects like severe pain during injections, and muscle fibrosis and contractures with repeated treatment.

Surgical Treatment of Dystonia

We reported the first successful deep brain stimulation (DBS) surgery in Lubag in 2007. The patient had parkinsonism and generalized dystonia, with severe disabling jaw-opening dystonia, drooling, dysphagia, and dysarthria. He only got partial relief with a combination of levodopa, piribedil, trihexyphenidyl, and zolpidem. The patient had a remarkable improvement of his generalized dystonia and parkinsonism after bilateral pallidal DBS, with sustained benefits 4-year post-DBS.

Prognosis

The clinical course in men with Lubag is highly variable. Those with pure parkinsonism with little or no dystonia have the best prognosis; they have nondisabling and slowly or nonprogressive symptoms. Those who develop a combination of parkinsonism and segmental dystonia in the orobuccolingual and cervical distribution early in the course (first year or two) have the worst prognosis. Such patients develop multifocal or generalized symptoms from the second to fifth years, become bedridden quite rapidly, and die prematurely from aspiration pneumonia, laryngeal stridor, or intercurrent infections resulting from being bedridden. Symptomatic women usually have a benign nonprogressive course with mild symptoms.

DYT4, Autosomal Dominant Type Dystonia or Whispering Dysphonia

M S Luciano and R Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Glossary

Dystonia – Cocontraction of agonist and antagonist muscles resulting in abnormal postures or repetitive movements.

Spasmodic dysphonia – A focal form of dystonia, associated with involuntary spasms of the vocal cords causing interruptions of speech and affecting the voice quality. It may be 'ab'ductor, with cords pulling outward, which often results in a breathy, whispery voice, 'ad'ductor, whereby the cords pull in causing breaks and a more staccato speech, or mixed abductor and adductor.

Definition and History

A large Australian family was described in 1985 by Parker et al. and subsequently by Ahmad et al. Twenty definitely affected family members through five generations were reported. Whispering dysphonia, frequently misdiagnosed as psychogenic in nature was the presenting feature in many members, acquiring the name 'hereditary whispering dysphonia'. In addition to dystonia, which is generalized in many cases, there was life threatening dysphagia in two, and early onset progressive dementia and behavioral disorders were also present in some members. A pair of siblings with indistinguishable phenotype from their other relatives had laboratory and clinical systemic evidence of Wilson's disease; however, linkage analysis excluded the Wilson's disease locus in other family members. The loci for DYT1, DYT6, and DYT7 were also excluded in these patients.

Pathogenesis and Pathophysiology

Because parent child transmission was noted in many members in five generations (although in 17 out of 20 cases, it was maternal), and there was male to male transmission, this suggested autosomal dominant inheritance with high penetrance. As mentioned above, in 1999, linkage analysis excluded the known loci of DYT1 ('early-onset dystonia'), DYT6 ('intermediate onset dystonia'), and DYT7 ('adult-onset dystonia'). Unfortunately, no other similar families have been described to date with similar phenotype, and specific genotype information is lacking. The pathophysiology of this type of generalized dystonia is unknown, but dysfunction of the basal ganglia or their pathways is suspected, as in other primary dystonias. Evidence of dysfunction of copper metabolism in two affected members may explain the disease in those two individuals, but normal biochemical status despite penicillamine therapy in the other relatives makes this explanation uncertain. The rostro-caudal spread of symptoms and prominent bulbar features is also suggestive of rapid-onset-dystonia-parkinsonism (RDP, DYT12). No reports suggest that testing for this condition was ever performed.

Clinical Features and Diagnostic Criteria

The Australian family described was of non-Jewish English origin and had no known consanguinity. Age of onset ranged between late childhood and early adulthood with most patients expressing the disease in their twenties. In all but three patients, dystonia affected speech first. Out of the three patients who did not have speech onset, two had torticollis and one obligate carrier had questionable foot and axial dystonia. Most living patients at the time of the report had mild focal or segmental dystonia.

In the original description of this family, choreiform involuntary movements are described in the older generations, and there was a consideration of an atypical Westphal variant of Huntington's disease. Sustained involuntary postures suggestive of torsion dystonia were more evident in the younger generation.

One case described at length in Parker et al. had onset of dystonia as transient torticollis and spasmodic dysphonia. In addition, he had low IQ and reported deviancy. His mother, who died young at an age of 43 of pneumonia, was thought to have Huntington's disease because of choreiform movements heralded by whispering dysphonia since early adulthood and early progressive dementia with features of aggression and mood disorders that lead to several suicide attempts. Another relative who died prior to the introduction of neuroleptic agents is also described with early onset dementia, no audible speech, and 'champing' movements of the jaw. Her daughter also developed a mood disorder followed by chorea and progressive dementia in her forties, but she received antipsychotic therapy.

Interestingly, a pair of siblings presented with hemolytic anemia, persistently abnormal liver function tests, and thinning of bones. Biochemical testing and liver biopsy confirmed Wilson's disease. Ataxia, labile mood, and severe dystonia followed the systemic manifestations including severe dysarthria and a sardonic smile. Other affected relatives did not have biochemical evidence of copper metabolism dysfunction.

Differential Diagnosis and Diagnostic Work-up/Tests

As with the other forms of dystonia, especially when presenting with craniobulbar and psychiatric symptoms and in view of the sibling pair mentioned earlier, Wilson's disease must be ruled out with appropriate biochemical and pathologic studies.

Presence of early-onset progressive dementia and mood and behavioral disorders is highly unusual for other primary dystonic disorders. However, it is relatively common for some neurodegenerative conditions such as Huntington's disease or panthotenase-kinase associated neurodegeneration (PKAN). Magnetic resonance imaging will show structural etiologies and iron accumulation. Genetic testing with appropriate counseling for Huntington's disease in individuals with dystonia, mood disorders, and cognitive decline may be considered.

There is no confirmatory test for this particular and rare condition. No specific imaging abnormalities were reported.

Management/Prognosis

Penicillamine therapy provided only minimal improvement in the siblings with documented Wilson's disease. Dopaminergic as well as chelation therapy was ineffective in other affected family members. One patient who was bedridden with generalized dystonia had marked improvement following stereotactic thalamotomy, but within a few years, her symptoms of leg and neck dystonia returned.

The prognosis in many of the reported subjects was of relatively rapid progression at onset followed by stabilization, with the exception of the affected members with progressive rapid dementia or severe dysphagia.

This family represents the first evidence for the now known locus heterogeneity for autosomal dominant inherited idiopathic torsion dystonia. However, the presence of two members with documented Wilson's disease and other members with progressive early-onset dementia and severe behavioral abnormalities may suggest neurodegeneration or an alternative etiology rather than a primary dystonia syndrome.

Glossary

Diurnal fluctuation – Improvement in the morning after sleep and deterioration at night.

Drug-induced dyskinesias – Hyperkinetic abnormal movement disorder as a side effect of medication(s).

Dyskinesia – Hyperkinetic abnormal movement disorder classically characterized by choreic movements, although the term can comprise the range of hyperkinesias including tics, dystonia, myoclonus, chorea, and tremor.
Dystonia – Dystonia is characterized by sustained twisting and posturing movements. Contractions of agonist and antagonist muscles cause these involuntary repetitive movements or abnormal postures.
Generalized dystonia – Dystonia involving both legs (or one leg and the trunk) and at least one other body region.
HUGO (Human Genome Organization) – An international organization of scientists promoting international collaboration within the Human Genome Project.

Definition and History

Dystonia is a syndrome characterized by sustained muscle contractions, producing twisting and repetitive movements or abnormal postures. The movements tend to be directional in nature. Dystonia can be classified as primary or secondary. In primary dystonias, dystonia is the only neurologic feature (except tremor, which may also be present). There is no laboratory or imaging data to suggest an acquired or degenerative cause, there is no sustained response to levodopa, and there is no history implicating an environmental, structural, or pharmacologic cause. An example of primary dystonia is DYT1 or Oppenheim dystonia. Secondary dystonias, on the other hand, are characterized by neurologic features in addition to dystonia and/or by the presence of a secondary etiology (acquired forms of dystonia). Dystonia related to metabolic disorders, heredodegenerative diseases, mitochondrial disorders, and toxic environmental exposures often show abnormalities of the basal ganglia on neuroimaging. However, patients with some secondary dystonias have normal neuroimaging. In this latter category are several rare disorders termed 'dystonia-plus' syndromes, which are caused by genetic defects that result in dystonia in association with another movement disorder. The dystonia-plus syndromes include dopa-responsive dystonia (DYT5), myoclonus-dystonia (DYT11) and rapid-onset dystonia and parkinsonism (DYT12).

DYT5 dystonia is classified in the dystonia-plus category, as it may be associated not only with dystonia and tremor but also with parkinsonism, spasticity, and hyperreflexia. It is commonly known as dopa-responsive dystonia because of its very dramatic response to low-dose levodopa. The condition was first described by Segawa in 1970, who reported about several girls with childhood onset dystonia with diurnal fluctuations and good response to levodopa, and hence is known as Segawa's disease. While most DYT5 dystonia is autosomal dominant (AD) GTP cyclohydrolase 1 deficient dopa-responsive dystonia (DYT5a), rarer autosomal recessive (AR) forms have also been identified (DYT5b). The HUGO designation DYT14 was given to a form of dopa-responsive-dystonia (DRD), which is actually due to DYT5, therefore DYT14 is no longer used, and DYT14 dystonia should be considered DYT5.

Pathogenesis/Pathophysiology

DYT5 is usually inherited in an AD fashion, and caused by mutations of the *GCH1* gene (DYT5a) encoding for the GCH1 enzyme (GTP cyclohydroxylase 1). GCH1 catalyses the first and rate-limiting step in the synthesis of tetrahydrobiopterin (BH4). BH4 is an essential cofactor for the enzymes phenylalanine hydroxylase and tyrosine hydroxylase (TH), which convert phenylalanine to tyrosine and tyrosine to levodopa, respectively. TH is the rate-limiting step in the synthesis of dopamine. It is important to note that, GCH1 activity is reduced in peripheral cells in GCH1 mutation carriers without disease, and the correlation between GCH1 activity and development of dystonia and/or parkinsonism is poorly understood. Because the penetrance is markedly increased in girls and women (3–4:1 compared to men and boys), it is assumed that activity may be modulated by gender specific factors, although this has not been definitively demonstrated. BH4 is also a cofactor for the aromatic amino acid tryptophan hydroxylase (which is responsible for the conversion from tryptophan to serotonin), as well as nitric oxide (NO) synthase, although the role of serotonin and NO in the DRD phenotype is not clear.

No nigral cell loss is demonstrated in brains of DYT5 patients, and no Lewy bodies are detected, however, neurochemical analysis shows striatal dopamine reduction which is thought to be due to both decreased TH activity from low BH4 as well as to loss of striatal TH protein, possibly by lack of regulation of BH4 on TH.

AR forms of dopa-responsive-dystonia (DYT5b) also exist, although these are rare. TH deficiency is inherited in an AR manner. TH is the enzyme catalyzing the first and rate limiting step in the synthesis of catecholamines (dopamine, norepinephrine, and epinephrine). It is responsible for the conversion of tyrosine into dopa, the precursor of dopamine.

Epidemiology/Risk Factors

The prevalence of DYT5a mutation is ~0.5 individuals per million in England and Japan. It has been described in

diverse ethnic groups, and no strong founder mutation is reported. Spontaneous mutations may be common, while AD mutations of the *GCH1* gene have an incomplete sex-related penetrance. Penetrance is increased in girls and women compared to boys and men, giving a female to male ratio of ~3–4:1.

Clinical Features and Diagnostic Criteria

DYT5a: GCH1 Dopa-Responsive Dystonia

GCH1 typically presents in childhood from age 1 to 12 (mean age is ~6 years). Children often develop early toe walking, and may have flat feet. Leg dystonia (equinovarus posture) causes gait difficulties and a tendency to fall. The hallmark of this disease is the diurnal fluctuation. Patients are typically better after sleep in the morning, and their symptoms are worse at night. If they are not treated, they experience a gradual progression of their dystonia, and this can lead patients to be wheelchair bound until treatment with levodopa is initiated. The dystonia typically remains more severe in the lower extremities, although trunk and arms (and less often, cervical muscles) may become involved. With progression, the diurnal fluctuation becomes less prominent. Patients may have brisk deep tendon reflexes in the lower extremities, ankle clonus and striatal toe (i.e., dystonic extension of the big toe). Unlike TH deficiency (DYT5b), cognition is normal. Some patients develop parkinsonism in addition to the dystonia, with tremor (either postural or rest) and sometimes postural instability. Dramatic and sustained response to low doses of levodopa is characteristic. It is important to note that these patients do not usually develop long-term motor fluctuations which occur in young-onset parkinsonism, although dose-dependent dyskinesias which improve with lower doses may occur.

DYT5a can also present in older patients; they may develop parkinsonism in isolation or with mild dystonia, for example, writer's cramp. Rarely DRD can present in adult patients with a focal dystonia (e.g., oromandibular, cervical, etc.).

There is a wide intra and interfamilial variability in the clinical presentation. For example, within the same family, one member can have a typical DRD presentation with spastic and dystonic gait, while another may present with adult-onset parkinsonism responding dramatically to levodopa.

DYT5b: TH Deficiency

AR TH deficiency is a rare disease with a wide range of clinical presentation, from mild to severe. At the milder end of the spectrum, TH deficiency presents as dopa-responsive dystonia, possibly with diurnal variation. Patients at the other end of the spectrum have severe disease and present with infantile parkinsonism poorly responsive to levodopa, oculogyric crises, truncal hypotonia with appendicular hypertonia, severe global developmental delay, cognitive impairment, and ptosis.

Differential Diagnosis

DYT5 or DRD is usually due to AD GCH1 deficiency (DYT5a) and rarely due to AR TH deficiency (DYT5b). Compared to DYT5a, DYT5b is typically more severe and is not more common in females. Cerebrospinal fluid (CSF) pterins (biopterin and neopterin) are useful to differentiate these two conditions (see 'diagnostic work-up/tests' section below for more details).

AD sepiaterin reductase (SR) deficient DRD (very rare) is an early-onset disorder which may present similarly to DRD (see **Table 1**).

Allelic disorders of DYT5a are worth mentioning in the differential diagnosis, even if the clinical presentation is somewhat different. Patients with AR GCH1 deficiency typically present in the first 6 months of life with severe neurological dysfunction (seizures, developmental delay, mental retardation, truncal hypotonia, appendicular hypertonia, involuntary movements) and a BH4 dependent hyperphenylalanemia. The treatment of this condition includes BH4 as well as neurotransmitter replacement. Dystonia with motor delay is an intermediate disease between the AD and AR forms of GCH1 deficiency. The patients reported with this phenotype were compound heterozygotes. These patients present with motor delay, truncal hypotonia, and limb dystonia progressing to generalized dystonia without hyperphenylalanemia.

Other causes of dystonia are also important in the differential diagnosis, including primary dystonias, and especially DYT1 or dystonia musculorum deformans. Secondary causes of dystonia may also be considered, including early onset parkinsonism. Early in the presentation of PARK2, for example, dystonia may be the prominent feature. Although with PARK2, the onset is usually slightly older (see **Table 1**). Other syndromes with dystonia and parkinsonism include the rare, rapid-onset dystonia parkinsonism or DYT12, a condition differentiated from DYT5 by the abrupt onset of symptoms, but mainly by the absence or suboptimal response to levodopa, and the Westphal variant of Huntington disease. Additional secondary causes of dystonia include acquired (e.g., hypoxic–ischemic encephalopathy, dyskinetic cerebral palsy, kernicterus as well as basal ganglia stroke, hemorrhage, tumor, etc.) and inherited causes (e.g., Wilson's disease, organic acidurias, pantothenate kinase associated neurodegeneration (PKAN), Lesch Nyhan, etc.).

Another group of diagnoses to consider is the group of diseases causing gait disorders in the pediatric population such as spastic diplegia and hereditary spastic paraparesis. Spastic diplegia is a form of cerebral palsy occurring

Table 1 Differential diagnosis of dystonia responding to levodopa

	GCH1 (DYT5a)	*TH (DYT5b)*	*DYT1*	*PARK2 (Parkin)*[a]	*SR*
Inheritance	AD, reduced penetrance	AR	AD, reduced penetrance	AR[b]	AR
Gene	Heterozygous mutations in *GCH1* in many	Heterozygous mutations in *TH* (11p15)	Heterozygous GAG deletion in *DYT1*	Homozygous or compound heterozygous *parkin* mutations	Homozygous or compound heterozygous *SPR* gene mutations
Testing	Screening for *GCH1* in select laboratories	Sequencing/CSF	Commercially available	Screening for some *parkin* mutations in select laboratories	Commercially available molecular testing (sequencing)
Age of onset	6 years (infancy to 70s)	First decade	13 years (4–60s)	Adolescence (7–50s)	First decade
Initial presentation	Leg > arm or trunk action dystonia, gait dystonic, and often spastic with toe walking	Gait disturbance attributable to dystonia in leg, flexion-inversion of foot, cognitive impairment	Arm or leg action dystonia, occasionally trunk or neck	Foot/leg > hand/arm dystonia, rest tremor, akinesia/rigidity	Motor delay, truncal hypotonia and appendicular hypertonia, cognitive delay, oculogyric crises +/− bulbar involvement, dystonia, +/− parkinsonism, +/− chorea,
Diurnal fluctuation	Common	Yes	Rare	May occur but usually not dramatic	Yes
Bradykinesia	Yes (maybe mild)	Yes	No	Yes	Some patients
Postural instability	Yes	Variable	No	Yes	Some patients
Initial levodopa response	Excellent (low dose)	Variable, some nonresponsive, some complete	Inconsistent, and usually not dramatic	Excellent and low to moderate dose	Yes, may be incomplete
Long-term	Sustained (infrequent dyskinesias)			Dyskinesias often prominent, motor fluctuations	
CSF					
HVA	⇓	⇓	Normal	⇓	⇓
Biopterin	⇓	Normal	Normal	⇓	⇑
Neopterin	⇓⇓	Normal	Normal	Normal	
Others					⇑ Sepiapterin ⇓ 5-HIAA
F-DOPA PET	Normal		Normal	Abnormal	
Prognosis	Sustained excellent response, near-complete resolution in most	Generalization	Progression, then stabilization	Slow to moderate progression	Good response to levodopa and serotonin, although cognitive or motor limitations persist

[a]PINK1- and DJ-1, also cause early onset parkinsonism and may also present with dystonia – see these sections.
[b]The role of heterozygous *parkin* mutations is debated, although most likely such mutations are disease causing.
GCH1 = GTP cyclohydrolase 1; 5-HIAA: 5-hydroxyindoleacetic acid; SR: Sepiapterin reductase; TH = tyrosine hydroxylase; HVA = homovanillic acid; AD = autosomal dominant; AR = autosomal recessive.

typically in expremature infants. The imaging correlate is periventricular leukomalacia. The history of prematurity and complicated perinatal history, together with the typical toe walking gait with or without motor delay and the abnormal imaging help to differentiate this condition from DRD. Further, while there may be a delayed onset of movement disorders in cerebral palsy (CP), it does not worsen as untreated DRD does. Hereditary spastic paraparesis is differentiated mainly by the quality of the gait; spastic with circumduction instead of dystonic with posturing of the foot or feet. Moreover, patients with spastic paraparesis do not have the typical diurnal fluctuation present in DRD patients. When there is any doubt regarding the diagnosis, a trial of levodopa should be performed to confirm the presence or absence of DRD, a treatable disease.

Finally, as with other causes of dystonia, a psychogenic movement disorder remains in the differential diagnosis. However, many individuals with DRD have been mistakenly labeled psychogenic and not treated with L-dopa, and the diagnosis of DRD should be seriously entertained in patients with possible DRD.

Diagnostic Work-up/Tests

It is critical to take a careful family history for all forms of movement disorders in all patients. Detailed past and current medication history should also be ascertained to eliminate the possibility of a tardive syndrome (e.g., tardive dyskinesia secondary to neuroleptics or antiemetics).

Brain imaging is usually performed in order to eliminate other causes of dystonia. It is also useful to differentiate DYT5 from periventricular leukomalacia, which can present with spastic diplegia. In DYT5, the brain imaging is normal. SPECT and PET imaging may help distinguish DRD from early-onset PD (see **Table 1**).

Investigations for Wilson's disease are usually undertaken because it is a treatable disease: serum ceruloplasmin, ophthalmologic evaluation for Kayser–Fleischer rings, and 24 h urine collection for copper. Wilson's disease typically presents with liver dysfunction in the prepubertal child; the neuropsychiatric presentation is more typical of adolescent and adult patients. Other investigations for the secondary causes of dystonia (e.g., metabolic work-up including urine organic acids, uric acid, etc.) should be performed for patients where the diagnosis is unclear and if a specific condition is suspected (e.g., if there are episodic decompensations suggesting a diagnosis of organic aciduria such as methylmalonic aciduria, or if there are symptoms such as automutilation, suggesting a diagnosis of Lesch Nyhan, etc.).

CSF studies, and more specifically the CSF pterins (biopterin and neopterin) and catecholamine metabolites, may be helpful in the diagnosis of DRD. However, these investigations are available in only a few laboratories, and may be difficult to obtain. CSF homovanillic acid (HVA) is reduced in GCH1 and TH deficiency. CSF biopterin and neopterin are both reduced in GCH1 deficiency, but are normal in TH deficiency. In PARK2 (young onset parkinsonism due to mutations in the *parkin* gene), biopterin is reduced and neopterin is normal (see **Table 1**). As samples must be collected in special tubes, contacting the laboratory is imperative prior to performing the lumbar puncture.

Molecular genetic testing for *GCH1* gene mutations can be performed as it is available on a clinical basis for suspected symptomatic patients. Even in an asymptomatic individual at risk for this disease (e.g., a family member of a known case of DYT5), it is reasonable to consider molecular genetic testing. However, even if a mutation in the *GCH1* gene is identified, the individual will not necessarily develop the disease as it is only partially penetrant. Moreover, there is no way to predict which patients with the mutated gene will develop the disease and which patients will not. Further, mutation sequencing does not identify all individuals with DRD (the range is from 20 to 80%) although when screening for deletions and screening of promoter sequences is performed, the likelihood of identifying a mutation is increased.

Abnormal peripheral activity of liver phenylalanine hydroxylase demonstrated by the phenylalanine loading test has also been suggested to screen for DRD, but both false-positives and false-negative findings have been reported. Measurement of GCH1 enzyme activity in cultured fibroblasts may eventually help with diagnosis, but at this time it remains limited to a few labs.

Because of the potential false negatives with gene testing and phenylalanine loading, the diagnosis of DRD can be most reliably made by the dramatic and sustained reversal of symptoms with an empiric trial of low dose levodopa.

Management

The mainstay of treatment is with low-dose levodopa (combined with a decarboxylase inhibitor, either carbidopa or benserazide). The suggested initial doses are of $\leq$25 mg per day levodopa in children and 50 mg per day in adults. The adult initial dose can be increased by 50 mg every few days, until there is a dramatic response or up to 300–600 mg. The pediatric dose needs to be increased by smaller increments. While most patients will have a response to 300 mg of levodopa, infrequent patients respond better at higher doses. Some patients will experience early dyskinesias which subside with a dose reduction. The effective doses used to treat these patients are typically low, and patients will not develop long-term motor fluctuations such as wearing-off and dose-failures. Of note, all patients respond to levodopa, even if the treatment is delayed, although these patients may require higher dose and take longer to achieve benefit.

Prognosis

GCH1-deficient DRD, if appropriately diagnosed and treated, has a very good prognosis. In fact, these patients respond extremely well to low doses of levodopa; their response is sustained, and they do not develop motor fluctuations over time. The association between DRD and psychiatric features has not been well-established, although concerns about comorbid depression and anxiety have been raised, as BH4 is also a cofactor for the synthesis of serotonin from tryptophan.

In contrast to the excellent response to L-dopa in GCH1 deficient DRD, patients with TH deficiency may have a worse phenotype. Patients with the milder form typically respond well to levodopa. At the other end of the spectrum is the severe form of the disease with significant neurological dysfunction resulting in important impairments and for some patients in a reduced life expectancy. These children do not respond well to levodopa and may even not respond at all. Some of these patients will develop side effects of the levodopa therapy (e.g., gastrointestinal side effects and motor fluctuations, including dyskinesias).

DYT6, Mixed Phenotype Primary Dystonia

R Saunders-Pullman and M San Luciano, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Glossary

Mixed phenotype – DYT6 was described as mixed, as it shared features with DYT1, early onset dystonia, particularly arm involvement, and early onset, as well as with adult onset dystonia and the prominent cranial and cervical involvement, which is infrequently seen in DYT1.

Primary dystonia – Dystonia is characterized by sustained patterned involuntary cocontractions of agonist and antagonist muscles resulting in abnormal postures and repetitive movements. Primary (torsion) dystonia is defined when dystonia is the only abnormality present, with the exception of tremor, and no known metabolic, structural, or toxic etiology is identified.

Definition and History

Since the 1960s, it has been demonstrated that most familial primary generalized dystonia primary torsion dystonia (PTD) is inherited in an autosomal dominant fashion with decreased penetrance and variable expression. Until the recent discovery of the DYT6 gene, only one gene for primary dystonia was known, DYT1, and only four loci for primary dystonia were mapped, including DYT7 and DYT13.

Almasy et al. mapped the DYT6 gene for PTD to chromosome 8p21–q22 in two apparently unrelated Amish-Mennonite families (M and C) who shared a haplotype of marker alleles across a 40 cM linked region. The identical haplotypes segregating with PTD suggested a common ancestor. Fifteen affected Amish-Mennonite family members were reported, and the dystonia was characterized by a relatively early but broad age of onset (mean 18 years, SD 10.9, range 5–38 years). The body regions first affected included the cranial muscles, neck, arm, and rarely the leg; almost all had some degree of progression of dystonia to other body regions, but this varied widely. In 2006, five additional members from the original families were characterized and contributed to the knowledge of the phenotype. In addition, three other multiplex Amish-Mennonite families were identified and tested for the known DYT6 haplotype and for recombination events. One of the three new families (Family R) carried the shared haplotype, whereas the region was excluded in the two other families, suggesting genetic heterogeneity for PTD in the Amish-Mennonites. Genotyping of additional markers in the DYT6-linked families revealed recombinations that placed the gene in a 23 cM pericentromeric region between markers D8S2317 and D8S2323 on chromosome 8.

In 2009, based on the Amish-Mennonite families (M, C, and R), Fuchs et al. reported that a mutation in the *THAP1* gene is responsible for DYT6 dystonia. They also showed that mutations in DYT6 are responsible for mixed phenotype dystonia in non-Amish Mennonite families.

Pathogenesis and Pathophysiology

DYT6 is inherited in an autosomal dominant manner with reduced penetrance and variable expressivity. The penetrance is estimated to be approximately 60%. While DYT6 is more common in women, it appears that the penetrance does not depend on gender.

In the three families of Amish-Mennonite origin, M, C, and R, a 5bp insertion/3bp deletion mutation resulting in premature termination of the THAP1 protein was discovered. In addition, the same mutation and disease haplotype was identified in additional family with more remote Amish-Mennonite ancestry supporting that this mutation is a founder mutation in this population. In addition, a different mutation, an exon 2 missense mutation was also identified in a German family without Amish-Mennonite ancestry. This suggests that *THAP1* plays a role in PTD families of diverse origins and is responsible for a portion of PTD in beyond those of Amish-Mennonite background.

The role of THAP1 in causing dystonia is not clear. THAP1 is a member of the recently described family of cellular factors sharing a highly conserved atypical zinc finger THAP domain. Through its DNA binding domain, THAP1 regulates endothelial cell proliferation. Analysis of the three-dimensional structure of the THAP domain from human THAP1 showed four Zn-binding residues participating in zinc finger formation, as well as a number of critical residues for DNA binding. Both the frameshift mutation in families M, C, and R, as well as the missense mutation in family Cr are likely to be sufficient to abolish the DNA binding activity of THAP1. The loss of DNA binding should cause transcriptional dysregulation, which is believed to affect downstream targets.

THAP1 has also been described to function as a nuclear proapoptotic factor, and in vivo, it interacts with prostate apoptosis response 4 protein (Par-4). Par-4 has been associated with programmed cell death in prostate cancer and neurodegenerative diseases, including Parkinson's disease. Par-4 may modulate also dopamine D2 receptor signaling. Several lines of evidence suggest that dystonia is associated with altered dopamine neurotransmission, and as such, THAP1 may also cause dystonia via dopaminergic dysfunction. However, in two cases treated with carbidopa/levodopa, there was no improvement of dystonia.

[18F]-Fluorodeoxyglucose PET studies are able to separate DYT1 subjects from DYT6 by network patterns. While both DYT1 and DYT6 manifesting carriers showed bilateral increases in the superior frontal gyrus, the precuneus and the inferior parietal cortex compared with nonmanifesting carriers, DYT6 carriers, irrespective of the presence of dystonia, had a decreased putaminal metabolism and temporal hypermetabolism. This is in contrast to the significant metabolic increases in the cerebellum seen in DYT1 carriers.

Clinical Features and Diagnostic Criteria

In the initial families described with DYT6 dystonia, the mean age of onset was 16.1 years (SD 10.0, range 5–38). In more than half, PTD began before age 16 years. Dystonia was most likely to start in an arm (46%); in 27%, first symptoms involved cranial muscles (larynx, tongue, facial muscles) and 22.7% had the onset in the neck. Unlike DYT1, the leg was rarely affected first (4%). Almost all had some degree of progression to other body regions, but final distribution varied widely. Two had focal dystonia,

eight had segmental dystonia, and 12 had generalized or multifocal dystonia involvement that included the leg. Despite the fact that half had leg involvement, only two required an assistive aid for mobility. Most had brachial dystonia (19/22), and in more than half (13/22) speech was affected. In most, the greatest disability derived from dystonia of the neck and cranial muscles. Speech difficulties were prominent. A greater percentage of affected individuals were female (68% vs. 32% male), and the age of onset did not vary by gender (female: mean 15.4 ± 9.0, male mean age onset 17.7 ± 12.33).

Recent discovery that DYT6 accounts for PTD in families other than those of Amish-Mennonite descent and that other mutations in addition to that seen in families M, C, and R cause dystonia, raises the question as to whether the phenotypic spectrum may be broader than previously realized. While there are only three exons in the *THAP1* gene, genotypic heterogeneity will make screening for *THAP1* mutations more arduous. Additional studies that evaluate similar familial or sporadic cases, as well as adult onset focal/segmental cases, will further determine the phenotypic spectrum associated with *THAP1* mutations.

Differential Diagnosis

The differential diagnosis for DYT6 dystonia includes inherited dystonia with prominent cranio-cervical involvement (DYT13, DYT7), as well as other forms of PTD with limb involvement (e.g., DYT1) and sporadic cervical dystonia. Secondary causes of dystonia are less likely, since this condition presents with isolated dystonia (with or without dystonic tremor, typically of the head); however, as it is a highly treatable disorder, Wilson disease should always be considered. If cervical dystonia is the sole feature, structural lesions that may result in head postures may also be considered. As with all other forms of early-onset dystonia, the dystonia-plus condition, dopa-responsive dystonia should also be kept in the differential.

In comparison with a group of Amish-Mennonites who did not show linkage to the region on DYT6, Amish-Mennonites harboring the DYT6 gene had earlier age of onset (16.1 vs. 46.9 years), and the dystonia was both less likely to be of focal distribution and unlikely to begin in the cervical muscles.

As previously noted, the prominence of cranio-cervical symptoms and high prevalence of speech abnormalities in DYT6 families differentiates this genetic form of dystonia from the characteristic prominent leg involvement and gait abnormalities of DYT1.

The DYT6 phenotype shares features to the Italian family members with dystonia mapped to the DYT13 locus on chromosome 1p. The age of onset is early (mean age 15.6, range 5–43) but also has a wide range, similar to DYT6. Similar to DYT6, the body regions first affected in DYT13 included the neck, cranial muscles, and arm. Few individuals had leg involvement and the disability from leg dystonia was mild. From the only 11 individuals described to date with DYT13, there appears to be less laryngeal involvement than in DYT6.

Diagnostic Workup/Tests

First, as it is the case for other types of dystonia, a careful and detailed history and examination should be performed to determine whether the dystonia is primary. This includes a careful medication history, including current and past exposure to neuroleptics and antiemetics to elucidate medication induced tardive dystonia. Because of the prominent oromandibular dystonia, as well as retrocollis in some cases, the phenotype may be similar to tardive dystonia. Further, a careful family history should be obtained. As this is an autosomal dominant disorder with reduced penetrance, in theory, apparently sporadic cases may harbor DYT6 mutations.

Since the DYT6 gene was only recently elucidated, no commercial testing for DYT6 exists at this time. However, it will likely not be long before such testing is available. Two caveats are important: (1) like DYT1, there is incomplete penetrance and variable expression, and hence, not all gene carriers will develop dystonia, and when they do, they may develop very mild dystonia or severely limiting dystonia. (2) Unlike DYT1, there are multiple mutations that are likely to account for DYT6 dystonia. This is more akin to DYT5 dystonia where a genetic test may be 'negative' yet the patient may harbor an identified mutation (which may be a deletion or a promoter sequence mutation). Genetic counseling, including discussing the ramifications of these two important issues, is strongly recommended.

For cases of suspected DYT6 dystonia, MRI of the brain should be considered. It is also prudent to consider the diagnosis of Wilson disease, a treatable neurodegenerative disease in patients presenting before the age of 50 years. The evaluation for Wilson includes serum ceruloplasmin and slit lamp examination and may include 24 h urine collection for copper. According to the patient's presentation, other secondary causes should be evaluated. In the presence of an isolated abnormal posture of the head (without dystonic tremor), one should consider MRI of the cervical spine to evaluate for a structural lesion of the spine or of the spinal cord. In addition, a levodopa trial should be considered in all individuals presenting solely with dystonia in which a genetic diagnosis is not known.

Management/Prognosis

Among the original three Amish-Mennonite families, fourteen of the 22 family members received treatment for

dystonia, including botulinum toxin for blepharospasm, spasmodic dysphonia, and cervical dystonia, with improvement. Those patients who had been tried on carbidopa/levodopa had mild benefit at best. Best oral medication responses were reported to trihexyphenidyl, lioresal, and clonazepam. Dopamine depleters and blockers, and carbamazapine were also tried, but without clear benefit.

The preferential treatment for a focal dystonia in the cranio-cervical region and brachial regions is botulinum toxin injections. When the dystonia involves multiple or other body parts or generalized, treatment options include anticholinergics (e.g., trihexiphenidyl), benzodiazepines (e.g., clonazepam), lioresal, or injections of botulinum toxin in the most affected muscle groups. None of the original Amish-Mennonite DYT6 family members has had deep brain stimulation surgery (DBS) yet, and the role of DBS, including stimulator settings, needs to be determined.

DYT7, Autosomal Dominant Focal Dystonia

M San Luciano and R Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Glossary

Blepharospasm – A form of focal dystonia that involves involuntary and sustained contractions of the muscles around the eyes.

Cervical dystonia – Also known as spasmodic torticollis, is the most common form of focal dystonia. It is characterized by abnormal movements or postures of the neck and head.

Dystonia – Cocontraction of agonist and antagonist muscles resulting in abnormal twisting and posturing movements.

Spasmodic dysphonia – A focal form of dystonia that involves involuntary spasms of the vocal cords which may cause interruptions of speech and affect the voice quality.

Definition and History

Focal adult-onset dystonia usually presents in the form of cervical dystonia, blepharospasm, spasmodic dysphonia, other cranial dystonia, writer's cramp, or a combination of the above. Cervical dystonia is the most common. There is usually little spread to other sites. Focal dystonia is much more prevalent than generalized dystonia, which usually starts in childhood.

While adult-onset focal dystonia had originally been thought to be primarily a sporadic condition, family studies support a genetic contribution. The incidence of dystonia in first-degree relatives of patients with focal dystonia is higher than that expected from population studies and several families have been identified showing apparent autosomal dominant inheritance, including a monozygotic twin pair.

Despite this, no genes for adult-onset focal dystonia have been elucidated. In 1996, a large German family with seven definitely affected and six possibly affected members plus three obligate carriers showed significant linkage to chromosome 18p, this region was termed DYT7. Autosomal dominant inheritance was inferred based on observations of affected members in successive generations, roughly equal sex distribution and male-to-male transmission. All definitely affected patients had adult-onset focal dystonia, most in the form of spasmodic torticollis or cervical dystonia, one with both cervical dystonia and spasmodic dysphonia and two patients had additional Meige syndrome and writer's cramp in addition to cervical dystonia. Several possibly affected individuals had postural hand tremor. The dystonic symptoms had remained focal over many years of disease duration in all patients. Linkage analysis to the DYT1 locus was excluded. This was the first linkage study of a primary dystonia gene with the most common form of dystonia, adult-onset focal dystonia.

Investigation of apparently sporadic patients with this type of dystonia from the same geographic region of Northwest Germany (Emsland) showed also linkage to the 18p locus, suggesting a common ancestor and low penetrance of the gene. The study also suggested that DYT7 is the predominant cause of focal adult-onset dystonia in this area of Germany and the location was further narrowed within 18p. The following year, genotyping of 18 families with similar phenotype from Central Europe, revealed that 15 of them shared the chromosome 18p haplotype, but 3 did not, suggesting both that DYT7 mutations are common even outside of the Emsland region in Germany and that there is locus heterogeneity for adult-onset focal torsion dystonia. There are also reports of focal dystonia associated to the 18p locus of non-German origin but it usually not found in non-German population. However, controversy exists in respect to how common this mutation actually is, as analysis of 85 patients with focal and segmental dystonia from Northern Germany did not reveal any evidence for linkage disequilibrium at the markers tested on chromosome 18p, including those previously identified in the initial proband family.

Genetic heterogeneity is thought to underlie the etiology of other large families with adult-onset focal dystonia who do not posses the 18p mutation.

Pathogenesis and Pathophysiology

The pathogenesis of DYT7 adult-onset focal dystonia is not known. Large deletions of the short arm of chromosome 18 may infrequently present with focal adult-onset dystonia among other neurological features. In a description of three patients with large 18p deletions, focal and segmental dystonia developed in mid to late adolescence, in addition to developmental delay and mental retardation. It is possible that the dystonia in these patients may have been caused by haploinsufficiency. As the gene has not yet been identified, the molecular substrate underlying the dystonia is unknown. No specific pathological changes have been associated with adult-onset focal dystonia in autopsy series.

Clinical Features/Diagnostic Criteria

Clinical features of DYT7 are not clearly distinguished from other forms of adult-onset focal dystonia of unknown genetic etiology. As noted, DYT7 dystonia is predominantly cervical, although associated writer's cramp, segmental cranial dystonia, and isolated spasmodic dysphonia were also reported. About a fourth of patients with cervical dystonia have postural hand tremor resembling essential tremor, and the prominent hand tremor is noted in DYT7 dystonia as well.

There is a remarkably narrow range of age of onset for various forms of dystonia. While DYT1 generalized dystonia usually begins in the late first and second decades of life, most patients with cervical dystonia or spasmodic dysphonia have their onset in the fourth or fifth decade, and this age of onset holds for DYT7 dystonia as well.

Differential Diagnosis/Diagnostic Work-up and Tests

When approaching a patient with suspected focal dystonia, it is important to rule out other conditions that mimic dystonia (pseudodystonia), that is, to make sure that the patient has, in fact, dystonia. Features unique to dystonia may help in the diagnosis, such as task specificity or the presence of a sensory trick or *geste antagoniste*. Some conditions that can cause pseudodystonia are atlanto-axial subluxation, posterior fossa tumors, Arnold–Chiari malformations, trochlear nerve palsy, stiff-person syndrome and, in children, Sandifer syndrome and congenital torticollis. Psychogenic movement disorders may also mimic dystonia.

An important step in the evaluation of the patient with dystonia is to evaluate for secondary etiologies. In primary dystonias, dystonia is the only neurological manifestation (except tremor). In the dystonia-plus syndromes, dystonia is present associated with parkinsonism. Secondary dystonias are common, usually due to toxin, drug exposure, or structural brain disease. Dystonia may also be a symptom of heredodegenerative diseases such as Wilson's disease – the only one that is potentially preventable – neuroferritinopathies, Fahr's disease, lysosomal storage disorders such as Niemann–Pick disease type C, amino and organic acidurias, mitochondrial disorders, other inborn errors of metabolism, trinucleotide repeat disorders like Huntington's disease or spinocerebellar ataxia type 3 (Machado–Joseph

disease), and parkinsonian syndromes like in idiopathic Parkinson's disease, multiple system atrophy or corticobasalganglionic degeneration.

Careful medication review with special focus on current or prior exposure to neuroleptic agents or antiemetics should be performed. Brain imaging, preferably magnetic resonance imaging, is recommended in all patients with hemidystonia to rule out structural disease. Copper studies to rule out Wilson's disease are recommended in all children and young adults presenting with dystonia. Although yield is low, a levodopa trial may be performed to assess for dopa-responsive-dystonia (DRD), as isolated cervical dystonia with DRD has been reported. Genetic testing for the DYT1 mutation is recommended for patients younger than 26 with limb-onset dystonia. While DYT1 positive individuals presenting with late-onset craniocervical dystonia have been described, the yield of a positive genetic result in these cases is low. There is some overlap with DYT6 dystonia, as some individuals affected with DYT6 may have adult-onset dystonia, although many have limb involvement. Commercial testing for DYT6 dystonia is not yet available; however, it is anticipated that it will be in the near future. As the DYT7 gene has not been elucidated, there is no commercially available testing for the DYT7 dystonia.

Management/Prognosis

Botulinum toxin injections are the treatment of choice for most forms of focal dystonia. The side effects are minimal and the duration of benefit is 3–4 months. Side effects range from discomfort at the side of the injection to excessive muscle weakness that, depending on location, may cause transient ptosis or dysphagia. Medications such as anticholinergic agents, baclofen, and benzodiazepines can be used but their use is limited by side effects, especially, in the adult population. Pallidal deep brain stimulation is a safe and effective treatment of primary generalized and segmental dystonia, including cervical dystonia; however, it is still reserved for patients with severe medication refractory symptoms.

DYT8, Paroxysmal Non-kinesiogenic Dyskinesia-PNKD

S A Schneider and K P Bhatia, Institute of Neurology, University College London, London, UK

Historical Background

Since the initial description of Mount and Reback, in 1940, quite a few families were reported with an autosomal dominant inheritance with a fairly similar clinical description between families.

Definition and Characteristics of an Attack

Paroxysmal nonkinesigenic dyskinesia (PNKD) is characterized by attacks of dyskinesia, which are frequently precipitated by alcohol, caffeine, stress, or fatigue. In contrast,

paroxysmal kinesigenic dyskinesias are typically triggered by sudden movements, as the name suggests.

Also, patients with PNKD have longer (10 min to 6 h) and less frequent attacks (1–3 per day) compared with the kinesigenic variant. The dyskinesia may be of any form but often tend to be more dystonic or choreic in nature. More males than females are affected (1.4:1) for sporadic cases, and onset is usually in childhood with a tendency for the attacks to diminish with age.

A detailed report of typical clinical features of a large English family with 18 affected members was provided by Jarman et al. In all cases, onset age was very early, in the second year of life and even earlier in some. Witnessed attacks consisted of generalized choreoathetosis in two individuals. Attacks started in one limb or one side and progressed to become generalized. In one case there was associated dysarthria during an attack. Coffee, alcohol, anger and excitement, hunger, and sleep deprivation were general precipitants as well as cold and exercise in two individuals. The attack duration varied from 10 min to 12 h; however, the majority of attacks lasted between 30 and 180 min. All adults reported a decline in attack duration and frequency with age. One 85-year-old member now experienced only one mild attack a year. All affected cases reported remarkable response to sleep with 5–10 min of sleep being sufficient to abort an attack while some found drinking cold fluids or vigorous exercise could abort an attack in an early phase. There was some diurnal fluctuation with a tendency to having more attacks in the afternoon or evening compared with the morning. Recently, Bruno et al. have made similar observations in 14 kindreds with classic PNKD.

Interictal Findings

Generally, PNKD cases have no detectable abnormalities between attacks, although there has been one report of patient with PNKD who also had some interictal dystonia. There has also been a family with PNKD with additional myokimia. However, these reports date back to the pre-molecular area (see below).

Investigational Findings

With regard to investigations, routine tests as well as EEGs and brain imaging in the idiopathic cases are normal. Pathological examination at autopsy in two cases revealed no significant abnormalities.

Linkage and Genes

In the mid-1990s, two groups of researchers separately linked families with PNKD to chromosome 2q. Fouad et al. also showed tight linkage between PNKD and microsatellite markers on distal 2q (2q31–q36) in a five-generation Italian family with 20 affected members. Fink et al., who performed a genome-wide search in a large American kindred of Polish descent with 28 affected members, have also mapped PNKD to chromosome 2q33–q35. The smallest region of overlap of the candidate intervals identified by these two groups placed the PNKD locus in a 6-cM interval. In a six-generation British family, Jarman and coworkers subsequently narrowed the candidate region down to a 4-cM interval. A German family, originally described by Przuntek and Monninger as a classic example of Mount and Reback-PNKD, and other typical PNKD families (one from North American of German descent as well as a Japanese family), were also found to link to the same genetic location designated FPD1 (familial paroxysmal dyskinesia type 1).

In 2004, the gene responsible for PNKD was discovered to be the *myofibrillogenesis regulator 1 (MR1)* gene. The gene (PNKD1/DYT8) contains 10 exons and has a transcript length of 3110 bps and a translation length of 385 residues. The reported single-nucleotide mutations caused substitution of valine for alanine in residue 7 and residue 9. The same mutations were found in a family originally reported by Raskind et al. and in a 15-year-old Serbian boy with PNKD1 described by Djarmati *et al.*

There is also suggestion of genetic heterogeneity, after Spacey et al., by genome-wide linkage analysis, identified a candidate locus, termed PNKD2 (DYT20) on chromosome 2q31 in a large family with PNKD. Onset was between teenage-life and mid-adult life. Episodes lasted for about 5 min and occurred daily to monthly. Some had associated migraines. Molecular studies revealed a parametric LOD score of 2.03 and a multipoint nonparametric LOD score of 7.0. Haplotype analysis delineated a 10-cM interval between markers D2S2188 and D2S364. Mutations in the *MR1* gene as well as the *GAD1* gene were excluded by molecular analysis. The gene underlying PNKD2 remains to be identified. However, all the families with the typical PNKD phenotype segregate with the *MR1* gene.

Pathophysiology

MR-1 encodes an enzyme in a stress response pathway. The identified mutations cause changes in the N-terminal region of two MR-1 isoforms. The MR-1L isoform is specifically expressed in brain and is localized to the cell membrane whereas the MR-1S isoform is ubiquitously expressed and shows diffuse cytoplasmic and nuclear localization.

Bioinformatic analysis revealed that the *MR-1* gene is homologous to the *hydroxyacylglutathione hydrolase (HAGH)* gene. HAGH plays a role in a pathway to detoxify methylglyoxal, a compound present in coffee and alcoholic beverages and produced as a by-product of oxidative stress.

This demonstrates a possible mechanism whereby alcohol, coffee, and stress are linked in and trigger attacks in PNKD.

Diagnostic Principles

Detailed history, family history, and clinical characterization of the type of paroxysmal dyskinesia. Exclusion of secondary causes of paroxysmal dyskinesias (demyelination, vasculopathy, infectious disease (HIV, CMV), cerebral and peripheral trauma, neurodegenerative disease, hormonal and metabolic dysfunction (diabetes mellitus, hyperthyroidism, hypoparathyroidism, pseudohypoparathyroidism), neoplasm, Chiari malformation, cervical syringomyelia, and cerebral palsy). In primary paroxysmal disorders, ictal and interictal EEG and sleep-EEGs are usually normal or show transient epileptic discharges.

Therapeutic Principles

Most importantly, triggering factors like caffeine, alcohol, or stress should be clarified and avoided or reduced. If treatment is required, the drug of first choice is clonazepam. In a study of 49 genetically proven *MR-1* gene mutation carriers, a favorable reponse was noted by 97% of those who had tried benzodiazepines. The response to antiepileptic treatment is, however, limited; although there may be an initial response, this is usually lost over the years. Haloperidol, gabapentin, and acetazolamide, as well as L-dopa may also bring some benefit. The prognosis is overall good as the attack frequency may tend to decrease with age.

DYT9, Paroxysmal Dyskinesia with Spasticity

S A Schneider and K P Bhatia, Institute of Neurology, University College London, Queen Square, London, UK

Definition and Characteristics

In 1996, Auburger et al. reported a large German family in which affected members had choreo-dystonic attacks of toes, legs, and arms induced by alcohol, fatigue, and exercise. A total of 18 affected and 11 unaffected members over four generations were clinically assessed (for pedigree see **Figure 1**). Inheritance was in an autosomal dominant pattern. Onset age was between age 2 and 15, but usually before age 6. Episodes lasted approximately 20 min and occurred twice daily to twice yearly.

In addition to involuntary movements, some affected members showed a rather complex phenotype with marked spastic paraparesis and other clinical features, including paresthesias periorally and of the lower limbs, double vision, and headache. During attacks, patients exhibited imbalance and dysarthria; however, there were no clear cerebellar signs. Examination was normal between attacks, except in five patients who had spastic paraplegia with pyramidal signs and increased latencies on electrophysiological assessment. One patient was cognitively impaired, whereas the remaining subjects were neuropsychologically normal. EEGs excluded epileptic activity. Neuroimaging using 31P NMR spectroscopy for assessment of pH in the cerebellum revealed values in the upper normal range. The condition was reported under the heading 'choreoathetosis/spasticity (CSE).'

Thus, clinically, they did not fit in with the main, well-described subtypes of paroxysmal dyskinesias, according to Demirkiran and Jankovic's classification. However, based on the triggering factors, there was overlap with the nonkinesigenic variant (PNKD, paroxysmal nonkinesigenic dyskinesia due to mutations in the MR-1 gene on chromosome 2q33–35), which is typically triggered by coffee or alcohol intake. There was also overlap with paroxysmal exercise-induced dyskinesia (PED). PED is a genetically heterogeneous syndrome. Recently, for some families, as well as in some sporadic cases, gene mutations in the *GLUT1* gene have been demonstrated by Weber et al. and Schneider et al. Notably, in some of the genetically proven *GLUT1* gene mutation carriers, PED was accompanied by epilepsy, migraine including hemiplegic migraine, mild developmental delay, and reduced cerebral spinal fluid (CSF) glucose levels.

Auburger et al., in their original report, also discussed the similarities with one of the episodic ataxia syndromes (episodic ataxia type 1, defined by the presence of additional myokymia due to mutations in the potassium channel gene *KCNA1* on chromosome 12p) and excluded linkage to that area.

Prevalence

Only limited data are available and, so far, the disease is reported only in a single large pedigree from Germany.

Linkage and Genes

Linkage to chromosome 12p (*KCNA* gene associated with episodic ataxia type 1) was excluded. However, linkage to chromosome 1p21–13.8 where a cluster of related potassium channel genes is located, could be demonstrated. Genotyping of 18 affected and 11 unaffected family members with 28 microsatellites over a region of 45 cM showed linkage with a LOD score of 7.2 at a recombination fraction $\theta = 0$ to D1S451/421/447/GGAT4C11. Crossing-over events in nine patients and four unaffected offspring suggested a probable assignment of the gene to a

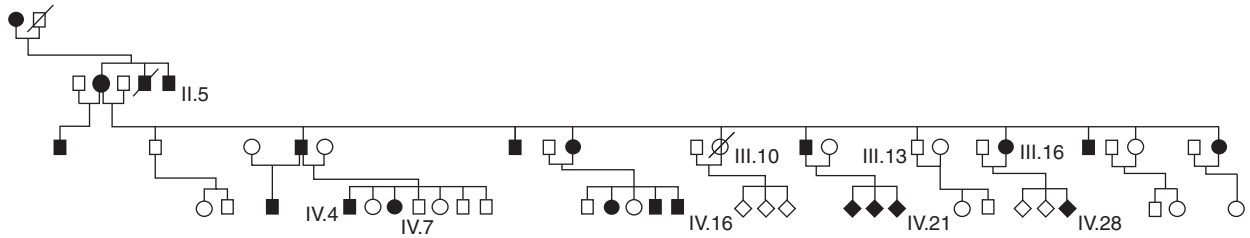

Figure 1 Pedigree with paroxysmal choreoathetosis/spasticity in four generations and 22 affected individuals. Affected individuals are shown as black symbols. Reproduced from Auburger G, Ratzlaff T, Lunkes A, et al. (1996) A gene for autosomal dominant paroxysmal choreoathetosis/spasticity (CSE) maps to the vicinity of a potassium channel gene cluster on chromosome 1p, probably within 2 cM between D1S443 and D1S197. *Genomics* 31: 90–94.

region of 2 cM between D1S443 and D1S197. The condition was allocated to the DYT9 locus.

Interestingly, the locus is in proximity to the gene locus of *GLUT1* (*SLC2A1)* associated with PED (chromosome 1p35-p31.3). Mutations in this gene can present with a spectrum of severity ranging from very severe (labeled as 'classic *GLUT1* deficiency syndrome') to mild (pure PED, which occurs episodicallys only). The severe syndrome of 'GLUT1 deficiency,' as recognized by paediatricians, is characterized by delayed development with microcephaly, drug-resistant seizures, ataxia, spasticity, hypoglycorrhachia, and decreased erythrocyte glucose uptake. Atypical forms of GLUT1 deficiency syndrome have a milder phenotype or late-onset, without seizures or presence of intermittent ataxia or dyskinesias triggered by exercise or coffee. The phenotype of the choreoathetosis/spasticity syndrome described by Auburger et al. is well compatible with the GLUT1 phenotype and mutations in the *GLUT1* gene remain to be excluded or confirmed.

Pathophysiology and Therapeutic Principles

The original family by Auburger et al. responded to acetazolamide and phenytoin; however, the response was variable.

To date, the exact gene underlying the choreoathetosis/spasticity syndrome (DYT9) is unknown. If it were to be due to mutations in the *GLUT1* gene, this may have implications for treatment. *GLUT1* encodes the GLUT1 transporter responsible for glucose entry into the brain. It has been found that the defect in this transporter can be bypassed by a ketogenic diet or a less restrictive modified Atkins diet. Oral medication which has been reported to produce benefit in PED includes gabapentin, clonazepam, levodopa, and acetazolamide.

Patients with *GLUT1* gene mutations were found to have reduced or borderline CSF glucose levels. There are no reports about CSF levels in the original CSE family.

Diagnostic Principles

Diagnostic principles include detailed history of the patient, family history, and clinical characterization of the type of paroxysmal dyskinesia. These exclude secondary causes of paroxysmal dyskinesias (demyelination, vasculopathy, infectious disease (HIV, CMV), cerebral and peripheral trauma, neurodegenerative disease, hormonal and metabolic dysfunction (diabetes mellitus, hyperthyroidism, hypoparathyroidism, pseudohypoparathyroidism), neoplasm, Chiari malformation, cervical syringomyelia, and cerebral palsy). In primary paroxysmal disorders, ictal and interictal EEG and sleep-EEGs are usually normal or show transient epileptic discharges.

Glossary

Centimorgan (cM) – A measure of distance of genes on a chromosome determined by the frequency with which recombination occurs between them. Two gene loci are one centimorgan apart if recombination occurs in 1% of meioses.
Choreoathetosis/spasticity (CSE) – The combination of choreic and athetotic involuntary movements and pyramidal involvement causing spasticity.
Cerebrospinal fluid (CSF) – The clear fluid within the subarachnoid space and the ventricular system around and inside the brain.
Electroencephalogram (EEG) – The recording of electrical activity of neurons and a diagnostic tool for example in the context of epilepsy.
Glucose transporter gene (*GLUT1* gene) – The gene encoding for a membrane protein that transports glucose across the membrane. Different subtypes of GLUT transporters have been identified. The GLUT1 transporter, in particular, is expressed at highest levels in erythrocytes as well as in the endothelial cells of barrier tissues inlcuding the blood–brain barrier.
Myofibrillogenesis regulator 1 gene (*MR-1* gene) – The gene associated with paroxysmal nonkinesigenic dyskinesia (PNKD).
Nuclear magnetic resonance (NMR) – A tool used to study molecular physics, crystals, and noncrystalline materials through NMR spectroscopy. NMR is also routinely used in advanced medical imaging techniques, such as in magnetic resonance imaging (MRI).
Paroxysmal exercise-induced dyskinesia (PED) – A form of episodic movement disorder where attacks are triggered by prolonged physical exercise.

Historical Background and Synonyms

Paroxysmal kinesigenic dyskinesia (PKD) were first described by Gowers in 1901 as attacks of an 'unusual character' that occur after sudden movement. In contrary to epileptic seizures, consciousness was not lost and movements were tonic without clonic component. However, despite this observation, the condition was classified as 'extrapyramidal epilepsy,' 'striatal epilepsy,' 'tonic seizures,' 'tonic motor attacks,' and 'reflex epilepsy.'

The first detailed description of clinical features was presented by Kertesz in a seminal review of 31 cases from the literature and 10 new cases, including one autopsied. Brain pathology was found normal except for a slight loss of neurons of the nucleus coeruleus.

Clinical Characteristics of PKD

In addition to a number of single case reports, there are two studies reviewing clinical features in larger cohorts. One of these is by Houser et al. (26 patients with PKD), and the other by Bruno et al., who reviewed features of 121 affected individuals with a presumptive diagnosis of idiopathic PKD and referred for genetic studies. On this basis, the latter authors also proposed new diagnostic criteria.

In view of the classification by Demirkiran and Jankovic, PKD episodes are by definition triggered by sudden movements, for example, getting up quickly to answer the door bell or the telephone; and the attacks are typically brief lasting seconds. Many patients (70–80% of patients) note an abnormal sensation prior to the movement ('aura') like numbness or 'pins and needles' in the affected limb or the epigastric region.

The clinical manifestation of the attack is most commonly with dystonia. There may also be chorea, ballismus, or a combination of these. Typically, attacks affect limbs on one side, although attacks can also be generalized. About one third of patients develop speech disturbance (dysarthria or anarthria), which may be due to the involvement of the face. There is usually no loss of consciousness (in 98%) and no 'postictal' confusion or drowsiness.

Most attacks (88–100%) are very brief, lasting only seconds. In the series by Houser et al., attacks lasted less than 2 min in 88% and between 30 and 60 s in two-thirds of patients. Similarly, in the study by Bruno et al., attacks were shorter than 1 min in 95% of patients. Longer lasting PKD-like attacks should thus make the clinician suspicious of a secondary cause including the possibility of a psychogenic paroxysmal movement disorder.

PKD attacks are frequent. Most patients have 1–20 attacks per day, while some may also have more than 20 attacks per day. The frequency of PKD episodes usually peaks in puberty with up to 30–100 attacks and then becomes less after age 20, and may even completely remit after age 30.

The age of onset in PKD varies between 6 months and 33 years, but onset is usually in teenage life between 7 and 15 years. Among the primary form, 65–72% of PKD

patients have a family history of a similar disorder with autosomal dominant inheritance. Pentrance was complete in more than half of the cases. There appears to be a higher prevalence in males (4:1 even up to 8:1) in the sporadic form but not in familial cases.

Diagnostic Criteria

Criteria as proposed by Bruno et al.:

- Identified kinesigenic trigger for the attacks
- Short duration of attacks (<1 min)
- No loss of consciousness
- Onset age 1–20 years, if no family history
- Control of attacks with phenytoin or carbamazepine
- Normal neurological examination; exclusion of other causes

Genetic Linkage of PKD

A genetic breakthrough of this disorder was achieved with the recognition of similarities between PKD and paroxysmal movements noted in the context of the syndrome labeled 'ICCA' because of the presence of *infantile convulsions and paroxysmal choreo-athetosis*. The ICCA syndrome had been mapped to a 10 cM interval of the pericentromere region on chromosome 16. Subsequently, a number of families with pure PKD were also linked to the same area.

Since then, idiopathic PKD cases have also been linked to the pericentromic region of chromosome 16 (spanning a 24 cM segment between D16S3131 and D16S408). However, despite various attempts and detailed analysis by Kikuchi et al. of 157 genes in this area, no mutations could yet be identified that are shared by unrelated families. Recently, nonsynonymous substitutions affecting the SCNN1G and *ITGAL* gene, which were segregated with disease in two families, have been proposed by Kikuchi et al. to play a role.

There is also evidence of genetic heterogeneity for PKD. One independent locus maps to chromosome 16 (EKD2/DYT19) as described by Valente et al. and there are also cases where linkage to chromosome 16 was excluded by Spacey et al. suggesting existence of a third locus elsewhere.

There is also overlap with the syndrome of rolandic epilepsy, paroxysmal exercise-induced dyskinesia, and writer's cramp (RE-PED-WC). In RE-PED-WC syndrome, there is a strong relation between symptom expression and age: both seizures and paroxysmal dystonia peaked in childhood. The onset of writer's cramp also was in childhood but did not cease with age. However, unlike typical PKD inheritance was autosomal recessive. Genome-wide linkage analysis identified a critical region spanning 6 cM on chromosome 16. In fact, the region of the ICCA syndrome entirely included this 6-cM-wide critical RE-PED-WC region. However, it remains unknown whether these conditions are caused by mutations of the same gene or two different genes.

Pathophysiological Mechanisms of PKD

Two studies recently investigated patients with idiopathic PKD, using transcranial magnetic stimulation. One of the studies assessed a proportion of patients on and off treatment. Here, Mir et al. found a reduced short intracortical inhibition, a reduced early phase of transcallosal inhibition, and a reduced first phase of spinal reciprocal inhibition. The abnormalities in transcallosal inhibition could be normalized by carbamazepine, while the other parameters did not change with treatment. Other measures like the cortical silent period, the startle response, and the second and third phases of reciprocal inhibition were normal. The authors concluded that the abnormalities of the cortical and spinal inhibitory system may be useful parameters to differentiate PKD from primary dystonia and epilepsy. In the other study, Kang et al. found normal measures for thresholds, intracortical facilitation, and silent period. In contrast to Mir et al., they found also normal short intracortical inhibition. Functional imaging studies like SPECT scans demonstrated an altered perfusion of the basal ganglia contralaterally to the affected side or bilaterally.

Diagnostic Principles

Detailed history, family history, and clinical characterization of the type of paroxysmal dyskinesia to exclude secondary causes of paroxysmal dyskinesias (demyelination, vasculopathy, infectious disease (HIV, CMV), cerebral and peripheral trauma, neurodegenerative disease, hormonal and metabolic dysfunction (diabetes mellitus, hyperthyroidism, hypoparathyroidism, pseudohypoparathyroidism), neoplasm, Chiari malformation, cervical syringomyelia, cerebral palsy). In primary paroxysmal disorders, ictal and interictal EEG and sleep-EEGs are usually normal or transient epileptic discharges.

Treatment and Prognosis of PKD

PKD attacks usually respond well to anticonvulsants: Carbamazepine is the drug of choice and 86% of patients studied by Bruno et al. responded well to either carbamazepine or phenytoin. The dose of phenytoin required to control PKD in children is comparable to the dose used for epileptic seizures. In adults, a lower dosage is sufficient and Houser et al. suggested for adults doses of

5 mg kg^{-1} per day of phenytoin or 7–15 mg kg^{-1} per day of carbamazepine.

An alternative or adjunct to carbamazepine in the treatment of PKD may be acetazolamide, especially when the condition is due to demyelinating lesions. Other drug options include hydantoin, topiramate, or barbiturates. Benzodiazepines were reported beneficial in patients with HIV-associated PKD.

The prognosis is generally good, as attack frequency decreases with age and patients have a normal life expectancy. However, if undiagnosed, this disorder can be very distressing and can affect life quality. During pregnancy, 50% of affected women may note improvement.

DYT11, DYT15, Myoclonus-dystonia

M San Luciano and R Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Glossary

Dystonia-plus – The term dystonia-plus refers to conditions in which dystonia is one of only two neurological conditions present, the other being myoclonus or parkinsonism, in the absence of neurodegeneration. This term applies to three conditions: myoclonus-dystonia, dopa-responsive dystonia, and rapid-onset dystonia-parkinsonism.
Myoclonus – Brief, rapid involuntary and random muscle jerk produced by muscle contraction. Myoclonus can also result from brief lapses in muscle contraction.

Definition and History

The nosology of myoclonus-dystonia is often confusing because in the historical record it has been variously described as 'hereditary essential myoclonus,' 'myoclonic-dystonia,' 'dystonia-myoclonus,' and most recently, myoclonus-dystonia. Some confusion arises as most but not all of the cases falling into this disorder category are actually myoclonus-dystonia. It was suggested that when myoclonus is part of primary dystonia, such as DYT1 it should be termed 'myoclonic dystonia' to distinguish it from the characteristic syndrome of myoclonus-dystonia.

Myoclonus-dystonia is characterized by a combination of rapid, brief muscle contractions (myoclonus) and/or

sustained twisting, and repetitive movements that result in abnormal postures (dystonia). While most reports on myoclonic dystonia are indeed referencing this condition, as noted above, myoclonic dystonia may also refer to primary dystonia, such as DYT1 dystonia, where there is myoclonus superimposed on the dystonia (discussed by Obeso et al.), but the myoclonus is not the prominent feature in the individual or the family, if it is familial.

Davidenkow first described in 1926 the association of truncal and neck dystonia with tic-like hyperkinesis of neck and facial muscles in a pair of siblings and labeled it 'hereditary myoclonic dystonia.' Quinn and Marsden described an additional six patients from four families of childhood onset 'myoclonic dystonia' inherited as an autosomal dominant trait with variable penetrance. Exquisite response to alcohol with potential for alcohol dependence and premenstrual worsening in female patients were also mentioned. In 1988, a study in one family in upstate New York by Kurlan et al. described eight affected family members with dystonia and/or myoclonus of onset around age 12. Dystonia manifested predominantly as writer's cramp and myoclonus was irregular, most commonly generalized and responsive to alcohol. Because of the early onset with absence of marked progression to generalized dystonia, the absence of gait impairment, and the electrophysiological evidence of subcortical myoclonus, they differentiated this entity from idiopathic torsion dystonia. Additional descriptions confirmed the same observation and the entity was further separated from hereditary benign chorea and hereditary essential myoclonus, although recently some cases originally described as hereditary essential myoclonus have been relabeled as myoclonus-dystonia. The description of a very large family in Sweden in 1990 helped confirm this condition as a separate entity and provided important data on its wide spectrum of clinical manifestations. Exhaustive genomic screens using two large families excluded major parts of the genome and linkage analysis in a German family excluded the DYT1 locus and the 13 subunits of the $GABA_A$ receptor. In 1999, Nygaard et al. mapped a locus for myoclonus-dystonia to the 7q21–q31 region and in 2001 the first mutations in the ε-sarcoglycan gene were identified. The locus was designated DYT11. In 2002, linkage analysis in a large Canadian family revealed a novel locus on the short arm of chromosome 18p11. In this family, the clinical characteristics were identical to those due to mutations in the *SGCE* gene. The locus was designated DYT15. Two additional families have been now potentially linked to this region, but the gene has not been identified yet.

Pathogenesis and Pathophysiology

The myoclonus-dystonia syndrome has been attributed to mutations in the ε-sarcoglycan gene (*SGCE*, DYT11) mapped to 7q21 and more recently to a novel locus in chromosome 18p11 (DYT15). The *SGCE* gene is composed of 12 exons that span 71 kb. Exon 10 is alternatively spliced and is missing in the majority of transcripts. Several different mutations have been described; the most common appears to be a nonsense mutation in exon 3 (304C > T, R102X), although missense mutations, insertions, deletions, and substitutions have been described. Novel mutations continue to be described including de novo mutations. The R102X mutation does not have a common allele and it does not appear to represent a common founder mutation. Most of the mutations lead to loss of function as a result of frameshift and protein truncation before the transmembrane domain. Missense mutations produce proteins that are not correctly localized to the plasma membrane and are degraded by the proteasome. Large exonic deletions in patients in which direct sequencing through polymerized chain reaction (PCR) did not reveal mutations in the *SGCE* gene have been described with similar phenotype as patients with point mutations. However, deletions extending beyond the *SGCE* gene have been associated with dysmorphism and other features.

The pattern of inheritance is autosomal dominant with decreased penetrance and variable expression. The reduced penetrance in the expression of the disease is thought to result from maternal imprinting, with most of manifesting offspring inheriting the affected gene from their father.

There is evidence of genetic heterogeneity, and the majority of patients with the clinical syndrome remains negative for *SGCE* mutations, although as mentioned before, large deletions may be overlooked if just direct sequencing without screening for changes in exon copy number is performed. *SGCE* mutation-positive cases and mutation-negative cases are phenotypically very similar, except that positive family history, truncal myoclonus and axial dystonia are more frequent in the mutation-positive cases.

The syndrome had been also associated in the past to mutations in the D2 receptor and also to an 18-bp deletion on the gene encoding for TorsinA (DYT1) However, in both cases, mutations were also found in the SCGE gene.

The pathophysiology of myoclonus-dystonia currently remains elusive. Some electrophysiological studies suggest a generator within the basal ganglia as both pallidal and thalamic stimulation ameliorates the symptoms. In addition, a preliminary functional MRI study in a single *SCGE*-related myoclonus-dystonia patient showed specific activation within the thalamus and dentate nucleus.

The *SGCE* KO mouse model showed myoclonus, deficits in motor coordination, balance and learning, and psychiatric alterations consistent with anxiety and depression, as well as compulsive checking behavior, demonstrating that the diverse symptoms in DYT11 myoclonus-dystonia syndrome are indeed the effects of a single gene mutation

involving *SCGE* gene. ε-Sarcoglycan is a major constituent of the dystrophin–glycoprotein complex in striated muscle. Mutations in α, β, γ, and δ-sarcoglycan cause different recessive limb girdle muscular dystrophies and they are primarily expressed in muscle. In contrast, ε-sarcoglycan is found in midbrain monoaminergic neurons, cerebellar Purkinje cells, and other brain regions. The pathophysiological relation of mutated ε-sarcoglycan to the development of the myoclonus-dystonia is not known.

Clinical Features and Diagnostic Criteria

The clinical spectrum is wide with marked variation even within members of the same family. Classically, the disease onset is on the first or second decades of life, although onset in early infancy has been described as well as onset in the sixth decade. Myoclonus is usually the first manifestation, ranging from mild distal segmental myoclonus in the arms that could be mistaken with tremor, to generalized violent jerks involving the entire body. The myoclonus is most prominent and frequent in the axial musculature. Dystonia commonly follows and tends to remain focal or segmental and affect the cranial–cervical musculature and the arms in the form of writer's cramp more often than the legs or trunk. In rare cases, it may be the presenting and only symptom. Both dystonia and myoclonus can markedly worsen with action, and myoclonus can be exacerbated by stress, sudden noise, touch, and caffeine. Mild parkinsonian features of reduced arm swing, postural instability, and rest tremor have also been reported in a few mutation positive individuals. Lastly, growth retardation, mild developmental delay, and facial dysmorphism have been described in patients with large deletions of the 7q21 locus; however, the deletions also included contiguous genes in those myoclonus-dystonia patients.

Exquisite alcohol sensitivity in many affected individuals is a classic feature of this condition. It was first noticed by Daube and Peters in 1966 and it has been widely documented. The effect of alcohol appears to be a palliative one, rather than a result of the mutated gene expression. Forty-four percent of manifesting carriers of the DYT11 locus in a study of three families prior to the identification of the gene met criteria for alcohol dependence, versus 12.8% of nonmanifesting carriers, while the rates of alcohol dependence between carriers and noncarriers did not differ. A larger cohort of patients with documented ε-sarcoglycan mutations showed similar results.

Independently from alcohol, psychiatric comorbidities such as obsessive–compulsive disorder and depression have been described associated with this syndrome.

By definition, in myoclonus-dystonia there is an absence of seizures, dementia, ataxia, or other neurological deficits, in order to distinguish it from the myoclonic epilepsies and other progressive ataxic syndromes. Routine electroencephalograms and somatosensory evoked potentials are normal in these patients and electroencephalogram (EEG) jerk-locked back averaging does not detect a premyoclonic cortical potential pointing towards a subcortical origin of the myoclonus in myoclonus-dystonia. However recent reports have demonstrated that there may be both seizures and EEG abnormalities in some cases with *SGCE* mutations.

Differential Diagnosis

When assessing a patient with myoclonus, it is imperative to consider that myoclonus, as a symptom, may arise from different brain regions (cortex, subcortical region, or brainstem), spinal cord and even peripheral nerves, and therefore has many different etiologies. Cortical myoclonus usually involves the distal hand or less commonly the foot. It is usually stimulus-sensitive, and may be rhythmic or arrhythmic. Reticular reflex myoclonus (brainstem myoclonus) is usually severe, causing generalized flexor jerks of the proximal upper and lower limbs and trunk. It is usually arrythmic and may be stimulus-sensitive. Spinal segmental myoclonus, typically involves one or two adjacent segments of the cervical or thoracic cord, is typically rhythmic, and may be stimulus-sensitive. Propriospinal myoclonus is rare, often involving the thoracic cord, and is characterized by a visible delay between jerks stimulated by reflexes.

Myoclonus can occur as a natural physiologic phenomenon (hiccups, hypnic jerks) and as part of the epileptic phenotype (epileptic myoclonus, like in juvenile myoclonic epilepsy (JME). It can also occur in a large number of disorders in the company of seizures and progressive neurologic deterioration, the so-called progressive myoclonic epilepsies like Lafora disease, myoclonic epilepsy with ragged red fibers (MERRF) or Unverricht–Lundborg disease, or in conditions like dendatorubralpallidoluysian atrophy (DRPLA) or the juvenile form of Huntington's disease (Westphal variant). Symptomatic myoclonus may arise from hypoxic–ischemic injuries, as part of myoclonic dementias such as Alzheimer's disease or Creutzfeldt–Jakob disease (CJD), as a side effect of certain drugs and withdrawal from opioids and alcohol. Lastly, myoclonus may appear in isolation without apparent external cause and without associated neurodegeneration, called essential myoclonus. The myoclonus of myoclonus-dystonia belongs to this latter type.

When dystonia and not myoclonus is the presenting or prominent symptom, other primary dystonic disorders and secondary dystonias need to be ruled out, including structural disease, Wilson's disease, especially when family history is missing or the pattern of inheritance is not clear for an autosomal dominant condition.

Diagnostic Work-Up/Tests

The work-up of the patient with suspected myoclonus-dystonia should be individualized based on the onset, age of the patient and the presence of other neurologic disturbances, like seizures or other neurologic deficits such as pyramidal signs, extrapyramidal signs, or cognitive impairment. Direct sequencing of the ε-sarcoglycan gene with screening for changes in exon copy number to additionally look for deletions can be performed although a negative result will not rule out myoclonus-dystonia, due to its genetic heterogeneity. Such testing should be performed together with a genetic counselor, if possible, as the explanation of the transmission pattern and its meaning in subsequent generations is complex. Particularly, it should be noted that while there is maternal imprinting and most gene carrying children of mothers with myoclonus-dystonia do not develop disease, the imprint is incomplete, and approximately 5–10% may develop symptoms.

The work-up should include a detailed review of medication use, as some medications may cause myoclonus. Further, careful assessment of alcohol intake to look both for a beneficial effect on the myoclonus and myoclonus resulting from alcohol withdrawal should also be performed. Routine laboratory studies to consider include: complete blood count (CBC), biochemistry panel, ammonia, liver function tests including copper biochemical studies and thyroid function tests. All patients should undergo brain imaging; magnetic resonance imaging is preferred when feasible. Serum ceruloplasmin and ophthalmologic examination for Kayser Fleischer rings should be considered.

Electrophysiological studies are of key importance in the evaluation of a patient with myoclonus. EEG is readily available and should be routinely obtained in any patient with myoclonus to rule out seizures and to evaluate different patterns and background, like periodic synchronous discharges such as in CJD and generalized periodic epileptiform discharges like in subacute sclerosing panencephalitis (SSPE). Electromyogram (EMG) is readily available and useful in defining the duration of the jerks (myoclonus is typically <100 ms) and in differentiating peripheral myoclonus from other muscle contractions like fasciculations and myokymia. EEG–EMG back averaging is a specialized test not readily available but it represents the most useful tool for confirming time-lock between the myoclonic jerks and the EEG signal and can definitively differentiate cortical from subcortical myoclonus.

Genetic testing is commercially available for some of the progressive myoclonic epilepsies like Lafora disease and Unverricht–Lundborg disease, as well as MERRF and JME, neurodegenerative conditions such as Huntington's disease and primary dystonias like DYT1.

Management/Prognosis

The condition usually follows a benign course compatible with normal life span. Spontaneous remission of dystonia in childhood or adolescence has been described and progression to worsening dystonia and myoclonus is rare but also reported.

Counseling regarding the negative long-term effects of alcohol should be considered in alcohol-responsive cases. As parents may not be affected (if the disease was transmitted through the grandmother) and may not be aware of the short term alleviation of symptoms with alcohol, they should be counseled that affected teenagers may start abusing alcohol to dampen the symptoms.

The treatment of myoclonus and dystonia is symptomatic and should be reserved for those patients in whom there is functional impairment. Response to medications targeted to treat myoclonus, in particular, benzodiazepines, sodium oxybate (γ-hydroxybutyric acid), valproic acid, levetiracetam, and L-5-H-triptophan has been reported; as has response of the dystonia to anticholinergic medications, although historically results have been far less than satisfactory for the treatment of myoclonus. Most patients with myoclonus require treatment with more than one drug and individual susceptibility to side effects varies considerably from patient to patient. Negative myoclonus is historically difficult to treat. Deep brain stimulation of the ventral intermediate thalamic nucleus and globus pallidus pars interna has been shown to alleviate both myoclonus and dystonia in mutation-positive selected individuals. Levodopa may be helpful in selected individuals.

DYT12, Rapid Onset Dystonia-parkinsonism

M San Luciano and R Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Glossary

Haploinsufficiency – Lower production of a protein as a result of a mutated gene, which in turn causes an abnormal phenotype.

Definition and History

Rapid onset dystonia parkinsonism (RDP, DYT12) is a rare movement disorder of autosomal dominant inheritance with incomplete penetrance and variable expression. It was first described in 1993 in a large Midwestern family in which the affected members had rapid development of both dystonia and parkinsonism over hours or days with some progression over the following days or weeks and a subsequent stable course. The symptoms were unresponsive or minimally responsive to levodopa and other dopaminergic therapies. A second unrelated Midwestern family had a very similar presentation which was published in 1997. The first case in a European family was described in Ireland in 1999. Since then, several sporadic cases in different countries as well as other familiar cases have been described.

Linkage analysis to an 8 cM region on chromosome 19q13 was demonstrated in 1999 in the two initial Midwestern families, confirmed in the Irish and in a Polish kindred but not in a German family and later refined to a 5.9 cM minimal interval in 2004. Missense mutations in the *ATP1A3* gene which codes for the α3 subunit of the Na^+/K^+-ATPase pump were identified in 2004 in patients with the previously described familial and sporadic cases.

Pathogenesis and Pathophysiology

The relation between the Na^+/K^+-ATPase pump dysfunction and the development of symptoms is not well understood. Voltage-gated sodium channels are essential for the initiation and propagation of action potentials in neuronal cells. The transmembrane sodium gradient is maintained by the activity of the Na^+/K^+-ATPase pump, which belongs to the P-type ATPase group. Its α subunit has a catalytic function and there are three isoforms expressed in the nervous system: α1, α2, and α3, with α3 being expressed exclusively in neurons. Mutations in the α2 subunit have been associated with familial hemiplegic migraine type II and epilepsy. The missense mutations described in RDP patients result in a loss of activity or loss of folding stability of the protein, or both. Hence, in RDP, there is haploinsufficiency with reduced activity and expression of α3. An inability to keep up with a high demand for ion transport activity after stressful events probably underlies the development of dystonia and parkinsonian symptoms. Given the

heterogeneity of presentation and the reduced penetrance, it is assumed that additional genetic and/or environmental factors influence expression.

Clinical Features and Diagnostic Criteria

The classic presentation is of abrupt onset of asymmetric dystonia and parkinsonism over hours or a few days to weeks, with more involvement of bulbar and upper extremity muscles than of leg (rostro–caudal gradient). Bradykinesia and postural instability are the primary features of the parkinsonism. RDP usually begins in late childhood or early adulthood, with a range in age of onset from 4 to 55 years. Physical stressors, including fever, infection, excessive exercise, childbirth, or alcohol binges, or psychological stressors, have been reported as triggers. Digoxin may also be a trigger. After a few days or weeks of progression, a stable course with minimal improvement may follow over many years. Additional episodes with worsening of the case and then further plateau of function may be observed. There is minimal response to levodopa, dopamine agonists, and other antispasmodic agents.

Some individuals develop mild antecedent symptoms prior to the sentinel development of dystonia-parkinsonism. These include mild brachial dystonia or limb cramping, or parkinsonism.

The phenotype is variable even within the same family, and no consistent clinical differences have been observed between patients bearing different mutations. Some patients from the different families reported mild limb dystonia and cramping, sometimes in the form of writer's cramp, also transient dysarthria and retrocollis prior to the development of the abrupt severe symptoms.

Reports of a slowly progressive course as well as of fluctuating daily symptoms coinciding with periods of fatigue and exhaustion, similar to other channelopathies such as the episodic ataxias exist.

Parkinsonism was demonstrated in most patients by facial hypomimia with open mouth postures and drooling, severe bradykinesia, variable degrees of rigidity, and shuffling gait with postural instability without tremor. Sardonic smile, facial grimacing, dysarthria, dysphagia, truncal, and asymmetric predominately upper limb dystonia with painful spasms were the most common dystonic manifestations. The cranial features are reminiscent of Wilson disease.

A few patients had transient oculogyric crises at the time of onset, reminiscent of von Economo's disease, and seizures at onset were described in three mutation-positive individuals. Hyperreflexia with flexor plantar responses was common. Clinical depression at the onset of symptoms, probably reactive, responsive to antidepressant therapy was also frequently described. In addition, other psychiatric comorbidities including social phobia and generalized anxiety disorder were described in the Irish kindred.

Table 1 Diagnostic criteria for RDP[a]

Main criteria	Rapid development of dystonia with features of parkinsonism over minutes to days
	Rostro-caudal gradient of involvement
	Prominent bulbar findings
	Minimal or no response to levodopa or dopaminergic agents
Additional criteria	Minimal or no tremor at onset
	Occasional mild focal limb dystonia before onset
	Identifiable trigger at onset
	Rare second 'onsets' or abrupt worsening later in life
	Stabilization of symptoms within 1 month
	Minimal improvement overall (except for mild gait improvement)
	Low levels of HVA in CSF

[a]Adapted from Brashear et al. (2007).

In all patients with *ATP1A3* mutations, the clinical manifestations were limited to the central nervous system. However, in the latest family described in which the DYT12 locus was excluded, several family members had renal disease in adulthood.

Diagnostic criteria and a severity scale were published at the same time in the second kindred's description and were recently revised. These are summarized in **Table 1**.

Most patients and some asymptomatic carriers had low CSF levels of the dopamine metabolite, homovanillic acid (HVA), without relation to the disease severity or duration. However, based on normal results of [^{11}C]β-CFT PET imaging of RDP patients, this observation was not accounted for by a decrease in the number of presynaptic dopaminergic cells and dopamine reuptake sites. Magnetic resonance imaging is normal. The first and only pathologic study to date detailed the absence of pathologic changes in the brain of a patient with RDP.

Differential Diagnosis

RDP needs to be differentiated from other childhood, adolescence, and young adult onset of primary and secondary dystonias. The primary dystonias include DYT1, DYT6, and DYT13. DYT1 is an early onset primary dystonia which often presents insidiously in a limb (frequently the legs) and usually progresses in a caudal-to-rostral pattern, although it may remain focal in the limb, classically the arm. Involvement of cranial and cervical muscles, while it may be present, is less common. Interestingly, predominant bulbar and upper extremity involvement is a feature of DYT6 and DYT13 dystonia. However, to date most DYT6 patients are of

Amish-Mennonite origin, and DYT13 is limited to a single Italian family.

Dystonia-plus syndromes (dopa-responsive-dystonia and myoclonus-dystonia) need to be included in the differential diagnosis of RDP. Dopa-responsive-dystonia (DRD, DYT5, Segawa's disease), most commonly associated with mutations in the GTP cyclohydrolase I (*GCH1*) and less frequently to mutations in the tyrosine hydroxylase gene (*TH*), appears early in childhood and affects legs and trunk more than the arms although cervical muscles may be involved. It has classic diurnal fluctuations, worsening at the end of the day. In addition, parkinsonian features have been described in some patients. However, contrary to RDP, it responds dramatically and consistently to levodopa at low doses. Myoclonus-dystonia (MD), an autosomal dominant disorder associated with mutations in epsilon-sarcoglican (*SGCE*), is characterized by myoclonic jerks mainly involving the arms and axial muscles in combination with dystonia. It also develops often during childhood or early adolescence. Contrary to the other dystonic syndromes, myoclonus is often the predominant feature, with 'lightning jerks' that frequently are responsive to alcohol.

The combination of parkinsonism and dystonia is not exclusive of RPD. About 40–60% of patients with Wilson disease have neurological dysfunction as initial clinical manifestation. Although most commonly presenting with tremor, the dysarthria, dysphonia, parkinsonism, and dystonia are frequent manifestations, and hence the possibility of Wilson disease should be taken into consideration. As noted, the sardonic facial expression in RDP is very reminiscent of that in Wilson disease. Levodopa-induced and levodopa-responsive dystonia are the common features of idiopathic Parkinson's disease and a common presenting symptom of young-onset Parkinson's disease. However, the dystonia tends to affect the limbs and not the bulbar muscles; the onset is gradual with subsequent progression, and the patients respond well to levodopa. Young-onset Huntington disease (Westphal variant) is an important diagnostic consideration, especially in the presence of an autosomal dominant pedigree, as these patients are characterized by an akinetic-rigid syndrome with dystonia. Severe intellectual decline, frequent seizures, and myoclonus are also present and are distinct features.

Diagnostic Work-up/Tests

RDP should be considered as a diagnostic possibility in cases of levodopa unresponsive parkinsonism and in cases of atypical presentations of parkinsonism and dystonia with predominately bulbar and upper extremity symptoms even in the absence of family history, as de novo mutations have been described.

As mentioned above, more common causes of primary and secondary dystonia and early-onset parkinsonism should be excluded. Screening for Wilson disease is paramount as this is a treatable degenerative disorder. Brain imaging is recommended to exclude a structural lesion. Genetic testing for DYT1 dystonia, parkin mutations, and Huntington disease may be considered with proper genetic counseling. A levodopa trial to evaluate for DRD is recommended, and a trial with dopamine agonist or levodopa for levodopa-responsive parkinsonism should be considered. At this point, measurement of CSF HVA levels is not indicated, and it is a nonspecific finding. Genetic testing is now available and can be considered in the setting of proper counseling. As noted, not all cases of RDP have identifiable mutations.

Management/Prognosis

There is minimal or no response to dopaminergic agents, and only a few patients respond to other antispasmodic agents. There is only one case reported of an RDP patient undergoing deep brain stimulation, and no benefit was observed with bilateral GPi DBS. In a handful of patients, selective botulinum toxin injections in the limbs were helpful.

Unfortunately, from the reports of the published cases, the symptoms rarely improve significantly after the primary onset, although there is documentation of mild improvement, especially in the leg symptoms, in a few patients. The bulbar and arm symptoms do not tend to improve at all with time. Supportive therapy is recommended: this includes treatment and monitoring for dysphagia, physical therapy to prevent contractures, and treatment of psychiatric features, if present. Genetic counseling is also recommended.

The utility of decreasing physical stress has not been demonstrated, however because infections and other stressors may be the triggers, it has been postulated that careful treatment of insipient infections could be beneficial, and alcohol, psychologic stress, and excessive exercise, should be avoided when possible.

Glossary

Dystonia – Disorder characterized by involuntary movements and postures which are usually directional in nature.
Focal dystonia – Dystonia involving only one body region.
Generalized dystonia – Dystonia involving both the legs and at least one other body region, or one leg and the trunk.
Geste antagoniste – Specific sensory modality (e.g., light touch) used by a patient suffering from dystonia to lessen the abnormal posture or repetitive movements (also called sensory trick).

Null point – Position in which a dystonic tremor diminishes.
Primary dystonia – Isolated dystonia (absence of other movement disorder except tremor) and no secondary cause or structural abnormality.

Definition and History

Dystonia is an involuntary hyperkinetic movement disorder characterized by simultaneous contraction of agonist and antagonist muscles leading to abnormal postures or movements. Dystonia is classified as primary when it is the only movement disorder (except tremor), and there is no secondary etiology, and as secondary when it is associated with other movement disorders or if it is due to inherited and/or degenerative disorder or an etiology or structural lesion is demonstrated. Primary dystonia can be further classified according to the age of onset: early (age of onset less than 26 years, typically DYT1), late (age of onset greater than 26 years), and mixed early and late onset. DYT13 is one of the two forms with a mixed age of onset (the other being DYT6). PYT13 is characterized by segmental upper body dystonia with myoclonic-like jerks of the neck and shoulders. It was first described in 1997 in a large non-Jewish Italian family. The locus for this disorder was identified in 2001, but the gene has not yet been elucidated.

Pathogenesis/Pathophysiology

DYT13 is inherited in an autosomal dominant fashion with reduced penetrance (58%). It is caused by a mutation in a yet unknown gene at the locus 1p36.32–p36.13. One of the candidate genes is the *cvHsp* gene, which is a member of the heat-shock protein family. The protein is present in the brain (striatum, substantia nigra, and amygdala) and other tissues. It is interesting to note that it bears similarity to torsinA, the abnormal protein in DYT1, which is also a member of the heat-shock protein family.

Epidemiology/Risk Factors

DYT13 is a rare form of primary torsion dystonia. Only 11 cases have been reported so far, and all were members of a large non-Jewish Italian family. No risk factor has been identified at this point.

Clinical Features and Diagnostic Criteria

DYT13 has a very variable age of onset: it typically presents in adolescence (mean age 15.6 years), but the range is from 5 to 43 years. The dystonia classically starts in the cranio-cervical region (neck, face, larynx, and pharynx), and less commonly in the upper extremities. The patients described with DYT13 did not have any other movement disorder other than dystonia, with the exception of prominent jerky (Myoclonic - like) neck and shoulder movements and tremor in some. Compared to the patients with DYT6, the other form of mixed onset primary torsion dystonia, there seems to be less laryngeal involvement. The progression is typically slow, with most patients, being relatively mild and able to perform their daily activities. Of the 11 cases described, generalization occurred in only two, and in both the cases, the dystonia remained relatively mild and the patients remained ambulatory, despite the fact that they had a more diffuse involvement. This is in contrast to DYT1 where severe generalized dystonia may lead affected individuals to be wheelchair bound.

Differential Diagnosis

The differential diagnosis includes sporadic cervical dystonia, inherited dystonia with prominent cranio-cervical involvement (DYT4, DYT6, DYT7) as well as other forms of primary torsion dystonia (e.g., DYT1). Secondary causes of dystonia are less likely since this condition presents with isolated dystonia (with or without dystonic tremor, typically of the head), however, as it is a highly treatable disorder, Wilson disease should be considered. Structural lesions which may result in head postures may also be considered. As with all other forms of early onset dystonia, the dystonia-plus condition, dopa-responsive dystonia should also be kept in the differential.

In case of a dystonic tremor of the head, the differential diagnosis should also include essential tremor (in this condition, when a tremor of the head is present, there is also a tremor of the upper extremities) and head titubation (which is usually accompanied by other cerebellar features). Occasionally, Parkinson's disease may have a head tremor, but other features of the disease, such as rest tremor, rigidity, bradykinesia are present, and the tremor typically involves mainly the chin.

To differentiate a dystonic tremor from another type of tremor, a few characteristics can be very useful to the clinician: first, the dystonic tremor is typically irregular in amplitude and rhythm, there is typically an accompanying abnormal posture, a null point may be present, and a geste antagoniste is typically used by the patient to stop the tremor or improve the abnormal posture

Diagnostic Work-up/Tests

First, as it is the case for other types of dystonia, a careful and detailed family history should be performed. As this is an autosomal dominant disorder with reduced penetrance, in

theory, apparently sporadic cases may have this condition. However, such cases will not be identified until the gene is elucidated. Second, a medication history should be obtained, including current and past exposure to neuroleptics and antiemetics to elucidate medication induced tardive dystonia.

There is no specific test for DYT13, and when the diagnosis of DYT13 is suspected, it is because a primary dystonia involving the cervical and cranial muscles is present. The work-up is accordingly. MRI of the brain should be considered. It is also prudent to consider the diagnosis of Wilson disease, a treatable neurodegenerative disease in patients presenting before the age of 50 years. Evaluation for Wilson disease includes serum ceruloplasmin and slit lamp examination, and may include 24 h urine collection for copper. According to the patient's presentation, other secondary causes should be evaluated. In the presence of an isolated abnormal posture of the head (without dystonic tremor), one should consider MRI of the cervical spine to evaluate for a structural lesion of the spine or of the spinal cord.

Genetic testing for the DYT1 GAG deletion may be considered in: (1) young patients (less than 26 years), (2) if there is a positive family history of early-onset dystonia, and (3) in patients with evolution to generalized dystonia. A trial of L-dopa may be considered as an empiric diagnostic test for DYT5 (GTPCH1 deficiency), a treatable cause of dystonia. This is more likely if there is diurnal fluctuation, spasticity, parkinsonism, or a family history of dystonia or parkinsonism, however, cases with isolated cervical or brachial dystonia have been reported.

Once other causes have been eliminated and when the diagnosis of DYT13 is still suspected, there is unfortunately no clinical genetic testing available for this condition at this point of time.

Management

The preferential treatment for a focal dystonia in the cranio-cervical region and brachial regions is botulinum toxin injections. When the dystonia involves multiple other body parts or is generalized, treatment options include: anticholinergics (e.g., trihexiphenidyl), benzodiazepines (e.g., clonazepam), baclofen, or injections of botulinum toxin in the most affected muscle groups. Of note, a 1 month trial of levodopa/benserazide was performed in two of the affected patients without success. None of the reported patients have been treated with deep brain stimulation to our knowledge.

Prognosis

This form of primary torsion dystonia typically has a slow but definite progression to other body region(s). Only two of the 11 reported patients evolved to generalized dystonia. In all patients, including the patients with generalized dystonia, the prognosis was good with no impairment of daily activities.

E

Electroencephalography (EEG)

P Motika and D C Bergen, Rush University Medical Center, Chicago, IL, USA

Glossary

Electroencephalogram (EEG) – A recording of electrical activity produced spontaneously by neurons in the brain, commonly used in the diagnosis and management of seizure disorders.
Seizure – Paroxysmal abnormal electrical activity produced by nerve cells in the central nervous system. These discharges may result in overt clinical symptoms or signs which may be experienced by the patient or observed by others.
Status epilepticus – A state of prolonged seizure activity or multiple seizures without a return to baseline.

Definition and History

Electroencephalography (EEG) is a technique used in the diagnosis and management of different forms of epilepsy and some movement disorders. EEG measures the electrical activity of the brain as a function of voltage potentials between different regions on the scalp. The electrical activity recorded is a summation of the activity of a large number of neurons in the cerebral cortex immediately beneath the skull. This registration provides useful information on both the normal activity of the brain in different states (e.g., sleep and wakefulness) and abnormal activities resulting from a variety of disease processes.

EEG has its origins in the long history of electrophysiology experimentation. However, the person generally credited with the first application of EEG to human subjects is Hans Berger (1873–1941), a German neuropsychiatrist, who began recording EEG from people in 1924. The use of EEG has increased significantly in recent decades, as technology has improved and new applications have been discovered.

Methods

The most routinely encountered method of EEG recording begins with the placement of recording electrodes (metal discs) at standardized anatomic locations on the scalp. The exact number and placement of electrodes can vary depending on the purposes of recording. Typically, all major regions of the brain will be covered to some extent. A conducting gel solution is used to reduce electrical resistance at the skin. The electrical signals acquired by the electrodes are then fed through an amplifier and filtered so that frequencies only within the usual bands, generated by cortical activity, are displayed. In the past, electrical signals were recorded on a continuously moving strip of paper by a pen that deviated up or down according to the changes in the voltage. Current EEG equipment allows the digitization of the analog EEG signals recorded by the electrodes, and therefore, they can be displayed and modified by a computer. In special cases, typically for localizing the epileptogenic cortex for the purpose of surgical resection, electrodes may be surgically placed inside the skull. They may be placed directly on the surface of the brain or stereotactically implanted within the brain in order to reach deep-lying brain structures. This enables much greater precision in the localization and characterization of electrographic abnormalities. Similar surface recordings may also be done during brain surgery to remove epileptic cortex, tumors, or other abnormal tissue.

EEG is sometimes necessary for the evaluation of the paroxysmal episodes of chorea or dystonia (paroxysmal dyskinesias). As these disorders are sometimes considered an interface between epilepsy and movement disorders, a search for a deep cortical or subcortical epileptic focus may require extra surface electrodes (double-density montages) or cortically placed electrodes.

The recorded electrical activity is routinely viewed as a series of continuous horizontal lines representing voltage differences between pairs of electrodes (**Figure 1**). Deviations of these lines, up or down, reflect changes in the

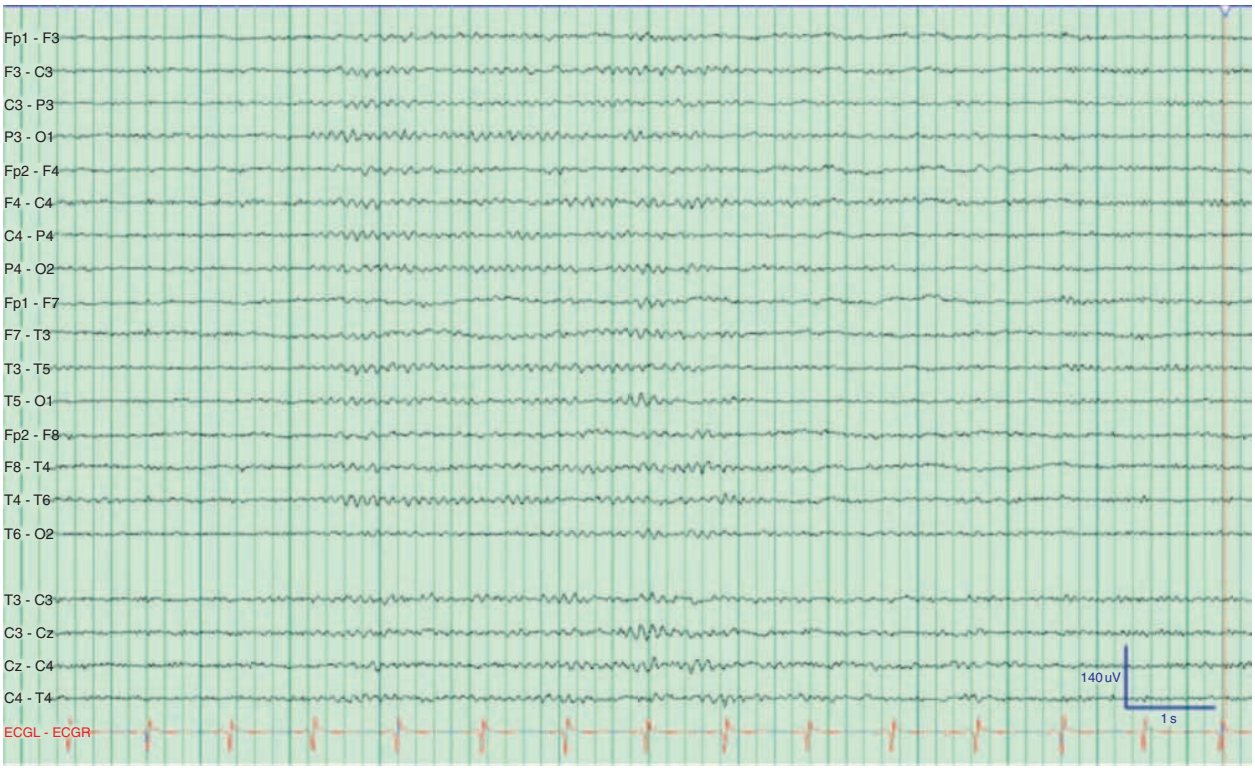

Figure 1 A snapshot of a normal EEG recording. Each vertical line represents 1 s. Each horizontal line represents the potential difference between two interconnected scalp electrodes. The letters refer to the brain region (Fp = frontopolar, F = frontal, C = central, P = parietal, O = occipital). Odd numbered electrodes are placed on the left side of the head and even numbers on the right. An ECG (cardiac) tracing is at bottom in red.

summated membrane potentials of large populations of cortical neurons. Rearrangement of the groupings of paired electrodes into different 'montages' allows an improved spatial analysis of the signals, and thus for an increased diagnostic efficacy. The actual amplitude or strength of a given signal may be measured, to a certain extent, by measuring the voltage between a single electrode and a relatively electrically neutral reference point such as the mastoid, or with the average of all electrical activity.

EEG interpretation is generally performed by neurologists, often with specialized training, by visual analysis. The complexity of EEG signals has precluded automatic, solely computerized EEG reading. Computerized EEG analysis has proved useful, however, in certain specialized situations such as long-term EEG monitoring in critically ill patients with strokes, brain trauma, and other life-threatening conditions.

Interpretation

The interpretation of the electroencephalogram rests on the differentiation between abnormal and normal electrical activity. The brain generates a continuous stream of activity that varies between wakefulness and the different stages of sleep, as well as with the level of alertness and environmental stimuli. These rhythms, generated or influenced by specific regions of the brain such as the thalamus, are the electrical representation of the normal function of the cerebral cortex. Well-established parameters for these findings are age specific. For example, a healthy adult in a state of wakefulness is expected to have a characteristic rhythm over the parietooccipital regions of the brain, consisting of monomorphic alpha (~8–13 Hz) waveforms. Other rhythms are normally seen over other parts of the brain. Changes in these basic patterns may suggest an underlying abnormality.

The types of abnormalities seen on EEG vary dramatically, and may include changes or loss of normal rhythms or the emergence of various abnormal rhythms. Abnormalities are analyzed in terms of their spatial location, waveform morphology, and rhythmicity, as well as their evolution over time. Although many different subtypes exist, there are only a few broad morphologic categories into which most abnormalities may be grouped:

1. decrease or increase of the underlying frequency;
2. decrease or increase in voltage/amplitude;
3. morphologically distinct activity.

These are further characterized by location (focal versus diffuse patterns), and more specifically, by their specific morphology and evolution.

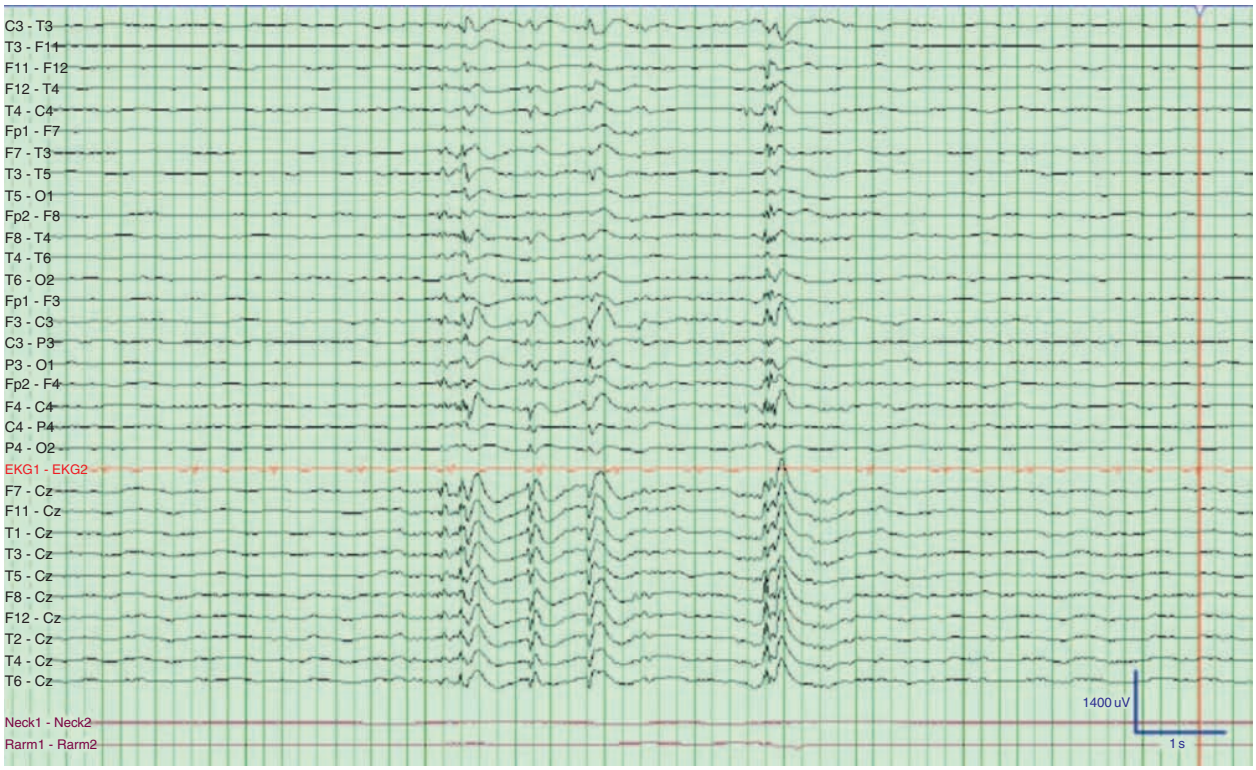

Figure 2 Abnormal epileptiform discharges are seen in the form of bursts of spike and slow wave activity.

The slowing of background rhythms may be seen in a wide variety of conditions, including metabolic abnormalities, medication effects, and postictal states. The EEG in patients with epilepsy characteristically shows interictal, sharply configured, and paroxysmal discharges called spikes, sharp waves, or epileptiform activity, a result of the hyperexcitability of these neuronal circuits (**Figure 2**). Sustained epileptiform discharges that evolve rhythmically are characteristic of seizures themselves. A normal interictal EEG, however, does not rule out a diagnosis of epilepsy.

Applications

In the evaluation of some movement disorders, EEG is a useful adjunctive tool when used in combination with the clinical history, physical examination, and other supportive data. When a clinical diagnosis of epilepsy is suspected, a routine EEG (~45 min) can often help confirm the diagnosis. In some cases, more information may be gleaned from a prolonged EEG that includes drowsiness and sleep, that is, states that often bring about abnormal activities that are absent in the awake state. Admission to a hospital for prolonged and continuous video EEG monitoring is useful in a variety of situations where diagnosis and management are difficult. The availability of ambulatory EEG devices has also extended the ability of the clinician to diagnose epilepsy.

EEG is also frequently used in the acute setting when serious and life-threatening conditions such as status epilepticus are of concern, particularly, as several studies have shown that subclinical status epilepticus tends to be underdiagnosed. In this setting, prolonged EEG monitoring may be the only objective way to ascertain if the seizure activity is ongoing and if the treatment is effective. Finally, the EEG is increasingly part of the physiologic monitoring performed in critical care units, to monitor ongoing cerebral activity and help identify and quantify serious conditions such as increased intracranial pressure or cerebral ischemia.

The standard EEG is invariably unchanged during abnormal movements related to movement disorders. For example, the intermittent movements of paroxysmal dyskinesia are often difficult to differentiate clinically from frontal lobe seizures. The EEG shows no changes during the dyskinesias. On the other hand, unless completely obscured by movement and muscle artifact, the EEG almost always shows abnormal activity during such seizures. Similarly, tics cause no EEG changes, whereas myoclonic seizures are invariably accompanied by diffuse spike/wave discharges.

Electromyography (EMG)

R M Enoka, University of Colorado at Boulder, Boulder, CO, USA

Glossary

Amplitude cancellation – The reduction in signal amplitude due to the summation of overlapping positive and negative phases of concurrent muscle fiber potentials.
Electromyogram (EMG) – A recording of the field potentials generated by the currents that underlie muscle fiber action potentials.
Field potential – The potential difference (voltage) between two locations caused by the currents associated with the muscle fiber action potentials.
Interference EMG – The signal obtained by the superimposition of many muscle fiber potentials.
Motor unit – A motor neuron, its axon, and the muscle fibers it innervates.
Rectification – A processed EMG recording in which the negative phases of the muscle fiber potentials are either eliminated (half-wave rectification) or converted to an absolute value (full-wave rectification).

Electromyography (EMG) is the technique used to record the electrical signals generated by muscle (myo) fibers in response to activation by the nervous system. The recording obtained with this technique is known as an electromyogram. The first report of the technique was published in 1849 when the German physiologist Emil de Bois-Reymond (1818–1896) demonstrated the existence of electrical currents in nerves and muscle.

The electrical signals measured with EMG correspond to the field potentials associated with the currents that underlie muscle fiber action potentials. The field potentials are recorded with electrodes that are either attached to the skin over the muscle or inserted into the muscle. Because the electrodes remain in the same location during a muscle contraction, they detect the field potentials as the action potentials propagate along the muscle fibers from the neuromuscular junctions to the ends of the fibers.

A typical electromyogram obtained during a muscle contraction comprises the summed field potentials due to the activation of many muscle fibers. The number of muscle fibers activated during a muscle contraction depends on the intensity of the contraction and is related to the number of motor neurons that are recruited for the task. A motor neuron and the few hundred muscle fibers it innervates are known as a motor unit and the nervous system controls muscle force by varying the amount of motor unit activity. Because there is usually a high fidelity between the generation of an action potential by a motor neuron and its subsequent appearance as muscle fiber action potentials, EMG recordings provide information about the activation of muscle by the nervous system.

Depending on the geometry and location of the electrodes, an electromyogram can range from a recording of the muscle fiber potentials belonging to a single motor unit through to those produced by many motor units (**Figure 1**). The most common approach used in EMG is to attach a pair of electrodes to the skin, connect the electrodes to a differential amplifier, and record the field potentials as the action potentials propagate along many muscle fibers. The subsequent recording, which is known as a surface EMG, comprises waveforms with varying numbers of positive and negative phases that result from the field potentials approaching, passing under, and then traveling away from the electrodes. Because the electromyogram comprises the sum of these waveforms, the field potential associated with each action potential is distorted by the summation of the overlapping positive and negative phases and the composite signal is referred to as an interference EMG.

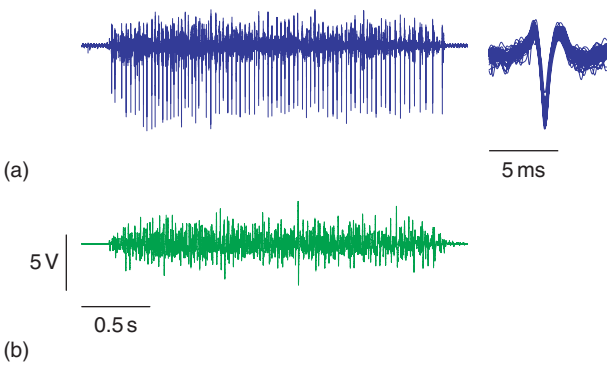

Figure 1 EMG recordings obtained during a voluntary contraction of the tibialis anterior muscle. (a) An intramuscular electrode detected a signal that was dominated by the field potentials associated with the activation of a single motor unit. The potentials for the single motor unit are superimposed to the right of the trace. (b) A surface recording of an interference EMG that comprised the summed potentials of many motor units.

A controversial issue in the interpretation of the electromyogram is to determine the information it provides about the output from the spinal cord. Because the electrodes record field potentials generated by muscle fiber action potentials, the structure of the interference EMG is also influenced by the properties of the muscle fibers and the characteristics of the recording configuration in addition to the activation of the motor units by the nervous system. One of the key properties of the interference EMG, which has been known for almost 100 years (Adrian, 1925), is that summation of the overlapping positive and negative phases of concurrent field potentials reduces the absolute amplitude of the signal. This effect is known as amplitude cancellation. The reduction in signal amplitude due to cancellation from the summation process increases progressively with contraction force and reaches a value of about 70% during a maximal contraction. Although EMG amplitude during a submaximal contraction provides a reasonable estimate of muscle force when normalized to the value recorded during a maximal contraction, the waveform associated with each motor unit is altered by cancellation. As a consequence, it is usually difficult to identify the waveforms generated by single motor units in an interference EMG. Technical advances with multiple-electrode systems, however, have enhanced the ability to decompose the interference EMG into its constituent motor unit waveforms.

Several measurements can be used to characterize the interference EMG. In general, these include quantifying its amplitude and estimating its spectral properties. Both assessments begin by band-pass filtering the recording in the range of 10–800 Hz to attenuate the contributions from sources other than the muscle of interest. Although filtering can reduce the contributions by movement artifacts and signals generated by radiofrequency sources, it does not alter contributions from neighboring muscles, which are referred to as cross talk. To estimate EMG amplitude, the filtered signal is rectified to obtain the absolute values and averages are calculated over specified intervals. EMG amplitude is reported in volts or as a percentage of the value obtained during a reference contraction. The standards advocated by the International Society of Electrophysiology and Kinesiology for reporting EMG data can be found at www.isek-online.org/standards_emg.asp. Note that rectification does not prevent amplitude cancellation because cancellation occurs before the signal is rectified.

Many investigators determine the spectral content of the electromyogram. Due to the significant influence of the shape of the recorded field potentials on the distribution of power in the density spectrum, changes in the shapes of the potentials, such as those that can occur during fatiguing contractions, cause the distribution to shift. Aside from the influence of such global effects on the activated muscle fibers, however, a spectral analysis provides limited information about the motor units that are activated during a contraction. The factors that also influence the frequency spectrum include: (1) distortion of the field potentials by the summation of overlapping positive and negative phases; (2) the distribution of the rates at which the motor neurons discharge action potentials; (3) the amount of correlation in the discharge times of the activated motor units to the frequency spectrum; (4) the anatomical properties of the muscle fibers (e.g., length, angle of inclination to the surface, and location of the neuromuscular junctions); (5) the distance between the activated muscle fibers and recording electrodes; and (6) rectification. Due to the multiple factors that can influence the frequency spectrum, a spectral analysis of the electromyogram does not provide information about such properties as the upper limit of recruitment, the types of motor units recruited during a contraction, or the fiber type proportions of a muscle.

Nonetheless, the electromyogram does provide useful information about the timing of muscle activation and, when normalized, an estimate of the force exerted by the muscle. These features are useful for applications that range from the control of prosthetic devices to the assessment of strategies used by the nervous system to perform various tasks.

Encephalitis Lethargica and Postencephalitic Parkinsonism

J A Vilensky, Indiana University School of Medicine Fort Wayne, Fort Wayne, IN, USA
R C Duvoisin, University of Medicine and Dentistry of New Jersey (Emeritus), New Brunswick, NJ, USA

Glossary

Ataxia – Incoordination and unsteadiness due to the brain's failure to regulate the body's posture, strength, and direction of limb movements.
Athetosis – Involuntary writhing movements particularly of the arms and hands.
Bradykinesia – Slowed ability to start and continue movements, and impaired ability to adjust the body's position.
Festination – A gait marked by an involuntary hurrying in walking.
Hypomimia – Masked-like facial expression.
Ptosis – An abnormally low position (drooping) of the upper eyelid.
Somnolence – Sleepiness, the state of feeling drowsy, ready to fall asleep.

Encephalitis Lethargica

Definition and History

Discovery

During the winter of 1916–1917, in the midst of World War I (WWI), a small number of patients developed a previously unknown acute infectious disease. Constantin von Economo in Austria, Cruchet in France, Hall in England, and others described a prodromal phase with symptoms of an upper respiratory infection, followed by profound lethargy and somnolence, usually associated with ocular and bulbar palsies and often with extrapyramidal manifestations, including a state resembling Parkinson's disease. Somnolence was distinctive in that, if awakened, patients were lucid and could readily answer questions and follow commands, but if left to themselves, they immediately returned to sleep (**Figure 1**). On 17 April 1917, at a meeting of the Vienna Society for Psychiatry and Neurology, von Economo presented his findings on

Figure 1 Somnolent female EL patient.

this new disease, which he named, encepha litis lethargica (EL). Subsequently, cases of EL were recognized throughout the world.

Epidemic

By 1920, EL had become a world epidemic spreading first through Europe and then overseas to North America. During this time, EL was reported under various names, including epidemic encephalitis, von Economo's disease, and the popular 'sleeping or sleepy sickness.' The available data indicate that the highest number of cases occurred in 1920 and again in 1924. Conservatively, there were 1 000 000 cases worldwide with a possible mortality of 50% during the epidemic period, with tapering rates after 1930. Since 1940, sporadic reports have continued to appear, suggesting that an EL epidemic might recur 1 day. One such 2004 report from England described 20 cases that seemed 'remarkably similar' to the acute cases described in the years of the epidemic. However, the absence of a pathognomonic sign associated with EL makes diagnosis problematic, and it is questionable whether the post 1940 phenotype is the same as that seen during the epidemic period.

Pathogenesis/Pathophysiology

Etiology

At the time of the EL epidemic, various toxicologic, bacterial, or viral causes were suspected. EL was suggested to relate to the Spanish influenza epidemic. Yet, epidemiological data failed to support a direct association of the two diseases. Furthermore, the improved understanding of influenza, brought by the isolation of its virus in 1934, rendered the notion of direct connections between influenza and EL largely untenable. Other studies that linked viral or bacterial infection to EL were later criticized for methodological weakness.

Modern efforts to identify influenza RNA segments in the brains of EL victims have not been successful, again casting additional doubt on the influenza hypothesis. However, these results are inconclusive, because very few brains are available and it is unknown whether RNA fragments survive for 80 years in nonrefrigerated formalin fixation. A recent English study that identified 20 putative new EL cases reported that 11 had preceding pharyngitis. The study suggested that the EL phenotype might be a secondary autoimmunity to Group A *Streptococcus* infection, that is, a PANDA (pediatric autoimmune neuropsychiatric disorders associated with *Streptococcus* infections) analogous to Sydenham's chorea.

Pathology

Postmortem study of patients who died during the acute phase of EL revealed findings that were later recognized as typical of viral encephalitis. The gross inspection of a fresh brain revealed congestion of meningeal and cerebral capillaries, causing the brain (**Figure 2**) to be reddish in cross-section. The microscopic examination of formalin-fixed sections showed perivascular lymphocytic and plasma cell infiltration, endothelial proliferation, and acute degenerative changes in neurons, including swelling, eccentric nuclei, chromatolysis, neuronphagia, and some glial reactions. The midbrain, particularly the substantia nigra, the pontine tegmetum, and the basal ganglia showed the most marked changes, but there was considerable variation from patient to patient. In cases coming to autopsy in the chronic phase (cf. below), there was a severe loss of neurons in the substantia nigra, more severe than that typically seen in idiopathic Parkinson's disease. This lesion of the substantia nigra was somewhat perplexing at the time, because the existence of the dopaminergic nigrostriatal system was then unknown and it was not until several decades later that the substantia nigra was recognized as the primary site of pathology in Parkinson's disease. Neurofibrillary tangles were prominent in surviving neurons, but in contrast to Parkinson's disease, Lewy bodies were absent.

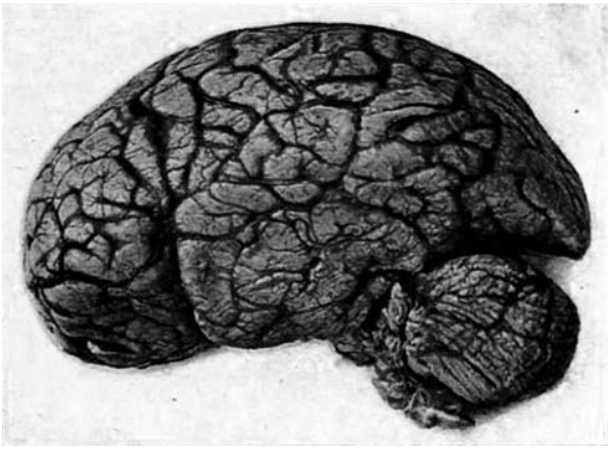

Figure 2 Left brain hemisphere of morbid EL case.

Epidemiology/Risk Factors

Transmission

There was no strong evidence suggesting that EL was contagious. Clinicians speculated that transmission was possibly through nonsymptomatic carriers or the air, because the 1919–1920 Italian and Austrian epidemics were only a week apart, which is consistent with strong winds across the Alps.

Risk factors

It was speculated that the conditions found during WWI, such as concentrated human populations and general hardship, predisposed a person to acquire EL. It has also been suggested that Jews had a higher incidence of EL.

Others suggested the correlation of physical or emotional trauma with the beginning of the acute or chronic phases. With the epidemic occurrence of influenza during the same time period, some clinicians thought that acquiring influenza could increase a person's risk of developing EL. Finally, some clinicians believed that multiple different pathogens could act as symbiotic partners with those of EL.

Clinical Features and Diagnostic Criteria

Prodromal stage

Many cases of EL were preceded by a typical 'grippe-like' prodromal stage of general discomfort, lassitude, seediness, shivering, headache, vertigo, vomiting, a slight fever, and mild pharyngitis. This stage was almost always short, often lasting only 1–2 days.

Disease stage

The gamut of signs and symptoms associated with the acute phase of the disease was wide, but several typical syndromes were identified: somnolent–ophthalmoplegic (somnolence, ocular movement disorders); parkinsonism with bradykinesia, rigidity, festination, spasticity, and tremor; psychiatric with no somatic symptoms; cerebellar with ataxic gait and speech; and hyperkinetic presentation with chorea, athetosis, seizures, and restlessness. Because the signs and symptoms varied between individuals, could change rapidly within any single individual, and could sometimes be very transient, some clinicians of the period did not consider these categories particularly useful. The variations in the manifestations of the disease were presumed to have resulted from the variation in the locus of the infection within the CNS.

Those who survived the initial disease state gradually recovered over several weeks to a year. However, they were typically afflicted with a persistent fatigue or inertia and were said to have 'neurasthernia.' Many had significant personality changes, and a broad variety of behavioral disorders (particularly in children) and bizarre compulsions and tics. The pejorative term, 'Apache,' was used to characterize these children, referring to the wild behavior attributed to Apache Indians.

In at least a third of the survivors, as the lethargy subsided, signs of parkinsonism developed with tremor, rigidity, bradykinesia, festinating gait, stooped posture, scoliosis, masked faces, hypophonic and tachyphemic speech, pallilalia, drooling, and seborrhea: this phase of the disease was termed postencephalitic parkinsonism (PEP). The Parkinsonian syndrome was distinctive because of features not typical of Parkinson's disease such as bizarre postural abnormalities, oculogyric crises, and ocular palsies, including ptosis, diplopia, and paralysis of upward gaze.

Oculogyric crises were a particular associated feature of PEP. In a typical crisis, the patient abruptly lapsed into a rigid state with the head and eyes deviated upward and to one side as if the patient were intently staring at the ceiling. These attacks lasted a few minutes to many hours and then suddenly stopped.

Follow-up studies documented that the majority of EL survivors developed sequalae, PEP being the most prominent. Some observers stated that if one included mild degrees of facial hypomimia, all survivors had PEP to some degree. In children, behavioral problems were also frequent. Some patients who had not experienced a clinically apparent acute phase of illness developed typical PEP insidiously. The long-term clinical course of EL was marked by periods of improvement interspersed with evidence of progression. In the 1920s, patients with PEP were more numerous than those with idiopathic Parkinson's disease. They formed a distinct population cohort that accounted for two thirds or more of the Parkinsonian patients seen in hospitals and clinics at that time. With the decline in the incidence of PEP after the epidemic, the proportion of Parkinsonian patients classified as PEP also declined to about a half during the 1950s compared with that in the period 1931–1942. By the early 1960s, the proportion was ~10%. By 1970, only rare elderly long-term survivors remained.

Severe disability and behavioral disorders led to institutional care for many of the chronic phase patients in the years of the epidemic. Groups of survivors could still be found in the 1960s in chronic care facilities, some specialized for their care such as the Highlands Hospital in England. PEP patients examined in the 1960s, four decades after the epidemic, appeared to have been stable for many years and showed few signs of continuing progression. One cluster of long-term survivors was popularized by Oliver Sacks in his 1973 book, *Awakenings*, and in the 1990 movie by the same name.

Differential Diagnosis

At the time of the epidemic, diagnosis in the acute phase was typically suggested by signs and symptoms of a generalized disturbance of the CNS, combined with disturbed sleep rhythm, usually lethargy and somnolence, ocular disturbances, diplopia, and bulbar palsies, unreactive pupils, and acute behavioral disturbances. However, diagnosis, especially of the nonsomnolent types, was often based on the exclusion of other neurological conditions. One monograph of EL from the period stated: 'And while no other disease, perhaps, presents so many difficulties in diagnosis as does this protean complex. . .that while it usually offers very close resemblance to one or another condition, careful and painstaking study and comparison will reveal either some incongruity, some essential

symptom lacking or a superabundance of elements, thus offering a definite aid or conclusive basis for differential diagnosis.' Since EL lacked any definitive sign, it is possible and perhaps likely that it was substantially overdiagnosed. The subsequent development of PEP is probably the best diagnostic sign. However, in children, seizures and the rapid development of antisocial behavior in the absence of traumatic brain damage were the most reliable diagnostic signs.

In patients in the chronic phase with PEP, the major differential diagnosis was that of Parkinson's disease. The relative youth of the PEP patients was an important point of distinction. However, as the affected PEP cohort aged through the 1940s and 1950s, the distinction occasionally presented more difficulty. Useful points of differentiation included tremor characteristics, because PEP patients rarely had the pill-rolling alternation characteristic of the idiopathic disease. Moreover, PEP featured prominent sleep disturbances, respiratory anomalies such as hyperpnea and respiratory tics, various dysarthrias, palilalia, and echolalia, and choreiforrn, dystonic, and athetotic movements. Psychiatric disturbances and personality changes were also common. Finally, the occurrence of ocuolgyric crises served as the most widely accepted sign of the PEP disorder.

Arteriosclerotoic parkinsonism was distinguished by the advanced age of the patients and the prominence of lower extremity involvement with gait apraxia. Wilson's disease presenting as juvenile parkinsonism and the rigid form of Huntington's disease could have readily been confused with PEP. The finding of the Kayser–Fleischer ring in the former and a positive family history in the latter would have suggested the correct diagnosis.

Several similar morbid entities unknown in the epidemic time have since been recognized, notably, progressive supranuclear palsy (PSP), multiple system atrophy (MSA), striatonigral degeneration (SND), and corticobasal degeneration (CBG). PSP, first identified by Richardson in 1964, may have been misdiagnosed as PEP during the epidemic period. However, the disturbance in ocular motility in PSP differed from PEP and the characteristic supranuclear palsy of PSP was never described in PEP. The combination of cerebellar signs with a primarily bradykinetic Parkinsonian syndrome, typical of MSA, was within the clinical spectrum of PEP, but the relentless progression of disability was not typical of PEP. Likewise, it is possible that some cases of familial spinocerebellar degenerations were included in reported series of PEP.

Diagnostic Work-Up/Test

Spinal fluid lymphocytosis sometimes occurred with increased protein levels, although rarely above 100 mg ml^{-1}. At the time of the epidemic, the value of determining the CSF sugar concentration was emphasized to exclude tubercular meningitis. Abnormal colloidal gold curves, similar to those observed in acute polio and neurosyphilis, were also reported. The significance of those curves is not clear, but many years later, oligoclonal bands in CSF were reported in contemporary cases of EL. There were no laboratory aids in the diagnosis of the chronic phase of PEP. CT and MRI scanning were not yet available. Pneumoencephalography was rarely performed.

Management

During the epidemic period, many different treatments for EL were utilized. In New York, a large-scale effort supervised by the Matheson Commission was devoted to developing vaccines to treat the disease, using the herpes simplex virus and *Streptococcus viridans* independently. The herpes vaccine was reported, by the Commission, to be an effective treatment, yet researchers have since disputed this claim. In relation to the focal infection theory of the time, oral infections were thought to be a precursor to EL, and patients were often prescribed to have some or all of their teeth extracted. In most cases, the management of EL patients during the epidemic period was primarily supportive. No specific therapy has emerged from recent experiences with the sporadic cases that have been reported. The possibility that some cases represent autoimmune disorders has suggested immunosuppressive therapy, and some recent cases have responded well to treatment with methylprednisolone.

The treatment of the chronic phase during and following the epidemic of the early twentieth century relied primarily on the then treatment of Parkinson's disease, Belladonna alkaloids. These anticholinergic agents were moderately effective in reducing parkinsonism and greatly reduced the frequency of oculogyric crises. High doses were often used and care was needed because of the antimuscarinic side effects, including xerostomia, blurred vision, constipation, hyperthermia, and delirium ('the Belladonna jag'). The Belladonna preparations were later superseded by synthetic anticholinergic agents such as trihexyphenidyl and benztropine. When levodopa therapy was introduced in the 1960s, there were few long-term survivors of EL. Levodopa was effective in suppressing symptoms in PEP patients, but the drug's efficacy was compromised by the side effects, including choreiform dyskinesias and a reappearance of behavioral disorders, psychoses, and compulsive tics that had been quiescent for many years. Insufficient experience with stereotaxic basal ganglia surgery such as thalamotomy in PEP patients does not permit any conclusions.

Epilepsia Partialis Continua

P V Motika and D C Bergen, Rush University Medical Center, Chicago, IL, USA

Glossary

Focal seizure – A seizure beginning locally in a specific part of the brain.
Clonic movement – Repetitive, rhythmic, jerking motions seen during some seizures; clonic activity is diffuse during a tonic–conic seizure, but may be restricted to a limb or to the face during a focal seizure.
Electrocorticography – An EEG recorded directly from the surface of the brain.
Rasmussen's encephalitis – A progressive, unilateral inflammatory disorder often associated with continuous focal motor seizures.

Definition and History

Epilepsia partialis continua (EPC) is a form of partial status epilepticus most commonly consisting of prolonged focal motor seizures affecting the motor strip of one hemisphere, and with a clinical correlate which tends to be localized to one motor region or side of the body. It was known in the past as Kojevnikov syndrome as he was the first to describe and document the syndrome in 1894. His patients suffered from very prolonged (up to 5 years) focal motor jerks, which Kojevnikov believed were secondary to injury of the motor strip. Other Russian physicians of the time observed similar phenomenon and linked it to encephalitis occurring in Siberia in the spring–summer cycle. Beginning in the 1950s, Rasmussen and colleagues described numerous cases of focal motor status epilepticus related to a rare, progressive, localized encephalitis. The continuous jerking movements of such seizures share some features with nonictal myoclonus or tics. Myoclonus, however, usually migrates from place to place on the body, and tics include more complex movements involving several muscle groups. In addition, unlike EPC, tics can usually be voluntarily suppressed for a time.

Pathogenesis/Pathophysiology

EPC is caused by focal injury to the cortex. The numerous possible etiologies for such injuries include inflammatory and infectious lesions, anoxia and ischemia, vascular lesions, metabolic abnormalities, and neoplastic or paraneoplastic lesions. EPC has been found to result from both cortical and subcortical sources based on both human and animal

studies. The pathophysiology is somewhat variable based on the cause. For instance, in Rasmussen's encephalitis, a common cause of EPC, pathologic analysis reveals evidence of acute and chronic inflammation with cytotoxic T cells which damage local neurons, resulting in abnormalities of normal neuronal communication and development of epileptic pathways.

Epidemiology/Risk Factors

The exact prevalence of EPC has not been clearly determined. A study in Great Britain estimated prevalence at less than one per million. There is increased incidence in certain disease states. In some studies, up to 50% of patients with Rasmussen's encephalitis will develop EPC. EPC has been reported in numerous diseases. Though not an exhaustive list, some of the other associated diseases include other forms of measles and other viral encephalitides, developmental malformations such as cortical dysplasia and migration abnormalities, mitochondrial diseases, cerebrovascular disease, neoplastic and paraneoplastic processes, metabolic abnormalities, multiple sclerosis, Alper's syndrome, Creutzfeldt–Jakob disease, human immunodeficiency virus (HIV), and progressive multifocal leukoencephalopathy.

Clinical Features and Diagnostic Criteria

EPC is characterized by continuous, repetitive clonic activity limited to a focal muscle segment or body region. This can be exquisitely focal (e.g., in the thumb) or can involve multiple muscle groups, and can even migrate over time. Though EPC is generally unilateral, cases of bilateral partial motor seizure status epilepticus have been reported, though it is not clear if these should be included under the description of EPC. In extreme cases, EPC can continue for a very prolonged period of time (up to years). Consciousness is typically maintained. The twitching varies in frequency but is typically once to twice per second. It continues during sleep. Focal of weakness or sensory abnormalities may be present. EPC is frequently accompanied by other types of seizures including 'Jacksonian' seizures (which move from place to place on the body) and tonic–clonic seizures. As EPC is a result of an underlying inciting process, other symptoms can often be present and are highly variable depending on the specific disease state.

Differential Diagnosis

The differential diagnosis for prolonged focal motor seizures is broad and can vary depending on whether clinical presentation, electroencephalographic record, or both are used in the diagnosis. The list includes nonepileptic myoclonus, sleep myoclonus, chorea, tremors, dystonias, hemifacial spasm, tics, sleep disorders, myoclonus with various types of generalized epilepsies, (e.g., juvenile mycoclonic epilepsy), and myoclonic status epilepticus.

Diagnostic Workup/Tests

Electroencephalography (EEG) may be useful in the diagnosis and management of EPC. However, it should be noted that EEG may be completely normal in a significant proportion of EPC, and thus a normal EEG does not necessarily rule out the diagnosis. It has been reported that in some cases of EPC with normal surface electrode recordings, abnormalities have been demonstrated using electrocorticography, indicating a deep or very focal source. In those cases that do show EEG correlates, there is no specific pathognomonic electrographic pattern that emerges, and there is wide variance in the numbers of clinically affected patients who demonstrate EEG changes. Abnormalities may include irregular sharp and spike waves, particularly over the motor cortex, and periodic lateralized epileptiform discharges (PLEDs). A full neurologic history and exam along with extensive diagnostic workup is generally indicated, and may include imaging with magnetic resonance (MR), single photon emission computed tomography (SPECT), positron emission tomography (PET), spinal fluid analysis, brain biopsy, or laboratory analysis for inherited or acquired forms of metabolic or hereditary abnormalities.

Management

Identification and treatment of the underlying is the primary goal. Medical treatment varies greatly depending on the diagnosis. Medical management of the seizure disorder itself is a somewhat controversial topic in recent years as there is a question as to whether aggressive treatment of partial motor seizures is effective and beneficial. The primary medications include valproate, ethosuximide, and piracetam for the myoclonic seizure activity. Carbamazepine may be effective in some cases, and benzodiazepines have also been reported as useful.

Prognosis

The prognosis of EPC depends largely on the inciting etiology. Often, EPC due to metabolic abnormalities or medication effect may resolve with removal of the agent. EPC secondary to focal lesions such as stroke or tumor may gradually resolve over time with surgical resection or medical management (and healing of the region). EPC due to infectious/inflammatory etiologies such as Rasmussen's encephalitis tends to have a more prolonged course, and are more refractory to treatment with antiepileptic medications. Rasmussen's encephalitis causes

progressive neurologic decline in the affected hemisphere, and hemispherectomy may be considered in refractory cases.

Essential Tremor: Animal Models

M S LeDoux, University of Tennessee Health Science Center, Memphis, TN, USA

Glossary

Essential tremor (ET) – A clinical diagnosis based on the presence of bilateral upper extremity appendicular tremor without other neurological signs.
$GABA_A$ receptor – One of two (A and B subtypes) ligand-gated ion channels that bind the 'inhibitory' neurotransmitter γ-aminobutyric acid (GABA). $GABA_A$ receptors harbor allosteric binding sites for benzodiazepines, ethanol, and several other small molecules.
Harmaline – A β-carboline found in plants. In mammals, harmaline produces a tremor by activating inferior olivary neurons and their climbing fiber projections to cerebellar Purkinje cells.
Penitrem A – A tremorgenic mycotoxin that is toxic to cerebellar Purkinje cells.
Tremor – An abnormal repetitive and rhythmic movement of any part of the body.

What is Essential Tremor?

Definition and Clinical Features

To this day, essential tremor (ET) remains a clinical diagnosis. ET is an action tremor with both postural and kinetic components. ET exhibits clinical heterogeneity in terms of anatomical distribution, the relative intensity of its postural and kinetic components, and concomitant neurological features. The NIH Collaborative Genetic Criteria and the Consensus Statement of the Movement Disorder Society (MDS) have been used for the diagnosis of ET in subjects entering clinical trials. The NIH Collaborative Genetic Criteria includes the categories of 'definite, probable, possible, and unrateable' ET. The Consensus Statement of the MDS defines 'classic ET' as a bilateral, largely postural or kinetic tremor involving the hands and forearms. Exclusion criteria for 'classic ET' include the presence of abnormal neurological signs, particularly dystonia.

The differential diagnosis of ET is broad since an appendicular action tremor may be a manifestation of numerous metabolic, structural, nutritional, and infectious disorders of the central nervous system (CNS). For example, action tremors may appear after an ischemic stroke or in the setting of hyperthyroidism. In addition, action tremors are side effects of many prescription drugs, particularly those used to treat psychiatric and neurological disorders. Well-known culprits include lithium and valproic acid.

In contrast to traditional views, ET is much more than isolated action tremor of the arms. In fact, the clinical spectrum of ET includes nonmotor and additional motor features. Nonmotor features may include mild cognitive decline, olfactory deficits, and sensorineural hearing impairment. In addition to head, voice, and leg tremor, many subjects with ET also exhibit mild gait ataxia. ET is probably a disorder with important etiological, pathological, and clinical heterogeneity, with action tremor of the arms as a common feature.

Epidemiology

ET is a common movement disorder with prevalence estimates ranging from 0.5% to 5%. Prevalence increases with age. ET appears to affect all racial and ethnic groups.

Neurophysiology

The frequency of ET is between 4 and 12 Hz. ET is an action tremor with postural and kinetic components. In general, tremor frequency decreases with age. Mechanical loads exert minimal effect on ET frequency, which distinguishes ET from enhanced physiological tremor. Multiple lines of experimental evidence suggest that ET is produced by a central nonlinear oscillator.

Genetics

Reported positive family history in subjects with ET has varied widely in published reports (17–100%). Population-based family and twin studies have provided stronger support for the idea that genetic factors contribute to the etiopathogenesis of ET. Genetic linkage studies have identified susceptibility loci on 3q13 and 2p24.1. A recent genome-wide association study using a sample of 452 Icelandic ET cases and 14 394 population controls identified two markers (rs9652490 and rs11856808) in intron 3 of *LINGO1* on 15q24.3 which showed significant association with ET. The encoded protein, LINGO1, exerts regulatory effects on neuronal survival, axon regeneration, and oligodendrocyte maturation.

Postmortem pathology

The neural pathology of ET has received much less attention than other common age-related neurological disorders such as Parkinson and Alzheimer diseases. Recent work has consistently identified cerebellar cortical pathology in ET. Important findings have included Purkinje cell loss, cerebellar cortical sclerosis with proliferation of Bergmann glia, and 'torpedoes.' Torpedoes are rounded swellings of Purkinje cells axons that appear to represent the misaccumulation of disorganized neurofilaments and other organelles including mitochondria. Another important site of pathology may be the locus ceruleus. In this regard, it is important to note that the locus ceruleus sends a dense noradrenergic projection to cerebellar cortex.

Treatment

A subcommittee of the American Academy of Neurology published practice parameters for ET. Based on Class A evidence, propranolol and primidone have proven efficacy in the treatment of limb tremor in ET. Alprazolam, atenolol, gabapentin, sotalol, and topiramate may also be effective in reducing limb tremor (Class B evidence).

Pathophysiology

Positron emission tomography (PET), functional magnetic resonance imaging, magnetic resonance spectroscopy, and clinical-pathological correlative studies point to olivocerebellar pathways as critical to the pathophysiology of ET. ET may be eliminated by ipsilateral cerebellar or contralateral pontine ischemic strokes and PET studies have documented increased cerebellar blood flow in subjects with ET. Indicative of neuronal damage, magnetic resonance spectroscopy documented reduced cerebellar *N*-acetylaspartate levels in subjects with ET.

Criteria for Judging Animal Models of ET

Animal models of human diseases may be judged by several criteria. In the case of movement disorders, animal models are oftentimes criticized because they do not visually mimic the human condition. With the partial exception of primates, the geometry and biomechanical properties of animal limbs show significant differences from humans. As such, animal models, particularly rodents, cannot replicate or mimic the kinematics of ET or any other movement disorder.

One criteria of an animal model is reliability. Simply put, does the model provide consistent results? Validity is another way of judging animal models. Validity comes in three flavors: face, etiological, and predictive. In the context of ET models, face validity means that the model exhibits a motor syndrome that resembles the human condition. Etiological validity indicates that the model derives from the same cause as the human condition. In general, knockin mouse models of neurogenetic disorders have etiological validity. Finally, a model that can be used to predict a key feature of the disorder, such as response to therapeutic intervention, has predictive validity.

As is the case for Parkinson and Alzheimer diseases, ET is probably a syndrome derived from various combinations of genetic and environmental risk factors. The heterogeneity of ET, as suggested by genetic studies and the mixed response to pharmacological interventions, indicates that several different animal models may be required for the purposes of hypothesis-driven functional experiments and drug or device testing.

Animal Models of Action Tremor

Numerous animal models of action tremor are readily available to laboratory researchers. However, most of these models have poor etiological validity. For example,

action tremor is a prominent phenotypic feature displayed by the Trembler-J (Tr^J) mouse which has a point mutation in the gene coding for peripheral myelin protein 22 (PMP22). Action tremors are also seen in other lines of mice (e.g., vibrator, shiverer and jumpy) and rats (e.g., zitter) with spontaneous mutations; however, unlike humans with ET, these rodents have striking pathological changes such as demyelination in the peripheral nervous system or spongiform degeneration in the CNS. Although occasional patients with Charcot–Marie–Tooth disease will exhibit a prominent action tremor, the presence of a severe neuropathy on neurological examination excludes the diagnosis of ET.

As is the case in humans, a wide variety of pharmacological agents can cause action tremors in primates and rodents. One example is the muscarinic agonist, oxotremorine, which produces a generalized tremor. The tremor elicited by oxotremorine does not require an intact olivocerebellar pathway, and, unlike many cases of ET, does not improve with ethanol. Oxotremorine produces a high-frequency tremor (>12 Hz) that slowly abates as the drug is cleared from the CNS.

Tremor can also be produced by nicotinic agonists. In rats, a tail-tremor can be induced by repeated daily subcutaneous (SC) administration of nicotine; at dosages of 0.5 mg kg^{-1} SC daily, tail tremors emerge on the third day of treatment. A collection of pharmacological studies suggests that the nicotine-induced tail-tremor model is mediated by central nicotine receptor systems. The nicotine-induced tail-tremor model has been proposed as a model for ET, and, in this regard, may have predictive validity. Nicotine-induced tail-tremor is suppressed by nonselective and lipophilic β-adrenergic receptor antagonists like propranolol and pindolol. The beneficial effects of propranolol and pindolol are probably mediated by β2-adrenergic receptors since the β1-selective adrenergic receptor antagonist, metoprolol, exerts minimal effect on nicotine-induced tail-tremor. In the context of ET, these cholinergic and other most other pharmacological models of action tremor have poor etiological validity.

Action tremors may appear as the consequence of strategically located structural lesions or cell-type specific neurotoxins. For instance, lesions of the dentate nucleus and/or superior cerebellar peduncle in monkeys cause an action tremor with significant intentional features. In primates, the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes cell death in the catecholaminergic cells of the substantia nigra and locus ceruleus and consistently produces three of the four cardinal features of Parkinson disease: rigidity, bradykinesia, and postural instability. The appearance of tremor after exposure to MPTP is dependent on several technical factors such as route of toxin administration, dosage, species, and dosing schedule. By most accounts, MPTP typically produces an action tremor rather than the classic pill-rolling resting tremor of idiopathic Parkinson disease. The tremorgenic effects of MPTP may evolve over time and depend on relative damage to the locus ceruleus, substantia nigra pars compacta, and other monoaminergic cell groups. Focused studies into the neuropathological and neurophysiological basis for MPTP tremor may provide insight into the clinical association between ET and Parkinson disease.

Neurotoxin (penitrem A), pharmacological (harmaline), and genetic models ($GABA_A$ receptor α-subunit and *Lingo-1* knockout (KO) mice) of ET with etiological and/or predictive validity are well characterized in the current medical literature. Most likely, penitrem A and harmaline have the capability of producing tremor in virtually all mammals. Accordingly, preclinical therapeutic trials can be performed in mice, rats, primates, and other species. In contrast, current genetic models are limited to mice although technology is readily available to generate KO models in rats, pigs, and a few additional mammalian species.

Harmaline

Harmaline is found in numerous species of plants. Harmaline and related alkaloids have been used in traditional/indigenous medicine (Asia, Middle East, and Amazonia) for thousands of years. Harmaline is readily absorbed from the gastrointestinal tract. In experimental studies, harmaline is typically delivered via SC or intravenous routes. All mammals exhibit a readily perceptible tremor after the administration of harmaline. Typical harmaline dosages in rodents are 5–10 mg kg^{-1} SC. After SC injection of harmaline, latency to tremor is less than 10 min. Tremor duration depends on route of administration and dosage, and ranges from 30 to 180 min. A critical aspect of harmaline pharmacology is the rapid development of tolerance to its tremorgenic effects. Tolerance to harmaline tremor is probably due to postsynaptic changes in Purkinje cells. Tolerance constrains the practical utility of the harmaline tremor model.

Harmaline tremor frequency ranges from 4.7 to 7.6 Hz in rhesus macaque monkeys and from 10 to 12 Hz in rats. Tremor amplitude depends on the dosage of harmaline. In contrast, tremor frequency is relative independent of dosage. Harmaline tremor is an action tremor accentuated by movement. In rodents, harmaline tremor is readily detected in the neck, trunk and proximal muscles. In addition, rats and mice typically exhibit ataxia, abducted hindlimbs and reduced locomotion in response to harmaline.

Harmaline tremor originates in the olivocerebellar pathways. Harmaline produces rhythmic firing of inferior olivary neurons. Inferior olivary neurons send climbing fibers to cerebellar cortex. These climbing fibers synapse on the somas and proximal dendrites of cerebellar

Purkinje cells. The climbing fiber input to Purkinje cells results in complex spikes whereas summated parallel fiber input generates simple spikes. Single-unit extracellular recordings from Purkinje cells have shown that harmaline administration is associated with rhythmic complex spike activity and suppression of simple spikes. Harmaline tremor improves with primidone and diazepam. In contrast, the β-blocker propranolol exerts no significant effect on harmaline tremor.

The harmaline tremor model has been employed as a therapeutic screening tool. For example, octanol isomers are structurally similar to ethanol which often exerts beneficial effects on ET. In rats, octanol isomers potently reduced harmaline tremor. In pilot clinical studies, small doses of 1-octanol produced significant reductions in ET tremor amplitude. Thus, the harmaline tremor model has shown predictive validity.

Penitrem A

Penitrem A is one of several known tremorgenic mycotoxins. Other tremorgenic mycotoxins include penitrem B, verruculogen, and fumitremorgen. In mice, dogs, sheep, and humans, tremorgenic dosages of penitrem A produce a neurological syndrome characterized by generalized tremors and ataxia. Higher dosages may produce vomiting and seizures. In rodents, tremors persist for 24–72 h after injection of penitrem A.

Penitrem A has been shown to block high-conductance Ca^{2+} channels and increase neurotransmitter release from synaptosomes. At the pathological and functional levels, the cerebellum appears to be particularly sensitive to penitrem A. Cerebellar cortical blood flow increases several fold shortly after intraperitoneal administration of penitrem A. With penitrem A dosages of 3 mg kg^{-1}, mitochondrial swelling can be detected in rat cerebellar stellate and basket cells although cell death does not occur. Similar mitochondrial changes are seen in cerebellar Purkinje cells. Purkinje cells, particularly those in the vermis and paravermis, also show vacuolation of the smooth endoplasmic reticulum and cytoplasmic condensation with eosinophila. Destruction of the inferior olive does not alter the tremorgenic or pathological effects of penitrem A.

$GABA_A$ Receptor α1-Subunit (GABRA1) KO Mice

$GABA_A$ receptors are pentameric ligand-gated ion channel receptors expressed throughout the CNS. Numerous subunits (α, β, γ, δ, ϵ, etc.) aggregate in various combinations to generate a constellation of channels providing a rich spectrum of pharmacological and electrophysiological attributes. Although widely distributed in brain, the α1 subunit is expressed at particularly high levels in cerebellar Purkinje cells. Deletion of the α1 subunit in KO mice is associated with compensatory changes in the expression of other $GABA_A$ subunits. In humans, mutations in *GABRA1* have been described in juvenile myoclonic and childhood absence epilepsy. To date, no *GABRA1* mutations have been associated with human ET.

Gabra1-KO mice exhibit a pathological action tremor in the frequency range of 16–22 Hz. Tremor amplitude increases with increasing postnatal age. The pathological action tremor of *Gabra1*-KO mice improves with ethanol, primidone and propranolol. Tremor amplitude and frequency increase with diazepam and the GABA agonist allopregnanolone.

LINGO1 KO Mice

LINGO1 stands for leucine-rich repeat and immunoglobulin-domain-containing protein 1. LINGO1 is part of the Nogo-66/p75 receptor signaling complex. Nogo binding activates RhoA, which inhibits axonal outgrowth. LINGO1 is upregulated during activity-dependent plasticity in the CNS. Overexpression of LINGO1 inhibits oligodendrocyte differentiation via downregulation of RhoA. In vivo work also indicates that LINGO1 signaling plays an important role during CNS myelination. In particular, *Lingo-1* KO mice contain more myelinated axon fibers and show earlier onset of myelination than their wild-type littermates. Despite these ultrastructural anomalies, *Lingo-1* KO mice do not exhibit overt developmental or behavioral abnormalities. Intriguingly, *Lingo-1* KO promotes functional recovery in the experimental autoimmune encephalomyelitis (EAE) model.

Currently, there is no evidence to suggest that *Lingo-1* KO mice have any validity as a model of ET. First of all, *Lingo-1* mice do not tremor. Second, it is not known if the intronic *LINGO1* SNPs associated with ET truly implicate downregulation, upregulation or other changes of LINGO1 in the pathophysiology of ET. Other markers, in linkage disequilibrium with these disease-associated SNPs, may reduce, enhance or alter the function of LINGO1.

Future Directions

The development of better animal models will depend on an improved understanding of human ET. Despite the relative prevalence of ET, the genetics, functional anatomy, and neuropathology of this important neurological disorder remain poorly understood. First of all, using genomic and molecular biological tools, the role of LINGO1 in ET must be deciphered. Next, with due

consideration of environmental factors, geneticists must identify other genes which contribute to the hereditability of ET. Clinical–pathological correlations and delineation of ET subphenotypes will require exacting prospective clinical data and equally sophisticated postmortem pathological examination of many ET brains. Ultimately, several animal models may be required to characterize the network and cellular biology of ET.

Event-Related Potentials: Slow Potentials

S Slobounov, Pennsylvania State University, University Park, PA, USA

Definition and History

From the initial demonstration of the electroencephalography (EEG) with animals, it was some 54 years later that the techniques were demonstrated in humans. In the 1920s, Hans Berger was able to show potential differences between recording sites related to cortical processes. He named this electrical activity the 'Elektrenkephalogramm.' In his first set of papers, Berger sought to determine what factors were involved in the production of the EEG and was able to determine that EEG was related to activity within the brain and to rule out other physiological activities such as cerebral pulsations, cerebral blood flow, blood flow through scalp vessels, heart rate activity, muscle activity, eye movements, and electrical properties of the skin. Berger took his studies beyond the physiological level and was one of the first to suggest that periodic fluctuations of the EEG might be related in humans to cognitive processes such as arousal, memory, and consciousness. In determining the nature of the EEG, Berger was initially surprised to discover that EEG changes were ones of quality rather than quantity. For example, as an individual moved from a relaxed state to one of stimulation and activity, Berger noted that the EEG did not increase in amplitude but rather changed in the quality of the wave forms. He initially identified these two different EEG wave forms as that of alpha activity and that of beta activity with alpha being associated in cortical inactivity and beta with cortical activity.

Event-Related Potentials

When EEG activity is recorded in relation to specific stimuli, it is called an event-related or evoked potential. For example, if a flash of light is viewed by a subject who has one electrode on the rear of his scalp and another on his earlobe, a predictable sequence of voltage variations will be recorded. A very small positive deflection (less than a microvolt) will follow the flash by about 40 ms. This response will be followed by a large negative deflection lasting 10–30 ms and peaking around 60 ms after the flash. Immediately following this wave, there appears a fairly large, positive wave with maximum amplitude occurring about 80 ms after the flash. This pattern is quite predictable; it follows each successive light flash, although it should be stressed, with some variability from flash to flash. By averaging individual stimulus presentations into a grand average, it is possible to note stable response patterns to a variety of stimuli. This succession of waveforms to visual stimulation is termed the

visual evoked response. When the distribution of the responses is examined, it is found to be of maximum amplitude over the occipital area of the brain, and to be less widely distributed than most spontaneous rhythms.

In general, evoked responses regardless of the nature of the stimulus are referred to as event-related potentials (ERPs). Unlike the spontaneous EEG which is recorded in a continuous fashion over a period of time, ERPs are time locked to specific stimuli or responses. In the literature, a distinction is sometimes made between endogenous and exogenous ERPs. Exogenous ERPs are seen to be controlled largely by the physical nature of the stimulus itself. On the other hand, endogenous ERPs are those that are influenced by the individual's perception or interpretation of the event. Overall, the ERP is smaller in voltage than the EEG and requires averaging procedures over many trials for patterns to be clearly seen. The most common ERP procedure is to time lock the EEG signal to a particular tone or visual stimulus. The basic procedure is to repeat the stimulus a number of times and then average the electrocortical signal to each of these stimuli. This results in a wave that is seen to represent the brain's response to a particular type of stimulation. Traditionally, ERPs are referred in terms of whether the deflection is negative or positive when the deflection occurs. Thus, a P300 component is a positive component occurring about 300 ms after the stimulus. It should be noted that the timing of the components is not precise but relative. While it is true that a P300 will follow an N200, the P300 may occur later than 300 ms. In viewing graphs of the ERP, a general procedure is to show the negative components as going upwards and the positive ones as downwards.

In terms of time, the initial components of the ERP are seen as reflecting automatic processing with the later components being more controlled and related to the cognitive processing of the stimulus. For example, if a pain stimulus was delivered to your right finger, then an initial response would be seen on the left side of the cortex. At about 250 ms, an evoked response is seen that some researchers believe to be associated with the subjective response of pain. One of the most well known ERP components is P300 that in actuality can appear anywhere from 300 to 800 ms after the response. P300 is seen as reflecting cognitive processing and has been used in a variety of paradigms. For example, this component is larger if individuals are told to respond to a stimulus than if they are instructed to ignore it. One common P300 paradigm is that of the oddball. In this procedure, a series of tones with a similar frequency is played in which a tone of a different frequency is played randomly. The novel stimulus or 'oddball' results in an increase in the amplitude of the P300. A related component involved with linguistic processing is that of the N400. This component is seen to be especially related to linguistic expectation. Numerous studies indicate alteration of ERP in patients suffering from movement disorders. For example, ERP data (i.e., reduced amplitude of P300 and N200) suggest that there is selective impairment of inhibitory function in Parkinson (PD) patients and that this deficit may be related to impaired inhibitory executive function in the frontal lobe.

Slow Potentials

If you were told that once you heard a tone a picture would follow a few seconds later, you would notice a slow negative potential being generated once the tone sounded. This slow negative potential generally measured at the vertex is the contingent negative variation (CNV). The CNV is generated in the laboratory by presenting the first or a warning stimulus which signals that a second stimulus will follow in a specific time period. In most studies, the second stimulus signals cognitive or task processing. Walter et al. (1964) described the CNV as an expectancy measure since the first stimulus suggests the second will follow.

Another form of event-related potentials is very slow potentials which precede and accompany movement or other activities. If a person is asked to press a button as he/she wishes, it can be seen that as early as a second movement begins, a recognizable EEG waveform starts to develop. A recording made with an electrode placed over the central areas of the cortex displays increasingly negative, in the few milliseconds before a movement occurs, until there is often a slight positive dip in the wave followed by a steep negative slope, which is terminated simultaneously with the beginning of the movement. The beginning of the movement is accompanied by a large positive deflection and a recovery to the original baseline. This complex of waveforms is not uniformly distributed. Technically, this slow increase in surface negativity is referred to as the *Bereitschaftpotential* (BP), see **Figure 1**. Significantly reduced amplitude of BP was consistently observed in patients suffering from traumatic brain injuries (TBI), Parkinson disease (PD), and other neurological populations.

The BP potential is maximal at the vertex and initially equal in amplitude over both hemispheres of the brain. One research paradigm is to signal the person which hand to use to make the movement. Prior to the movement, this potential begins to lateralize and becomes maximal over the motor cortex contralateral to the body part moved. Early speculation suggested that this beginning of lateralization reflects the point in time at which the response side is determined. Since the information contained within the BP includes nonmotor processes as well as motor processes, researchers have suggested that by subtracting the response of one hemisphere from that of the opposite hemisphere, it would be possible to obtain a more pure measure of motoric preparation for a response. This measure has been referred to as the lateralized readiness potential (LRP) and has become an important tool in the study of the neural basis of human cognitive– motor processing.

To summarize, the development of this measure was based on the assumption that the asymmetry of the RP could be used as an index for the preparation of specific

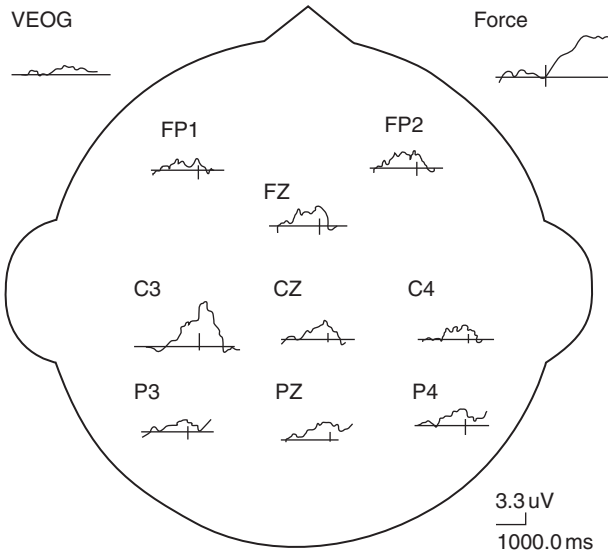

Figure 1 Typical example of BP waveforms and its spatial distribution prior to initiation of isometric force task produced task by the right finger.

motor acts. To eliminate any RP asymmetries that may contain activity lateralized with respect to nonmotoric processes, the LRP was calculated as the difference between recording sites contralateral and ipsilateral to the responding hand, averaged over left- and right-hand responses. The LRP's special significance in cognitive and sensorimotor research stems from the fact that this component offers a continuous analog measure of the differential engagement of the left versus right hand associated with cued or uncued voluntary reactions. The alteration of LRP as an indication of impairment of movement initiation in PD patients has been documented in a number of studies.

Executive Dysfunction

D J Zgaljardic, Transitional Learning Center, Galveston, TX, USA
P J Mattis, North Shore University Hospital, Great Neck, NY, USA
A Charness, University of Texas Medical Branch, Galveston, TX, USA

Glossary

Abulia – Lack of will power or drive, accompanied by a lack of spontaneity of speech, thought, and action.
Akinetic mutism – A state characterized by poverty of speech and reduced limb movements, with preserved eye movements.

Chorea – Involuntary, intermittent jerky movement of muscle groups that is associated with disruption of the basal ganglia.
Disinhibition – The temporary removal of an inhibitory process.
Freezing of gait – A temporary inability of movement that is typically associated with Parkinson's disease

or parkinsonism. This event can occur when a patient transverses a threshold (e.g., doorway) or encounters a change in floor pattern.

Subcortical Dementia – Cognitive symptoms may include decreased initiation, slowing of responses, and difficulties with strategy formation and problem solving. A lack of cortical involvement should not be implied; however, specific functions mediated by the cortex are typically spared. Subcortical dementia is common in neurodegenerative disorders such as Parkinson's disease and Huntington's disease.

Definition

Executive function is a term used to describe higher order mental processes, mediated by the frontal lobes of the cerebral cortex, that are involved in the regulation of cognitive and behavioral responses to environmental contingencies. Owing to high connectivity the frontal lobes maintain with various cortical regions, *executive dysfunction* can occur following nonfrontal damage (e.g., to the posterior association cortex and dorsomedial thalamic nucleus). Executive dysfunction has been attributed to several neurological disorders including traumatic brain injury, neoplasms, vascular lesions, as well as cortical and subcortical neurodegenerative processes.

Executive functions are not a unitary construct; in fact, they comprise an assortment of behaviors including: (1) planning and organization, (2) cognitive flexibility/decision making, (3) initiation and self-generation, and (4) response inhibition. First, *planning and organization* involves selecting and executing behaviors necessary for goal attainment that may occur in the near or distant future. Second, given the unpredictable nature of an ever-changing environment, an individual must maintain aspects of *cognitive flexibility* with preserved *decision making ability*. When making a decision, individuals base their responses on various environmental contingencies and past successful or unsuccessful decisions along with their resulting consequences. Other factors that are paramount when weighing in on response options during the decision making process include, the inherent value and emotional salience of a given option. Individuals experiencing executive dysfunction secondary to a brain insult may no longer make decisions that are advantageous. In fact, these patients may decide against their best interests, and fail to learn from past mistakes. Third, in order to successfully achieve a desired goal, one must *initiate and sustain* behaviors. Despite preserved intellect, patients with prefrontal cortical damage may not execute a given behavior or activity due to lack of motivation and/or behavioral self-generation (i.e., abulia or apathy). Lastly, one individual with executive dysfunction may find it difficult to initiate or sustain a given behavior, whereas others may fail to *inhibit behavioral responses*, especially those responses that are socially maladaptive or fail to lead to successful goal attainment. In 'real world' settings, this may be interpreted by others as *behavioral impulsivity* and can have grave consequences on social functioning and social acceptance.

Neuroanatomical Correlates of Executive Functions

Previous work has identified three 'closed loop' frontostriatal cortical circuits that reportedly have a role in mediating executive functions. These circuits originate from the (1) anterior cingulate, (2) orbitofrontal, and (3) the dorsolateral regions of the prefrontal cortex. Each circuit projects to specific striatal regions (via excitatory glutaminergic transmission) in a topographical fashion and remains segregated throughout the basal ganglia and thalamus, allowing other areas of the brain to communicate with each circuit along its respective pathways. The frontostriatal circuits receive inputs from dopaminergic, noradrenergic, serotonergic, and cholinergic cell groups that modulate information processing. All circuits eventually return to the portion of the frontal cortex where they originated.

Individuals with prefrontal cortical damage can present with a myriad of cognitive and behavioral deficits that may fall into one of the three executive dysfunction subtypes. First, an *apathetic–akinetic syndrome* can result from medial prefrontal cortical damage. This syndrome is typically characterized by diminished responsiveness to environmental stimuli along with reduced initiation and maintenance of desired behaviors. Orbitofrontal damage (including the ventromedial cortex) can result in a *disinhibited syndrome*. This syndrome is characterized by personality changes involving poor regulation of inhibitory and emotional mechanisms that can result in socially maladaptive behaviors. Lastly, a *dysexecutive syndrome* can result following damage to the dorsolateral aspect of the prefrontal cortex. This syndrome is typically characterized by 'cognitive' deficits including problems with working memory, associative learning, shifting and maintenance of cognitive set, and memory retrieval.

Anterior Cingulate Cortex

Cognitive impairment following anterior cingulate cortex (ACC) disruption can include deficits in attention such as sustained attention, spontaneous response production, error monitoring, and response intention. By 'intention,' we are referring to attention to action, which

influences the propensity to respond via behavioral readiness, anticipation, and response maintenance. Psychiatric disturbance following ACC disruption is typically characterized by apathy. Apathy is defined as having indifference to one's surroundings, loss of interest or motivation in goal-directed behaviors, and/or flattening of affect that is not attributed to declines in levels of arousal or intellect (i.e., apathetic–akinetic syndrome). Neurological populations with significantly high levels of apathy typically perform worse on neuropsychological measures of executive functions compared to those patients with lower levels of apathy. In the most extreme case, bilateral lesions of the ACC can result in *akinetic mutism* that involves profound apathy with a lack of impulse for speech, action, and psychic initiative. Overlapping projections from the anterior and posterior cingulate with other limbic system nuclei, and the lateral frontal and parietal cortices, along with efferent projections from the ACC to frontal subsystems, may account for the role the ACC maintains in attentional, cognitive, and behavioral processes.

Orbitofrontal Cortex (OFC)

Orbitofrontal cortex (OFC) disruption can lead to emotional instability (e.g., disinhibition, depression, and obsessive–compulsive disorder) due to a dissociation of frontal monitoring systems from limbic input. Brain-damaged patients may exhibit social and/or behavioral deficits such as euphoria, diminished affect, impulsivity, social irresponsibility, and poor reasoning and decision-making abilities with relatively preserved intellect (i.e., disinhibition syndrome). For instance, while engaged in an experimental card gambling task, OFC brain-damaged patients have a tendency to profit from short-term rewards at the expense of long-term consequences. Interestingly, these patients can at times accurately describe the reinforcement contingencies of the task, but are unsuccessful in implementing this knowledge in an attempt to maximize their profits. Moreover, patients with OFC damage have also been reported to present with a diminished ectodermal response (i.e., measure of emotional arousal) when engaged in high-risk responses on a card gambling task, suggesting that the OFC may have a significant role in triggering autonomic reactions while anticipating a reward or punishment. The diminished ectodermal response may reflect a reduction or lack of emotional salience attributed to a given set of response options and their associated consequences, which can negatively impact the decision making process.

Dorsolateral Prefrontal Cortex

The dorsolateral prefrontal cortex (DLPFC) is an area that is considered central to executive functions in humans. Patients with damage to this region may exhibit 'cognitive' difficulties in organizing a behavioral response, memory retrieval, maintaining and shifting behavioral sets, generating motor programs, strategy generation, and use of internal cues to guide behavior (i.e., executive dysfunction syndrome). The DLPFC is critical to new learning when working memory, set-shifting, and attention to action are necessary. Further, this region has been aptly labeled the 'central executive' because its activation tends to overlap with that of the ACC and OFC by maintaining a role in working memory and top-down processing.

Executive Dysfunction and Movement Disorders

The cognitive and behavioral profile of patients with subcortical neurodegenerative processes are similar to those observed in patients with damage to prefrontal and subcortical (i.e., basal ganglia) regions secondary to acquired brain injury. Hence, executive dysfunction in patients with neurodegenerative movement disorders such as Parkinson's disease (PD) or Huntington's disease (HD) (i.e., subcortical dementia) has been attributed to frontostriatal circuit disruption.

Parkinson's Disease

Parkinson's disease (PD) is a neurodegenerative hypokinetic movement disorder characterized by insidious onset with progressive motor and cognitive decline. Previous work has suggested that PD may arise from either one or a combination of several different etiological factors including: environmental toxins, free radical production, mitochondrial abnormalities, abnormal protein degradation and removal, genetic predisposition, and/or aging. The motor impairments characteristic of PD include the clinical triad of resting tremor, bradykinesia (slowness or retardation of movement), and rigidity. Other symptoms such as hypokinesia (impaired movement initiation), freezing phenomena (difficulty with congruent and sequential movements), and postural abnormalities are also common.

Neuropsychological impairment in PD has been documented across all cognitive domains. However, cortical syndromes such as aphasia and alexia are not common. Executive dysfunction is typically regarded as the 'core' deficit in PD, as it appears to influence most cognitive changes observed. The cognitive profiles of patients with PD vary both in frequency and severity across studies due to the multiplicity of factors pertaining to patient samples (e.g., the age of disease onset or presence of a dementing process). Neuropsychological assessment of patients with PD typically yields poor performance on tasks of working memory, trial-and-error learning, planning, memory retrieval, verbal fluency, response monitoring, set-shifting,

and attentional control. Moreover, mood disturbance is common and is often ascribed to symptoms related to depression and/or apathy. Symptoms related to depression and apathy can overlap considerably in any given individual with PD. The relationship between symptom expression and severity across the two is an inconsistent one and may be attributed, in part, to differential frontostriatal circuit involvement (i.e., ACC and OFC).

Executive dysfunction in PD has been characterized by the difficulty that patients may experience in developing their own plan of action or initiating goal-directed behavior as well as maintaining adequate levels of processing resources. In theory, a mechanism such as a central processor within the prefrontal cortex may distribute mental resources according to processing demands so as to govern nonroutine behaviors. This process is believed to influence inhibitory resources by allowing for the suppression of routine behaviors in favor of more goal appropriate ones. For instance, patients with frontal brain-damage, as in PD, may exhibit typical or expected behaviors in familiar settings, but may find it difficult to modify their behaviors when confronted with a novel environment or situation. Furthermore, executive dysfunction in patients with PD may be attributed, in part, to imposing greater resource demands. As a consequence, they may present with difficulties in suppressing competing mental programs. PD patients may find it challenging to inhibit nonrelevant resources while performing a task, which may lead to excessive cognitive load with subsequent decreases in information processing speed with inefficient strategy formation. Thus, it is not surprising that patients with PD can present with deficits across most, if not all, cognitive domains.

Gait Pattern and Postural Abnormalities in PD

Subcortical structures, including the basal ganglia, have a role in maintaining normal gait patterns and postural stability. These structures generate internal cues to initiate sequences of movement at an unconscious level. Further, the success of any given purposeful movement requires the preparation and maintenance of movement plans via connectivity that the basal ganglia maintain with frontal motor regions (e.g., premotor cortex and the supplementary motor area).

Gait pattern and postural abnormalities in patients with PD can be characterized by bradykinesia, reduced stride length and step amplitude, increased stride duration and step cadence, stooped posture, forward head positioning, excessive flexion of the legs, and increased duration of double limb support. Additional influences can include flat foot ground contact, inadequate toe clearance for swing, loss of arm swing and trunk rotation, festinating gait, and freezing phenomena.

Patients with PD demonstrate increased stride variability, a marker of arrythmicity, and reduced automaticity of gait, which compromises both balance and gait. It is believed that impaired internal cueing mechanisms (resulting from executive dysfunction) in PD transform gait rhythmicity into an attention demanding parameter. Thus, patients with PD must recruit additional attentional resources as a compensatory mechanism in order to improve gait pattern discrepancies. The greater demand for the allocation of attentional resources may reduce their ability to appropriately adapt to challenging terrain (uneven paths, narrow areas, etc.) and/or novel environments, leading to a greater fall risk.

Huntington's Disease

Huntington's disease (HD) is a relatively rare neurodegenerative process characterized by a disorder of movement (e.g., chorea), cognitive decline, and psychiatric disturbance. HD has an autosomal dominant pattern of inheritance with full penetrance. Although multiple brain regions, cortical and subcortical, are affected by HD, the area of the greatest and earliest degeneration is the corpus striatum (caudate nucleus and putamen). This is a region with extensive connectivity to the frontal lobe, and as discussed above, it is intimately involved in the frontostriatal circuits important in the processing of cognition and mood. Although they are distinct in their cognitive deficits, the cognitive dysfunction associated with HD is generally similar to the pattern observed in PD (i.e., executive dysfunction). That is, the cognitive decline associated with HD is consistent with the broad concept of subcortical dementia including psychomotor slowing and impairment of recall memory with intact recognition memory.

Patients with HD have been reported to demonstrate early decline in executive functions associated with all three frontostriatal circuits, with deficient memory retrieval, response initiation, and decision making skills. Indeed, changes in cognition and mood are believed to be common in presymptomatic HD gene carriers. Interestingly, early in the course of the disease, patients are often described as exhibiting personality changes, such as increased irritability and short temper, which could be better characterized as the behavioral manifestation of executive dysfunction. Depression is also very common among patients with HD, and there is an increased rate of suicide even prior to the onset of clinical motor symptoms. This could be hypothesized to be related to the presence of depression and impulsivity within the context of poor problem solving, suggesting dysfunction within the OFC and DLPFC systems.

Eye Movement Abnormalities in Movement Disorders

J C Rucker, Mount Sinai Medical Center, New York, NY, USA

Glossary

Antisaccade task – Display of an unpredicted visual target with request of the patient to look in the direction opposite to the target.

Convergence insufficiency – Inability to converge or adduct the eyes upon a gaze shift from a distant visual target to a near target.

Convergence spasm – Excessive convergence of the eyes usually due to nonphysiologic causes.

Ocular motor apraxia – Inability to move the eyes voluntarily to objects of interest.

Saccade – Rapid, conjugate eye movement with which gaze is shifted to point the eye at visual targets of interest.

Saccade latency – Time delay between request for saccadic eye movement and initiation of the actual movement.

Supranuclear gaze palsy – Abnormal eye movements because of brainstem premotor, cerebral hemispheric, or cerebellar dysfunction.

Introduction

Eye movements are of considerable importance in movement disorders. From a research perspective, eye movements, especially rapid saccadic movements, offer an opportunity to study the role of the basal ganglia in a motor system in which brainstem neural mechanisms have been extensively studied and are fairly well-understood. From a clinical diagnostic perspective, abnormal eye movements are the key features of certain movement disorders, and recognition is essential to accurate diagnosis. Lastly, from a clinical patient care perspective, patients with movement disorders often experience visual impairment in the presence of normal visual acuity, which may be attributable to disorders of eye movements.

Basal Ganglia Control of Eye Movements

The shared goal of all eye movements is the maintenance of clear, single vision by placement of an object of visual interest on the fovea, the retinal region with the highest

density of photoreceptors, and the best visual acuity. Several functional classes of eye movements coexist to meet this shared goal. These include saccades, smooth pursuit, vergence, optokinetic responses, and vestibular reflexes. Separate premotor command networks exist for initiation and modulation of each functional class of eye movements. These networks converge upon the final common pathway of ocular motoneuron, neuromuscular junction, and extraocular muscle to elicit eye movement.

The premotor networks governing saccades are understood to the greatest extent. Saccades are rapid, conjugate eye movements with which we shift gaze to point the fovea at pertinent details in the visual world. Saccades may be voluntary or reflexive and generated to actual targets (visually-guided) or to memory for target location (memory-guided). The primary source of commands to immediate brainstem premotor saccadic networks is the superior colliculus (SC). The SC has important roles in visual target selection, saccade amplitude and direction preparation, and possibly in the conversion of spatial saccadic target selection signals into temporal signals required for motor output.

The role of the basal ganglia in eye movement control has been extensively studied, and is primarily related to the control of voluntary visually- and memory-guided saccades. This control is predominantly mediated through striato-nigro-collicular connections, as summarized in **Table 1**. In the 1980s, inhibitory connections mediated by γ-aminobutyric acid (GABA) were identified between the primary basal ganglia output structure, the substantia nigra pars reticulata (SNr), and the SC. The importance of the SC in the initiation of eye movements postulated a role of the SNr in eye movement control. This role was subsequently proven by extensive experimentation mostly involving single cell recordings in various basal ganglia structures over the past 20 years. It is now understood that the SNr tonically inhibits the SC, and that just prior to a voluntary visually- or memory-guided saccade, a pause in SNr activity releases the SC from inhibition, resulting in an increase in discharge from the SC and initiation of the saccade. There is no change in the tonic SNr discharge rate for spontaneous saccades in darkness or light and, therefore, no proposed basal ganglia role in initiation of spontaneous reflexive saccades.

Saccadic abnormalities may be induced via biochemical manipulation of striato-nigro-collicular connections, and this may have direct implications with regard to saccadic abnormalities in clinical movement disorders such as Parkinson's disease (PD) and Huntington's disease (HD). Enhancement of the inhibitory effect of SNr on SC with a GABA agonist results in voluntary saccades with longer latency to onset, decreased amplitudes, and lower velocities. Conversely, impaired suppression of saccades and excessive saccades result from administration of a GABA antagonist and excessive release of the SC.

The caudate facilitates saccades via phasic inhibition of the SNr prior to a saccade, allowing the pause in SNr tonic activity with release of the SC to occur. Chemical depletion of dopamine in the caudate results in a decrease in spontaneous saccades and voluntary saccades with decreased velocity and amplitude and increased duration. The caudate, in addition to being directly involved in the motor control of voluntary saccades, also has an important role in cognitive aspects of visual stimulus anticipation and modulation of saccade behavior based on reward expectation. Remarkably, caudate neurons can anticipate the spatial direction of a rewarded stimulus. Such anticipation is modulated by the input of midbrain dopaminergic neurons into the caudate. It is hypothesized that cortical signals for spatial saccadic control and dopaminergic inputs with reward-related signals are integrated in the caudate to guide the eyes to the place where a reward is anticipated. Loss of midbrain dopaminergic neurons, as in PD, has an adverse affect on predictive saccadic behavior.

Table 1 Role of basal ganglia in normal eye movements

Basal ganglia structure	*Role*	*Effect of biochemical alteration on voluntary saccades*
Substantia nigra pars reticulata	Tonic inhibition of SC (neurotransmitter GABA)	GABA agonist (enhances SC inhibition) Increased latency Decreased amplitude and velocity
	Pause just before voluntary saccade releases SC from inhibition, allowing saccade to occur	GABA antagonist (decreased SC inhibition) Impaired suppression of saccades
Caudate	Facilitates voluntary saccades via inhibition of SNr just prior to saccade (allows SNr pause to occur)	Depletion of dopaminergic input Increased duration Decreased amplitude and velocity
	Anticipation of visual saccadic targets and reward-based modulation of voluntary saccades	
Subthalmic nucleus	Suppression of saccades via excitation of SNr Switch from reflexive to voluntary saccades	Not applicable

Abbrevations: SC – superior colliculus; GABA – γ-aminobutyric acid; SNr – substantia nigra pars reticulata.

Table 2 Eye movement abnormalities in movement disorders

Parkinson's disease
Quantitative saccadic eye movements
Increased latency and hypometria of voluntary predictive saccades
Increased latency and hypometria of voluntary memory-guided saccades
Increased latency and high error rates with antisaccades
Abnormal smooth pursuit
Bedside eye movement examination
Hypometric saccades
'Saccadic' smooth pursuit
Mild impairment of upgaze
Convergence insufficiency
Progressive supranuclear palsy
Supranuclear palsy
Saccades affected more than smooth pursuit
Vestibulo-ocular reflexes spared until late in disease
Vertical eye movements affected before horizontal
Slowed saccadic velocities prior to range limitation
Excessive square wave jerks
Decreased latency and high error rates with antisaccades
Corticobasal degeneration
Increased saccadic latency
Square wave jerks
Impaired smooth pursuit
Slowed saccadic velocities (rare and late in disease course)
Oculomotor apraxia with Balint's syndrome (rare)
Multiple system atrophy
Cerebellar subtype
Square wave jerks
'Saccadic' smooth pursuit
Mild saccadic hypometria
Downbeat nystagmus
Gaze-evoked nystagmus
Parkinsonian subtype
Abnormalities of voluntary saccades similar to PD
Huntington's disease
Increased latency, reduced velocity, high error rates of memory-guided saccades
Increased latency, reduced velocity, high error rates with antisaccades
Prominent slowing of saccades with young onset disease
Prominent increased saccadic latency with older onset disease
Impaired fixation
Inability to suppress saccades to novel visual stimuli
Increased saccadic latency in presymptomatic gene carriers
Wilson's disease
Saccadic smooth pursuit – vertical greater than horizontal
Abnormal vertical optokinetic nystagmus
Spinocerebellar ataxias
Cerebellar eye movement abnormalities
Saccadic dysmetria
Saccadic smooth pursuit
Gaze-evoked nystagmus
Downbeat nystagmus (common in SCA6)
Decreased saccadic velocity (SCA2)
Decreased saccadic velocity and supranuclear gaze palsy (SCA7)
Abnormal vestibulo-ocular reflex (SCA3, SCA6, autosomal recessive ataxias)
Oculomotor apraxia (ataxia–telangiectasia)
Psychogenic
Voluntary nystagmus
Convergence spasm

Complete discussion of basal ganglia control of eye movements must include the role of the subthalamic nucleus (STN), especially in light of its current importance in PD treatment with deep brain stimulation (DBS). The STN sends excitatory signals to the SNr, and may have a role in suppression of eye movements via enhancement of SNr inhibition of the SC. Direct afferent projections reach STN from the cortical eye fields. In addition to the suppression of eye movements and enhancement of visual fixation, STN may also mediate behavioral switching between automatic reflexive saccades and deliberate, controlled voluntary saccades via the direct cortical connections.

Idiopathic PD

Quantitative Saccadic Eye Movements

Detailed studies utilizing mechanisms to record and quantify saccadic tasks in patients with PD reveal saccadic abnormalities that correspond well with expected deficits based on predictions from the anatomic and physiologic role of the basal ganglia described in the earlier section (**Table 2**). In general, complex, voluntary, predictive saccades are abnormal, while reflexive saccades are often unaffected. For predictive saccades, increased saccadic latency and hypometric saccades (saccades that fall short of the target) are common. Deficits are particularly marked in tasks requiring memory-guided saccades. Saccadic velocity is, however, typically normal. One specific task, the antisaccade task, has been frequently studied as a measure of the capacity to suppress a reflexive saccade and to generate a volitional one in its place. In this task, the subject is shown an unanticipated visual target and requested to look in the opposite direction of the target. Patients with PD tend to have increased saccadic latencies and high error rates with this task, although these findings are not consistent across all studies. Increased latency on this task may correlate with the degree of bradykinesia in advanced disease. Saccadic latency is of interest as a potential biomarker of PD, as it does correspond to disease severity and the presence of dementia. However, there is wide intersubject variability, as well as overlap of saccadic latency distribution between PD patients and controls, that may hinder its use as a diagnostic biomarker.

Reported treatment effects on saccadic abnormalities are variable. Several studies report beneficial effects on voluntary saccadic latency and amplitude and enhancement of reflexive saccade inhibition with dopaminergic drugs. Others show no effect, and one even demonstrates prolongations of voluntary saccadic latency. The ocular motor effects of DBS in the STN support an STN role in eye movements, with changes in STN neuronal firing rates similar to those in nonhuman primates identified in humans during intraoperative single unit recordings, while the patient performed voluntary saccadic tasks. The accuracy of memory-guided saccades may be improved with bilateral STN stimulation, although an increase in fixation instability with excessive saccades may also occur.

Clinical Abnormalities and Convergence Insufficiency

Although often unremarkable, a number of eye movement abnormalities may occasionally be evident on standard bedside evaluation of ocular motility in PD patients (**Table 2**). These include hypometric saccades, impaired smooth pursuit with 'catch-up' saccades, and mild impairment of upgaze. The antisaccade test can be performed at the bedside by holding up both hands and intermittently, unpredictably moving one finger on one hand and instructing the patient to look in the opposite direction of the moving finger. Abnormalities of vergence eye movements warrant special mention, as they are often symptomatic.

Vergence is a disconjugate eye movement by which a single foveal image is maintained with gaze shifts from near to far (divergence) or from far to near (convergence). The primary stimuli for vergence are retinal blur and retinal disparity. Retinal blur is loss of visual image sharpness, and retinal disparity is image separation when images fall on noncorresponding areas of each retina. Convergence insufficience (CI) is a common cause of binocular diplopia or visual blurring with viewing of near objects in PD. It may occur both in advanced and in early, untreated disease. The most common complaints with CI are binocular horizontal doubling during attempts to read or nonspecific reading difficulty. Examination reveals a full range of eye movements, with possible exception of impaired adduction of each eye during viewing of a near target. The eyes are misaligned significantly at near with outward deviation relative to one another (exotropia). A lesser exotropia is present while the patient views a distant target and is typically only detectable with disruption of binocular fixation during measures of ocular alignment such as cross cover testing.

Two additional examination features helpful in diagnosing CI are the convergence amplitude and the near point of convergence (NPC). Convergence amplitude measurements are performed by using a horizontal prism bar to determine the extent to which a patient can converge the eyes before the development of diplopia or an exotropia. To measure the NPC, the distance at which a patient can maintain convergence without the eyes breaking down into an exotropia (one eye turning out laterally) is measured as the patient views a near object moving closer to the nose. An NPC of >10 cm is highly suggestive of CI. In early PD, the NPC may be normal, but convergence amplitude decreased with resultant symptoms prior to the development of frank CI.

CI can be treated with prisms in the patient's glasses. A prism oriented with its base toward the nose may eliminate diplopia or blurred vision during reading. If prismatic treatment is ineffective, monocular occlusion during reading can be tried. CI may also be responsive to dopaminergic medications.

Oculogyric Crisis

In the early twentieth century, oculogyric crisis (OGC) was a classic feature of postencephalitic parkinsonism. OGC is a forced deviation of the eyes – frequently in an upward or upward and lateral direction. Most cases currently are related to pharmacologic dopamine antagonists utilized as antipsychotic medications.

Progressive Supranuclear Palsy

One of the most salient features of progressive supranuclear palsy (PSP) is a supranuclear ocular motor gaze palsy that initially tends to affect vertical gaze to a greater extent than horizontal gaze (**Table 2**). Within 3–4 years of disease onset, 79% of patients have a vertical supranuclear palsy, with downgaze affected in 67%. This finding is not only helpful in diagnosing PSP, but may also provide prognostic information with early impairment of downgaze predicting shorter survival time.

In keeping with its supranuclear nature, saccades are affected to a much greater extent than smooth pursuit, and the oculocephalic reflex (Doll's eye maneuver) is spared. The earliest feature is slowing of vertical saccades (which may be initially detectable only with quantification on eye movement recordings), followed by limitation in the range of vertical movement. Late in the disease, eye movements may be completely absent. The location of pathology responsible for the saccadic abnormalities in PSP is thought to be the brainstem premotor burst neurons that relay saccadic commands to the ocular motoneurons. Two hypotheses have been proposed to explain the clinical involvement of vertical eye movements prior to horizontal eye movements. The first hypothesis is that GABAergic vertical premotor saccadic neurons may be more susceptible to injury than glycinergic horizontal premotor saccadic

neurons. The second hypothesis is related to the location of vertical versus horizontal premotor saccadic neurons; vertical neurons are located in the mesencephalon nearer to the SC than the more caudal pontine neurons. Degeneration of the SC occurs early in the disease course. This, in combination with the absence of SC pathology in a PSP patient lacking the supranuclear gaze palsy, suggests that the SC may be a 'gateway' via which ocular motor saccadic circuits are affected in PSP.

In addition to the supranuclear gaze palsy, excessive square wave jerks are common in PSP. These are very small saccades that occur during visual fixation and take the eye off the fixation target and return it to the target within ~200 ms. The antisaccade test in PSP characteristically reveals decreased saccadic latencies and a high error rate, demonstrating an inability to suppress reflexive saccades. There is a correlation between decreased saccadic latencies and increased frontal lobe dysfunction, which is not surprising, given the importance of the frontal cortex to the suppression of reflexive saccades.

Corticobasal Degeneration

Abnormal eye movements may occur in corticobasal degeneration (CBD) (**Table 2**). The most characteristic findings are increased saccadic latency, excessive square wave jerks, and impaired smooth pursuit. Saccadic velocities are typically normal. In rare instances, eye movement abnormalities similar to the supranuclear gaze palsy of PSP may be found in patients pathologically identified as CBD. However, they tend to develop much later in the disease course. This is not entirely surprising, given that both conditions are tauopathies, with neuronal and glial inclusions of microtubule-associated tau protein. The presence of a supranuclear gaze palsy at presentation, or even while the patient remains ambulatory, should suggest an alternative diagnosis.

Rare cases of CBD with Balint's syndrome are reported. Balint's consists of a triad of findings: simultanagnosia (inability to see 'the whole picture' – perception of only portions of the whole), optic ataxia (defective visually-guided limb movements), and ocular motor apraxia (inability to move the eyes voluntarily to objects of interest). Eye movements are often elicited by blinks or head thrusting in oculomotor apraxia. The localization of Balint's syndrome is in the bilateral parietal lobes.

Multiple System Atrophy

Studies of eye movements in multiple system atrophy (MSA) are limited, but suggest a wide range of abnormalities, some of which are directly related to cerebellar involvement in the cerebellar subtype of MSA such as downbeat or gaze-evoked nystagmus (**Table 2**). Excessive square wave jerks, 'saccadic' smooth pursuit, and mild saccadic hypometria are common. Supranuclear gaze palsies are infrequently present and tend to be very mild. The presence of a significant supranuclear gaze palsy should suggest an alternative diagnosis. Much of this data is from studies lacking pathologic proof of diagnosis and is not definitive. In the parkinsonian subtype of MSA, abnormalities of voluntary saccades similar to those seen in idiopathic PD may be occur.

Huntington's Disease

A number of eye movement abnormalities are common in HD, most of which are detectable only with quantified eye movement recordings, and most of which involve saccades (**Table 2**). In keeping with the neurophysiologic nonhuman primate knowledge of the effects of the basal ganglia on eye movement control described earlier, the saccadic deficits in HD are primarily related to voluntary saccade tasks such as memory-guided saccades and antisaccades. Abnormalities include delayed initiation with increased latencies, reduced velocity, and high error rates. In patients with younger onset of disease (<30 years), slowing of saccades is more prominent; whereas, in older onset of disease (>30 years), increased saccadic latencies are more common. In addition to voluntary saccadic deficits, impaired fixation with excessive distractibility and the inability to suppress saccades toward novel visual stimuli are very common. Such distractibility is the same regardless of the age of disease onset. Greater involvement of frontal lobe – basal ganglia connections in HD, as compared to parietal lobes, is responsible for these eye movement abnormalities. The relative sparing of the parietal lobes is compatible with the finding that the ability to direct visual attention to a stimulus is normal in HD.

Much attention has been given to the utilization of eye movements as a biomarker to identify presymptomatic HD gene carriers. One study found a decreased number of memory-guided saccades and subtle delay in the initiation of volitional saccades in presymptomatic HD gene carriers compared to nongene carriers. Another study found similar initiation deficits of voluntary-guided saccades. A third study found increased error rates and increased latencies. All studies support abnormalities of eye movements as a sensitive biomarker in the prediagnostic and early stages of HD. The extent of presymptomatic voluntary saccadic deficits has also been shown to correlate with decreasing connections between the frontal cortex and caudate body on diffusion tensor imaging.

Wilson's Disease

Eye movements have not been extensively studied in Wilson's disease, with the exception of one recent study of 34 patients who underwent quantitative eye movement

recording. The most frequent abnormal eye movement is saccadic vertical smooth pursuit, which is relatively nonspecific (**Table 2**). Impairment of vertical optokinetic nystagmus and saccadic horizontal smooth pursuit may be present. Rarely, Wilson's disease may present with OGC or forced deviation of the eyes.

Spinocerebellar Ataxias

Eye movements have been studied in great detail in the hereditary spinocerebellar ataxias (SCA) with the hope that ocular motility phenotypes would allow specific diagnosis of genotype. With a few exceptions, this is generally not the case since many of the SCAs exhibit abnormal eye movements that are nonspecific and generally attributable to cerebellar involvement. Common cerebellar eye movement abnormalities include saccadic dysmetria (saccadic overshooting or undershooting of the visual target), saccadic smooth pursuit, gaze-evoked nystagmus, and downbeat nystagmus. Severe slowing of saccadic velocity, especially in the horizontal direction, is characteristic of SCA2. Slowing of saccades and supranuclear gaze palsy may occur in SCA7. Abnormalities of the vestibulo-ocular reflex (VOR) are common in SCA3, SCA6, Friedrick's ataxia, and ataxia–telangiectasia. Ocular motor apraxia (inability to move the eyes voluntarily to objects of interest) is a characteristic feature of ataxia–telangiectasia. Downbeat nystagmus is very frequently present in SCA6. A recent study of patients with presymptomatic SCA6 identified eye movement abnormalities in this group, including gaze-evoked nystagmus, square-wave jerks, and impaired smooth pursuit.

Psychogenic (Nonphysiologic) Eye Movement Disorders

Nonphysiologic movement disorders are often accompanied by abnormal eye movements that introduce diagnostic uncertainty. The two most common are voluntary nystagmus and convergence spasm (**Table 2**).

The term 'voluntary nystagmus' is actually a misnomer, as the condition would be more accurately called 'psychogenic flutter.' Nystagmus, by definition, is caused by a slow drift of the eyes away from a desired position. Slow phases are often then followed by corrective fast phases. In contrast, the initial abnormality in voluntary nystagmus is a fast saccadic movement that removes the eye from desired position. Low amplitude (small), high frequency (fast), back-to-back conjugate horizontal saccades (saccadic oscillations) are voluntarily generated. Voluntary nystagmus is found in ~5–8% of the population, and may occur as a familial trait. The patient may complain of a sense of visual motion (oscillopsia) or blurred vision. In addition to the characteristic appearance of the eye movement, additional diagnostic clues are the frequent association with eyelid flutter, a strained facial expression, and excessive convergence of the eyes. Individuals who are able to produce voluntary nystagmus may also be able to superimpose voluntary saccades on smooth pursuit eye movements. The clinical challenge is distinguishing voluntary nystagmus, which has no pathologic significance, from ocular flutter and opsoclonus, which are associated with underlying disease. Ocular flutter and opsoclonus are often larger in amplitude and more sustained.

Convergence spasm, the second common nonphysiologic eye movement finding, may mimic unilateral or bilateral cranial nerve VI (abducens nerve) palsies. The eyes are deviated in toward one another (esotropia), and the patient may be unable to abduct one or both eyes just as in sixth nerve palsies. However, the patient with convergence spasm is voluntarily invoking the near triad of convergence, accommodation, and miosis of the pupils. Careful examination should reveal specific features to suggest convergence spasm. The small size of the pupils during convergence is a major clue. Often, the patient is unable to sustain convergence when one eye is covered and the esotropia will resolve and the pupil will enlarge. Abduction deficits are variable – sometimes present, sometimes absent – over the course of a single examination, and they often alternate sides.

Eyelid Opening Apraxia

J C Rucker, Mount Sinai Medical Center, New York, NY, USA

Glossary

Apraxia – The inability to execute a voluntary motor movement despite normal muscle function.
Blepharokolysis – Another term for the clinical findings of eyelid opening apraxia.
Blepharospasm – Involuntary forced eyelid closure because of orbicularis oculi muscle contraction.
Pretarsal – The portion of the orbicularis oculi muscle in the main entropion of the eyelids; outside of the pretarsal segment are the preseptal and orbital portions of the muscle.
Ptosis – Drooping of the eyelid due to mechanical, nerve, neuromuscular junction, or muscle pathology.
Tarsal plate – Another term for tarsus; the fibrous or cartilaginous plate supporting and shaping the eyelid.

Introduction

Eyelid opening apraxia (EOA) is the inability to initiate and sustain eyelid opening despite the absence of clinically evident weakness in the levator palpebrae superioris (LPS). This statement in isolation may suggest that EOA is a true apraxia, defined as the inability to execute a voluntary motor movement despite normal muscle function. However, careful electrophysiologic studies of the orbicularis oculi (OO) and LPS reveal abnormal function. The term 'apraxia' was initially applied to this disorder with the first clinical descriptions in 1965. Regardless of its inappropriateness, it is widely used and deeply ingrained in the published literature on the topic. Additional terms applied to the disorder include blepharokolysis (from the Greek blepharo, meaning eyelid, and kolysis meaning inhibition), akinesia of lid opening, and lid freezing. EOA may render a patient functionally blind. It is a frequent, likely under-recognized, finding in a variety of movement disorders. In order to understand EOA, a baseline understanding of normal eyelid function is necessary.

Normal Eyelid Function

The primary structure responsible for eyelid elevation is the LPS muscle (**Table 1**). The sympathetically innervated Muller's muscle contributes to a very small degree (1–2 mm of lid opening). The LPS is innervated by the superior division of the oculomotor nerve (cranial nerve III), with motoneurons originating for both LPS muscles in the single midline central caudal subnucleus of the oculomotor nucleus in the midbrain. Tonic activation of the LPS muscles in the awake state maintains eye opening at all times other than when inhibition of LPS occurs to permit eye closure. The premotor source of this tonic activation is not known, but may be located in the periacqueductal gray 'supraoculomotor area' in the midbrain just dorsal to the oculomotor nucleus.

The LPS has reciprocal innervation with the main structure responsible for eyelid closure, the OO muscle. Just prior to a blink, the LPS is inhibited and the OO motoneurons generate short, high-frequency discharge bursts resulting in OO contraction. At the end of the blink, OO activity ceases and the eye opens with return of LPS activation to its tonic baseline. Blinks may be spontaneous (in the absence of external stimuli), reflexive (secondary to external stimuli), or voluntary, with

Table 1 Neurologic control of eyelid movements

Anatomic structure	*Role*	*Effect of biochemical alteration on voluntary saccades*
Levator palpebrae superioris	Elevates the eyelid, tonically innervated by the superior division of the oculomotor nerve (cranial nerve III) Innervation inhibited prior to a blink and maintained until after the blink is completed, this inhibition precedes and outlasts orbicularis oculi contraction	N/A
Muller's muscle	Small contribution to elevation of the eyelid, innervated by oculosympathetics	N/A
Frontalis muscle	Assists with eyelid elevation in extreme upgaze, innervated by the facial nerve (cranial nerve VII)	N/A
Orbicularis oculi	Closes the eyelid, innervated by the facial nerve (cranial nerve VII) Innervation reciprocal with LPS: when orbicularis oculi is active, LPS is inhibited	N/A
Cerebral cortex	Provides premotor control for eyelid movements Pathways not entirely delineated Medial frontal lobes, including supplementary motor area, involved in control of blinking	N/A
Substantia nigra pars reticulata	Tonic inhibition of SC (neurotransmitter GABA)	Dopamine depletion lessens inhibitory effect of striatum on SNr and, thereby, increases SNr inhibitory output to SC Decreased blink rate
Superior colliculus	Mediates tonic inhibition of the blink reflex	GABA agonist (enhanced SC inhibition) Decreased blink rate Increased blink reflex excitability GABA antagonist (decreased SC inhibition) Increased blink rate Decreased blink reflex excitability

LPS – levator palpebrae superioris; SC – superior colliculus; GABA – γ-aminobutyric acid; SNr – subtantia nigra pars reticulata.

different portions of the OO contracting for different types of blinks. The pretarsal (innermost part near the lid margins) portion of the OO is responsible for involuntary (spontaneous and reflexive) blinks, and the preseptal (intermediate portion of the muscle between pretarsal and orbital) portion, for voluntary blinks and intentional eyelid closure. Spontaneous blinks are highly dependent on dopaminergic neurotransmission.

The premotor, or supranuclear, control of eyelid function and the mechanisms of LPS disinhibition are not entirely understood, but the cerebral cortex, basal ganglia, and superior colliculus (SC) are thought to play a role (**Table 1**). Functional imaging studies suggest that the medial frontal lobes, including the supplemental motor area, are involved in the control of blinking. The role of the basal ganglia in eyelid control, while not as extensively studied as their role in eye movements, has been studied in normal and dopamine-deficient animal models. This control is mediated primarily through nigro-collicular connections, as summarized in **Table 1**. The substantia nigra pars reticulata (SNr) has an inhibitory effect on the SC via γ-aminobutyric acid (GABA). Experimental biochemical manipulation of the SC confirms its role in inhibition of the blink reflex. Enhancement of SC inhibition with a GABA agonist results in a decreased blink rate and increased reflex blink excitability. It is also known that dopamine depletion similarly decreases blink rate. Even in the absence of EOA, abnormal eyelid and blink function are evident in Parkinson's disease (PD) and fit the model well, with decreased spontaneous blink rates and increased blink reflex excitability with prolonged voluntary blinks due to delayed return of LPS to baseline tonic activity. In contrast, decreased SC inhibition with a GABA antagonist increases the blink rate and decreases blink reflex excitability. This demonstrated role of dopaminergic transmission and the role of the basal ganglia in eyelid function may also be involved in the genesis of EOA in movement disorders.

EOA Versus Blepharospasm

The diagnostic criteria for EOA include inability to initiate and sustain eyelid opening without evidence of ongoing OO contraction (**Table 2**). It must be differentiated from ptosis and blepharospasm (**Table 3**). Marked

frontalis contraction is typically present, but its absence should not exclude the diagnostic possibility of EOA. Electrophysiologic studies with eyelid electromyography (EMG) have revealed two different mechanisms that may result in the clinical appearance of EOA. Initial EMG studies revealed prolonged involuntary LPS inhibition following eyelid closure as the mechanism of EOA. The absence of OO activity was confirmed in these patients and was consistent with the proposed diagnostic criteria. However, additional EMG studies revealed prolonged contraction of the pretarsal portion of the OO that was not visible on clinical examination (probably because the orbital OO was not involved). Some patients with the clinical appearance of EOA have one or the other mechanism and some demonstrate both EMG findings. There is controversy over whether or not both of these mechanisms should be diagnosed as EOA. Patients with isolated persistence of motor activity in the pretarsal OO are sometimes diagnosed with 'pretarsal blepharospasm' – which some believe is a variant of EOA and some believe is a subclinical variant of blepharospasm.

Table 2 Diagnostic criteria for eyelid opening apraxia

1. Inability to initiate and sustain lid opening
2. No evidence of ongoing orbicularis oculi contraction[a]
3. Marked frontalis muscle contraction during a period of inability to raise eyelids
4. No ocular motor or ocular sympathetic nerve dysfunction and no ocular myopathy

[a]Classically defined as no clinically visible evidence of ongoing orbicularis oculi contraction, although some have proposed inclusion of EMG recording to eliminate the presence of abnormal orbicularis oculi activity. Other authors include patients with EMG evidence of ongoing orbicularis oculi activity in the absence of clinically visible evidence of ongoing orbicularis oculi contraction ('pretarsal blepharospasm') as a subtype of eyelid opening apraxia.

Etiology and Treatment of EOA

EOA is occasionally an isolated finding, especially in patients with a family history of dystonia; however, it more often occurs in the setting of coexisting benign essential blepharospasm (BEB). The prevalence of EOA in patients with BEB ranges from 11 to 75% in various studies. Isolated EOA most commonly has onset in the sixth decade and has a female preponderance. EOA is a common finding in progressive supranuclear palsy. These patients also typically have very decreased blink rates. Additional causes of EOA include idiopathic PD, corticobasal degeneration, subthalamic nucleus stimulation (in up to 30% of patients), and cerebral hemispheric infarction. Very rare cases have been reported with putaminal infarction, Wilson's disease, and lithium treatment. Although some cases are responsive to dopaminergic medications, cases of EOA onset or worsening are also reported.

Treatment options for EOA include pretarsal OO botulinum toxin injection, pharmacologic therapy with dopaminergic or anticholinergic medications, eyelid crutches or goggles, and ophthalmologic surgical procedures. Eyelid EMG to identify those patients with the EOA mechanism of persistent pretarsal OO activity may assist

Table 3 Eyelid abnormalities resulting in excessive eye closure

Eyelid sign	*Clinical features*	*Features distinguishing eyelid movement from eyelid opening apraxia*
Ptosis	Partial or complete eyelid closure due to mechanical (LPS dehiscence), neurogenic (oculosympathetic denervation of Muller's muscle, oculomotor nerve denervation of LPS), neuromuscular junction (myasthenia gravis), or myopathic causes Unilateral or bilateral with LPS dehiscence, worse with downgaze Usually unilateral with oculomotor palsy, accompanied by diplopia and abnormal eye movements Unilateral and mild (1–2 mm) with oculosympathetic denervation of Muller's muscle (Horner's syndrome), accompanied by pupillary miosis Unilateral or bilateral and fatigable with neuromuscular junction	Fixed ptosis without intermittent spontaneous opening of eyelid (unless neuromuscular junction, in which ptosis is variable, not fixed) With neuromuscular junction, fatigability with prolonged upgaze
Eyelid opening apraxia	Involuntary inability to open the eyes after lid closure No visible orbicularis oculi contraction Intermittent, spontaneous opening of the eyes	N/A
Blepharospasm	Involuntary, intermittent, forced eye closure with visible contraction of orbicularis oculi During episodes of eyelid closure, eyebrows are located beneath the superior rim of the orbit (Charcot's sign)	Visible contraction of orbicularis oculi

LPS – levator palpebrae superioris.

with identification of the patient group most likely to have a therapeutic response to botulinum toxin injection. Patients with isolated prolonged LPS inhibition are less likely to respond to this treatment. Treatment with eyelid crutches or goggles takes advantage of the phenomenon of 'geste antagonistique,' or alleviation of EOA by sensory stimulation on or around the eyelids via a presumed proprioceptive feedback mechanism. Ophthalmologic surgical procedures of potential use include blepharoplasty, myectomy, frontalis suspension, and aponeurosis repair.

Eye-of-the-Tiger Sign

S J Hayflick, Oregon Health & Science University, Portland, OR, USA

Definition and History

The eye-of-the-tiger sign refers to the characteristic MRI pattern found in PKAN. Specifically, the sign describes hypointense signal in the globus pallidus in conjunction with a region of central or anteromedial hyperintensity on T_2-weighted imaging (**Figure 1**). These changes are also evident on proton density (PD) and fluid attenuated inversion recovery (FLAIR) imaging. T_1-weighted imaging is normal.

Originally coined in 1988 by Sethi et al. in reference to coronal MRI sections, the term is more commonly used to refer to a similar pattern on sagital sections.

Pathogenesis/Pathophysiology

The eye-of-the-tiger sign is observed as a result of a specific pattern of damage to the globus pallidus in PKAN. The hypointense signal in the globus pallidus on T_2-weighted imaging represents high tissue iron; the central hyperintense signal is associated with edema. These changes are consistent with the current hypothesis of disease. The only other MRI change consistently seen in PKAN is hypointense signal in substantial nigra, which is often not evident until later in disease.

PKAN is an inborn error of coenzyme A metabolism. As such, the very early pathogenic changes in the basal ganglia are hypothesized to arise from perturbed fatty acid metabolism, leading to tissue damage and edema. Early MRI changes in presymptomatic, mutation-positive individuals show a predominance of hyperintense signal indicating less iron. As the disease progresses, iron accumulates and the hypointense signal intensifies. In addition, the hyperintense signal appears to condense.

MRI changes may predate clinical symptoms. Characteristic MRI changes have been documented in clinically normal, mutation-positive siblings of affected individuals. In contrast, at least one case suggests that clinical symptoms may predate MRI changes, although this is probably rare.

Differential Diagnosis

The eye-of-the-tiger sign is considered to be virtually pathognomic for PKAN. Rare reports have offered evidence to refute this notion; however, none of these has provided sufficient data to challenge this robust association. Therefore, especially in the context of supporting clinical data, the eye-of-the-tiger sign indicates PKAN.

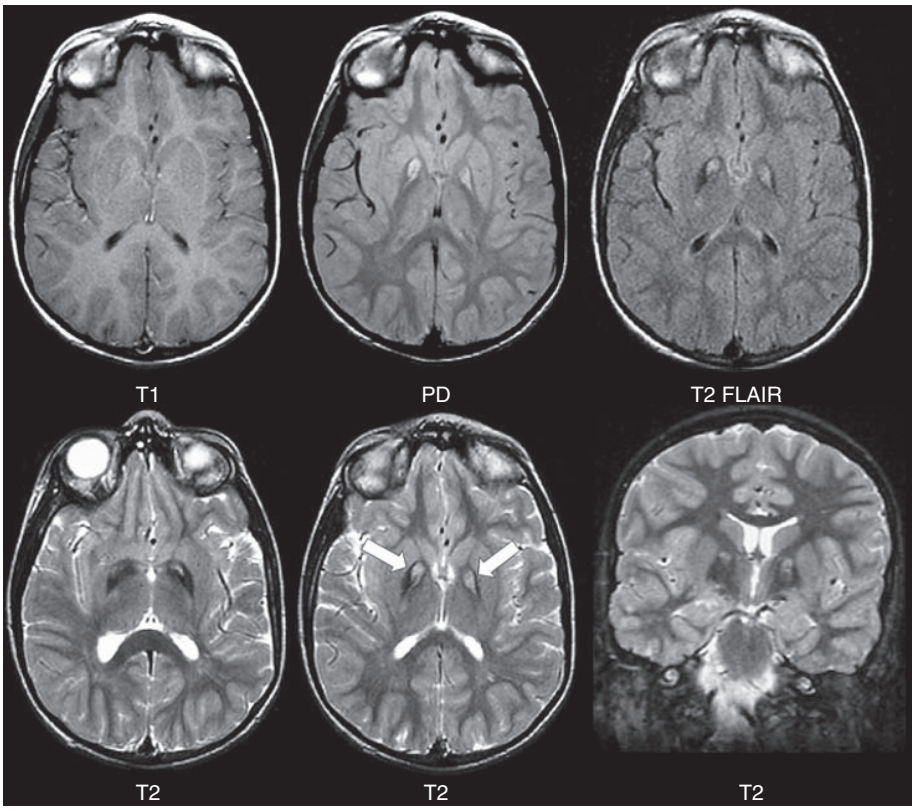

Figure 1 Eye-of-the-tiger sign (arrows). This *PANK2* mutation-positive child shows MR features characteristic of PKAN. The T_1-weighted images appear normal, but high signal can be seen in the globus pallidus on proton density (PD), T_2-weighted fluid attenuated inversion recovery (FLAIR), and T_2-weighted images in both the axial and coronal planes. With increasingly heavier T_2 weighting (PD<FLAIR<T_2), there is increasingly conspicuous T_2 hypointensity at the periphery due the magnetic susceptibility effects of excess iron.

Neurodegeneration with brain iron accumulation (NBIA) describes a heterogeneous group of disorders that includes PKAN. Others are neuroferritinopathy, aceruloplasminemia, infantile and atypical neuroaxonal dystrophy, and idiopathic NBIA. The specific MRI patterns associated with these disorders differ from that of PKAN, although all include high regional iron in the basal ganglia.

Diagnostic Work-up/Tests

When MRI shows the eye-of-the-tiger sign, diagnostic studies for PKAN are indicated. PKAN is a genetic disorder caused by mutations in *PANK2*, the gene encoding pantothenate kinase 2. Blood may be sent for DNA sequencing of *PANK2* in order to confirm the diagnosis. Laboratories currently offering clinical testing can be found at GeneTests. The sensitivity of current screening tests is >98%. Gene Tests: Medical Genetics Information Resource (database online). University of Washington, Seattle. 1993–2009. Available at http://www.genetests.org.

Factitious Disorders

E C Alcera and D T Williams, Columbia University, New York, NY, USA

Glossary

Antisocial personality disorder – Antisocial personality disorder is a psychiatric diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders.* The essential feature for the diagnosis is a pervasive pattern of disregard for, and violation of, the rights of others that begins in childhood or early adolescence and continues into adulthood. Deceit and manipulation are considered essential features of the disorder.

Borderline personality disorder – Borderline personality disorder is a psychiatric diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders* that describes a prolonged disturbance of personality function characterized by depth and variability of moods. The disorder typically involves unusual levels of instability in mood; 'black and white' thinking, or 'splitting'; chaotic and unstable interpersonal relationships, self-image, identity, and behavior; as well as a disturbance in the individual's sense of self.

Confabulations – The formation of false memories, perceptions, or beliefs about the self or the environment as a result of neurological or psychological dysfunction.

Histrionic personality disorder – Histrionic personality disorder is a personality disorder characterized by a pattern of excessive emotionality and attention-seeking, including an excessive need for approval and inappropriate seductiveness, usually beginning in early adulthood. The essential feature of histrionic personality disorder is an excessive pattern of emotionality and attention-seeking behavior.

Malinger – To feign illness, injury, or incapacitation in order to avoid work or obligation, or to secure tangible benefits.

Projective identification – A psychological process in which a person engages in the ego defense mechanism projection in such a way that his behavior towards the object of projection invokes in that person precisely the thoughts, feelings, or behaviors projected.

Pseudologica fantastica – Terms applied by psychiatrists to the behavior of habitual or compulsive lying; pathological lying.

'Sick role' – Term widely used in medical sociology concerning the social aspects of falling ill; individual who has fallen ill is not only physically sick, but now adheres to the specifically patterned social role of being sick.

Somatoform – Manifesting physical symptoms whose primary cause is psychological.

Splitting – Can be explained as thinking purely in extremes, for example, good versus bad, powerful versus defenseless, and so on. Splitting can be seen as a developmental stage and as a defense mechanism.

Definition and History

Factitious disorder is diagnosed when a person *intentionally* feigns or produces physical or psychological symptoms in order to assume the sick role. By definition, these symptoms are produced *consciously*; however, the underlying motivation to produce them may be *unconscious.* Distinguishing conscious from unconscious intention and motivation are important for differentiating a factitious disorder from somatoform disorders and malingering. These distinctions can be challenging for the clinician because even though patients with factitious disorder often present to the healthcare provider requesting medical care intentionally concealing the known source of their symptoms, they may not be consciously aware of why they are seeking the sick role.

DSM-IV-TR outlines three diagnostic criteria for factitious disorder:

1. The intentional production of physical or psychological signs or symptoms.
2. The motivation is to assume the sick role.
3. External incentives for behavior such as financial gain or avoidance of legal responsibility, or improving physical well-being (as in malingering) are *absent*.

The DSM-IV-TR further subclassifies factitious disorders into those with predominantly *psychological* signs and symptoms, those with predominantly *physical* signs and symptoms, those with combined *psychological and physical* signs and symptoms, or factitious disorder, not otherwise specified.

Evaluating physicians who suspect factitious disorder need to rule out undiagnosed illness that may not have been previously detected, or an undiagnosed illness that may coexist with a superimposed factitious disorder. At the same time, clinicians need to balance a thorough evaluation of the patient's symptoms with the need to avoid extensive and unnecessary medical procedures, which bear their own risks, expenses, and liabilities.

Munchausen syndrome refers to a subtype of factitious disorder. It is a severe, chronic form of factitious disorder characterized by three traits: fabrication of signs or symptoms that are often bizarre and marked ('pseudologica fantastica'); 'doctor seeking,' including migrating from hospital to hospital for multiple and often invasive procedures; and disguising one's identity.

Munchausen syndrome by Proxy, also known as factitious disorder by Proxy, involves a caretaker inducing symptoms in a child which results in unnecessary medical testing and procedures, presumably motivated by the caretaker's wish to assume the 'sick role' via the child. It is considered a form of child abuse.

Clinical Features and Diagnostic Criteria

Clinical presentations are quite variable, and patients may present with a wide array of symptoms, diseases, and conditions. Factitious disorder in its milder forms may present with minimal symptoms, which may not inspire the clinician to consider factitious disorder as a diagnosis. Early identification of patterns common to factitious disorder can help the clinician initiate early intervention when appropriate, which may help avoid progression to a more chronic course.

A number of features in the presentation of factitious disorder that are nonspecific may be useful diagnostic clues. History obtained from patients often contains unexplained gaps, confabulations, or fabrication of symptoms. Familiarity with medical terminology and procedures are often evident in patients with factitious disorder, and this may in part be explained by the frequency with which these patients have intimate familiarity with healthcare settings. A review of cases conducted by Krahn et al., found that 72% of these patients were women and 65.7% either had healthcare-related jobs or training. Ingestion of psychoactive substances to produce symptoms, such as emetics, hormones, anticoagulants, laxatives, or even utilizing contaminants like feces, bacteria, and sputum to induce illness, have been reported. Tampering with instruments such as thermometers, IV lines, or laboratory specimens may mislead healthcare providers to order unnecessary procedures. Patients often become highly indignant when questioned about discrepancies in their reports. Reactions can range from denial to extreme rage, or making threats of legal action if the clinician continues to question their reports. Factitious disorder patients are often uncooperative with attempts to obtain collateral information. Typically, nurses on inpatient units note that these patients do not receive phone calls from friends or family, and are deemed 'loners' and introverts.

Pathogenesis/Pathophysiology

Current understanding of the pathogenesis of factitious disorder is speculative, based mainly on clinical observation and interpretation thereof. Factitious disorder patients often implicitly express an intense need to be taken care of as part of their assuming the sick role. Ongoing psychiatric evaluation is required to understand why this need has developed, and why this strategy has been undertaken in order to meet this need. Stress-related issues, either past or present, are often exposed during thorough interviews with patients, which may influence the desire to adopt the sick role. These issues can include loss, abandonment, illness, disappointment, or abuse. Personality disorders are a common finding, specifically, those that utilize 'splitting' and 'projective identification' such as borderline, antisocial, and histrionic personality disorders.

Epidemiology

Prevalence data are sparse and difficult to collect. A survey of 26 physicians in independent practice, and 83 senior hospital consultants in the specialties of internal medicine, surgery, neurology, and dermatology estimated that a 1 year prevalence of factitious disorder averaged 1.3% (0.0001–15%). Poor recognition of symptoms and associated diagnosis results in underreporting of this disorder. Suspected cases, when confronted, may sign out of the hospital, evading diagnosis and follow-up. Typically, only the most severe cases are reported, giving a diminished picture of the disorder's prevalence.

Differential Diagnosis

Undiagnosed medical illness is the most important exclusion for the evaluating physician. The investigation of possible underlying medical illness should proceed even if strong evidence points to the presence of a psychogenic component of the presenting symptoms, since these two conditions may coexist.

Malingering, which is not a psychiatric disorder, involves the intentional production of physical or psychological signs or symptoms with the clear objective of pragmatic gain. This includes financial gain, evasion of legal responsibility, obtaining narcotics or other controlled substances, or avoidance of work or other responsibilities. The history given in both malingering and factitious disorder can be sophisticated and convincing. Poor cooperation during the evaluation and treatment process are common in both. Furthermore, both these conditions can coexist.

Somatoform disorders connote the presence of signs or symptoms suggestive of a medical condition, but no underlying organic etiology is established after appropriate diagnostic evaluation. The symptoms are deduced to be of psychological origin, but on a basis that is *not* consciously evident to the patient. These disorders cause significant impairment in functioning, and are not due primarily to substance abuse or another psychiatric disorder. Some psychological or minor 'secondary gain' benefits may pertain, but they are not intentionally pursued by the patient.

Diagnostic Work-up

Taking a thorough history, along with a meticulous chart review and collaboration with other medical care providers is essential. Obtaining prior medical records and speaking with past caretakers may legitimately be made a precondition for treatment, once this diagnosis is suspected. Laboratory studies and imaging can be useful to help rule out organic disease, and also to assist in confirming suspicions of feigned illness. As with any evaluation, these studies need to be based on clinical indication. For example, checking serum insulin/c-peptide ratio in hypoglycemic patients with suspected exogenous insulin administration can confirm a diagnosis of self-induced hypoglycemia. Diagnosis relies on a high index of suspicion, and making full use of all obtainable clinical information.

Utilizing a nonjudgmental approach, however, predicated on the possibility of a somatoform disorder (without conscious intent) is important to avoid alienating the patient by premature confrontation. Early introduction of the psychiatrist as an integral part of the evaluating team can help clarify psychopathological features and enhance receptivity to a treatment plan that includes a psychiatric component.

Management

Once a factitious disorder is suspected or identified, psychiatric consultation is needed for further diagnostic assessment and treatment formulation. To facilitate collaboration with medical and psychiatric services, a supportive, nonconfrontational approach is desirable. Delineating the role of 'stress' in many medical illnesses, and delineating neurotransmitter roles in the neuropsychiatric genesis of many medical conditions may allow a more nuanced and less judgemental approach to the issue of intentionality and unconscious motivating factors, while allowing the team and patient to focus on symptom attenuation. If possible, engaging a stable family member in the diagnostic debriefing and treatment planning, with the patient's consent, can be a valuable resource. Psychotherapeutic modalities, along with psychopharmacology, may help ameliorate symptoms. However, due to the absence of controlled clinical trials, evidence-based treatment strategies cannot be currently delineated. Supportive individual psychotherapy and family therapy may be helpful in identifying patient needs and uncovering predisposing, precipitating, and perpetuating factors that can inform treatment strategies. Psychopharmacologic agents may be useful in treating comorbid conditions such as affective and anxiety disorders. Addressing coexisting personality disorders is warranted if the patient is amenable.

Prognosis

In the absence of controlled treatment trials and follow-up studies, but based on uncontrolled clinical experience, it is generally assumed that the prognosis for factitious disorders is less favorable than that of somatoform disorders. Some uncontrolled studies suggest that chronic and severe factitious disorders follow an unremitting course. This, however, is true for many psychiatric disorders; it should not dissuade the clinician from concerted efforts at early diagnosis and treatment.

Fahn–Marsden Rating Scale

G Bernard, Montreal Children's Hospital, Montreal, QC, Canada
S Chouinard, University of Montreal, Montreal, QC, Canada
R Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Glossary

Dystonia – Sustained muscle contractions of agonists and antagonists causing involuntary twisting movements and postures.
Reliability – Consistency of the assessment or measurement of a given tool (e.g., a scale), at different times or by different evaluators.
Validity – Degree to which a test (e.g., a scale) measures what it is intended.

Definition and History

Dystonia is a hyperkinetic movement disorder characterized by sustained twisting and posturing movements, which may affect single or multiple body areas. While there are characteristic electrophysiologic features of dystonia, such as muscle agonist–antagonist cocontraction, these do not yet allow quantification of severity of dystonia in different body sites. Further, the features of dystonia are not static and vary according to activity. In order to better characterize the clinical course, and to assess the efficacy of treatments, scales to capture both the severity of the dystonia (including the dynamic features) and the functional disability of the dystonia are needed. Scales may encompass dystonia affecting all body sites, such as the Fahn–Marsden (F–M) rating scale, which may be used for generalized, segmental, or focal dystonia, or may be focused on one body area, such as cervical dystonia.

Both the structure and validity and reliability of the F–M rating scale were first reported in 1985. The scale was subsequently first used in the context of a therapeutic trial with trihexyphenidyl for the treatment of torsion dystonia.

The F–M rating scale is composed of two sections: a movement scale based on the neurological examination and a disability scale based on the patient's opinion of his disability in activities of daily living. The movement scale is further divided in nine body regions: eyes, mouth, speech and swallowing, neck, right arm, left arm, trunk, right leg, and left leg. Individual scores are obtained for each body region; from 0 to 8 for the eyes, mouth, and neck, and from 0 to 16 for the other body parts. The individual scores are calculated for each body region using a formula that takes a provoking factor, a severity factor and a weighting factor into account. The eyes, mouth, and neck are 'down-weighted' because when involved, these regions were not suggested to cause as much disability. The provoking factor is scored from 0 to 4 as following: 0 – No dystonia, 1 – Dystonia on particular action, 2 – Dystonia on many actions, 3 – Dystonia on action of a distant body part (overflow) or intermittently at rest, and 4 – Dystonia at rest. For speech and swallowing, the provoking factor is slightly different, and is based on frequency. The severity factors are scored similarly for all regions except speech and swallowing. Some site-specific criteria apply according to the specific abnormal movement or posture caused by the dystonia (e.g., bending of the trunk with truncal dystonia, blinking or spasms of eye closure with blepharospasm). In general, the severity factors range from 0 to 4, with 0 – No dystonia, 1 – Slight dystonia, 2 – Mild dystonia, 3 – Moderate dystonia, and 4 – Severe dystonia, with different ratings for speech and swallowing. Once individual scores for each body part are calculated, they are summed to obtain the movement scale score. The scale ranges from minimum of 0 to maximum of 120.

For the disability score, seven activities of daily living are rated according to the patient's perception of his/her disability: speech, writing, feeding, eating, hygiene, dressing, and walking. The scores are from 0 to 4 (except for walking, from 0 to 6), and scores are task specific. In general, scores are determined according to the following scale: 0 – Normal, 1 – Slight difficulty, 2 – Some difficulty, 3 – Marked difficulty, and 4 – Severe difficulty, unable to perform the activity. The scale for walking is slightly different, ranging from 0 to 6; with a score of 6 assigned if the subject is wheelchair bound. Once the scores for all the individual activities of daily living are obtained, they are summed to obtain the total disability score, which ranges from 0 to 30.

Metrics of the Scale: Reliability and Validity

The validity of the scale assesses how well the scale reflects a gold standard rating. As clinical assessment of dystonia remains the de facto 'gold standard,' the validity of the motor portion of the scale reflects how well the scores correlate with the clinical impression of dystonia severity. For example, when the dystonia is perceived as severe by an experienced neurologist, a valid scale would lead to a high score. The converse is true for a dystonia perceived as mild by the clinician. On the other hand, the reliability of the scale corresponds to how reproducible the score is, among different examiners (interrater reliability), but also from the same examiner at different times (intrarater reliability).

The validity and reliability of the F–M rating scale were first evaluated by Burke and colleagues in 1985. The validity was evaluated by comparing the F–M score with the global clinical impression of severity and with the disability score. The reliability was assessed by first, comparing evaluations of the 10 patients on two occasions by two examiners (intrarater validity) and second, by examining the correlation of the ten evaluations of the three examiners. The scale was shown to be both reasonably valid and reliable for patients with primary torsion dystonia. However, only a small number of patients were assessed, and because dystonia is so heterogeneous, the broader spectrum of dystonia was not tested. Further, the degree of agreement for individual body sites was not reported.

Two large multicenter studies have since evaluated the F–M scale. Comella and colleagues evaluated the reliability of the scale using 20 videotaped patients, and 25 dystonia experts, and compared the scale to the UDRS (Unified Dystonia Rating Scale) and GDS (Global Dystonia Rating Scale). They concluded that all three scales were internally consistent, showed good to excellent interrater reliability (intraclass correlation coefficient, 0.71–0.78), but that the provoking factor in the F–M demonstrated less interrater agreement than the motor severity ratings. Further, they found that the GDS (which includes rating for proximal and distal limbs separately, and does not include subjective speech and swallowing ratings, and does not include weighting factors) was easier to administer than the F–M. Krystkowiak and colleagues further demonstrated reliability in a prospective assessment of the F–M scale used to track severity and disability of primary generalized dystonia treated with deep brain stimulation.

Applications of the Scale

The F–M scale was first used to assess the efficacy of trihexyphenidyl as a treatment for primary and secondary dystonia. It is now primarily used to assess the efficacy of deep brain stimulation surgery in both primary and secondary dystonia, usually in cases with generalized dystonia.

Problems with the Scale

As noted, the F–M rating scale has several limitations. The major drawback in using the F–M scale is lack of ease in administration, which relates to separately determining provoking and severity factors. The GDS was developed as an alternative to the F–M, and has been shown to be at least as reliable and valid but simpler and easier to apply. The UDRS was developed to address the F–M scale's limitations regarding the flexibility to report specific sites as the rated areas are smaller and more defined, and shows great promise. The F–M scale is also limited in its applicability for some dystonia plus syndromes and secondary dystonias as it is focused on dystonia, and additional movement disorders, such as myoclonus and features of secondary dystonia, such as that due to Wilson disease, or spasticity associated with other forms of secondary dystonia are not captured. In these situations, disease specific scales, such as the Wilson Disease Scale, may be more applicable.

Foot Print Analysis

F P T Hamers, Rehabilitation Hospital 'De Hoogstraat,' Utrecht, The Netherlands

Glossary

ALS – Amyotrophic Lateral Sclerosis, a syndrome in which peripheral and central motor neurons degenerate leading to progressive paralysis and eventually death due to respiratory failure (generally several years after diagnosis).
CNS – Central nervous system, the brain and spinal cord.
Contact electrode – Electrode fitted under the paw on an animal which is used to sense presence of paw–floor contact.
Gait diagram – Graphical representation of timing and duration of paw–floor contact in relation to the other foot or paws. Support and Gait formulas are simplifications hereof (see e.g., Hamers et al., Figure 1).
Gait formula – See Gait diagram.
SFI – Sciatic functional index, a measure that is used to assess completeness of functional motor recovery after sciatic nerve lesion.
Support formula – See Gait diagram.

Introduction

The ability to walk is taken for granted by healthy people, and regaining this ability after it has been lost because of an accident or disease is often one of the most important goals of patients in rehabilitation medicine: In my current practice, 'to leave the hospital walking' is among the most formulated wishes of patients when asked for their goals. Many eventually attain this goal although gait may never completely normalize.

Causes of gait disturbances are many: In principle, every disorder affecting the nervous system (peripheral as well as central), the skeleton, the muscles, the tendons, the skin, and the senses potentially affect gait.

Animal models are important both in the elucidation of the pathogenesis of such disorders, and in the search for effective therapies. Because gait is easily observed, gait disturbances have the potential both for assessing the degree of malfunctioning as well as for testing experimental therapies. However, theory is simple, practice is not: The rats and mice most often employed in such research are moving considerably faster than humans and describing and especially quantifying gait is far from easy.

In this paper, I will introduce methods to describe and quantify gait in rats and mice (foot print analysis being one of them), and their application to specific disease models. Given the limited space, I can only discuss the basics and some of the most interesting techniques. The interested reader is referred to the *Further Reading list* at the end.

Describing and quantifying gait

Open field testing

The oldest and most simple way of performing gait print analysis is by visual observation: Although hampered by the speed with which animals move around, one can by focusing on specific elements of gait such as plantar/dorsal stepping (does an animal trip over its toes at initial contact?), gross rotation of the feet (inner/outer rotation as opposed to parallel placement) and toe drags (which are listened for) obtain sufficient data to create sensitive scoring systems with excellent reproducibility. Two of the most important scoring systems in this respect are the Basso, Beattie, and Bresnahan (BBB) rating scale,

and the Basso Mouse Score (BMS), developed for respectively spinal cord injured rats and mice.

Foot Print Analysis

One of the most widely used methods to quantify gait disturbances caused by experimental sciatic nerve lesions was developed by de Medinaceli: Measurements of stride length, print length, and toe spread are measured from walking tracks and the Sciatic Functional Index (SFI) – essentially a measure for the degree of asymmetry between lesioned and control paw – is computed hereof: recovery of symmetry (SFI of 0) indicates functional recovery. By using only specific terms in the equation, one can also discriminate between recovery of innervation of the triceps surae muscle and intrinsic foot muscles. Because of its simplicity, it is still widely used in some way or another. Prints may, however, be difficult to recognize, especially in the first weeks after sciatic nerve injury when most of the recovery of the SFI occurs, and interobserver variability can be quite large.

Weight Bearing

An animal may place its paw without bearing weight. If you have a painful wound in your foot, you try to do the same by shifting weight to some other part of the foot (which is clearly visible to the trained observer). Tetrapods can keep one of their paws (almost) completely unloaded, which is neither visible in the open field nor on de Medinaceli walking tracks. However, the possibility to quantify weight bearing has the potential to uncover subtle gait disturbances due to central nervous system (CNS) disease and can also be used to measure pain (in an indirect manner). Two techniques have the potential to do so, one quantitative technique relying on pressure sensor grids which was recently described by Boyd and coworkers, the other one being semiquantitative and to be discussed later (**Figure 1**).

Timing Relationships

Among the most difficult parameters to assess are timing relationships between paw placements. Nonetheless, they have been used for a long time in the description of gait, for example, in the characterization of horse gait (e.g., trot, gallop, walk).

Timing of paw placement relative to other paws can be expressed in the gait diagram and its derivatives, the support and gait formulas. These have been used to describe changes between gaits in a single animal (e.g., from trotting to galloping) and changes induced by disease. Hildebrand extensively used them in his description of a gait in a wide variety of tetrapods. Until recently such research was prohibitively expensive and time consuming, at least on a regular basis. Nonetheless, changes in timing relationships, or phase shifts, can provide deeper insight in the control of gait. Majczynski, Zmyslowski, and coworkers developed a rather elegant method which circumvents the need of high speed photography to study such relationships by using contact electrodes in spinal cord injured animals. Few others have followed their lead, however.

With the ready availability of fast and cheap computers and video capture hardware, high throughput systems for gait analysis have been developed for animals and humans. Essentially two different techniques that have been used in disease models have been introduced in the past decade. The first is the CatWalk, based on a walkway with some special properties that enable easy visualization of paw prints and (semi)quantitative pressure estimations for these prints, the other, DigiGait, is treadmill based and does not offer pressure estimation. A third technique which requires significantly more user interaction and which will

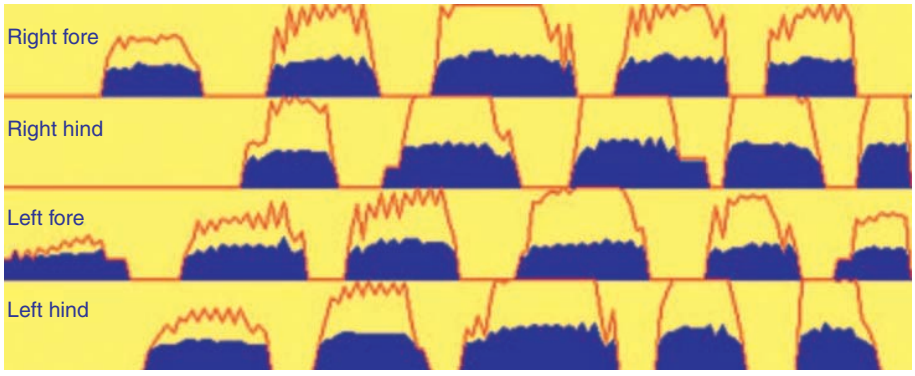

Figure 1 The average intensities (filled area: averaged over the whole contact area of the paw at any moment) and the max intensity (upper line) anywhere at that moment as function of time. These intensities are related to weight bearing. In this experiment we were not interested in weight bearing, otherwise we would have made sure that max intensity did not exceed the dynamic range of the camera.

not be discussed further in this manuscript was developed by Gruntman, Benjamini, and Golani.

CatWalk

Development of CatWalk started in 1996 after I visited the Beattie–Breshanan lab for learning to use the newly developed BBB score. The goal was to better assess forelimb–hindlimb (FL–HL) coordination than is possible in the open field. I build a walkway such as originally described by Dr Kenneth Clarke of the University of Sheffield, a walkway which was based on a device originally developed by Drs Betts and Duckworth for measuring plantar pressures under human feet. The most important property of this walkway is that only places of paw–floor contact light up, with paws that are only minimally raised being invisible. In short: walkway crossing are filmed from underneath with a CCD-camera connected to a PC and controlled by the CatWalk software which stores the films in a format that retains the important details (most video compression algorithms discard the details!). The program can be used to measure almost every parameter discussed thus far. Input from my own research (experimental spinal cord injury) and many collaborators from all over the world (on neuropathic and arthritic pain, developmental (Hox genes) mutants, cerebellar disease, hereditary motor-sensory neuropathy) was incorporated in the analysis section.

Although originally developed to quantify locomotor disturbances in models of spinal cord injury, the method has from its inception also been used in other models. The use in pain models was suggested already in 1999 by Dr Tinna Angeby-Möller. Dr Guido Koopmans, working on his PhD thesis in Dr Bert Joosten's lab, eventually combined CatWalk provided evidence for normal FL–HL coordination with open field BBB scoring, ending up with a more sensitive BBB score. For our paper on insulin-like growth factor-1 (IGF-1) and enriched environment housing we also performed some major quantitative analyses of timing relationships (couplings) between FLs and HLs, an area with great potential when it comes to understanding the generation of gait and its feedback loops. CatWalk has also proved its value in models for Refsum's disease, Stroke, Parkinsonism, and Sciatic Nerve Injury.

DigiGait

DigiGait was developed by Dr Thomas Hampton in the early years of this decade. Animals are filmed from underneath while walking on a transparent treadmill belt and almost the same set of data as that acquired with CatWalk can be analyzed, although paw–floor contact is probably somewhat less reliably assessed than with CatWalk. However, animals can be forced to walk at chosen speeds and for longer periods, which may be helpful to find deficits that only show up under greater stress. Publications exist on the use of this system in models of ethanol intoxication, in trisomic mice (a model for Down syndrome) and models for Parkinson's disease and Huntington's disease. Interestingly, early changes in neurological functioning in a model for amyotrophic lateral sclerosis (ALS) have also been described employing this system, which can be helpful to identify animals with subtle but well described locomotion deficits very early in the disease process, enabling one to gain more insight in the early stages of the disease process.

Conclusion

Gait analysis has evolved significantly over the years. The availability of fast and inexpensive computers and video acquisition hardware in the last decade has led to powerful new analyses that can be performed routinely. This review has only tipped some of the basics and the interested reader is kindly referred to the papers listed in the *further reading list* below for further background.

Fragile X-Associated Tremor/Ataxia Syndrome (FXTAS)

E Berry-Kravis, Rush University Medical Center, Chicago, IL, USA

Glossary

FMR1 – Fragile X mental retardation 1 gene, the gene mutated in fragile X syndrome and fragile X tremor/ataxia syndrome.
FXTAS – Fragile X-related tremor/ataxia syndrome, neurodegenerative disorder resulting from small (premutation size) expansion mutations in a CGG repeat sequence in *FMR1*.
MCP sign – High signal in the middle cerebellar peduncle seen on T2 and flair MRI.
POI – Primary ovarian failure, early ovarian insufficiency; FX-POI, ovarian insufficiency related to the *FMR1* premutation.
Premutation – Small mutation which does not cause disease, but just propensity to pass disease to descendants.

Definition and History

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a recently discovered late-onset (>50 years) neurodegenerative disorder, occurring in carriers of a premutation CGG repeat expansion in the fragile X mental retardation 1 (*FMR1*) gene. The disorder is associated with a variable presentation which may include intention tremor, ataxia, parkinsonism, executive dysfunction and cognitive decline, neuropathy, and psychiatric features. FXTAS was first described in 2001, when it was noted that grandfathers of individuals being seen for management of fragile X syndrome (FXS) often had unexplained neurological symptoms categorized as tremor or atypical parkinsonism.

Genetics/Molecular Pathogenesis/ Pathophysiology

The *FMR1* gene, located on the X chromosome, has a trinucleotide (CGG) repeat sequence located in the first exon of the gene, which functions as part of the promoter, and codes for a sequence in the 5′ untranslated region of the *FMR1* mRNA. The normal repeat length is 5–44 CGG triplets; 'gray zone' alleles are defined as 45–54, premutation alleles as 55–200, and full mutations as above 200 CGG repeats. Repeat lengths in the gray zone may occasionally be unstable, or expand, when passing from one generation to the next, but are not known to cause disease.

Full mutation alleles cause hypermethylation and silencing of the *FMR1* promoter and a consequent deficiency or absence of *FMR1* protein (FMRP). FMRP is an RNA-binding protein that regulates translation at dendrites

in response to neural activation, thereby modulating synaptic plasticity and dendritic morphology. Absence or deficiency of FMRP results in FXS, a developmental disorder associated with intellectual disability, autistic-features, and characteristic physical signs.

Two phenotypes are specifically associated with permutation alleles. The first is fragile X-associated primary ovarian insufficiency (FX-POI) which leads to ovarian dysfunction, and, in 20% of female carriers, to premature ovarian failure (POF). The second phenotype is FXTAS, which occurs in a proportion of carriers, predominantly in men.

Although FXS results from lack of FMRP, there are normal or near-normal levels of FMRP in premutation carriers with FXTAS. Thus, an alternative molecular mechanism has been proposed for FXTAS based on the finding of a mild translational deficit of FMRP compensated by elevated *FMR1* mRNA levels in cells from premutation carriers, particularly at larger CGG repeat sizes. Accumulated *FMR1* mRNA containing the CGG repeat is thought to exert a neurotoxic effect by sequestering and perturbing function of nuclear proteins. This mechanism is consistent with the findings of nuclear inclusions in mice expressing an *fmr1* gene with a premutation expansion allele (~100 CGG repeats) and neurodegeneration in *Drosophila* expressing expanded CGG repeats. As predicted by the *FMR1* mRNA toxicity mechanism for FXTAS, individuals with the *FMR1* full mutation and FXS do not develop FXTAS because the *FMR1* gene silencing in FXS results in absent or reduced *FMR1* mRNA and FMRP. **Figure 1** illustrates the relationships between FMR1 CGG repeat length, type of mutation, FMR1 mRNA levels, FMRP levels, and clinical phenotype.

Pathological findings in humans with FXTAS, including ubiquitin-positive intranuclear inclusions in neurons and astrocytes throughout the brain, are also consistent with the RNA toxicity mechanism. Immunohistochemical and mass spectrometric analyses of purified brain inclusions show they are composed of more than 20 proteins and include the FMR1 mRNA. Proteins identified in the inclusions also include lamin A/C, a nuclear structural protein associated with neuropathy, suggesting some features of FXTAS may reflect a functional laminopathy. Indeed, disruption of nuclear architecture and abnormal nuclear lamin localization has been observed in neurons in brain autopsy samples from individuals with FXTAS.

The nuclear inclusions in FXTAS are seen throughout the brain, most numerous in the hippocampal formation, and only rarely seen in Purkinje cells. The number of CGG repeats is highly correlated with the fraction of inclusion-bearing neural cells. Inclusions are found in spinal autonomic neurons and astrocytic nuclei of the spinal cord, but not in motor neurons of the spinal cord. Patches of subcortical and deep cerebellar white matter show pallor and spongiosis with axonal spheroids, accompanied by loss of axons and myelin, and correspond to areas of increased T2-weighted signal intensity on MRI images.

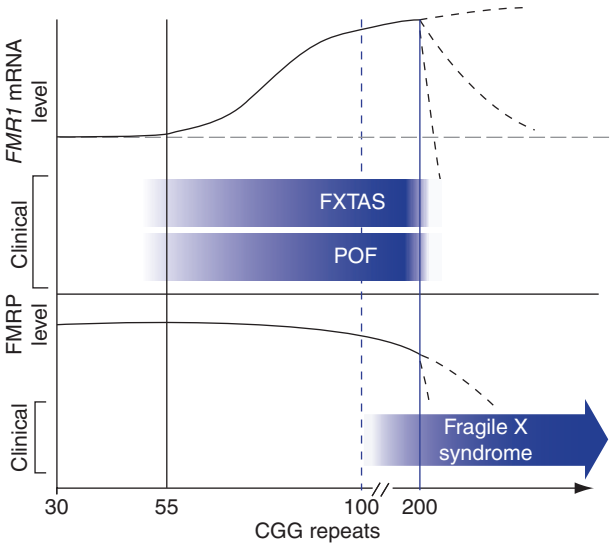

Figure 1 Graphs of the relative levels of *FMR1* mRNA and protein (FMRP) as a function of the number of CGG repeats, and the associated clinical phenotypes. FXTAS and premature ovarian failure (POF) are largely confined to the premutation range, and are thought to occur through an RNA toxic gain-of-function due to excess *FMR1* mRNA; however, occasional patients with full mutation alleles continue to express mRNA and are at risk of developing FXTAS. By contrast, FXS is caused by reduced/absent FMRP, due to silencing of the *FMR1* gene in the full mutation range, and is generally confined to the full mutation range. Features of the FXS spectrum may occur in the upper premutation range due to reduced protein production. Dashed lines for mRNA levels in the full mutation range reflect variations in degree of silencing; dashed lines for FMRP levels represent reductions due to both lowered mRNA levels and intrinsic reductions in translational efficiency.

Clinical Features and Diagnostic Criteria

The major motor features of FXTAS are demonstrated on accompanying video clips. Tremor on the Clinical Rating Scale for Tremor (CRST) and limb and gait/stance ataxia on the International Cerebellar Ataxia Rating Scale (ICARS) were distinct clinical features identified in adult male premutation carriers as compared to age-matched control groups. As evidenced by the statistically significant differences in all subdomains of the CRST, tremor in FXTAS is multidimensional, involving rest, postural, and kinetic elements. Postural and kinetic tremors are typically more obvious initially and rest tremor may appear as the condition progresses. The gait is typically slow and lurching, and patients have difficulty with tandem stance and gait, consistent with cerebellar ataxia. Parkinsonian signs, primarily rigidity, are usually less obvious. This suggests that the phenotype in FXTAS premutation carriers is not a

typical presentation of Parkinson disease (PD), but an overlapping tremor-predominant syndrome with cerebellar ataxia and mild parkinsonism. Despite high interindividual variation, even within families, the mixture of gait ataxia, postural/intention tremor, and parkinsonism in older men is characteristic of FXTAS but overlaps the spectrum of clinical features seen in inherited cerebellar ataxias and multiple system atrophy – cerebellar subtype (MSA-C). The mean age (±SD) of FXTAS onset is 60.2 (±7.2), and larger CGG repeat numbers in the *FMR1* premutation correlates with earlier age of onset of both tremor and ataxia.

In addition to tremor and ataxia, neuropathy and autonomic dysfunction also occur in FXTAS. Signs of peripheral neuropathy, including decreased reflexes and impaired vibration sense in the distal lower extremities, are present in many affected persons and are more frequent in male premutation carriers than in matched controls. Severity of neuropathic signs correlates with CGG repeat length and with severity of ataxia in both male and female premutation carriers.

Cognitive deficits are frequent in FXTAS, most often a dysexecutive syndrome. The initial signs of cognitive impairment in FXTAS are relatively subtle deficits of the executive cognitive functions (ECF) and working memory, which may be overlooked until they begin to affect behavior. There are deficits on the WAIS III performance IQ, and the speed of information processing is slowed and its capacity is decreased relative to normal persons of the same age and education. Deficits in semantic memory – especially retrieval – are common, probably secondary to the dysexecutive syndrome. There appears to be little impairment of primary declarative memory, especially episodic recall, until much later in the disorder, and constructional praxis, visuospatial functioning, language, and verbal reasoning are typically intact. One of the most striking executive cognitive deficits as FXTAS advances is impairment in the initiation of purposeful, goal-directed activity, and in the inhibition of inappropriate or irrelevant behavior. The neuropsychiatric inventory (NPI), which quantitates behavioral consequences of dementia, may be more abnormal in FXTAS than overall cognitive screening instruments such as the Folstein Mini Mental State Examination (MMSE). This MMSE may be paradoxically relatively well-preserved early FXTAS dementia, as it does not assess executive cognitive deficits directly. FXTAS can be associated with a combination of psychiatric features, predominantly generalized anxiety disorders and mood disorders of the depressed type that evolve with disease progression. Some of the psychiatric symptoms in FXTAS may be due to the stress of living with a disabling illness.

It is not known when cognitive impairment begins in relation to the neurological signs of FXTAS or whether progression of motor and cognitive signs correspond. Further, given findings of anxiety, subtle executive and social disorders, and mood disorders among carriers of premutation alleles without FXTAS, cognitive and psychiatric issues may in some cases be a developmental manifestation of the premutation, unrelated to FXTAS.

FXTAS affects predominantly male premutation carriers, although individual female carriers can have clinical and neuropathological features of FXTAS. The prevalence of FXTAS in females has been estimated at 8% over age 40. Female carriers with and without FXTAS experience higher rates of neuropathy, muscle pain, and thyroid dysfunction in addition to FX-POI. Neurological disability is typically much milder in females than in males, presumably due to protection provided by the expression of *FMR1* from the normal allele on the active X chromosome in a percentage of cells. Indeed, females with FXTAS symptoms tend to have skewed X-inactivation, with a greater fraction of cells expressing an active premutation.

Radiological features associated with FXTAS (**Figure 2**) include increased signal intensity on FLAIR or T2-weighted brain MRI in white matter of the middle cerebellar peduncles (MCP sign), and in underlying cerebellar white matter lateral to the dentate nuclei. The MCP sign is not specific to FXTAS; and not all persons with FXTAS demonstrate this finding. FXTAS-associated MRI findings also include patchy or confluent areas of increased signal intensity on T2-weighted or FLAIR images in periventricular and deep white matter of the cerebral hemispheres and corpus callosum, and significant volume loss involving the cerebellum, cerebral cortex, amygdalo-hippocampal complex, thalamus, and brainstem. Cerebellar volume loss, increased ventricular volume, and whole brain white matter hyperintensity correlate with CGG repeat length in premutation carriers.

Diagnostic criteria for FXTAS have been proposed (**Table 1**) for use in clinical studies. In routine medical practice the diagnosis can be made by finding the *FMR1* premutation in a person with a late-onset neurological disorder consistent with previously published cases. Presence of the MCP sign on MRI is useful in confirming the diagnosis, but not necessary, since it is observed in only about 60% of affected carriers.

Epidemiology/Risk Factors

The penetrance of FXTAS in male *FMR1* premutation carriers over 50 years is ~40%, with an age-related penetrance of 17%, 38%, 47%, and 75% for male carriers aged 50–59, 60–69, 70–79, and ≥80 years, respectively. It has been estimated that 1/100–1/250 females and 1/250–1/800 males in the general population are carriers of an *FMR1* premutation, suggesting that for males, FXTAS may be one of the most common late-onset, progressive neurological diseases associated with a single gene mutation, similar in prevalence to MSA and amyotrophic lateral sclerosis.

FXTAS represents the etiology of disease in ~1.5–2.1% of cases presenting with ataxia and 2.4% of cases with the cerebellar subtype of MSA. Results of published screening studies likely underestimate the true contribution of the *FMR1* premutation to movement disorders because the overall clinical picture for many patients with FXTAS is complex and the multiplicity of neurological problems in FXTAS would often result in atypical presentations, difficulty with classification, and thus exclusion from studies involving groups of subjects with typical ET, PD, or ataxia.

Differential Diagnosis

The differential diagnosis of FXTAS is broad and depends on what symptoms are most evident in the individual being evaluated. For patients presenting with the most common features of FXTAS the differential might include MSA (especially MSA-C), olivopontocerebellar atrophy, other inherited ataxias, syndromes with mixed tremor such as thyroid disease, Wilsons disease, lithium toxicity, multiple sclerosis or even severe essential tremor, atypical PD, and parkinsonism-dementia syndromes. A fraction of cases diagnosed with multiple sclerosis or PD with dementia, likely actually have FXTAS, particularly when multiple family members are affected. For a patient presenting with symptoms of FXTAS, a family history of mental retardation, autism, behavioral/learning disorders in children or grandchildren, infertility or premature menopause suggestive of POI in daughters or female relatives, or syndromes of difficult-to-classify neurological and psychiatric problems in other family members, suggest a diagnosis of FXTAS.

Diagnostic Work-up/Tests

Diagnosis of FXTAS is accomplished through DNA analysis designed to evaluate the size of the CGG repeat sequence in *FMR1.* The DNA test performed is the same for identification of either FXS or FXTAS, and may be

Table 2 Testing guidelines for FXTAS[a]

Clinician should test for FMR1 mutation if the patient has any of the following:
Onset of cerebellar ataxia of unknown cause in an individual over 50 years
1. Onset of action tremor of unknown cause in individual over 50 years with parkinsonism or cognitive decline
2. Prior diagnosis of multiple system atrophy, cerebellar subtype
3. MCP sign on T2/FLAIR images of MRI in a patient with signs consistent with FXTAS[b]
4. Positive family history of *FMR1* mutation in an individual who could be a carrier based on position in pedigree if signs consistent with FXTAS are present[b]
5. Family or patient history of infertility/premature menopause in a patient with signs consistent with FXTAS[b]

[a]Presence of an MCP sign (increased T2 signal intensity in the middle cerebellar peduncles), family history of *FMR1* mutation and possible carrier status, and patient history of POF (premature ovarian failure), even without clinical signs of FXTAS would be appropriate criteria for *presymptomatic* screening for an *FMR1* mutation.
[b]Signs consistent with classic FXTAS include action tremor, cerebellar gait ataxia, parkinsonism, and cognitive decline, especially executive function deficits. Additional features that are often associated with, or may be the presenting features of FXTAS, include peripheral neuropathy, parkinsonism, autonomic dysfunction, dementia, a family history of ataxia, autism spectrum disorder or mental retardation, and a family or personal history of POF. Males are more commonly affected than females.

termed *fragile X DNA test*, *FMR1 DNA test*, or *FXTAS DNA test*, depending on the laboratory. The fragile X DNA test is readily available at numerous University and commercial laboratories in the USA and through health services laboratories in many countries. Based on current literature, reasonable guidelines for testing for FXTAS are presented in **Table 2**.

Management

Currently, there is no specific treatment for FXTAS targeted to the underlying pathogenic mechanism. Strategies for supportive intervention and clinical monitoring include: (1) treatment for specific neurological and psychiatric symptoms; (2) monitoring for progression and degeneration; (3) treatment of hypertension; (4) referral to psychiatry, gerontology, movement disorder specialist, speech therapy for evaluation and management of swallowing, occupational therapy and/or physical therapy as necessary; and (5) genetic counseling for the patient and family. Symptomatic treatment of tremor with primidone or β-blockers. parkinsonism with carbidopa/levodopa or amantadine, neuropathic pain with gabapentin, anxiety and depressive symptoms with antidepressants or benzodiazepines, and dementia with donepezil, rivastigmine, galantamine, or memantine may be helpful.

Genetic counseling is imperative for all individuals diagnosed with FXTAS, but is challenging because of the complex multigenerational inheritance, variable phenotype, and implications for families. All women with a premutation are at risk of having offspring with a full mutation and FXS. All daughters of males with a premutation will be obligate carriers of the premutation. Thus, when a male patient with FXTAS is identified, the patient's mother is then an obligate carrier and offspring and relatives of the patient and his mother are at risk for FXS or for carrying a prermutation and possible FX-POI and FXTAS.

Prognosis

Definition of the natural history of FXTAS is difficult because the initial symptoms may be subtle (ECF dysfunction or mild tremor) and difficult to recognize and because the disorder has only recently been discovered. A single family-based, retrospective, longitudinal study analyzed the progression of FXTAS in 55 male premutation carriers. Defining onset as the first report of tremor or ataxia, tremor usually occurred first, with median-onset at ~60 years. From occurrence of the initial motor sign, median delay of onset of ataxia was 2 years; onset of falls, 6 years; dependence on a walking aid, 15 years; and death, 21 years. Preliminary data on life expectancy were variable, ranging from 5 to 25 years. In the few months before death patients were bedridden, dysarthric, dysphagic, without bladder or bowel control, and had severe parkinsonism (rigidity, rest tremor, and bradykinesia). Given the relentless course of the disease in some patients, extensive support, including psychological support, for the patient and family may be needed. It is hoped that in the future, mechanism-specific treatments that can reverse the course of the disease will become available through molecular and translational research. Specifically small molecules including siRNAs that disrupt the *FMR1* RNA CGG repeat interactions are being investigated.

Freezing of Gait

S W Mahabier and A H Snijders, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands
A Delval, Lille Regional University Hospital, Lille, France
B R Bloem, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

Glossary

Cueing – Using sensory signals (visual, auditory, tactile, haptic, etc.) to facilitate initiation or ongoing motor activity (gait).
Festination – Taking increasingly rapid and small sequential steps during walking in an attempt to maintain the center of gravity above the feet, while the trunk leans progressively forward.
Freezing of gait – Sudden feeling of 'being glued to the floor' with an impossibility to generate effective forward stepping movements, in the absence of another cause than parkinsonism or higher cortical deficits.
OFF state freezing of gait – Freezing of gait that is mainly present when the response to dopaminergic treatment has vanished.
ON state freezing of gait – Freezing of gait that is mainly present when the response to dopaminergic treatment is optimal.
Sequence effect – Progressive decrease in step length combined with disturbed timing of steps, commonly seen prior to a freezing of gait episode.

Definition and History

Freezing of gait (FOG) is a common and disabling feature of Parkinson's disease (PD). It is a remarkable gait disorder, because of its episodic character. Patients with FOG experience sudden and often unexpected episodes during which their feet subjectively are 'being glued to the floor,' while their trunk continues to move forward. A FOG episode is thus defined as a brief episode during which patients find it impossible to generate effective forward stepping movements, in the absence of another cause than parkinsonism or higher cortical deficits. It is most commonly experienced during turning and step initiation, but also when faced with spatial constraint, stress, and distraction. Focused attention and external stimuli (cues) can overcome the episode. Because of the sudden and unpredictable nature, FOG often leads to falls and injuries.

Already in 1817, James Parkinson described in his classical essay '*The Shaking Palsy*' the typical 'propensity to bend the trunk forwards, and to pass from a walking to a running pace.' This phenomenon is currently known as 'festination': taking increasingly rapid and small sequential steps during walking, in an attempt to maintain the center

of gravity above the feet while the trunk leans progressively forward. Although festination and FOG appear to be closely related, James Parkinson did not specifically describe FOG. The first description of a FOG episode presumably stems from Charcot in 1877 who described gait initiation failure, followed by forward propulsion with festination. During the last 10 years, interest in the clinical impact, underlying pathophysiology and treatment methods of FOG have increased rapidly.

Epidemiology/Risk Factors

Epidemiology as Related to Different Etiologies

FOG is common in idiopathic PD; it occurs in 20–80% of PD patients, depending on disease severity, disease duration, and treatment status. Interestingly, some patients experience FOG in early stages of their disease, while other patients never develop FOG. It is also seen in some 25–60% of patients with atypical parkinsonism caused by vascular parkinsonism, normal-pressure hydrocephalus, or neurodegenerative diseases such as progressive supranuclear palsy or multiple system atrophy. FOG is less often seen in patients with corticobasal degeneration (8–25%) and rarely occurs in neuroleptic-induced parkinsonism. Primary progressive FOG is an uncommon condition starting with FOG, often with frequent falls. Patients initially do not experience bradykinesia, rigidity, or tremor and usually do not respond to treatment with levodopa. With extended follow-up, this condition may clinically progress to progressive supranuclear palsy or corticobasal degeneration. Post-mortem examination in these patients may reveal pallidonigroluysian degeneration or diffuse Lewy body disease, underscoring how heterogenic the underlying etiology can be.

Risk Factors

In idiopathic PD, the most important risk factors for developing FOG include a more advanced disease and a longer disease duration. A longer duration of levodopa treatment is also seen as a risk factor for FOG, although it is difficult to uncouple this from the disease duration and disease severity. Also, medicated patients may show more FOG simply because they can walk for a longer period, increasing the likelihood of witnessing FOG episodes. Other risk factors include disturbances in gait, posture, and speech, but bradykinesia and rigidity are not related to the occurrence of FOG. Remarkably, the presence of tremor is associated with a lower risk of developing FOG. FOG is further associated with frontal cognitive (executive) deficits, including even overt dementia and urinary incontinence (which may also reflect frontal dysfunction). FOG is itself a strong risk factor for falls and ensuing injuries.

Clinical Features/Diagnostic Criteria

Circumstances of Freezing

FOG episodes most commonly occur in complex environments that necessitate integration of multiple sensory stimuli. Therefore, they are typically seen during a shift of attention or a circumstantial or directional change. Thus, in daily life, FOG particularly occurs under specific conditions such as starting, turning, walking in tight quarters (e.g., passing a narrow doorway), or upon reaching a destination, but it may also occasionally occur during straight walking in open space. Turning around appears to be the strongest provoking factor. Dual tasks or stressful demands may also increase the occurrence of FOG. Furthermore, the majority of FOG episodes occur when the response to dopaminergic treatment has vanished (i.e., during an OFF phase), when FOG is both lengthier and more severe (see also the section on Management).

Characterization

The main characteristic of FOG is a loss of efficient forward movement generation, which can manifest itself as three different subtypes. The least severe subtype consists of taking very small shuffling steps, with only minimal forward movement. A more severe subtype includes trembling of the leg, without any effective forward motion, known as 'trembling in place.' The most severe subtype is a complete akinesia, without any observable motion of the legs. The duration of a FOG episode is usually very brief, typically ranging from less than a second to up to 10 s. Episodes longer than 10 s are very rare and only occur during the OFF phase, when FOG episodes last longer compared to the ON phase.

Diagnosis

The current 'gold standard' of diagnosis of FOG is the observation of FOG by an experienced examiner. However, FOG is notoriously difficult to elicit in the examination room, so the patients' subjective feeling of periodically being 'glued to the floor' often serves as surrogate marker to establish the diagnosis. FOG is currently only classified as being either 'present' or 'absent,' and reliable gradations of severity are not yet available. More elaborate assessment techniques will be discussed under section Diagnostic workup.

Pathophysiology

The precise pathophysiology underlying FOG remains unknown, but the following hypotheses are commonly heard.

Neuroanatomical Substrate

FOG appears to be an independent motor symptom, caused by a pathology different from tremor, bradykinesia, or rigidity. Dopaminergic cell implants into the putamen of PD patients improve bradykinesia and rigidity of the legs, but do not improve FOG, whereas levodopa can decrease FOG in PD patients that do not improve rigidity or bradykinesia. Hence, FOG might be related to dopamine deficiency outside the putamen. Case reports of freezing after stroke and after misplaced deep brain stimulation (DBS) electrodes suggest a role for the pedunculopontine nucleus (PPN). Furthermore, studies using neuroimaging techniques have implicated the caudate nucleus, the orbitofrontal cortex, and central noradrenergic systems as being possibly involved in generating the freezing phenomenon. It is most likely that FOG does not result from localized pathology within a specific locus in the brain, but rather reflects dysfunction in an organized network that involves the frontal cortex, the basal ganglia (perhaps mainly the caudate nucleus), and the connections between these areas. For at least some of the patients, non-dopaminergic circuitries (possibly involving noradrenergic pathways) may be additionally involved.

Neurophysiology

Basal ganglia dysfunction in patients with PD leads to a faulty production of adequate amplitude and timing of movements. The basal ganglia play two important roles in the performance of learned automatic movement sequences. The first role is to match and maintain the movement amplitude of a cortically selected movement plan (motor set), and the second role is to run each component of the plan in a timely manner (motor cue production). In patients with FOG, basal ganglia dysfunction leads to failure in generating adequate movement amplitudes (reflected by a progressive decrease in step length), combined with a disturbed timing of steps, a phenomenon known as the 'sequence effect.' Movement timing difficulties in freezers are reflected by a disturbed timing of stepping movements during gait. This becomes apparent as an increased variability of gait (even outside overt FOG episodes) and a premature timing of muscle activations immediately prior to FOG episodes. More recent work specifically pointed to disturbances in the fine regulation of interlimb coordination, as reflected by a marked temporal gait asymmetry in patients with FOG. This indicates an impairment in controlling the simultaneous timing and pacing of stepping movements of both legs, rather than an inability to regulate steps per se. Finally, a newly emerging concept is that failure to initiate compensatory stepping could be due to impairment of anticipatory postural adjustments (a lateral weight shift is normally required to allow for a contralateral limb swing). Apparently, a walking problem (gait akinesia) may be caused by a deficit in the integration of balance and gait programs, or by a primary balance deficit, that is, the inability to shift weight. This notion is supported by the finding that PD patients, when provided with an assistive (externally imposed) anticipatory postural adjustment, can step faster.

Neuropharmacology

Levodopa generally alleviates FOG, both with respect to severity and frequency, which implies that dopamine depletion in the striatum is the main neurochemical substrate of FOG. Methylphenidate may improve gait and reduce FOG in PD, conceivably by increasing the availability of striatal dopamine or by improving attention. Furthermore, increasing striatal dopamine using monoamine oxidase type B (MAO-B) inhibitors (selegiline, rasagiline) is also associated with reduced FOG, although the effects in clinical practice are rarely convincing.

However, FOG is sometimes resistant to dopaminergic therapy. This does not necessarily exclude a role for dopamine deficiency in the underlying pathophysiology, because the threshold for therapeutic relief may simply be higher for FOG than for other symptoms, falsely creating the impression of 'levodopa-resistance.' More puzzling is the observation that dopaminergic therapy can also paradoxically cause or aggravate FOG, and this may be particularly true for dopamine receptor agonists. This might point to a role for excessive dopaminergic stimulation in extra-nigrostriatal circuitries (much like the dopamine dysregulation syndrome), or alternatively, to a role for lesions within non-dopaminergic circuitries. The latter assumption is supported by the fact that FOG rarely occurs in patients with neuroleptic-induced parkinsonism. Further support could be derived from therapeutic trials with non-dopaminergic compounds, such as the noradrenaline precursor L-threo-dihydroxyphenylserine (L-threo-DOPS), but this has only been tested in small series and with crude outcome measures.

Differential Diagnosis

FOG should be differentiated from a voluntary stop or hesitation (e.g., because the patient feels unsafe), overall rigidity, or festination. Overall rigidity differs from FOG because the episodic character is absent: patients with overall rigidity have the feeling of being glued all the time, while patients with FOG experience the glued feeling only episodically. Festination should also be differentiated from real FOG episodes. During festination, the feeling of being glued to the floor is lacking. Festination typically occurs during gait, while FOG mainly occurs during gait initiation and turning. Moreover, festination leads to a fastening instead of slowing of walking velocity. Finally, FOG should also be differentiated from central nervous system overloading that occurs during complex

multitasking, as may occur when patients undertake a secondary task during walking (e.g., carrying a tray). A classical example is the 'stops walking when talking' phenomenon, where patients stop walking because the task of maintaining a simultaneous conversation is too demanding. Such multitasking can provoke real FOG, but some stops simply reflect a conscious adaptive strategy: it is better to temporarily stop walking when the overall task has become too complex. Voluntary stops lack the typical trembling of the legs, the preceding sequence effect, and the flexed posture seen in FOG.

Diagnostic Workup

History Taking: Subjective Assessment

Patients often do not realize what FOG is, which may complicate history analysis. It is essential to specifically ask about the characteristic feeling of 'being glued to the floor.' In addition, details can be obtained about the frequency, circumstances, and characteristics of the FOG episodes. These questions are incorporated into a specialized Freezing of Gait Questionnaire (FOG-Q). A recently modified version of this FOG-Q also uses a video to ascertain that the patient and caregiver accurately realize what FOG episodes look like. It often helps when the examiner gives a demonstration of the different subtypes.

The influence of medication on FOG episodes should also be ascertained, as this has important implications for therapy, and because it may provide clues about the underlying etiology. In contrast to ON period FOG, OFF period freezing is present upon awakening prior to the intake of medication, and improves with treatment. Sometimes, the presence of falls is the only clue about the presence of FOG. Typical falls that are associated with FOG are forward falls, lateral falls during turning, and unexplained, seemingly spontaneous falls.

Physical Examination

Clinical assessment of FOG should be done in both a subjectively 'good ON' state and a 'practically defined OFF' state (at least 12 h after intake of the last dose of antiparkinson medication). It is crucial to use a standardized gait trajectory where patients are instructed to execute a series of walking tasks that typically elicit FOG episodes such as turning, negotiating a narrow passage, initiating gait, and performing dual tasks while walking. The best way to provoke a FOG episode is through rapid axial turns (360°, with a narrow turning circle because wide turns are less likely to provoke FOG). Ask the patient to turn in both ways (leftward and rightward), because FOG can show a marked directional dependence. The type of FOG, the duration of an episode, and the frequency of FOG should be noted. Note that FOG can be asymmetric and may affect only one leg, usually on the clinically most affected side. No validated instrument to objectively assess FOG exists, so the clinical eye of an experienced clinician remains the gold standard (see **Figure 1**). Cognitive examination, especially concerning the frontal executive and attentional functions, should always be a part of the physical examination. The effect of external cues (to improve FOG) and dual tasking (to provoke or worsen FOG) should also be monitored.

Quantitative Assessment

There is a need for validated methods to quantitatively assess FOG, for example using kinematic gait analyses, pressure-sensitive insoles, or surface electromyography of leg muscles. This may be done during overground walking with specific provoking circumstances (narrow passages, turning, dual tasks). Recent work has shown that it may be possible to provoke FOG in a gait laboratory, asking patients to walk on a treadmill using obstacle avoidance tasks. Specific spatiotemporal characteristics, that is, an increase in cadence and decrease in stride length, precede a FOG episode. Furthermore, accelerometers placed on the shanks during walking show characteristic high-frequency components of leg movement when FOG episodes occur. However, these assessments have not yet been validated, and a general problem is that the sheer awareness of being tested typically suppresses FOG during the measurements. Therefore, quantitative assessment is currently used only for research purposes.

Neuroimaging

Structural neuroimaging helps unravel the differential diagnosis, for example, by showing leukoaraiosis in a patient suspected of having vascular parkinsonism, or atrophy of the mesencephalon in a patient suspected of having progressive supranuclear palsy. Nuclear imaging and functional neuroimaging are currently used to study the pathophysiology of FOG, but this is currently only utilized in a research setting.

Management

Medication

Most patients suffer from OFF state FOG, with more frequent and severe episodes when the effect of medication has worn off. However, a minority of the patients experience FOG in the ON state. Paradoxically, dopaminergic medication (especially dopamine receptor agonists) can sometimes cause FOG. In patients with mainly OFF state FOG, increasing the dose of antiparkinson medication often leads to improvement, while ON state FOG may be alleviated by tapering the antiparkinson medication.

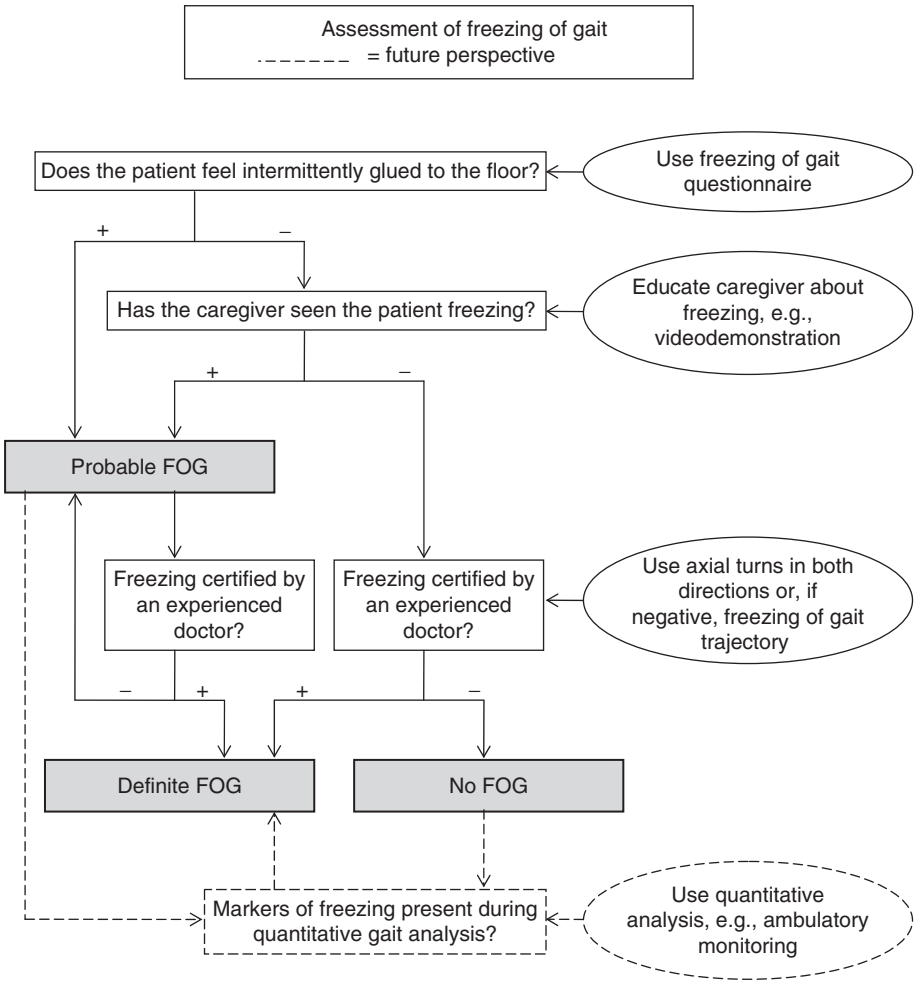

Figure 1 Flow-chart for diagnosing freezing of gait.

Selegiline may prevent the development of FOG – possibly by the improvement of the visuomotor system – but is less effective once the symptoms are fully developed. Another MAO-B inhibitor, rasagiline, improved FOG in a double-blind, placebo-controlled study. However, the small improvement seen in this study is unlikely to be clinically relevant.

Other pharmacological approaches focus on improving attention and executive function, but only small case series have been published. Methylphenidate may improve OFF state FOG in PD, but a negative study has also been published. Methylphenidate is mainly seen as a dopaminergic agent, but may also improve FOG by influencing noradrenergic systems. L-threo-DOPS, an immediate precursor of noradrenaline, was effective in Japanese patients with primary progressive FOG, but subsequent studies failed to confirm this. Small studies using donezepil, an acetylcholinesterase inhibitor specifically used to enhance attention, had beneficial effects in patients with pure FOG. Further placebo-controlled blinded studies with adequate numbers of patients and proper outcome measures remain much needed.

Physiotherapy

Specific cueing techniques using rhythmic auditory cues can reduce the severity of FOG by improving step length and walking speed. Furthermore, physiotherapists can teach patients to avoid or better deal with dual tasks, as FOG typically occurs during a shift of attention. Avoiding stress might also be beneficial to prevent FOG episodes. Using a wide arc while turning, instead of making an axial turn 'in place,' is also effective in preventing FOG episodes.

Deep Brain Stimulation

A relatively new method for the treatment of FOG is DBS. Currently, the preferred target for DBS in advanced PD is the subthalamic nucleus (STN), but the globus pallidus remains a good alternative according to some. There is

evidence that STN stimulation improves FOG, but only when it occurs in the OFF state. The general rule of thumb is that FOG that fails to improve with dopaminergic treatment will neither respond to DBS. Moreover, there are concerns about the development of secondary gait worsening or postural deficits postoperatively, not immediately after surgery but only after several years, even in the face of a persistent beneficial effect on 'appendicular' motor control. Possibly, reducing the frequency of DBS (to frequencies more typically used to stimulate the PPN) can be used to optimize DBS treatment.

A new area of interest is DBS of the dorsal mesencephalon where the PPN is situated, because the PPN has extensive connections with the basal ganglia, as well as with descending spinal pathways. Furthermore, the PPN has been suggested to play an important role in the initiation and maintenance of locomotion. Patients with FOG may respond to PPN stimulation, even when STN stimulation and drug treatment are optimized, but only small groups were tested. Moreover, the precise localization of the PPN for DBS remains difficult.

Prognosis

FOG will worsen with advancing disease. Most treatment methods fail to provide a lasting effect and may even paradoxically aggravate FOG. Patients with gait disorders such as FOG have an increased mortality risk, mainly due to a direct result of falling. In addition, the ensuing immobility results in secondary cardiovascular disease and cognitive decline. The mobility problems related to FOG are among the most distressing symptoms of PD. Hence, there is an urgent need for further understanding and management of this intriguing phenomenon.

Friedreich's Ataxia and Variants

R Bhidayasiri, Chulalongkorn University Hospital, Bangkok, Thailand; David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Glossary

Ataxia – Impaired coordination, dexterity, or gait in the absence of significant muscular weakness.
Frataxin – A highly conserved nuclear-encoded protein localized in mitochondria.
***FRDA* gene** – The *FRDA* gene is localized on the long arm of chromosome 9, just below the pericentromeric heterochromatic region.
Friedreich's ataxia – The most common autosomal recessive and hereditary ataxia due to the hyperexpansion of a GAA triplet repeat in the first intron of the *FRDA* gene.

Definition and History

In 1863, Nicholaus Friedreich described a specific form of spinal degeneration with distinctive clinical and pathological findings in nine members of three siblings attending the university clinic. Originally termed 'degenerative atrophy of the posterior columns of the spinal cord,' Friedreich was able to pinpoint all essential clinical and pathological features of the disease, including progressive ataxia, sensory loss, muscle wasting and weakness, often with scoliosis, foot deformity, and heart disease, but just to miss deep tendon reflexes. He also noted the tendency of the disease to afflict several individuals in a sibship, but not affect parents. Initially suspected to be a form of neurosyphilis, it was not until 1882 when the new disease was given the name Friedreich's ataxia [MIM229300] (FRDA) or Friedreich's disease by some authors since ataxia is not always a principal feature. During the past 40 years, a number of landmark studies were carried out to establish the autosomal recessive (AR) pattern of inheritance as well as define vigorous diagnostic criteria, which are the key for the collection of clinically homogeneous families to be used for biochemical and molecular genetic studies.

Pathogenesis

Neuropathology

Despite Friedreich's emphasis on the degeneration of the posterior columns of the spinal cord as the hallmark of the disease, the main pathological features of FRDA are not limited to the central nervous system, but start with an early loss of large sensory neurons in dorsal root ganglia, followed by degeneration of posterior columns, spinocerebellar and pyramidal tracts. Indeed, the pattern of atrophy of the long tract fibers suggests a 'dying back' process (severely atrophic at the lumbar level, much less so in the cervical cord and in the brainstem, and of normal appearance in the cerebral peduncle), suggesting that the degenerative process more likely affects first the axon before cell bodies.

Difference from the severity of ataxia is observed in patients, and cerebellar atrophy is not a characteristic feature of FRDA. Only a mild loss of Purkinje cells and axonal torpedoes are observed in the cerebellar cortex. This is in contrast to the early loss of large primary sensory neurons in the dorsal root ganglion, while the motor component is well preserved, resulting in the presence of sensory axonal polyneuropathy on clinical examination.

In summary, the main neuropathological findings in FRDA are characterized by atrophy of the central sensory and cerebellar efferent pathways as well as the distal portion of the corticospinal tracts, which carry crucial information to the brain and cerebellum for correct execution of movement and for equilibrium. As a result, the degeneration of each of these systems contributes to the characteristic clinical picture of FRDA.

Systemic Consequences

Since many patients with FRDA die as a consequence of heart disease, we may assume that degeneration probably affects independent sites outside the nervous system. Indeed, the heart is clinically or subclinically affected in the vast majority of patients. While hypertrophic cardiomyopathy is the typical finding in most patients, dilated cardiomyopathy is frequently observed after a long disease course. Microscopically, hypertrophic cardiomyocytes are intermingled with fibers undergoing atrophy or granular degeneration. In addition, 10% of FRDA patients have diabetes mellitus at later stages due to a loss of β-pancreatic islet cells.

Genetics and Frataxin

By the application of molecular genetic methods, we now understand that degeneration in FRDA develops as a result of a loss of frataxin, a highly conserved

210-amino acid nuclear encoded protein localized to the mitochondria. Current evidence suggests that loss of frataxin, which is caused by a GAA triplet repeat expansion within the first intron of the *FRDA* gene (previously known as *X25*) on chromosome 9q13 in 98% of mutant alleles impairs mitochondrial iron handling and respiratory chain function and contributes to increased oxidative stress and cellular damage. Frataxin expression is generally higher in mitochondrial-rich cells, as cardiomyocytes and neurons, explaining a disease predilection to the nervous system and the heart. While there are 33 or fewer GAA triplets normally, pathological expansion accounts from 67 to more than 1000 triplets. The expansion is homozygous in 96% of patients while the remaining patients carry a GAA expansion on one allele and an inactivating mutation in the coding region of the other allele. Point mutations are rare, accounting for only 2–4% of patients but can cause the disorder. There is an inverse correlation between the size of the expansion measured by the number of GAA repeats, in particular the shorter of the two expanded alleles, and a number of clinical features, including age at onset, cardiomyopathy, and scoliosis.

Table 1 Diagnostic criteria for FRDA according to Harding

Autosomal recessive inheritance
Onset before age 25
Within 5 years from onset
Limb and truncal ataxia
Absent tendon reflexes in the legs
Extensor plantar responses
Motor NCV>40 m/sec in upper limb with small or absent SNAPs
After 5 years since onset
As above plus dysarthria
Additional criteria, not essential for diagnosis, present in >2/3 of cases
Scoliosis
Pyramidal weakness of the legs
Absent reflexes in upper limbs
Distal loss of joint position and vibration sense in lower limbs
Abnormal EKG
Other features, present in <50% of cases
Nystagmus
Optic atrophy
Deafness
Distal weakness and wasting
Pes cavus
Diabetes

NCV: Nerve conduction study; SNAP: Sensory nerve action potential; EKG: Electrocardiogram

Epidemiology

FRDA is the most common autosomal recessive ataxia and the most common hereditary ataxia, comprising about 50% of cases in large series, with an estimated prevalence of 1 in 29 000 – 1:50000 populations in central Europe and a carrier frequency of approximately one in 110 in European populations. Birth incidence has been estimated to be from 2.1 to 5.4×10^{-5} in the United Kingdom and from 3.6 to 4.0×10^{-5} in southern Italy. However, the incidence is probably much lower in Asians and those of African descent.

Clinical Features, Diagnostic Criteria, and Prognosis

Although progressive, unremitting ataxia is the cardinal feature of the disease, detailed genetic and family studies have recently emphasized the potential heterogeneity in presenting phenotype and age of onset of patients with FRDA. As a result, strict diagnostic criteria have been proposed by Quebec Cooperative Study on FRDA and by Harding to define a homogeneous group of patients. Primary criteria initially proposed for the diagnosis of FRDA included progressive gait ataxia without remission, dysarthria, loss of joint position sense in the lower limbs, muscle weakness, deep tendon areflexia in the lower limbs, and onset before the age of 20 years. These criteria were later modified, with the upper limit for the age of onset increased to 25 years and the realization that dysarthria, signs of pyramidal tract dysfunction and sensory changes were not necessarily present in the first 5 years after onset of the illness (**Table 1**). Less common but supportive manifestations include scoliosis, pes cavus, optic atrophy, oculomotor abnormalities (fixational instability), and deafness. Patients who exhibit all these clinical features listed by Harding (**Table 1**) are considered to have the 'typical' or 'classic' form of the disease.

Symptoms in FRDA usually begin with clumsiness in gait and frequent falls. Hand coordination, dysmetria, and intention tremor later follow. As with age at onset, there is a great variability in clinical features, including the rate of progression, severity, and the extent of the disease involvement. However, progression is usually steady in each individual until patients lose the ability to perform fine motor activities to walk, stand, and eventually sit without support. Slow jerky speech is usually evident within 5 years after onset, and most patients become wheelchair bound within the first 15 years. While muscular weakness is common, affecting the proximal muscles of the lower limbs first, most patients indicate that ataxia, and not weakness, is the primary cause for their loss of ambulation.

In contrast to intact pain and temperature perception, loss of vibration and position sense is another cardinal manifestation of FRDA. As a consequence, tendon reflexes are usually diminished or absent at least in the lower limbs, due to axonal degeneration of afferent fibers. Extensor plantar responses may be later elicited, reflecting the pyramidal tract involvement. About 30% of the patients

develop optic atrophy, particularly in the later stages of the disease. More than half of the patients manifest progressive scoliosis, pes cavus, pes equinovarus, and clawing of the toes. Interestingly, optic atrophy and sensorineural hearing loss tend to be associated in the same patients, and with diabetes, more often than expected by chance alone, but rather as a sign of more severe, widespread disease. Similarly, skeletal deformities and cardiomyopathy are found in a majority of patients who also have an increased frequency of impaired glucose tolerance and diabetes.

Progression in typical FRDA is relentless and death usually occurs in the third or fourth decade of life as a consequence of arrthythmias and heart failure. While a significant portion of FRDA patients may deny cardiac symptoms, electrocardiographic evidence of cardiomyopathy was observed in two-thirds of patients, and all patients were found to have abnormalities on more detailed studies, including ambulatory monitoring, echocardiography, and isotope ventriculogram. Atrial fibrillation has been considered as a negative prognostic sign as it precedes fatal cardiac complications by 6 months or less in almost 25% of patients in which these occur. Despite its clinical heterogeneity, a recent multivariate analysis demonstrated that age at diagnosis, which may incorporate other genetic and environmental factors, is more important than GAA length in predicting cardiomyopathy, scoliosis, and ultimately disease progression.

For an autosomal recessive disease, patients with FRDA display an unusual degree of clinical variability. It is now recognized that up to 25% of patients may be considered atypical with respect to the established diagnostic criteria. At least 10% of patients with recessive or sporadic ataxia who do not fulfill the FRDA diagnostic criteria were also homozygous for GAA expansion. As a result, the phenotype of FRDA has been broadened to include the following variants, which are considered atypical FRDA.

Late-Onset FRDA (LOFA)

While the onset of typical FRDA is usually before 20 years of age, it may also vary from 2 to 3 years of age to over 25 years of age. Arbitrarily, LOFA patients are defined as having onset between 25 and 39 years and very late-onset FRDA (VLOFA) refers to onset at 40 years and after ($\geq$40 years). These patients tend to have an overall milder, slowly evolving disease associated with smaller GAA expansion. The time from disease onset to wheelchair confinement was also slower in patients with LOFA. Compared with patients with typical FRDA, those with LOFA have fewer skeletal abnormalities. The frequency of cardiomyopathy in LOFA was found to be similar to that in typical FRDA in some studies, but significantly lower in others.

FRDA with Retained Reflexes (FARR)

Although lower limb areflexia is considered as essential criterion for typical FRDA, there are, however, families with retained reflexes who are homozygous for GAA expansion. The occurrence of FARR is not rare, ranging from 5 to 10% in reported series. The sequences of GAA repeats on the smaller allele are shorter in FARR than typical FRDA without tendon reflexes, suggesting a correlation between allele sizes and preservation of tendon reflexes. In addition to retained reflexes in the lower limbs, patients with FARR may exhibit increased tone in the lower limbs associated with milder form of the disease, including later onset, lower incidence of impaired vibration sense, pes cavus, and echocardiograohic signs of left ventricular hypertrophy. Furthermore, these patients may not demonstrate electrophysiological evidence of the usual severe afferent axonal neuropathy as in patients with typical FRDA.

Acadian Ataxia (Louisiana Form)

A FRDA variant has been described among the descendants of French colonizers who settled in eastern Canada during the seventeenth century. These people, known as Acadians, later moved to Louisiana, where they became known as 'Cajuns' while some returned to the Canadian Atlantic provinces. Acadian ataxia has probably been introduced into this population by very few individuals, a so-called 'founder effect.' However, both Acadian ataxia and FRDA share the same dynamic mutations at the same locus on chromosome 9, but the specificity of the Acadian phenotype is still unexplained at the molecular level. In general, Acadian ataxia is milder than classical FRDA as it starts at later age of onset, evolves more slowly with less severe cardiomyopathy. Recently, a subtype of Acadian ataxia (Spastic ataxia of Acadian, SPA-Acadian) has been described in four patients from New Brunswick families. They had a slowly progressive ataxia with retained reflexes and spasticity, but without cardiomyopathy.

Differential Diagnosis

As in FRDA, the key feature in all progressive cerebellar ataxias is spinocerebellar ataxia, involving cerebellum, brainstem and spinocerebellar tracts, typically characterized by poor balance with falls, imprecise coordination, kinetic tremor, dysarthria, vertigo, and diplopia. With these clinical features, the physicians may be unable

Table 2 Differential diagnosis of autosomal recessive ataxias

Differential diagnosis	*Gene/Protein*	*Gene name*	*Protein function*
1. Friedreich's ataxia-like syndromes			
-Friedreich's ataxia	Frataxin	FRDA	Mitochondrial iron
-Ataxia with vit.E deficiency	α-tocopherol transfer protein	TTPA	Vit. E homeostasis
-Abetalipoproteinemia	Microsomal triglyceride transfer protein	MTP	Lipoprotein metabolism
-Refsum's disease	Phytanol-CoA-hydroxylase	PHYH	Fatty acid oxidation
2. FRDA-like with cerebellar atrophy			
-Late-onset Tay-Sach's disease	β-hexosaminidase A	HEXA	Glycosphingolipid metabolism
-Cerebrotendinous xanthomatosis	Sterol 27-hydroxylase	CYP27	Bile-acid synthesis
-DNA polymerase γ disorders	DNA polymerase γ	POLG	Mitochondrial repair & replication
-SCA with axonal neuropathy	Tyrosyl-DNA phosphodiesterase 1	TDP1	DNA repair
3. Early-onset ataxia with cerebellar atrophy			
-Ataxic-telangiectasia (AT)	AT-mutated	ATM	DNA damage response
-AT-like disorder	Meiotic recombination 11	MRE11	DNA damage response
-Ataxia with oculomotor apraxia type 1	Aprataxin	APTX	DNA repair
-Ataxia with oculomotor apraxia, type 2	Senataxin	SETX	DNA repair
-Ataxia of Charlevoix-Saguenay	Sacsin	SACS	Protein folding
-Infantile-onset SCA	Twinkle, twinky	C10orf2	DNA replication
-Cayman ataxia	Caytaxin	ATCAY	Neurotransmitter metabolism
-Marinesco-Sjögren's syndrome	BiP-associated protein	SIL1	Protein folding

FRDA: Friedreich's ataxia; SCA: Spinocerebellar ataxia
Modified from Fogel BL and Perlman S (2007) Clinical features and molecular genetics of autosomal recessive cerebellar ataxias. *Lancet Neurology* 6(3): 245–257.

to differentiate AR ataxia from other forms unless the patient can disclose a characteristic family history of affected relatives. However, most AR ataxias are early onset, but not universally applicable. In contrast to autosomal dominant spinocerebellar ataxias (ADCAs), which may have diverse neurological features (such as retinopathy, extrapyramidal signs), most AR ataxias are generally associated with peripheral sensorimotor neuropathy, notably with loss of proprioception and vibration sense. In further contrast to ADCAs, AR ataxias tend to have involvement outside the nervous system.

From a diagnostic viewpoint, once AR ataxias are suspected, they can be categorized to either resembling FRDA phenotype or as having early-onset phenotype with cerebellar atrophy (**Table 2**). Due to the heterogeneity among these disorders, further differentiation will generally require detailed assessment of the phenotype as well as additional diagnostic studies, particularly neuroimaging. Patients with ataxia due to vitamin E deficiency can present with a clinically similar phenotype to FRDA, but serum concentrations of vitamin E are low. Like FRDA, age at onset is before 20 years, and cardiomyopathy is the most common systemic finding. However, decreased visual acuity or retinitis pigmentosa may be an early finding to distinguish this disorder from FRDA. Another FRDA-like syndrome; abetalipoproteinemia, neurological manifestations may occur before the age of 20 but is associated with lipid malabsorption, hypocholesterolemia, acanthocytosis, and retinitis pigmentosa. With an early onset by age 2 years and severely disabled, ataxic-telangiectasia has a complex multiorgan phenotype, including immune deficiency, high incidence of hematologic malignancies, gonadal failure, truncal instability, oculomotor apraxia, ataxia, and hypotonia.

Diagnostic Tests

Once FRDA is suspected, magnetic resonance imaging (MRI) of the brain and cervical cord is usually indicated, and its appearance closely reflects the findings of postmortem neuropathological studies. The cervical spinal cord is the most severely affected structure, appearing much more compromised than any other part of the central nervous system (CNS), including the cerebellum. Indeed, this pattern contrasts with other inherited degenerative ataxias in which the cerebellum is much more atrophic than the cervical spinal cord. Thinning of the cervical spinal cord can be observed on sagittal and axial images in almost all FRDA patients. Other CNS structures, including brainstem, cerebellum, and cerebrum are less evidently affected, but not completely spared.

Electromyographic and nerve conduction studies in FRDA generally disclose the presence of 'dying-back'

axonal sensory neuropathy, with severe reduction of sensory nerve action potentials (SNAPs) and relatively preserved motor and sensory nerve conduction velocities. These findings help distinguish an early case of FRDA from demyelinating hereditary sensorimotor neuropathy. Furthermore, the amplitudes of the visual evoked potentials (VEPs) are markedly reduced with a normal P100 latency.

Because of its prevalence and its variability in presentation, almost all patients with AR ataxias should be screened initially for FRDA. In addition, direct genetic testing can be done to definitely establish the diagnosis. Currently commercially available, the most common mutation causing FRDA (98%) is the hyperexpansion of a GAA triplet repeat in the first intron of the *FRDA* gene. While repeats in normal chromosomes contain up to 40 triplets, disease-associated repeats contain from approximately 70 to more than 1000 triplets, most commonly in the range between 600 and 900.

Additional biochemical investigations, including lipoproteins, vitamin E level, lactate, pyruvate, urinary organic acids, serum very long chain fatty acids, serum phytanic acid, and leukocyte or fibroblast lysosomal enzymes, are usually performed to exclude the diagnoses of abetalipoproteinemia, ataxia with vitamin E deficiency, mitochondrial disorders, adrenoleukodystrophy, Refsum's disease, and a number of lysosomal storage disorders. The cost of each individual test can be expensive and the decision to perform above tests should be considered on a case-by-case basis.

Management

FRDA is a progressive neurodegenerative disorder due to a loss of frataxin. The downstream consequences of frataxin deficiency result in excess of mitochondrial iron and oxidative stress, incorporating by other unknown genetic and environmental factors. On the basis of these principles, therapeutic approaches aimed at free radical control and respiratory chain activation may be attempted. However, no currently available drug can specifically remove iron from the mitochondrial compartment, as well as protect the cells against the damage caused by the free radicals involved in the disease. Nevertheless, antioxidant molecules, and respiratory chain stimulants, such as coenzymeQ-10 (CoQ-10) and idebenone have shown some promising results, not only in experimental models, but also in clinical trials. A recent uncontrolled, open-label, 4-year pilot study of patients taking CoQ-10 and vitamin E reported improvement in cardiac function and suggested possible stabilization or reduce decline in certain neurological symptoms. Similarly, studies of low-dose idebenone, a synthetic analog of CoQ-10, seem to show reduction of cardiac wall thickness, but no improvement of neurological symptoms was observed. Unfortunately, no drugs have led to any improvement in ataxia or other associated neurological features and primary treatment for this disease still remains symptomatic. Therefore, rehabilitation programs and orthopedic interventions should be aimed at maximizing the residual capacity of motor control.

Remarkable progress has been made in understanding the pathogenesis of FRDA since the discovery of responsible gene in 1996. If it were possible to increase the patients' frataxin production even to levels that are similar to healthy carriers, one could possibly halt the progression of the disease and may even lead to improvement. The possible role of frataxin in controlling mitochondrial iron homeostasis suggests ways of pharmacological intervention that may be worth considering. Although still in their infancy, all these approaches are under study and encouraging results have been obtained at least for gene replacement therapy.

Friedreich's Ataxia Rating Scale (FARS)

T Schmitz-Hübsch, Unversitätsklinikum Bonn, Bonn, Germany

Glossary

Ataxia – Literally (Greek) absence of order. Clinically referred to as a specific motor syndrome with difficulty to stabilize the trunk against gravity, difficulty to stabilize gaze, difficulty in goal-directed limb movements, and dysarthria.
Cerebellar sign – Neurological sign attributed to lesions of the cerebellum.
Clinical rating scale – Assessment tool used to document and compare disease status, for example, in clinical trials, that is based on a standardized clinical examination of selected disease features. Standardization refers to instructions of test performance and rating.
Outcome parameter – Type of assessment that is chosen to document and compare the effects of an intervention in clinical trials. This can be a clinical scale or any instrumental or laboratory test known to change with disease severity.
Reliability – Accuracy of an assessment tool, that is, how consistent or repeatable are the measurements. For clinical rating scales, reliability is usually documented by good internal consistency and minimal variance between different raters (interrater), or between test and retest.
Sensitivity – Ability of an assessment tool to pick up differences between different disease states. Sufficient sensitivity (or responsiveness) to change over time is a prerequisite for use of a clinical rating scale as an outcome parameter in clinical trials.
Validity – Appropriateness of content of an assessment tool, that is, does it measure what it is intended to measure. It is usually documented by good correlations with other assessments of the same construct: for example, a clinical scale supposed to measure disease severity could be compared to other measures known to change with disease severity.

Definition and History

The conduct of multicenter therapeutic trials requires reliable and sensitive assessment tools. Consequently, clinical rating scales have been established for different diseases once therapeutic agents became available for testing. Friedreich ataxia is an autosomal-recessive disorder, with typically juvenile onset that is genetically characterized by GAA repeat expansions in the frataxin gene, in the majority of cases. Clinically, the disease manifests with progressive gait and limb (sensory) ataxia, loss of vibratory and position sense, dysarthria, diabetes, scoliosis, and cardiomyopathy. A larger size of the shorter expanded allele has been associated with younger age of onset and more severe disease. The Friedreich Ataxia Rating Scale (FARS) published in 2005 was developed as a disease-specific rating scale for use in Friedreich ataxia (see **Figure 1**).

Development

As no validated clinical assessment tool was available, previous trials in Friedreich ataxia often preferred surrogate markers of disease severity like echocardiography as outcome parameters. Therefore, the North-American Cooperative Ataxia Group (CAG) developed the FARS

to evaluate both function and neurological deficits in Friedreich ataxia patients. The authors of the scale acknowledged the need for more sensitive outcome measures in this rare disorder with variable and slow progression. Further, Friedreich ataxia patients often present with concomitant nonataxia (such as muscle weakness) and non-neurological manifestations (such as cardiac, endocrine, or skeletal abnormalities). In contrast to other ataxia rating scales, the FARS does not aim to measure only ataxia, extracted from a more complex neurological syndrome, but instead includes all clinically meaningful neurological signs that reflect the neural substrates of Friedreich ataxia. These disease-specific signs are assessed by clinical examination, assessment of functional level, and quantitative performance measures.

Scale Structure

In the original publication, the FARS was presented as a four-component assessment to test functional disability and neurological deficits in Friedreich ataxia. Part I is a global staging of patient's mobility, which ranges from 0 (normal) to 6 (confined to wheelchair) and allows 0.5 ratings. Part II is a nine-item functional assessment that ranges from 0 (normal) to 36 (total dependence) and also allows 0.5 increment. Part III consists of 23 items based on a standardized neurological examination, which are grouped into five subscales A–E for bulbar, upper limb coordination, lower limb coordination, peripheral nervous system, and upright stability/gait function (the specific subscales have 4, 5, 2, 5, and 7 items with maximal scores

Rating Scale for Friedreich's Ataxia

I. Functional Staging for Ataxia
(Increment by 0.5 may be used if the status is about the middle between two stages)

STAGE 0: Normal.

STAGE 1.0: Minimal signs detected by physician during screening. Can run or jump without loss of balance. No disability.

STAGE 2.0: Symptoms present, recognized by patient, but still mild. Cannot run or jump without losing balance. The patient is physically capable of leading an independent life, but daily activities may be somewhat restricted. Minimal disability.

STAGE 3.0: Symptoms are overt and significant. Requires regular or periodic holding onto wall/furniture or use of a cane for stability and walking. Mild disability. (Note: many patients postpone obtaining a cane by avoiding open spaces and walking with the aid of walls/ people etc. These patients are grades as stage 3.0)

STAGE 4.0: Walking requires a walker, Canadian crutches or two canes. Or other aids such as walking dogs. Can perform several activities of daily living. Moderate disability.

STAGE 5.0: Confined but can navigate a wheelchair. Can perform some activities of daily living that do not require standing or walking. Severe disability.

STAGE 6.0: Confined to wheelchair or bed with total dependency for all activities of daily living. Total disability.

II. Activites of Daily Living
(increments of 0.5 may be used if strongly felt that a task falls between 2 scores)

1. Speech
0 -Normal
1 -Mildly affected. No difficulty being understood.
2 -Moderately affected. Sometimes asked to repeat statements.
3 -Severely affected. Frequently asked to repeat statements.
4 -Unintelligible most of the time.

2. Swallowing
0 -Normal.
1 -Rare choking (< once a month).
2 -Frequent choking (< once a week, > once a month).
3 -Requires modified food or chokes multiple times a week. Or patient avoids certain foods.
4 -Requires NG tube or gastrostomy feedings.

Figure 1 (Continued)

of 11, 36, 16, 26, and 28, respectively). Upper limb and lower limb coordination items are rated separately for each limb. The subscores can be summed to an unweighted FARS part III total score, ranging from 0 (no neurological deficit) to 117 (maximal deficit). Part IV contains two items of instrumental testing, a timed test of speech (syllable repetition rate) and performance time for the nine-hole pegboard test (9HPT) in each hand. In addition, time for a 25 ft walk is taken in the gait function subscale of part III. Further studies suggested the use of Sloan charts for visual acuity as an additional performance measure in Friedreich ataxia. Of note, some later studies using FARS refer to it as only neurological examination. In this text, we use FARS part III for the neurological examination and FARS for the whole multicomponent scale.

3. Cutting Food and Handling Utensils
0 -Normal.
1 -Somewhat slow and clumsy, but no help needed.
2 -Clumsy and slow, but can cut most foods with some help needed. Or needs assistance when in a hurry.
3 -Food must be cut by someone, but can still feed self slowly.
4 -Needs to be fed.

4. Dressing
0 -Normal.
1 -Somewhat slow, but no help needed.
2 -Occasional assistance with buttoning, getting arms in sleeves, etc. or has to modify activity in some way (e.g. Having to sit to get dressed; use velcro for shoes, stop wearing ties, etc.).
3 -Considerable help required, but can do some things alone.
4 -Helpless.

5. Personal Hygiene
0 -Normal.
1 -Somewhat slow, but no help needed.

2 -Very slow hygienic care or has need for devices such as special grab bars, tub bench, shower chair, etc.
3 -Requires personal help with washing, brushing teeth, combing hair or using toilet.
4 -Fully dependent

6. Falling
(assistive device = score 3)
0 -Normal.
1 -Rare falling (< once a month).
2 -Occasional falls (once a week to once a month).
3 -Falls multiple times a week or requires device to prevent falls.
4 -Unable to stand or walk.

7. Walking
(assistive device = score 3)
0 -Normal.
1 -Mild difficulty, perception of imbalance.
2 -Moderate difficulty, but requires little or no assistance.
3 -Severe disturbance of walking, requires assistance or walking aids.
4 -Cannot walk at all even with assistance (wheelchair bound).

8. Quality of Sitting Position
0 -Normal.
1 -Slight imbalance of the trunk, but needs no back support.
2 -Unable to sit without back support.
3 -Can sit only with extensive support (Geriatric chair, posy, etc.).
4 -Unable to sit.

9. Bladder Function
(if using drugs for bladder, automatic score of 3)
0 -Normal.
1 -Mild urinary hesitance, urgency or retention (< once a month).
2 -Moderate hesitance, urgency, rare retention/incontinence (> once a month, but < once a week).
3 -Frequent urinary incontinence (> once a week).
4 -Loss of bladder function requiring intermittent catheterization/indwelling catheter.

TOTAL ACTIVITIES OF DAILY LIVING SCORE:

Figure 1 (Continued)

Metric Properties and Validation Studies

The FARS was originally published with data on interrater reliability in a sample of 14 patients examined separately by seven examiners over 1 day. The sample included patients with a wide range of impairment. Time to complete was <30 min, and no effects of practice or fatigue were noticed with repeated testing over 1 day. Factorial analysis (excluding 25 ft walking time) yielded two factors that roughly represented upper and lower body function.

III. Neurological Examination

**(rate each item on the basis of the patient status during examination.
To the extent possible, sequential patient examinations should be carried out at the same time of the day. If the patient is taking any medication, the examination should be carried out prior to dosing, or at a fixed time following the dosing based on the maximum expected therapeutic response. Increments of 0.5 may be used if examiner feels an item falls between 2 defined severities)**

A. BULBAR

1. Facial Atrophy, Fasciculation, Action Myoclonus, and Weakness:
0 -None
1 -Fasciculations or action myoclonus, but no atrophy.
2 -Atrophy present but not profound or complete.
3 -Profound atrophy and weakness.

2. Tongue Atrophy, Fasciculation, Action Myoclonus and Weakness:
0 -None.
1 -Fasciculations or action myoclonus, but no atrophy.
2 -Atrophy present but not profound or complete.
3 -Profound atrophy and weakness.

3. Cough: (Patient asked to cough forcefully 3 times)
0 -Normal.
1 -Depressed.
2 -Totally or nearly absent.

4. Spontaneous Speech (ask the patient to read or repeat the sentences "The President lives in the White House" or "The traffic is heavy today"):
0 -Normal.
1 -Mild (all or most words understandable).
2 -Moderate (most words not understandable).
3 -Severe (no or almost no useful speech).

TOTAL BULBAR SCORE:

B. UPPER LIMB COORDINATION

1. Finger to Finger Test
(The index fingers are placed in front of each other with flexion at the elbow about 25 cm. from the sternum. Observe for 10 seconds. Score amplitude of oscillations):
Rate both sides separately
0 -Normal.
1 -Mild oscillations of finger (< 2 cm.).
2 -Moderate oscillations of finger (2-6 cm.).
3 -Severe oscillations of finger (> 6 cm.).

2. Nose-Finger Test
(Assess kinetic or intention tremor during and towards the end of movement: examiner holds index finger at 90% reach of patient; test at least 3 nose-finger-nose trials; movement slow > 3 sec.)
Rate both sides separately
0 -None
1 -Mild (< 2 cm. amplitude).
2 -Moderate (2-4 cm. amplitude or persisting through movement).
3 -Severe (> 6 cm. & persisting through movement).
4 -Too poorly coordinated to perform task.

Figure 1 (Continued)

3. Dysmetria (Fast Nose-Finger) Test
(Assess dysmetria: The patient touches tip of examiner's finger 8 times as rapidly as possible while the examiner moves his finger and stops at different locations at about 90% reach of the patient. Assess dysmetria – i.e. inaccuracy of reaching the target-at examiner's finger):
Rate both sides separately
0 -None.
1 -Mild (misses 2 or fewer times).
2 -Moderate (misses 3-5 times).
3 -Severe (misses 6-8 times.).
4 -Too poorly coordinated to perform task.

4. Rapid Alternating Movements of Hands
(Forearm pronation/supination 15 cm. above thigh; 10 full cycles as fast as possible; assess rate, rhythm, accuracy; practice 10 cycles before rating, if time > 7 sec. add 1 to score. Use stopwatch):
Rate both sides separately
0 -Normal.
1 -Mild (slightly irregular or slowed).
2 Moderate (irregular and slowed).
3 -Too poorly coordinated to perform task.

5. Finger Taps
(index fingertip-to-thumb crease; 15 reps as fast as possible; practice 15 reps once before rating; if time > 6 sec., add 1 to rating. Use stopwatch):
Rate both sides separately
0 -Normal.
1 -Mild (misses 1-3 times).
2 -Moderate (misses 4-9 times).
3 -Severe (misses 10-15 times).
4 -Cannot perform the task.

TOTAL UPPER LIMB COORDINATION SCORE

C. LOWER LIMB COORDINATION

1. Heel Along Shin Slide
(under visual control, slide heel on the contralateral tibia from the patella to the ankle up and down, 3 cycles at moderate speed, 2 sec./cycle, one at a time. May be seated with contralateral leg extended or supine but perform same way each time. Circle which: supine - seated):
Rate both sides separately
0 -Normal (stay on shin).
1 -Mild (abnormally slow, tremulous but contact maintained).
2 -Moderate (goes off shin a total of 3 or fewer times during 3 cycles).
3 -Severe (goes off shin 4 or more times during 3 cycles).
4 -Too poorly coordinated to attempt the task.

2. Heel-to-Shin Tap
(patient taps heel on midpoint of contralateral shin 8 times on each side from about 6-10", one at a time. May be seated with contralateral leg extended or supine but perform the same way each time. Circle which: supine seated):
Rate both sides separately
0 -Normal (stays on target).
1 -Mild (misses shin 2 or < times).
2 -Moderate (misses shin 3-5 times).
3 -Severe (misses shin > 4 times).
4 -Too poorly coordinated to perform task.

TOTAL LOWER LIMB COORDINATION SCORE

Figure 1 (Continued)

However , a recent study in 96 FRDA patients determined five different factors, only one of which - bulbar function - coincided with the proposed FARS III subscale. Interrater reliability was excellent for all FARS parts, and the part III subscales upper limb, lower limb, and upright stability/gait. Of note, some rater bias was reported for FARS part I, part II, and part III, and its upper limb coordination and peripheral nervous system subscores, but not for part IV. In a later study, reliability of performance measures was high in immediate retest, but method errors were within the range of predicted yearly changes. Floor effects were noted with 25 ft walk and 9HPT in later disease stages, that is, severely affected patients were mostly unable to perform the tests. Therefore, a composite score of two or three performance measures was proposed to improve sensitivity over the whole course of the disease. Validity

D. PERIPHERAL NERVOUS SYSTEM

1. Muscle Atrophy
(score most severe atrophy in either upper or lower limb):
Rate both sides separately
0 -None.
1 -Present -mild/moderate
2 -Severe/total wasting

2. Muscle Weakness
(Test deltoids, interossei, iliopsoas and tibialis anterior. Score most severe weakness in either upper or lower limb):
Rate both sides separately
0 -Normal (5/5).
1 -Mild (movement against resistance but not full power 4/5).
2 -Moderate (movement against gravity but not with added resistance 3/5)
3 -Severe (movement of joint but not against gravity 2/5).
4 -Near paralysis (muscular activity without movement 1/5).
5 -Total paralysis (0/5).

3. Vibratory Sense
(Educate patient regarding the sensation. Tested with 128 cps tuning fork set to near full vibration; eyes closed; test over index finger and great toe. Abnormal < 15 seconds for toes and <25 seconds for hands):
Rate both sides separately

Time felt for toes: _____ _____
Time felt for fingers: _____ _____
0 -Normal.
1 -Impaired at toes.
2 -Impaired at toes or fingers.

4. Position Sense
(test using minimal random movement of distal interphalangeal joints of index finger and big toe)
Rate both sides separately
0 -Normal.
1 -Impaired at toes/or fingers.
2 -Impaired at toes and fingers.

5. DTR
(0-absent; 1 -hyporeflexia; 2 -normal; 3 -hyperreflexia; 4 -pathologic hyperreflexia)
Right:
BJ_____ BrJ_____ KJ_____ AJ_____
Left:
BJ_____ BrJ_____ KJ_____ AJ____
Rate both sides separately
0 -No areflexia.
1 -Areflexia in either upper or lower limbs.
2 -Generalized areflexia.

TOTAL PERIPHERAL NERVOUS SYSTEM SCORE

Figure 1 (Continued)

of FARS part III was demonstrated by the association with FARS parts I and II (lower for bulbar subscore) and by correlation with 9HPT, 25 ft walking time, and disease duration. In a two other studies in 74 and 76 FRDA patients, part III correlated well with ICARS ratings, SARA rating, and different functional measures. Independent effects of age and the length of the shorter GAA repeat were seen on FARS part III total and subscores as well as 9HPT and 25 ft walk. Estimates of progression rates were derived from regression with disease duration: progression in FARS part III scores was higher at patient's age below 30 or with length of the shorter repeat above 250 GAA repeats. The authors

E. UPRIGHT STABILITY

(For sitting posture patient can sit in a chair or examination table. For standing and walking assessment instruct patient to wear best walking shoes and record below if barefoot, footwear or AFOs used. Stance assessment begins with feet 20 cm apart. Place marker tapes in the exam room 20 cm apart and the insides of the feet are lined up against these. Subsequent stance tests get more difficult. For feet together the entire inside of the feet should be close together as much as possible. For tandem stance, the dominant foot is in the back and the heel of the other foot is lined with the toes of the dominant foot but not in front of the toes (because this makes it even more difficult). For one foot stance, the patient is asked to stand on dominant foot and the other leg is elevated by bringing it forward with knee extended; this gives some advantage to the patient. If a patient can stand in a particular position for 1 minute or longer in trial 1, the trials 2 and 3 are abandoned. Otherwise each of 3 trials is timed and then averaged. Grading scores are then given as noted. Tandem walk and gait are performed in a hallway. Preferably no carpet but at least serial examinations should be on the same surface. For gait place markers 25 feet apart. Patient walks the distance turns around and comes back and the activitiy is timed. Note if the gait was achieved with or without device and serial examinations should be done with the same device as in the first examination. Stance and gait tests may be done barefoot if patient does have appropriate footwear, however, it should be done the same way for serial measurement.)

Circle which: Barefoot - Footwear
Also, indicate if AFOs are used: Yes - No

1. Sitting Posture
(Patient seated in chair with thighs together, arms folded, back unsupported; observe for 30 sec.):
0 -Normal.
1 -Mild oscillations of head/trunk without touching chair back or side.
2 -Moderate oscillations of head/trunk; needs contact with chair back or side for stability.
3 -Severe oscillations of head/trunk; needs contact with chair back or side for stability.
4 -Support on all 4 sides for stability.

2. Stance feet apart
– Inside of feet 20 cm apart marked on floor. (use stopwatch; 3 attempts; time in seconds):

Trial 1
Trial 2
Trial 3
Average:_____

0 -1 minute or longer.
1 -<1 minute, >45 sec.
2 -<45 sec., >30 sec.
3 -<30 sec., >15 sec.
4 -<15 sec. or needs hands held by assistant/device.

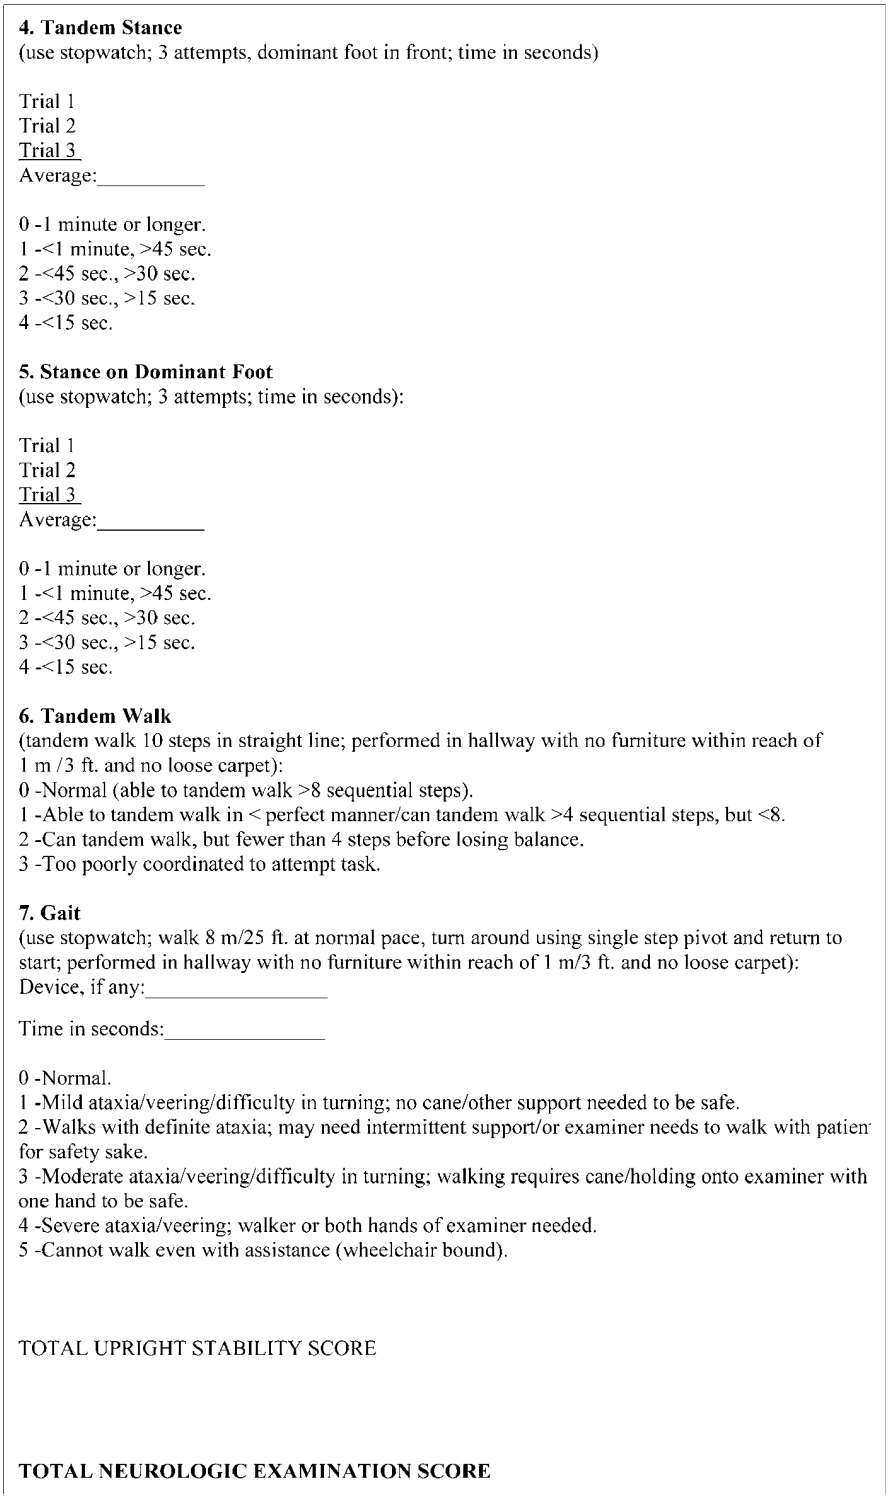
3. Stance -Feet Together
(use stopwatch; 3 attempts; time in seconds):

Trial 1
Trial 2
Trial 3
Average:_____

0 -1 minute or longer.
1 -<1 minute, >45 sec.
2 -<45 sec., >30 sec.
3 -<30 sec., >15 sec.
4 -<15 sec.

Figure 1 (Continued)

of that study suggested stratifying future patient samples in this respect. In an evaluation of scale responsiveness, FARS seemed to perform better than ICARS with respect to effect size. The clinical relevance of FARS part III and IV score differences was supported by correlations with health-related quality of life measures (physical component of the SF-36). Further, velocity in 25 ft walk predicted everyday ambulation measures in Friedreich ataxia in one study.



4. Tandem Stance
(use stopwatch; 3 attempts, dominant foot in front; time in seconds)

Trial 1
Trial 2
Trial 3
Average:_____

0 -1 minute or longer.
1 -<1 minute, >45 sec.
2 -<45 sec., >30 sec.
3 -<30 sec., >15 sec.
4 -<15 sec.

5. Stance on Dominant Foot
(use stopwatch; 3 attempts; time in seconds):

Trial 1
Trial 2
Trial 3
Average:_____

0 -1 minute or longer.
1 -<1 minute, >45 sec.
2 -<45 sec., >30 sec.
3 -<30 sec., >15 sec.
4 -<15 sec.

6. Tandem Walk
(tandem walk 10 steps in straight line; performed in hallway with no furniture within reach of 1 m /3 ft. and no loose carpet):
0 -Normal (able to tandem walk >8 sequential steps).
1 -Able to tandem walk in < perfect manner/can tandem walk >4 sequential steps, but <8.
2 -Can tandem walk, but fewer than 4 steps before losing balance.
3 -Too poorly coordinated to attempt task.

7. Gait
(use stopwatch; walk 8 m/25 ft. at normal pace, turn around using single step pivot and return to start; performed in hallway with no furniture within reach of 1 m/3 ft. and no loose carpet):
Device, if any:_____

Time in seconds:_____

0 -Normal.
1 -Mild ataxia/veering/difficulty in turning; no cane/other support needed to be safe.
2 -Walks with definite ataxia; may need intermittent support/or examiner needs to walk with patien for safety sake.
3 -Moderate ataxia/veering/difficulty in turning; walking requires cane/holding onto examiner with one hand to be safe.
4 -Severe ataxia/veering; walker or both hands of examiner needed.
5 -Cannot walk even with assistance (wheelchair bound).

TOTAL UPRIGHT STABILITY SCORE

TOTAL NEUROLOGIC EXAMINATION SCORE

Figure 1 (Continued)

Clinical Trials

The FARS part II and part III have been used as secondary outcome measures in a recent NIH trial of high-dose idebenone in Friedreich ataxia. In a sample of 47 patients with mean baseline scores in part II/III of 13.7/51.4, mean changes in the treatment and placebo arm over a 6 month interval were reported between 1 and −1.5 for part II and between −2 and −6 for part III (estimates from figures in the original publication). As no treatment effect was detected, these data can be seen as an estimate of the 'natural' progression in Friedreich ataxia. FARS parts II and III are also used as secondary outcome measures in an ongoing multinational trial of high-dose idebenone in Friedreich ataxia. One single-center study related eye movement abnormalities to FARS part III, and found correlations with saccadic latency.

Criticism

The development of the scale as disease-specific has advantages and disadvantages, including limiting its use to Friedreich ataxia. While the time to administer and

IV. Instrumental Testing

1. PATA Rate
(Use a tape recorder that can play at slow and fast speeds (1.2 & 2.4 cm/sec).
Record at normal (2.4) speed. Use a digital stopwatch. Patient seated comfortably and instructed to repeat the syllable "pata" as quickly and distinctly as possible for 10 seconds until told to stop. Start recorder and record patient's name and date. Preset stopwatch for 10 seconds. Say "go" and as soon as patient starts speaking, start timer. Say "stop" when timer beeps at end of 10 seconds. Perform test twice and count # of "patas" for each 10 seconds, using playback at slower speed. Record number for each trial and also the average score):

Trial 1
Trial 2
Average:_____

2. Nine-Hole Pegboard
(Make sure the stopwatch is set to zero. Introduce this section by saying, "Now, we're going to be measuring your arm and hand function." If this is the first visit, as, "Are you right-or left-handed?" Make a note of the dominant hand for subsequent instructions. Place the 9-HPT apparatus on the table directly in front of the patient. Arrange the apparatus so that the side with the pegs is in front of the hand being tested and the side with the empty pegboard is in front of the hand not being tested. Secure with Dycem. Read the following instructions to the patient: "On this test, I want you to pick up the pegs one at a time, using one hand only, and put them into the holes as quickly as you can in any order until all the holes are filled. Then, without pausing, remove the pegs one at a time and return them to the container as quickly as you can. We'll have you do this two (2) times with each hand. We'll start with your [DOMINANT] hand. You can hold the peg board steady with you [NON-DOMINANT] hand. If a peg falls onto the table, you retrieve it and continue with the task. If a peg falls on the floor, keep working on the task and I will retrieve it for you. See how fast you can put all the pegs in and take them out again. Are your ready? Begin." Start timing as soon as the patient touches the first peg, and stop timing when the last peg hits the container. If a peg drops on the floor, the examiner will retrieve it and put it back in the peg box. However, if a peg drops onto the table, the patient is to retrieve it unless it is beyond their arm reach then you can retrieve it for them. It is possible that a peg may fall beyond the reach of the examiner therefore; we recommend that you keep a few extra pegs in hand so that testing is not interrupted. Do not put extra pegs in the testing apparatus as this may confuse the subject. Record the patient's time under "Dominant hand --Trial 1." If the subject stops after having put all the pegs into the holes, prompt the subject to move them as well by saying, "And now remove them all." If the subject begins to remove more than one peg at a time, correct him/her by saying, "Pick up one peg at a time."

The total time to complete the task is recorded in seconds including one decimal place rounded as needed. Round up to the next tenth if hundredth's place is > = .05, round down in hundredth's place is < 0.5.)

Rate both sides separately

Trial 1
Trial 2
Average:_____

Figure 1 Illustration of full FARS text. From Subramony et al. (2005) Measuring Friedreich ataxia: Interrates reliability of a neurologic rating scale. *Neurology* 64(7): 1261–1262.

interrater reliability are acceptable for clinical trials, the rater bias for part II, II, and III reported in the original paper underlines the need for rater training. The metric properties, validity, and specificity (as well as the standards of application) of part II have not yet been sufficiently specified. Although reliability and validity data are sufficient for part III, data on factorial analysis are controversial and question the proposed subscale structure. According to the variance in the validation studies, part III seems sensitive over a wide range of disease severity while part IV items have some shortcomings with floor effects in later stages. Depending on the study purpose, additional information would be desirable, for example, no data are available from assessments in controls, and sensitivity to change as well as linearity of FARS parts have not been established.

Conclusion

FARS has recently been published as a compound assessment of Friedreich ataxia severity. Part I functional staging seems useful to classify study samples, while the usefulness of part II is not well established; it might give a more subjective perspective of functional deficits, but without further validation seems currently not recommendable as an outcome parameter for interventional trials. The neurological examination (part III) total score can be used separately and has already been used in clinical studies, which suggested sensitivity to change and yielded estimates of progression rates. However, these are currently derived only from a small sample. Part IV performance measures have shown less rater bias than part III, but their sensitivity seems restricted in later disease stages. A total sum score of all four FARS parts is currently not supported (although used in one validation trial). In sum, FARS part III provides an appropriate measure for any intervention that aims to change severity or progression of neurological deficits in Friedreich ataxia patients.

Frontotemporal Dementia-Parkinsonism

C W Wider and Z K Wszolek, Mayo Clinic, Jacksonville, FL, USA

Glossary

FTD (frontotemporal dementia) – One of the FTLD phenotypes characterized by behavioral troubles and personality changes.

FTDP-17 (frontotemporal dementia-parkinsonism linked to chromosome 17) – Familial FTLD with evidence of genetic linkage to chromosome 17q21.

FTLD (frontotemporal lobar degeneration) – Generic term encompassing, among others, FTD, SD, PNFA, FTDP-17, PSP, and CBD.

MAPT (microtubule-associated protein tau) – Mutations in this gene on chromosome 17q21 cause FTDP-17 (tau-positive).

PGRN (progranulin) – Mutations in this gene on chromosome 17q21 cause FTLD-U (tau-negative, ubiquitin-positive).

PNFA (progressive nonfluent aphasia) – One of the FTLD phenotypes characterized by progressive nonfluent language impairment.
SD (semantic dementia) – One of the FTLD phenotypes characterized by progressive fluent language impairment.
TDP-43 (TAR DNA-binding protein 43) – Major ubiquitinated protein content of neuronal and glial inclusions in FTLD-U, FTD-MND, and ALS.

Definition and History

Arnold Pick was the first to demonstrate patients with dementia and severe atrophy of the frontal and temporal lobes in 1892. Almost two decades later, Alois Alzheimer reported the neuronal inclusions characteristic of this condition, which was soon to be known as Pick's disease.

Frontotemporal lobar degeneration (FTLD) is a group of neurodegenerative diseases in which patients display behavioral and language impairment, with atrophy of the frontal and temporal lobes. The behavioral variant of FTLD is clinically referred to as frontotemporal dementia (FTD) or as its behavioral variant (bvFTD), whereas language impairment is the core feature in progressive nonfluent aphasia (PNFA) and semantic dementia (SD). Some authors refer to FTD as a group of diseases encompassing bvFTD, PNFA, and SD. In this article, however, we will refer to FTLD as an umbrella term designating the clinical and pathological entities, FTD, PNFA, and SD. Some FTLD patients can also develop associated features of motor neuron disease (FTD-MND). In addition, FTLD has clinical and pathological similarities with other motor syndromes such as corticobasal degeneration (CBD) and progressive supranuclear gaze palsy (PSP), which are considered a part of the same spectrum. CBD and PSP are presented elsewhere in this encyclopedia.

FTLD is the second most common cause of early-onset dementia (<65 years) after Alzheimer's disease (AD), and the third cause of overall cortical dementia. Behavioral, cognitive, and motor impairment begins in the fifth of sixth decade, and has a relentless progression. A positive family history is reported in up to 50% of patients, mostly those with FTD and PNFA. Conversely, only ~10% of SD patients display familial aggregation.

Parkinsonism is a frequent finding in patients with FTLD, particularly in those with a familial form of the disease. In this article, we discuss the clinical, genetic, and neuropathologic features of FTLD, with emphasis on familial forms associated with parkinsonism.

Pathogenesis/Pathophysiology

The cause of FTLD remains largely unknown, and the main risk factors are age and a positive family history. However, recent advances in genetics and neuropathology have shed light into mechanisms that may be involved in the FTLD pathogenesis.

Genetics

Over the past decade, two major genes have been identified as causally involved in familial FTLD, progranulin (*PGRN*), and microtubule-associated protein tau (*MAPT*) (**Figure 1**). Screening for both genes is now commercially available (see Relevant Websites). Two other genes and one locus have been associated with rarer forms of FTLD, valosin-containing protein (*VCP*), charged multivesicular body protein 2B (*CHMP2B*), and a locus on chromosome 9, which will not be discussed in this article.

Microtubule-associated protein tau (MAPT)

The first family in which linkage to chromosome 17q21 was reported displayed the disinhibition–dementia–parkinsonism–amyotrophy complex phenotype. In 1996, at a consensus conference, the term 'frontotemporal dementia' with parkinsonism linked to chromosome 17 (FTDP-17) was coined. Two years later, this was followed by the discovery of pathogenic mutations in *MAPT*. Since then, over 40 *MAPT* pathogenic mutations have been described (**Figure 1**), accounting for about one-third of familial FTLD patients and 5–10% of all FTLD cases.

MAPT encodes the tau protein, which is implicated in microtubule assembly and stabilization. The protein has six human isoforms, generated by alternative splicing of exons 2, 3, and 10. These isoforms can be divided into those with three (3R) and four (4R) microtubule binding domains, which differ in their binding and assembling properties. Hyperphosphorylated tau protein assembles into filaments in human disease, defining taupathies which include Pick's disease, AD, PSP, CBD, argyrophilic grain disease, and FTDP-17 with mutations in *MAPT*. Mutations in *MAPT* alter the expression of the 4R or both the 3R and 4R isoforms, thereby modifying the interaction with microtubules or the formation of fibrils.

Subtypes of *MAPT* mutations are clinically relevant, since they may be associated with distinct phenotypic features. For example, mutations in exons 9 and 13 are usually not associated with motor symptoms, whereas mutations altering the *MAPT* splicing are more commonly found in patients with FTD and parkinsonism. Furthermore, mutations altering the first two microtubule binding domains seem to be associated with earlier age of onset and shorter disease duration.

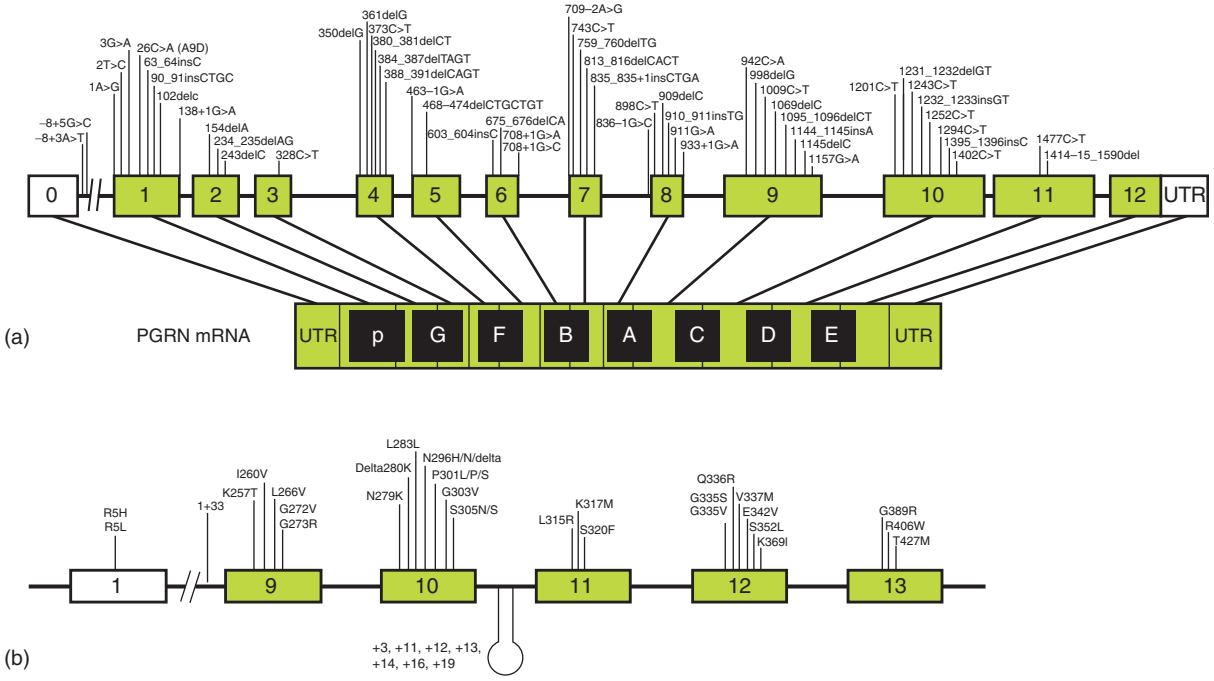

Figure 1 Schematic representation of the *PGRN* (a) and *MAPT* genes (b) with known mutations. Exons are numbered in Roman numerals. *PGRN* mRNA is depicted and lettered boxes represent individual granulin repeats.

Progranulin (PGRN)

Only 2 years after its discovery, over 50 pathogenic mutations have been identified in *PGRN* (**Figure 1**), which account for 5–10% of FTLD cases and 20–30% of familial cases. All the mutations discovered so far create functional null alleles resulting in reduced protein levels (haploinsufficiency). *PGRN* encodes a precursor protein which can be proteolytically cleaved in a family of granulins. The exact function of the protein in the brain remains to be established, but studies have suggested a role in cell cycle regulation and cell migration, tumorigenesis, inflammation and wound repair, and as a mitogenic factor. Recently, a functional link has been established between the PGRN protein and TAR DNA-binding protein 43 (TDP-43), the major protein content of intraneuronal inclusions in FTLD-U (see below).

Neuropathology

In recent years, neuropathologic classification of FTLD has seen marked changes, which have stemmed from new immunohistochemistry techniques and genetic discoveries. Macroscopically, FTLD is characterized by cortical degeneration of the frontal and temporal lobes. Histologically, there is neuronal loss and gliosis in affected areas. Immunohistochemistry, however, has allowed defining two main categories of FTLD, FTLD with tau-positive pathology (tau-positive FTLD), and FTLD with tau-negative, ubiquitin-positive inclusions (FTLD-U). Most cases previously referred to as dementia lacking distinctive histopathology have been reclassified as FTLD-U, which has emerged as the major pathology found in FTLD. About 45% of FTLD cases display tau-positive pathology (tau-positive FTLD), whereas ~50% of patients have ubiquitin-positive inclusions (FTLD-U). Recently, TDP-43 has been identified as the major ubiquitinated protein component of ubiquitin-positive neuronal and glial inclusions in FTLD-U, FTLD-MND, and amyotrophic lateral sclerosis (ALS). Based on these findings, consensus criteria for the pathological diagnosis of FTLD were revised, and now include TDP-43 proteinopathy as a distinct category that encompasses FTLD-U with or without MND, FTLD-U caused by *PGRN* or *VCP* mutations, FTD-MND linked to chromosome 9p, and ALS.

FTLD with tau-positive pathology includes classical Pick's disease with Pick cells (tau-positive swollen achromatic neurons) and Pick bodies (round argyrophilic inclusions), CBD, PSP, argyrophilic grain disease, and familial cases of FTLD with a mutation in *MAPT*. Histology and immunohistochemistry show neuronal loss, gliosis, and accumulation of hyperphosphorylated tau protein in the cytoplasm of neurons and glial cells. Specific tau isoforms are found preferentially in some taupathies, defining 3R taupathies (e.g., Pick's disease) and 4R taupathies (e.g., PSP and CBD).

FTLD-U pathology includes neuronal cytoplasmic (NCI) and intranuclear (NII) inclusions, glial inclusions, and dystrophic neurites. Heterogeneity exists in the relative intracortical and hippocampal distribution of NIIs, NCIs, and dystrophic neurites. Four main subtypes have

been identified, which are clinically relevant and associated with different phenotypes. Most of the Mackenzie type-I patients have FTD or PNFA, type-II is associated with SD, and cases with FTD-MND have type-III pathology. Patients with *PGRN* mutations display atrophy in the frontotemporal lobes, caudate nucleus, medial thalamus, substantia nigra, and in the CA1 sector of the hippocampus. Immunohistochemistry shows NCIs, NIIs, dystrophic neurites, and glial inclusions.

Although the link between *PGRN* mutations, TDP-43 positive inclusions, and the disease phenotype remains elusive, a recent cell biology study has shown that the PGRN protein alters caspase-dependant cleavage of TDP-43. Suppression of *PGRN* expression by small interfering RNA led to an altered cleavage and redistribution of TDP-43 from the nucleus to the cytoplasm, a pattern seen in FTLD-U patients.

Epidemiology

In the United Kingdom, FTLD prevalence was reported to be 15 per 100 000 among subjects between 45 and 64 years. Figures were comparable in The Netherlands, with a prevalence rate of 3.6 per 100 000 between ages 50 and 59, 9.4 per 100 000 between ages 60 and 69, and 3.8 per 100 000 between ages 70 and 79. Incidence (new patients per 100 000 person-years) in Rochester, MN, was found to be 2.2 for ages 40–49, 3.3 for ages 50–59, and 8.9 for ages 60–69. In comparison, the incidence of AD in the same series was expectedly lower for ages 40–49, similar for ages 50–59, and higher for ages 60–69. Most of the studies have not reported significant gender differences.

Clinical Features and Diagnostic Criteria

Clinical Features

Frontotemporal dementia (FTD)

The core presenting symptoms of FTD are personality changes and impaired social behavior (**Table 1**). These include mental inflexibility, loss of volition, emotional blunting, lack of insight, inertia, and impulsive and inappropriate behavior. Changes in religious or political beliefs may occur. In addition, patients present a wide range of frontal-type behaviors, mostly of the disinhibited form, along with speech alterations, albeit without true aphasia. Frontal release signs and parkinsonism are commonly observed in FTD patients. Parkinsonism tends to occur late in the disease, and usually consists of akinesia and rigidity, sometimes with postural tremor. Rest tremor is virtually always absent. Severe amnesia, aphasia, and spatial perceptual alterations are the clinical diagnostic exclusion criteria.

Progressive nonfluent aphasia (PNFA)

Expressive language is mostly affected in PNFA patients, who present with (nonfluent aphasia), including agrammatism, anomia, alexia, agraphia, and phonemic paraphasia. The meaning of words is retained in early stages, in contrast with SD patients. With disease progression, patients often present with frontal behavioral impairment, along with parkinsonism, mostly of the akinetic-rigid type. Mutism is common in end-stage disease.

Semantic dementia (SD)

SD patients present with fluent aphasia and early loss of the meaning of words, characterized by altered comprehension and naming, empty speech, impaired face (prosopagnosia) and object (agnosia) recognition, and semantic paraphasias. Patients often retain the ability to read aloud and write to dictation, which can be misleading; however, their understanding of the content is severely impaired. As in FTD and PNFA, parkinsonian signs may occur in later stages of the disease.

FTD-MND

About 10% of FTLD patients present with MND symptoms, particularly those with the FTD phenotype. Any degree of association may occur, ranging from subclinical motor neuron involvement, only seen at autopsy, to severe MND compatible with a diagnosis of ALS. The common clinical association of FTLD and MND is reflected at the neuropathologic level, where similar neuronal and glial inclusions are found in both conditions. The anatomic distribution of pathology (frontotemporal cortex vs. motor neurons) determines the proportion of FTLD or MND phenotypes, respectively.

FTD with parkinsonism linked to chromosome 17

FTDP-17 designates patients with a familial form of the disease, who display evidence of genetic linkage to chromosome 17. Two genes, *MAPT* and *PGRN*, have been identified within this locus and causally associated with disease.

FTDP-17 families with tau-positive pathology

Tau-positive FTDP-17 is caused by mutations in *MAPT*. The clinical phenotype is dominated by personality and behavioral changes, cognitive impairment, and motor symptoms, with an earlier age of onset (49 years, range: 25–76) than that of the overall FTLD population (**Figure 2**). Motor impairment consists of parkinsonism with rigidity, bradykinesia, postural tremor, and postural instability. In contrast with sporadic FTLD, parkinsonism often occurs early in the disease, sometimes resembling Parkinson's disease (PD), thereby leading to misdiagnosis. However, similar to sporadic FTLD, response to levodopa is usually poor and, if present, is not long-lasting. There is a high variability in clinical presentation not only across but also within families. In addition to FTD and parkinsonism, vertical

Table 1 Diagnostic criteria for FTLD

(a) Frontotemporal dementia (FTD)		
Core criteria	Insidious onset, gradual progression	
	Early occurrence of	• impaired social behavior
		• impaired personal conduct
		• emotional blunting
		• loss of insight
Supportive criteria	Behavioral disorder	• personal hygiene decline
		• mental rigidity, inflexibility
		• distractibility, impersistence
		• hyperorality, dietary changes
		• perseveration, stereotyped behavior
		• utilization behavior
	Speech, language	• altered speech output, stereotypy, echolalia, perseveration, mutism
	Physical signs	• primitive reflexes, incontinence, parkinsonism
(b) Progressive nonfluent aphasia (PNFA)		
Core criteria	Insidious onset, gradual progression	
	Nonfluent spontaneous speech, with at least one of the following: agrammatism, phonemic paraphasia, anomia	
Supportive criteria	Speech and language	• stuttering, oral apraxia, impaired repetition, alexia, or agraphia
		• early preservation of word meaning
	Behavior	• early preservation of social skills, late behavioral changes similar to FTD
	Physical signs	• late controlateral primitive reflexes, parkinsonism
(c) Semantic dementia SD		
Core criteria	Insidious onset, gradual progression	
	Fluent empty spontaneous speech or loss of word meaning	
	and/or	• prosopagnosia or agnosia
		• preserved drawing reproduction
		• preserved word repetition
		• preserved ability to read aloud and write to dictation
Supportive criteria	Speech, language	• press of speech, idiosyncratic word usage, no phonemic paraphasia, preserved calculation
	Behavior	• loss of sympathy and empathy, narrowed preoccupation
	Physical signs	• absent of late primitive reflexes, parkinsonism

Figure 2 Clinical (*left, middle*) and MR findings (*right*) in a patient from the pallido-ponto-nigral degeneration family carrying the N279K *MAPT* mutation. A 49-year-old woman presented, at age 42, with right-predominant tremor, postural instability, and rigidity. Associated findings over the next few years included dystonia, depression, personality changes, insomnia, and cognitive impairment. Symptoms responded partly to levodopa with dyskinesia. The patient currently requires help for ambulation. The figure shows staring gaze and frontal dystonia (*top left*), eye opening apraxia with upper eyebrows above the superior orbital rim (*bottom left*), upper limb dystonia (*top middle*), foot dystonia (*bottom middle*), frontal atrophy (*top right and bottom right*), and temporal atrophy (*bottom right*).

gaze palsy, anosmia, pyramidal signs, severe memory loss, myoclonus, dystonia, autonomic dysfunction, and rarely, epileptic seizures have been described.

FTDP-17 families with tau-negative, ubiquitin-positive pathology

Mutations in the *PGRN* gene cause FTLD with ubiquitin-positive inclusions (FLTD-U). The mean age of onset is 59 years (range: 48–83 years), with an age-dependant penetrance (>90% mutation carriers affected by age 70). The most common phenotype is FTD with some degree of language impairment, followed by PNFA. Parkinsonism occurs in ~50% of patients, and tends to appear late in the disease. It is mainly characterized by akinetic-rigid and axial symptoms, although postural tremor may occur. As in *MAPT* mutation carriers, response to levodopa is poor. The association with MND is distinctly rare. Hallucinations have been described in as many as 30% of patients. Families have been reported with phenotypes suggestive of CBD, PD, dementia with Lewy bodies, and AD.

Diagnostic Criteria

Clinical diagnostic criteria were published in 1998 by Neary et al., and have proven very useful for both clinical practice and research purposes (**Table 1**). However, several drawbacks have emerged, related to the dynamic nature of FTLD and to the poor sensitivity in early stages of the disease. For example, patients may present with a FTD phenotype and later evolve into SD or PNFA. Studies have found that two-thirds of FTLD patients present additional phenotypes with disease progression. Also, while some studies have reported good sensitivity and specificity (80% and 99%, respectively), other authors have found that only about one-third of the patients fulfill all the core diagnostic criteria at presentation, hence, a poor sensitivity in early stages (60%). Finally, while anterograde amnesia is an exclusion criterion, patients have been described even with AD type memory impairment. Other diagnostic criteria have been proposed by McKhann et al., which are easier to use in a general neurology setting (**Table 2**). These criteria are, however, prone to miss patients with SD. No specific criteria have been developed for FTDP-17; useful diagnostic tools are given in **Table 3**.

Table 2 Clinical diagnostic criteria for FTLD

Behavioral or cognitive deficits	Early progressive personality changes with difficulty in modulating behavior, inappropriate responses, or activities; or Early progressive language difficulties, with expression impairment or severe naming difficulties and problems with words meaning
Behavioral/cognitive deficits cause significant functioning impairment, and clearly represent a decline	
Gradual onset, progression	
No other cause is identified	
The deficits do not occur exclusively during a delirium

Table 3 Clinical features of the most common forms of autosomal dominant FTLD

	MAPT	*PGRN*
Mean age of onset (years)	49 (range 25–76)	59 (range 37–84)
Mean duration (years)	7 (range 2–30)	7 (range 2–30)
Symptoms	Personality or behavioral changes, language impairment (mostly *PGRN*), parkinsonism (mostly *MAPT*), cognitive impairment, parkinsonism, corticobasal syndrome, amyotrophy, gaze palsy, motor neuron disease (rare)	
Treatment	Levodopa ineffective but may have a limited effect for some time	

Differential Diagnosis

The high clinical heterogeneity of FTLD makes it prone to clinical misdiagnosis, particularly in early stages. In most cases, the key is long-term follow-up of patients, as both sensitivity and specificity of diagnostic criteria improve with disease progression. Early behavioral changes may suggest psychiatric conditions. Behavioral and language impairment along with absence of severe memory loss usually allow differentiating FTLD from AD. However, clinico-pathological studies have shown that some patients display significant anterograde amnesia even in early stages of FTLD, often leading to a false AD diagnosis. In some patients, particularly those with a familial form of FTLD, the phenotype may suggest PD, although response to levodopa is poor or absent.

Diagnostic Work-up/Tests

Biological tests include standard dementia work-up to exclude metabolic, endocrine, immunologic, and paraneoplastic disorders. Imaging studies are crucial to establish a diagnosis of FTLD.

Morphologic imaging often shows mild or no atrophy in the early stages of the disease. However, as the disease progresses, atrophy becomes more apparent by standard CT and MRI scans (**Figure 2**). Atrophy usually predominates in the frontal and temporal lobes in FTD, in the left frontal lobe in PNFA, and in the left temporal lobe in SD, however with wide variability and overlap. Some studies have shown that patients with normal or borderline MRI scans had a longer survival than those with prominent frontotemporal atrophy.

Functional imaging shows hypometabolism on glucose positron-emission tomography (FDG-PET) and hypoperfusion on single photon-emission computed tomography (SPECT). FDG-PET studies have found hypometabolism in the lateral and medial prefrontal cortices, caudate nucleus, insula, and thalamus, with later involvement of temporal and parietal cortices. The severity of apathy and disinhibition has been correlated with the degree of hypometabolism/reduced blood flow in the posterior orbitofrontal, ventromedial prefrontal and temporal cortices. ^{18}F-Fluoro-dopa PET (FD-PET) has shown both pre and postsynaptic reduced tracer intake in patients with FTDP-17 due to a *MAPT* mutation, explaining the short-lasting response to levodopa seen in some patients. Presymptomatic FD-PET abnormalities have been reported in *MAPT* mutation carriers, showing this method may be used as a surrogate marker when studying the effect of putative neuroprotective interventions.

Management

No specific pharmacological treatment is currently approved for FTLD, and management is symptomatic. Off-label use of acetylcholinesterase inhibitors or memantine has been found useful in some patients, but no benefit has been established for cognitive symptoms. In patients displaying significant behavioral or mood alterations, atypical antipsychotics and antidepressants should be considered. Speech therapy may benefit patients with language impairment. Physical therapy is indicated for gait impairment and activities of daily living. Levodopa is usually not effective.

Prognosis

FTLD progression is faster than that of AD, and recent studies have found a median survival of 3 years after diagnosis, and of 6 years after initial symptoms. Absent or mild atrophy in early stages may be associated with a better prognosis. No strategy has been proven effective in preventing the disease or in halting its progression. Prognosis may even be poorer in some FTDP-17 patients with survival rates of less than 2 years.

Fumarase Deficiency

L De Meirleir, UZ Brussel, Brussel, Belgium

Definition and History

Fumarase hydratase (FH) deficiency belongs to the group of inborn errors of metabolism of the tricarboxylic acid cycle. FH deficiency is also named fumaric aciduria, since it results in excessive urinary excretion of fumarate.

Fumarase deficiency was first described in 1983 by Whelan who reported fumaric aciduria in two adult sibs with mental retardation and speech impairment. The enzyme defect was discovered three years later by Zinn in 1986 in a patient with the clinical picture of an early-onset severe encephalopathy. The first molecular diagnosis was published in 1994 by Bourgeron. Generally, the disease is characterized by early-onset encephalopathy with seizures and hypotonia, associated with excessive fumaric acid excretion. Milder cases are also described. In 2002, heterozygous germline mutations of FH were described in patients with multiple cutaneous and uterine leiomyomas.

Pathogenesis and Metabolic Consequences

Human fumarate hydratase is a homotetramer with mitochondrial and cytosolic isoenzymes. It catalyzes the reversible conversion of fumarate and malate. No cofactors are required. The mitochondrial isoenzyme is involved in the tricarboxylic acid cycle in the mitochondria, and the function of the cytosolic isoenzyme is still unclear.

The pathogenesis of fumarase deficiency and other TCA cycle defects includes impaired energy production caused by interrupting the flow of the TCA cycle and secondary enzyme inhibition associated with accumulation of metabolites proximal to the primary enzyme deficiency. The first mechanism limits the number of enzymatic steps at which reducing equivalents can be generated and transferred to the ETC. In addition, this mechanism may lead to depletion of oxaloacetate, preventing continued influx of acetyl-CoA into the TCA cycle via citrate synthase. The second mechanism may involve other pathways of oxidative metabolism. Finally, the primary mechanism of how a metabolic enzyme can also work as a tumor supression has not yet been solved.

Epidemiology and Genetics

There is an unusually high incidence of fumarase deficiency in the southwestern United States among members of the Fundamentalist Church of Jesus Christ of Latter Day Saints (FLDS).

The genetic defect was traced to one of the community's founding patriarchs and the first of his plural wives, who had 14 children together.

The disease is usually very rare and is inherited as an autosomal recessive trait. The two isoforms of fumarase, mitochondrial and cytosolic, differing in electrophoretic mobility, are encoded by a single locus on chromosome 1. The same gene and the same mRNA encode both proteins, but the fumarase transcript is alternately translated to generate the two isoforms. The two peptides are identical after the latter initiation methionine; heterozygous carriers have about 50% of the fumarase hydratase activity of normal controls, while deficient patients have undetectable or less than 10% levels of activity of normal controls.

The fumarase gene has been mapped to chromosome 1q42.1. Bourgeron described the first mutation in a consanguineous family with two affected sibs A homozygous missense mutation was found. Different mutations have been demonstrated in several unrelated families. One paper describes a case with uniparental isodisomy. The unaffected father was found to be heterozygous for the mutation of the child who was homozygous, while the mother was found to be homozygous wild-type. Analysis of chromosome 1 markers showed that the patient inherited both paternal alleles with a complete absence of maternal alleles.

Most mutations are private mutations except for the 435insK mutation, which was described in several patients.

Heterozygous mutations in the FH gene are associated with a predisposition to cutaneous and uterine leiomyomas and to kidney cancers; later also to ovary adenocarcinomas, Leydig cell tumors, and cerebral cavernomas. The tumors are generated after somatic loss of the normal allele.

It has been proposed that the mutations cluster at the 5′end of the FH gene in patients with tumor predisposition, whereas mutations associated with FH deficiency tend to cluster in the 3′end of the gene.

Clinical Features and Diagnostic Criteria

Approximately, less than 40 patients with fumarase hydratase deficiency have been reported. The first biochemically proven case started at 3 weeks of age with vomiting and hypotonia. He developed microcephaly (associated with dilated lateral ventricles) and severe axial hypertonia and had no developmental progression. An EEG showed abnormal background rhythms and bitemporal spike-wave patterns. Elevated plasma lactate levels and urinary fumarate and other Krebs cycle intermediates in the organic acid analysis suggested the diagnosis, which was biochemically confirmed. Petrova-Benedict reported in 1987 a case of fumarase deficiency in a mentally retarded child with microcephaly of consanguineous parents. Using iso-electrofocusing, they could demonstrate that the enzyme in the cytosolic compartment appeared to be more severely affected. Bourgeron in 1994 described the first mutation in the fumarase hydratase gene in a consanguineous family with two affected sibs. The children presented with a severe encephalopathy and became microcephalic and quadraplegic. In these sibs, plasma lactate was normal, but CSF lactate was consistently elevated. A severe FH deficiency (<0.5% of control activity) was found in all tissues investigated and affected to the same degree as the cytosolic and the mitochondrial isoenzymes.

Until the publication of Kerrigan in 2000, only 13 patients were described, all presenting in infancy with a severe encephalopathy and seizures, with poor neurological outcome. Kerrigan reported on eight patients from a large consanguineous family. All the patients had a profound mental retardation and presented it as a static encephalopathy. Six out of the eight developed seizures. The seizures were of various types and of variable severity, but several patients experienced episodes of status epilepticus. All had a relative macrocephaly (in contrast to previous cases) and large ventricles. Dysmorphic features such as frontal bossing, hypertelorism, and depressed nasal bridge were noted.

Visual impairment, optic nerve hypoplasia, and areflexia have been clinical features in other patients. Infantile spasms have been commonly reported. Milder cases with developmental delay and epilepsy have been described, for example in a 5-year-old girl with a previous diagnosis of cerebral palsy, nonprogressive psychomotor retardation, and hypotonia. She was found to excrete excessive fumaric acid in urine. Fumarate hydratase activity in skin fibroblasts was 10% of the control value.

Maradein described a girl in whose case both the mother and grandmother had uterine myomas. She had been hypotonic since birth; walked by the age of 4 years; and started having epilepsy at the age of 7 years and was moderately to severely mentally delayed.

The diagnosis is made by organic acid analysis in urine revealing increased fumaric acid and increases of one or more of the Krebs cycle intermediates, such as succinic, α-ketoglutaric acid, citric, and malic acid. Metabolic acidosis can be absent. The diagnosis can be confirmed by measuring FH in cultured skin fibroblasts, in mononuclear blood leukocytes, skeletal muscle, or liver by monitoring the formation of fumarate from malate. Other diagnostic indicators are an increased lactate in CSF and a variable leucopenia and neutropenia.

Neuropathological changes include agenesis of the corpus callosum with communicating hydrocephalus as well as cerebral and cerebellar heterotopias. Periventricular cystes have also been described, as is seen in pyruvate carboxylase deficiency.

According to Kerrigan characteristic neuropathological abnormalities in fumarase deficiency are also polymicrogyria, open operculum, colpocephaly, and angulations of frontal horns, choroid plexus cysts, decreased white matter and a small brainstem.

Differential diagnosis should be made with other defects in Kreb's cycle, and in cases of a more static encephalopathy with mental retardation and speech delay, or developmental abnormalities of the brain, fumaric aciduria should be looked for.

Prenatal diagnosis is possible by measuring fumarase activity and/or mutational analysis in chorionic villi samples or cultured amniocytes.

Treatment and Prognosis

There is no specific treatment. In early-onset cases, prognosis is usually severe with no or little progress in psychomotor development.

K Krnjević, McGill University, Montreal, QC, Canada

Glossary

Ataxia – Ataxia (from Greek 'lack of order'), gross incoordination of muscular action, is a nonspecific manifestation of dysfunction of any part of the nervous system that regulates movements.

GABA (γ-Amino-butyric acid) – GABA and glycine are the main inhibitory neurotransmitters in the vertebrate central nervous system (CNS). GABA is an omega amino-acid, produced from glutamate by the enzyme glutamate acid decarboxylase (GAD) specifically present in inhibitory neurons. GABA acts mainly through two types of receptors: $GABA_A$ and $GABA_B$ receptors. As ligand-gated anionic channels, permeable to chloride ions (Cl^-), $GABA_A$ receptors generate inhibitory postsynaptic potentials (IPSPs) that inhibit neurons by hyperpolarization and membrane shunting. $GABA_A$ receptors are found in all parts of the CNS. They are blocked by specific antagonists such as gabazine, bicuculline, and picrotoxin. Their activity can also be modified by ethanol and by allosteric modulators such as benzodiazepines, barbiturates, and some endogenous steroids. $GABA_A$ receptors form heteropentameric chloride channels assembled from a large family of subunits (α1–6, β1–3, γ1–3, δ, ε, π, and θ in mammalian brain). Like glycine receptors, most $GABA_A$ receptors are found at inhibitory postsynaptic sites where they are anchored by gephyrin to the cytoskeleton. By contrast, $GABA_B$ receptors have a dimeric structure with two heterologous subunits R1 and R2 and are metabotropic, being G protein-coupled to K^+ or Ca^{2+} channels: they are selectively activated by baclofen. They have a dual action: they reduce cell firing postsynaptically by opening K^+ channels; they inhibit transmitter release presynaptically (including GABA) by blocking Ca^{2+} channels.

Glycine (Gly) – Unlike GABA, glycine, the smallest amino acid, can form peptidergic bonds. Glycine is also a major inhibitory neurotransmitter in the CNS, especially in the spinal cord and brainstem. Like GABA, glycine activates Cl^- influx, causing an IPSP. Strychnine is a specific antagonist of glycine receptor. $GABA_A$ and glycine receptors are often colocalized. At low concentrations, glycine is also an essential coagonist at NMDA-type glutamatergic synapses.

Hypotonia and Spasticity – Insufficient or excessive tonic motor signals result in seriously disabling muscle weakness or overactivity, hypotonia or spasticity, respectively, which may interfere with motion, gait, and also speech.

Motoneuron (Mn) – Motoneurons are located in the ventral spinal cord and motor nuclei of the brainstem. Their axons innervate muscles. In vertebrates, all motoneurons are cholinergic: by releasing acetylcholine from their terminals, they initiate muscle excitation and contraction. Motoneurons are excited by glutamatergic and inhibited by GABAergic and/or glycinergic inputs.

Transmembrane anionic gradient and Potassium-Chloride Cotransporter (KCC) – The effect of a large increase in anionic conductance – produced by GABA or glycine – depends on the anionic electrochemical gradient, determined mainly by the cytosolic concentration of Cl^- ($[Cl^-]$). As a rule, in the mature CNS, a relatively low internal $[Cl^-]$ favors Cl^- influx: hence, GABA and glycine tend to hyperpolarize (inhibit) neurons. Internal $[Cl^-]$ homeostasis is maintained by several mechanisms, including the cation-chloride cotransporters (CCCs) and Cl^--HCO_3^- exchangers. Two dominant CCCs are especially relevant: the K^+-Cl^- cotransporter isoform 2 (KCC2), which extrudes Cl^-; and the Na^+-K^+-$2Cl^-$ cotransporter (NKCC1), which mediates Cl^- uptake. Note that in immature CNS, the

net Cl^- transport is inward, and both GABA and glycine tend to depolarize central neurons and can thus cause excitation. As HCO_3 ions also permeate these Cl^- channels (albeit less effectively), under some conditions, metabolic changes that affect tissue [HCO^-_3] can affect the inhibitory action of GABA and glycine.

Introduction

Both the initiation and the execution of movements depend on a fine balance between excitatory and inhibitory actions in the CNS: this is as true in the spinal cord, where specific neuronal networks called *central pattern generators (CPGs)* determine their execution, as in the motor cortex, basal ganglia, and cerebellum, where movements are initiated, the appropriate CPGs selected, and the overall performance continually monitored and optimized. At all levels, as the predominant inhibitory agent, GABA's role is crucial. It is not surprising that movement disorders are often caused by GABAergic dysfunction and that GABA receptors are key targets for drug design to treat various pathological conditions.

Motor Reflexes and Locomotion

Underlying most movements are spinal reflexes. Albeit regulated or initiated by supraspinal structures (**Figure 1**), movement patterns are generated in the spinal cord by the CPGs. As inhibitory neurotransmitters, GABA and glycine play a crucial role in the organization of CPGs and in movement synchronization. Pharmacological block of GABA or glycine receptors soon leads to an uncontrolled motor activity, such as epileptiform seizures.

As shown in **Figure 2**, some basic CPGs are propriospinal reflexes:

- In **Figure 2(a)**, groups of neurons with antagonistic motor functions (ex: flexion and extension) are *reciprocally inhibited* via GABAergic and/or glycinergic inhibitory Ia interneurons monosynaptically activated by low-threshold (Ia) afferents from muscle. Hence, antagonist muscles relax during the contraction of agonist muscles.
- *The flexion (withdrawal* or *nociceptive) reflex* (**Figure 2(b)**) quickly removes limb from a painful stimulus by contracting the appropriate muscles (usually flexors) and relaxing their antagonists.
- *The crossed-extension reflex* (**Figure 2(c)**): the contraction of flexor muscles on one side of the body is accompanied by the contraction of the contralateral extensors, which hold the body upright. The relevant CPG is also involved in gait.

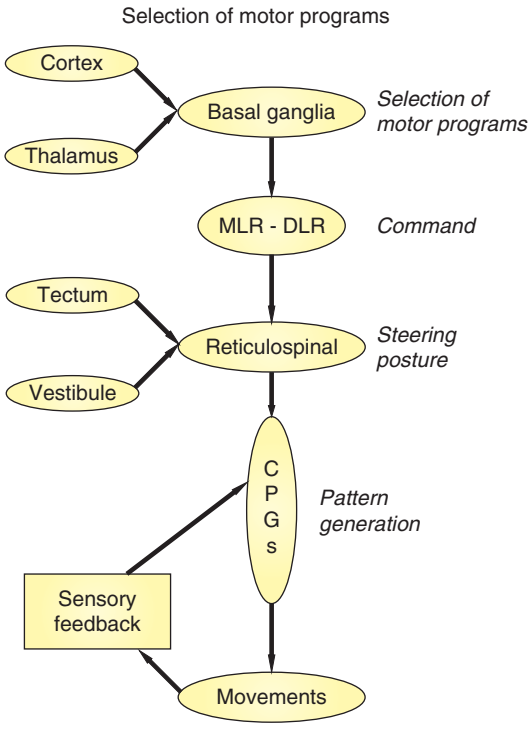

Figure 1 Supraspinal and spinal systems involved in the control of locomotion. Motor program is selected in basal ganglia which receive inputs from cerebral cortex and thalamus. At rest, basal ganglia inhibit command centers in mesopontine and diencephalic locomotor areas (MLR and DLR). Locomotion is initiated by controlled disinhibition which allows reticulospinal (RS) neurons to activate the spinal central pattern generator (CPG) for locomotion. Tectal (visual) and vestibular inputs to brainstem further control both steering and posture. In addition, spinal CPG network is modulated by local sensory feedback. Reproduced from **Figure 1** in Grillner S, Wallen P, Saitoh K, Kozlov A, and Robertson B (2008) Neural bases of goal-directed locomotion in vertebrates – An overview. *Brain Research Reviews* 57: 2–12, with permission from Elsevier.

- *Recurrent inhibition* by *Renshaw cells* auto-regulates firing of α-motoneurons (**Figure 2(d)**). These cells release both GABA and glycine. The excitation of Renshaw cells by specific sensory inputs, which reduces motoneuronal activity, is also important in gait.

Of clinical interest is that all inhibitory interneurons are targeted by tetanus toxin. From contaminated wounds, toxin travels to the spinal cord where it suppresses the release of GABA and glycine: the resulting motoneuronal hyperactivity leads to intense spasms (*tetanus*).

Complex patterns of motor activity, including locomotion, have been studied much in 'simpler' animals.

GABA and Animal Models of Locomotion

Nematodes (Caenorhabditis Elegans)

Although nematodes and vertebrates diverged >800 Mya, many proteins governing exocytosis and neurotransmitter functions remain conserved in vertebrate nervous

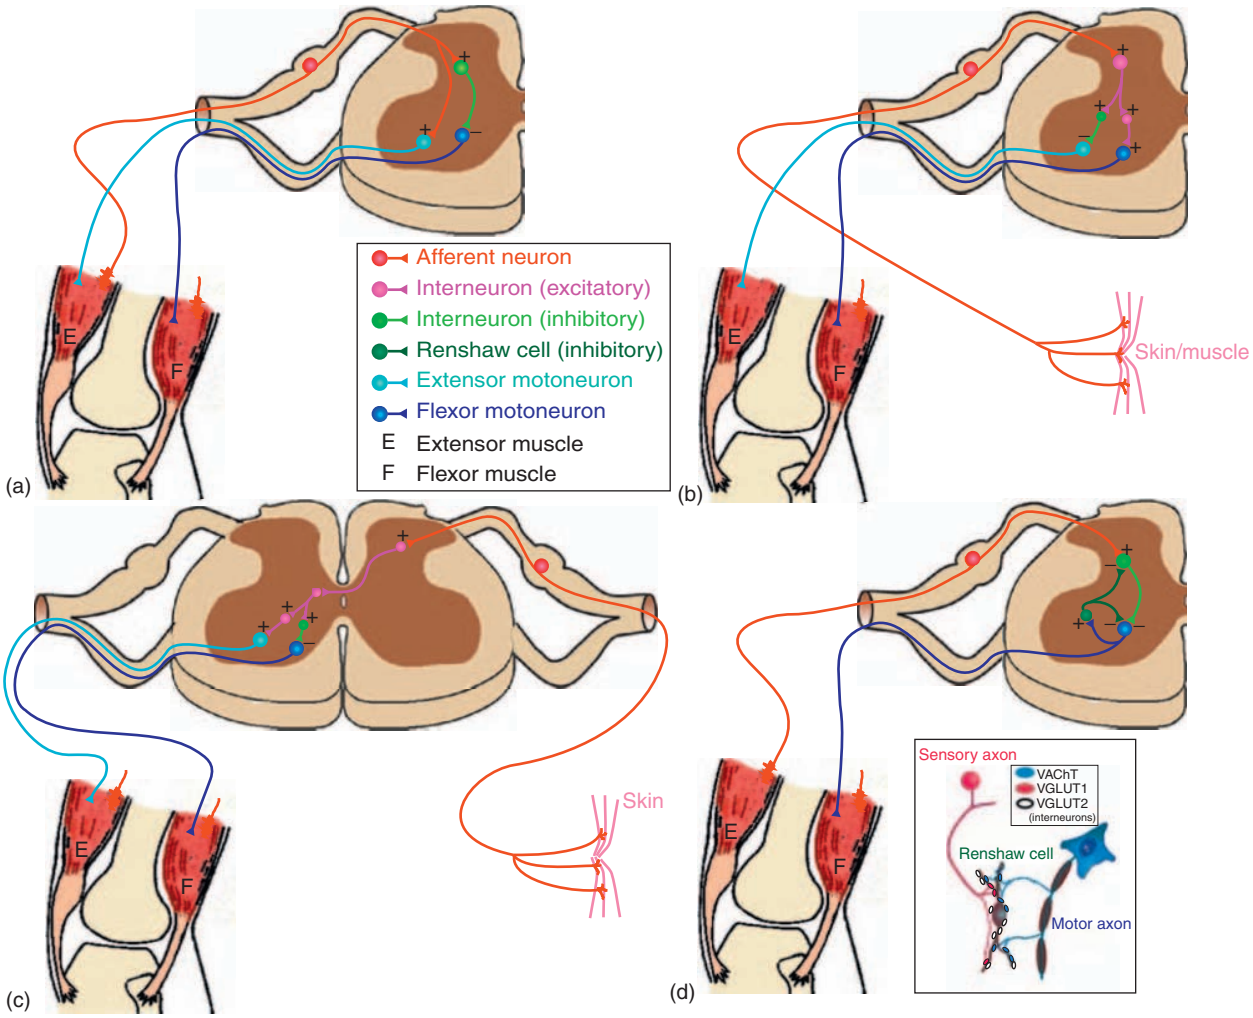

Figure 2 GABA and spinal reflexes. (a) Tendon jerk and reciprocal inhibition. The tendon jerk (myotatic reflex) is the simplest reflex and also the most rapid because it involves only two neurons (monosynaptic connection). Thus, a brief tap to the tendon of quadriceps (knee extensor) muscle excites primary muscle spindle ending of Ia-afferent axon which excites homonymous motoneuron by a glutamatergic synaptic connection. The cholinergic motor axon innervates the muscle from which the group Ia afferent fiber originated: the homonymous muscle thus contracts. The knee extension is facilitated by relaxation of knee flexors, mediated by Ia-afferent collateral excitation of Ia interneurons that inhibit the antagonist flexor motoneurons by releasing mostly glycine but also GABA. (b) Flexion reflex. This protective reflex withdraws limb from noxious stimulation. Strong excitation of peripheral sensory endings (typically in the skin) activates parallel excitatory and inhibitory polysynaptic pathways initiating contraction of the flexor muscles and relaxation of the antagonist extensors. (c) Crossed extension reflex. This 'mirror' reflex accompanies the flexion reflex by causing contraction of contralateral muscles. Operating in alternation from side to side, it is a part of the mechanism of locomotion; and, as an important component of nociceptive reflexes, contralateral extension helps to preserve the upright posture. (d) Recurrent inhibition. Renshaw inhibitory neurons are directly activated by intraspinal motor axon collaterals which release ACh. They are also excited by glutamatergic sensory axons; because these terminals accumulate glutamate in their presynaptic vesicles, they display the vesicular glutamate transporter type-1 (VGluT1). Various glutamatergic interneurons also excite Renshaw cells, but their terminals can be identified by a different vesicular glutamate transporter (VGluT2). Renshaw cells inhibit motoneurons, inhibitory Ia interneurons and even other Renshaw cells. Overall, Renshaw cells down-regulate motoneuronal activity. Framed scheme reproduced with permission from **Figure 2** Alvarez FJ and Fyffe RE (2007) The continuing case for the Renshaw cell. *The Journal of Physiology* 584: 31–45, with permission.

systems. In nematodes, as in crustacea, GABAergic inhibition relaxes body muscles during locomotion (**Figure 3(a)**). However, GABA causes enteric muscles to contract during defecation. Thus in nematodes, GABA inhibits or excites different muscles. Studies of GABA functions in worms greatly advanced genetic screening and the identification of the GABA biosynthetic enzyme, plasma membrane and vesicular transporters, inhibitory and excitatory receptors, and a transcription factor required for the differentiation of GABAergic cells (**Figure 3(b)**).

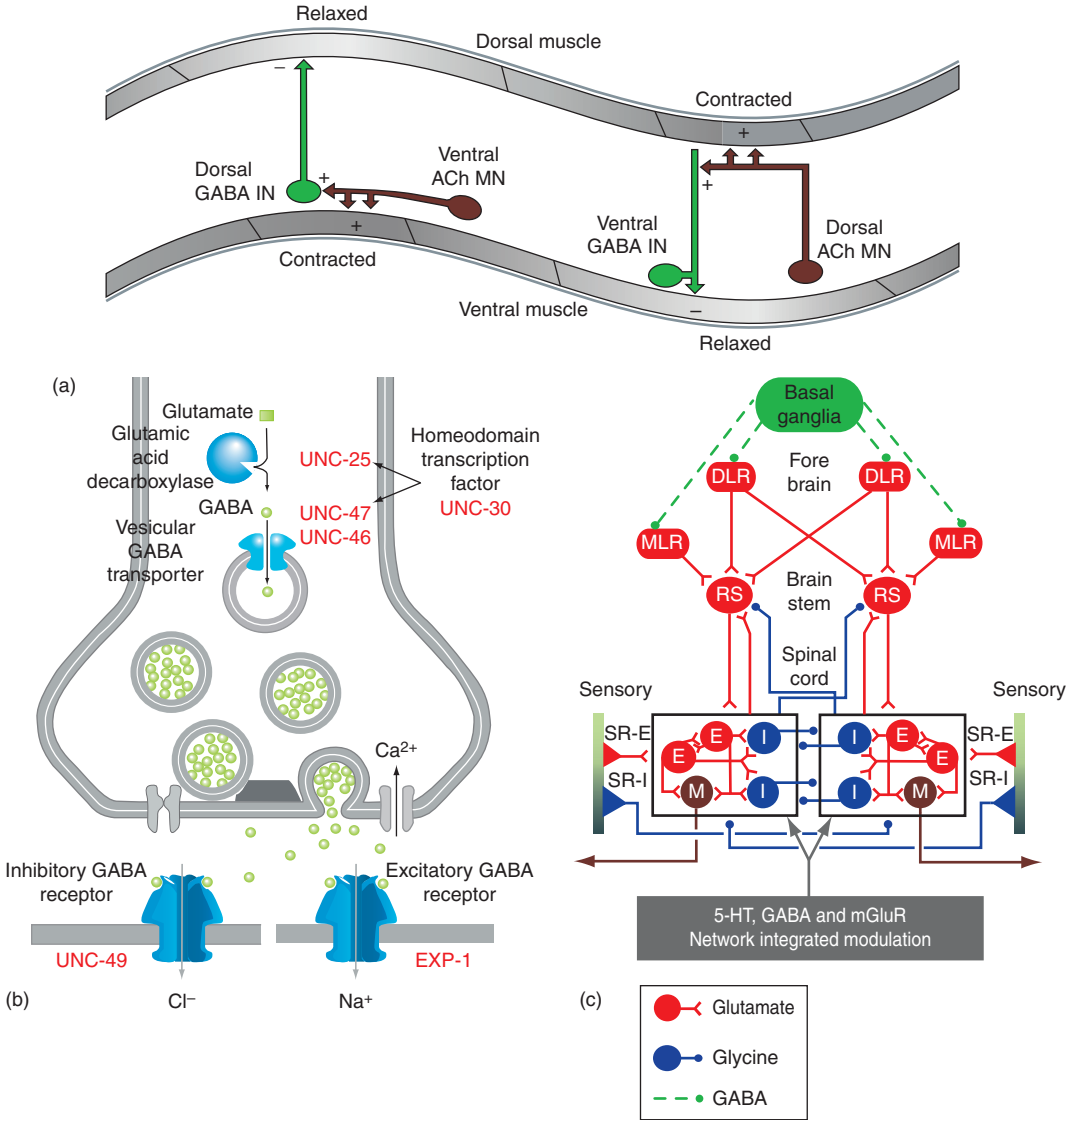

Figure 3 GABA in some 'simpler' motor systems. (a) *C. elegans* locomotor network. Neuronal cell bodies in ventral cord form synapses on dorsal and ventral body wall muscles. Cholinergic motor neurons (ACh MN in brown) send inputs to ventral and dorsal muscles, as well as to GABA interneurons (GABA IN in green). Release of ACh leads to contraction of muscle on one side and GABA release and relaxation of opposite muscle, causing body to bend. Coordinated waves of excitation and inhibition generate locomotion. Reproduced from **Figure 2** in Schuske K, Beg AA, and Jorgensen EM (2004) The GABA nervous system in *C. elegans*. *Trends in Neurosciences* 27: 407–414, with permission. (b) Genes and proteins involved in the *C. elegans* GABAergic synapses. In presynaptic terminal, GABA is synthesized from glutamate by glutamic acid decarboxylase (GAD), which is encoded by the unc-25 gene. GABA is then transported into synaptic vesicles by the vesicular GABA transporter (VGAT), encoded by the unc-47 gene. UNC-46 probably modulates vesicular GABA loading. The UNC-30 transcription factor is required for UNC-25 and UNC-47 expression in GABA neurons. Reproduced from **Figure 4** in Schuske K, Beg AA, and Jorgensen EM (2004) The GABA nervous system in *C. elegans*. *Trends in Neurosciences* 27: 407–414, with permission. After release, by acting on postsynaptic $GABA_A$-type UNC-49 receptor, GABA promotes hyperpolarization by Cl^- influx, thus causing muscles to relax. In the gut, GABA release from another type of motor neuron activates novel excitatory EXP-1 GABA receptors; Na^+ influx-mediated depolarization causes contraction of the enteric muscles. Reproduced from **Figure 4** in Schuske K, Beg AA, and Jorgensen EM (2004) The GABA nervous system in *C. elegans*. *Trends in Neurosciences* 27: 407–414, with permission. (c) Lamprey locomotor network. Schematic representation of forebrain, brainstem, and spinal neural circuitry that generates locomotor activity. Dashed lines from GABAergic basal ganglia illustrate indirect connections. All symbols represent cell populations. The reticulospinal (RS) projection and excitatory spinal interneurons (E) are all glutamatergic. Axons of spinal glycinergic inhibitory interneurons (I) cross the midline to inhibit contralateral interneurons and motoneurons (M). The stretch receptor neurons either excitate (SR-E) ipsilateral spinal neurons, or inhibit (SR-I) contralateral neurons. RS neurons are excited by signals from the diencephalic and mesopontine locomotor regions (DLR and MLR, respectively), which are under GABAergic control from the basal ganglia and receive visual and olfactory inputs. Activation of metabotropic receptors (5-HT, $GABA_B$ and mGluR) is also an integral part of locomotion. Reproduced from **Figure 6** in Grillner S, Wallen P, Saitoh K, Kozlov A, and Robertson B (2008) Neural bases of goal-directed locomotion in vertebrates – An overview. Brain Research Reviews 57: 2–12, with permission.

Cyclostomes (Lamprey)

The CNS of this primitive vertebrate offers many advantages for research: it can be studied in vitro, for several days, without the need of dissection. Overall, the motor control system is very much as in higher vertebrates (**Figure 3**(**c**)). Under cortical and thalamic influence, motor programs are selected in basal ganglia and then transmitted via brainstem and reticulospinal neurons to the spinal cord. The core of the spinal locomotor network consists of ipsilateral glutamatergic neurons and glycinergic neurons projecting contralaterally. This spinal network can generate autonomous motor activity driven by coordinated patterns of firing. Such CPGs are triggered by the descending glutamatergic reticulospinal axons. The crossed glycinergic axons are indispensable for burst generation, alternating between the two sides, and thus for correct locomotion. By contrast with mammals, in the lamprey's spinal network, only glycinergic neurons play a major role.

GABA and Transgenic Mice

The effects of targeted deletion of the gene encoding $GABA_A$ receptor α subunits has been studied, for example, in the cerebellum of $\alpha^{-/-}$ mice. Recently, knock-in mice have much advanced our understanding of the function of different $GABA_A$ receptor subtypes. In transgenics, with a point mutation in the gene encoding $GABA_A$ receptor α subunits, the corresponding receptor was still sensitive to GABA but not to benzodiazepines. Combining increasing doses of diazepam with behavioral tests revealed the physiological role of the knocked-in α subunit (insensitive to benzodiazepines). Such differential studies have clarified the respective functions of different benzodiazepine-sensitive α subunits in sedation, motor impairment, myorelaxation, anxiety, and pain. Behavioral tests clearly demonstrated that the $\alpha 1$ subunit mediates sedation, but other α subunits (**Figure 4**) may be involved in myorelaxation or motor impairment.

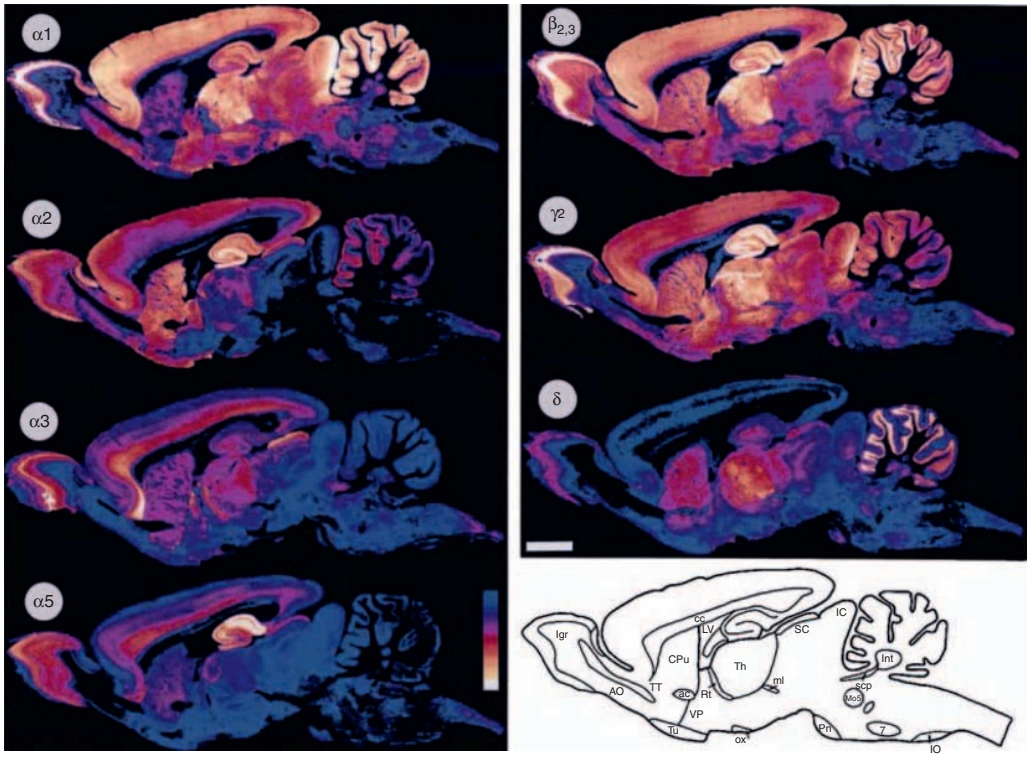

Figure 4 Distribution of various $GABA_A$ subunits in the rat brain: α-benzodiazepine-sensitive subunits, $\beta 2$–3, $\gamma 2$, and δ subunits. Color-coded images of regional variations in immunohistochemical staining of seven $GABA_A$-receptor subunits. Parasagittal sections of adult rat brain, processed for immunoperoxidase staining with subunit-specific antibodies, were digitized by high-resolution computer-based image analysis system. For each subunit, intensity of pixels was color-coded by a normalized scale (strongest signals in white and background in dark blue). Note minimal signal in white matter: regions rich in fiber bundles (e.g., brainstem reticular formation) are only lightly stained for each subunit. Cytoarchitectonic landmarks are indicated in the schematic drawing. Scale bar = 2 mm. Igr, internal granular layer of olfactory bulb; AO, anterior olfactory nucleus; TT, tenia tecta; CPu, caudate putamen (striatum); ac, anterior commissure; Tu, olfactory tubercle; cc, central canal; LV, lateral ventricle; VP, ventral posterior thalamic nucleus; Rt, reticular thalamic nucleus; Th, Thalamus; ox, optic chiasm; ml, medial lemniscus; SC, superior colliculus; IC, inferior colliculus, Pn, pontine nuclei; Mo5, motor trigeminal nucleus; scp, superior cerebellar peduncle; Int, intercalated cerebellar nucleus; 7, facial nucleus; 10, dorsal motor nucleus of vagus. GABA in Basal Ganglia and Associated Neurodegenerative Diseases

The basal ganglia (or *basal nuclei*), the major components of the 'reptilian brain,' are situated deep in the forebrain (**Figure 5**). They consist of the *striatum*, which includes the *putamen* and the *caudate nucleus*; the *external globus pallidus (GPe)*, the *internal globus pallidus (GPi)*, the *caudal subthalamic nucleus (STN)*, and *the substantia nigra pars compacta (SNc) pars reticulata (SNr) pars lateralis (SNl)*. The basal ganglia are involved in cognitive functions such as learning, and especially in motor control. The main input is from the *cerebral cortex* to the *striatum*. The striatum is regulated by dopaminergic input from the *SNc* acting on D1 and D2 types of dopamine receptors. *The basal ganglia* operate through two pathways: one excitatory (direct pathway, on left in **Figure 5**) and one inhibitory (indirect pathway, on right in **Figure 5**). Working together, they process corticofugal information and respond with appropriate output signals. From the main output nuclei, *SNr* and *GPi*, signals are sent to the *ventral nuclei of the thalamus*, and from there back to *motor cortex*. By disinhibiting cortical motor neurons, the excitatory pathway initiates a movement that is modulated by the inhibitory pathway. In this system, GABAergic neurons are crucial for the maintenance of a good equilibrium between excitation and inhibition. In basal ganglia disorders, this equilibrium is disturbed owing to degeneration of specific neuronal groups – as illustrated by some well-known neurological diseases.

Huntington's Disease

Huntington's disease, a well-characterized genetic disorder, causes defective inhibition in supraspinal structures of the motor network (**Figure 6(a)**). Early selective degeneration of striatal enkephalin-containing GABA neurons projecting to GPe diminishes the moderating striatal influence on motor cortex mediated via the indirect pathway and thalamus. In spite of compensatory upregulation of GPe postsynaptic $GABA_A$ receptors,

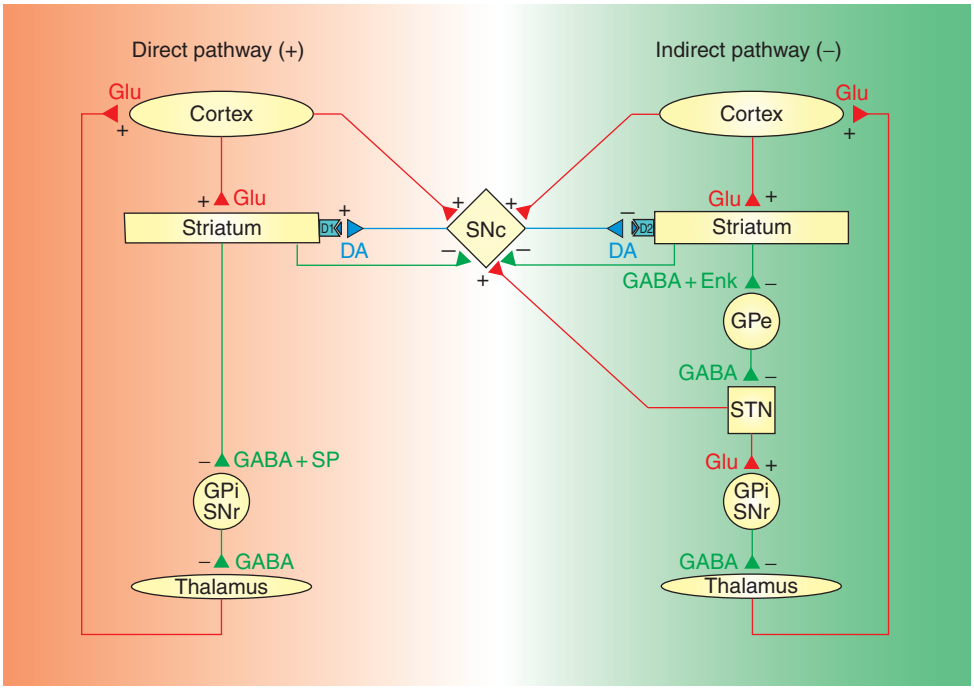

Figure 5 Internal architecture of mammalian basal ganglia. In the two main pathways, excitatory glutamatergic connections are in red, inhibitory GABAergic ones in green. The major excitatory projections to striatal neurons come from the motor and prefrontal cortex (prefrontal insular cortex, cingulate sensory motor area, supplementary motor and premotor areas). The direct pathway (at left) relays two successive inhibitions (to GPi–SNr and then to thalamus) that make its overall output to thalamus excitatory (by disinhibition). The indirect pathway (at right) includes three inhibitory relays that make its overall output to thalamus inhibitory. Note that striatal inhibitory neurons in the direct pathway contain substance P (SP) as well as GABA, whereas enkephalin (ENK) is present in the striatal GABAergic neurons of the indirect pathway. These different peptides may modulate the postsynaptic inhibitory action of GABA. The two types of striatal neurons also express different dopamine (DA) receptors (D1 for the direct pathway and D2 for the indirect one). Because D1 receptors are excitatory and D2 receptors inhibitory, DA from the SNc tends to activate the direct pathway and inhibit the indirect pathway, thus enhancing signals to the thalamus–which in turn activates the motor cortex. Note that SNc is also activated by axons from the cortex and the STN, and inhibited by negative feedback from striatal neurons. Glu, Glutamate; D1 and D2, dopaminergic receptors D1 and D2; GPi and GPe, internal and external globus pallidus; STN, subthalamic nucleus; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulate.

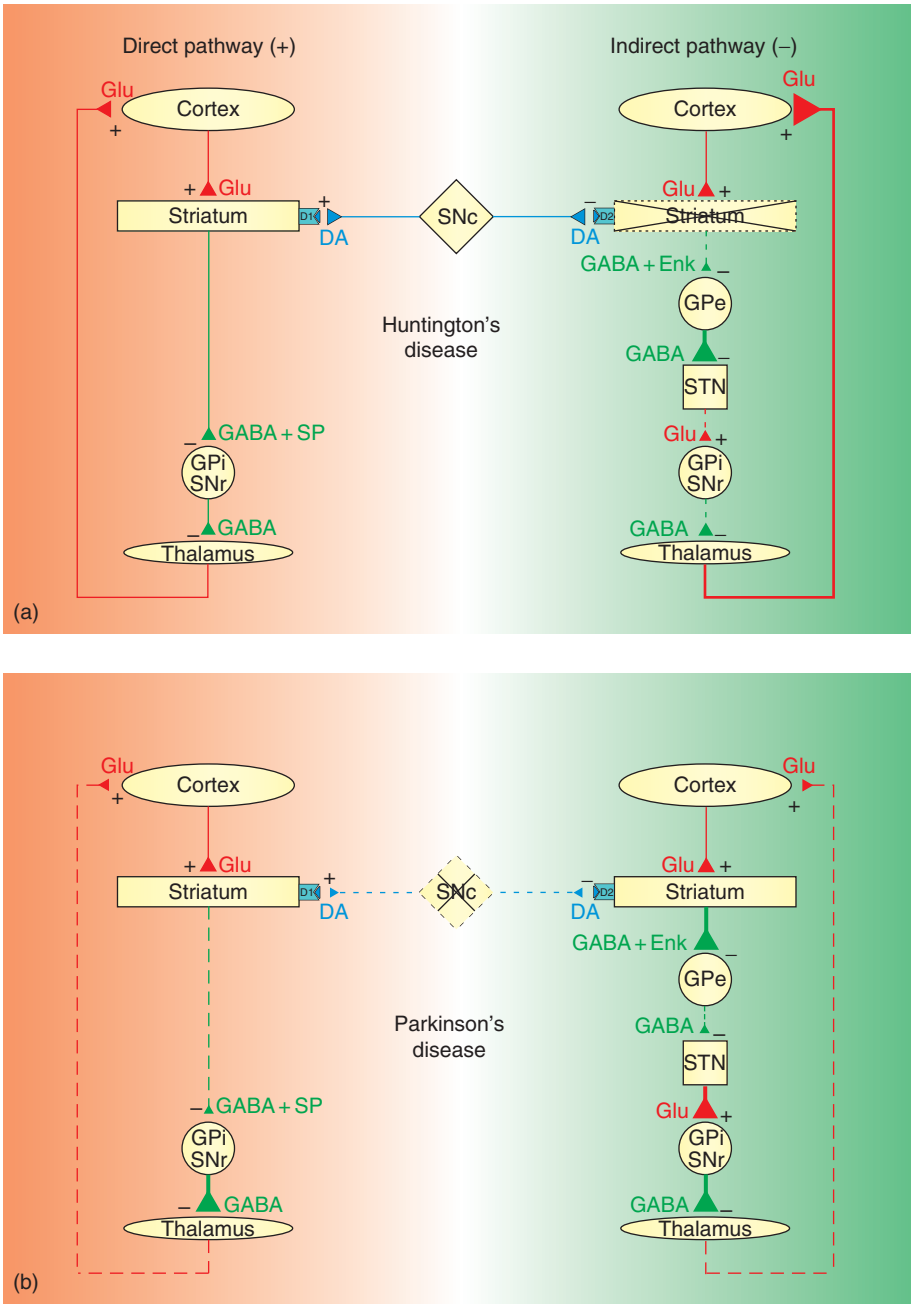

Figure 6 Involvement of GABAergic transmission in Huntington's and Parkinson's diseases. (a) Huntington's disease is characterized by selective degeneration of striatal GABAergic neurons which contain enkephalin and are inhibited by SNc via D2 receptors. Consequently the inhibition of thalamus by the indirect pathway is much weakened, resulting in over-excitation of cortical neurons involved in motor control. (b) In Parkinson's disease, the dopaminergic substantia nigra pars compacta (SNc) degenerates, with opposite consequences for the direct and indirect pathways: reduced dopaminergic inhibition of striatal neurons of the indirect pathway and reduced excitation of striatal neurons of the direct pathway. Overall, diminished activation of thalamus has a depressant effect on cortical motor neurons, making movement initiation more difficult. Abbreviations as in **Figure 5**.

deregulated thalamic activity overexcites cortical motor areas, leading to characteristic motor symptoms. In Sydenham's chorea – a more benign condition, seen most often in children as a temporary after-effect of infections such as rheumatic fever – Valproate has proved useful for the treatment of choreic manifestations.

Parkinson's Disease

The selective degeneration of dopaminergic neurons in pars compacta of *substantia nigra* (**Figure 6(b)**) leads to tremor and increasing rigidity, at later stages progressing to a drastic reduction (bradykinesia) or complete absence

of movements (akinesia). Albeit not directly involved in the primary neuronal degeneration, GABAergic neurons are essential components of the neural circuits that generate the typical movement disorders. In healthy individuals, by opposite actions on striatal neurons of the direct and indirect pathways, the nigrostriatal projections facilitate cortical initiation of movements. When this dopaminergic track degenerates in Parkinson patients, the direct pathway, which is excitatory, receives less D1 receptor-mediated stimulation, whereas the inhibitory indirect pathway is less inhibited via D2 receptors. As a result of the stronger GABAergic action, the overinhibited thalamus no longer activates motor cortical neurons. Consequently, the generation of movements is seriously impaired.

The most effective treatment of Parkinson disease is pharmacological: the loss of dopamine production is compensated for by the administration of the dopamine precursor L-dopa and dopaminergic agonists and by the inhibitors of dopamine breakdown. When drug therapy becomes less effective, Parkinsonism can be alleviated surgically by direct thalamotomy and pallidotomy. More recently, deep brain stimulation, by an electrode implanted in *the thalamus, the subthalamic nuclei* or *the GPi,* has proved quite effective. The electrode for deep brain stimulation is connected to a pacemaker-like electrical stimulator, implanted under the skin. Unlike lesional surgery, this approach minimally damages the brain; the stimulation can even be automatic, the deep electrode applying suitable stimulation whenever it senses aberrant neuronal activity.

Tourette Syndrome

Like Huntington's and Parkinson's diseases, Tourette syndrome is caused by dysfunction of the thalamus, basal ganglia, and frontal cortex. It is an inherited neuropsychiatric and movement disorder, associated with uncontrolled speech and motor tics. Tourette syndrome is probably a multigenic disease. Underlying mechanisms enhance dopaminergic function. Through multiple connections with the striatal pathways, dopaminergic hyperactivity could lead to overall circuit *disinhibition.*

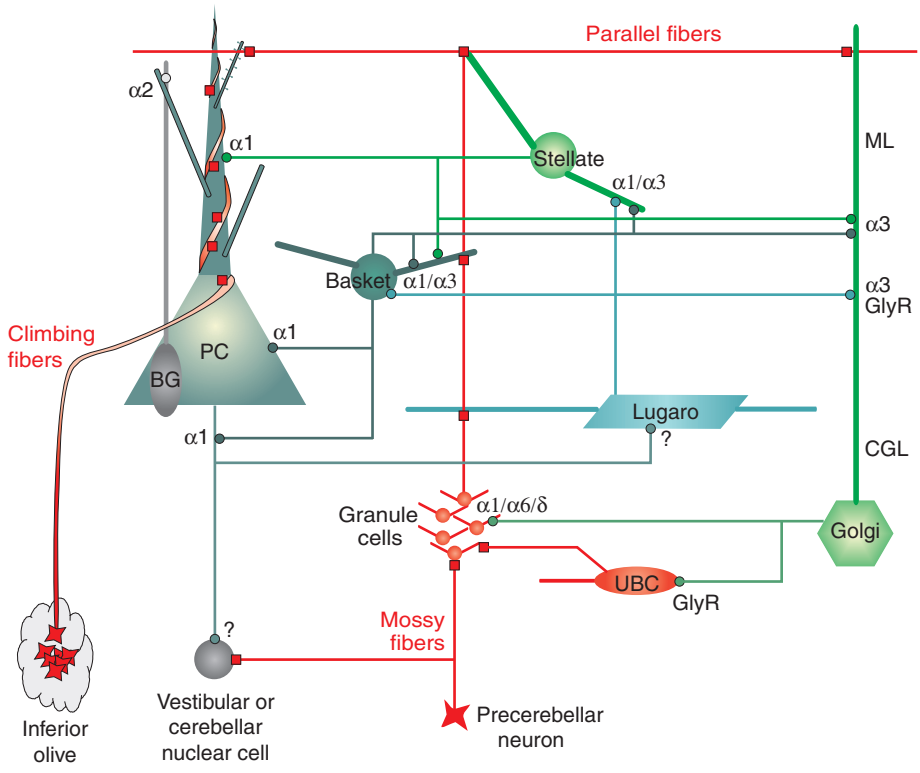

Figure 7 GABAergic networks of the cerebellar cortex. Excitatory neurons are red; inhibitory ones in different types of green. Thick lines are dendrites and thin lines axons. At inhibitory synapses (green circles) the main postsynaptic $GABA_A$ receptor ($GABA_AR$) subtype(s) or glycine receptors (GlyR) are indicated. Glutamatergic synapses are denoted by red squares. Note that Lugaro cells inhibit all cell types in molecular layer except Purkinje cells (PC). In turn, their only inhibitory input comes from PCs; the subtype(s) of GABARs on Lugaro cells is not known. Basket/stellate cells express both α1- and α3-$GABA_ARs$. Bergman glia (BG) express an unusual $GABA_AR$ subtype, containing the α2 and γ1 subunit, which is enriched at sites of contact with PC. PC, Purkinje cell; BG, Bergman Glial Cell; GCL, granule cell layer; ML, molecular layer; UBC, unipolar brush cell. Adapted from **Figure 1** in Fritschy JM and Panzanelli P (2006) Molecular and synaptic organization of $GABA_ARs$ in the cerebellum: Effects of targeted subunit gene deletions. *Cerebellum* 5: 275–285, with permission.

GABA and Cerebellar Disorders

Through reciprocal links to both motor cortex and spinal cord, the cerebellum exerts an important control over patterns of motor signals initiated in the cortex and their spinal execution. As in the basal ganglia, $GABA_A$ receptor-mediated inhibition is predominant in the internal organization and the output of the cerebellum (**Figure 7**). Hence, many symptoms of cerebellar ataxia arise from GABAergic deficits. For example, *the stiff-person syndrome*, associated with cerebellar ataxia, can result from an autoimmune disease targeting GAD, the enzyme necessary for GABA synthesis. In this kind of progressive cerebellar ataxia, a high anti-GAD antibody titer in the cerebrospinal fluid (CSF) is an early indication of decreased GABAergic transmission and deregulation of the output signals of the cerebellum. In the same vein, deficiency of a GABA transporter (GAT1) causes tremor, ataxia, and increased GABA-induced tonic conductance in cerebellar neurons. Another cerebellar pathology, *Angelman's syndrome*, is characterized by mental retardation and motor symptoms, including ataxia, as well as a genetic abnormality of the maternal chromosome 15q11–13. This gene encodes the β3 $GABA_A$ receptor subunit: albeit important constituents of $GABA_A$ receptors, β subunits, unlike α subunits, have no role in Cl^- conductance.

In the internal network of the cerebellum, $GABA_A$ receptors are differentially segregated as a function of cell types and synaptic circuits (**Figure 7**). Compared with the strong effects of acute pharmacological blockage or stimulation of $GABA_A$ receptors, some mutants with profound loss of cerebellar $GABA_A$ receptors paradoxically have only minor impairments in motor function, presumably owing to compensatory changes during development.

Spasticity

Painful muscle spasms are a feature of a variety of neurological disorders, notably multiple sclerosis and spinal injury or degenerative changes (as in amyotrophic lateral sclerosis). Such spasms, caused by spinal hyperreflexia, can be prevented by the $GABA_B$ selective agonist Baclofen; as a lipophilic agent (unlike GABA), Baclofen can be given orally, or most effectively, intrathecally.

Gait Disturbances in Parkinsonism

N Giladi, Tel-Aviv University, Tel-Aviv, Israel
A Nieuwboer, Katholieke Universiteit Leuven, Leuven, Belgium

Glossary

Cueing – Providing external stimuli as a movement target or reference to initiate or facilitate walking.
Fall – An event that results in a person coming to rest unintentionally on the ground or other lower level and not as the result of a major intrinsic event or overwhelming hazard.
Freezing of gait (FOG) – An episodic inability to generate effective stepping at the onset of or during ongoing walking and turning.
Gait – Alternating steps of left and right lower limbs, that leads to forward progression while being in an upright position.

Introduction

Parkinsonian gait is classified as a hypokinetic, rigid type of gait disorder within the wider spectrum of neurological gait disorders (**Table 1**). The underlying mechanisms responsible for gait disturbance in Parkinson's disease (PD) are heterogeneous and complex. Gait is affected by muscle rigidity, hypokinesia, and bradykinesia. Several additional or underlying factors influence gait disturbance, such as: decreased force generation, dysrhythmicity, left/right dyssynchrony, abnormal scaling of step size, abnormal preparation and execution of motor set, as well as frontal dysexecutive syndrome. In addition, the ability to initiate and maintain locomotion is heavily dependent on postural reflexes, which are frequently abnormal in PD. The contribution of each dysfunction to the clinically observed 'parkinsonian gait' differs from one patient to another and in the same individual at different times of the day ('On'–'Off') or stage of the disease.

The Evolution of Gait Disturbance

Clinically significant gait disturbance is rare at the time of diagnosis, but more common among patients with motor symptoms onset in older age. If important gait disturbance or postural instability (early falls) are the presenting symptoms or early problems, atypical parkinsonism or Parkinsonism-plus syndrome should be suspected. The main differential diagnosis in such early fallers is: progressive supranuclear palsy (PSP), multiple-system atrophy (MSA), normal-pressure hydrocephalus (NPH), higher level gait disorder (HLGD), or vascular parkinsonism, while PD is less likely to be the final diagnosis. As PD progresses, gait disturbances are very common and constitute 'the leading edge of disability.' Eventually, most patients will experience gait disturbances, dependency, and significant fall risk (Hoehn & Yahr stages 3–5). Loss of independent walking may lead to partial use of a wheelchair, but some limited ability to walk will nearly always remain. In the advanced stages of parkinsonism, wheelchair use may be the last resort to avoid falls and all their devastating consequences.

Since the introduction of levodopa, the relationship between PD progression and deterioration of gait has become more complex. Because of recent therapeutic advances, patients can often walk in the 'On' state, even in the advanced stages of the disease, whereas akinesia can be seen throughout the course of the disease as part of the 'Off' state. Furthermore, the beneficial effects of levodopa treatment have created new types of gait disturbances, such as choreic or dystonic (dyskinetic) gait and 'On'-freezing. Moreover, levodopa therapy and functional neurosurgery have increased the PD patient's life expectancy and years of mobility. Consequently, disturbed postural reflexes, orthostatic hypotension, severely distorted posture, as well as cognitive disturbances have become major contributory factors to gait disturbance in the advanced stages of PD.

Parkinsonian Gait: Special Features

Parkinsonian gait is slow, with reduced stride length, decreased cadence (steps per minute), and an increased proportion of the gait cycle spent in the double limb support phase of stance. Decreased arm swing can also be considered as a hypokinetic and bradykinetic gait feature, partially influenced by rigidity as well. Asymmetrically decreased arm swing while walking is commonly observed by the spouse as a very early or even as a presenting motor symptom of parkinsonism.

Probably, the most fundamental gait disturbance indicative of underlying basal ganglia dysfunction is impaired stride length regulation. However, the basal ganglia regulate not only the automatic maintenance of the scale of movement (motor set) but also the running of each

Table 2 Locomotion gait disturbances in parkinsonism

Continuous	*Episodic*
• Shortened stride with increased cadence gait	• Freezing of gait
• Bradykinetic gait/ turning	– Start/turning hesitation
• Shuffling gait/ turning	– Tight quarters hesitation
• Dysequilibrium gait	– Hesitation while reaching destination
• Fear of falling gait/ turning	– Hesitation during mental over-load or stressful situations
• Dysrhythmic gait	• Festinating gait
• Dyskinetic gait	
• Stiff gait/turning	

component of the motor plan in a timely manner (internal cue production). Recent findings of higher step-to-step variability of stride duration and increased variability of leg muscle activation in PD bear evidence of this fact. Stride length is normalized by the use of visual cues or strategies that increase attention to gait performance. In contrast, tasks that compete for the individual's attention while walking (dual task distraction) decrease gait speed, increase stride-to-stride variability (dysrhythmicity) and decrease left/right swing synchronization. Normal locomotion in PD is a motor task influenced by cognition. Furthermore, the vulnerability of locomotion to dual tasking is directly correlated with the performance of executive function and attention. In summary, parkinsonian gait is primarily the result of abnormal scaling of stride length (motor set) but variable timing of dynamic stepping may also reflect the basal ganglia deficit, and rely on allocation of extra cognitive resources (**Table 2**).

Freezing of Gait

Freezing of gait (FOG) is a typical episodic gait disturbance, which may occur suddenly against the background of relatively good and fluent locomotion. Recently a clinical definition for FOG was proposed by Giladi and Nieuwboer: 'an episodic inability (lasting seconds) to generate effective stepping in the absence of any known cause other than parkinsonism or high level gait disorders. It is most commonly experienced during turning and step initiation but also when faced with spatial constraint, stress, and distraction. Focused attention and external stimuli (cues) can overcome the episode.'

Patients struggle with FOG most frequently in their home and as part of the 'Off' period, demonstrating that FOG is primarily a consequence of hypodopaminergic state. Freezing episodes are difficult to observe in the doctor's office or the gait laboratory, situations which may evoke higher levels of arousal. In contrast, FOG is negatively influenced by dysfunction of the frontal executive system, anxiety or depressed mood.

The severity of freezing seems not correlated with other cardinal features of parkinsonism, supporting its unique and independent pathophysiology. FOG can be classified according to the response to levodopa or apomorphine ('On' vs. 'Off' freezing) or based on the motor state during the episode itself. There are three classical motor response strategies that can be observed during a freezing episode: (1) no movement-akinesia (the patient is not making any observed effort to overcome the block), (2) trembling in place (rapid, 3–6 Hz, synchronized movement of both legs as part of an attempt to overcome the block but no significant movement forward is seen), and (3) shuffling forward (the patient makes an effort to overcome the block and is partially successful). Stepping is abnormally small and rapid and no effective step is taken.

Patterns of leg muscle activation in relation to freezing sometimes show reciprocal and sometimes simultaneous EMG activity in flexors and extensors. EMG activity during the steps preceding freezing indicate a premature timing in the lower limb muscles with overall preservation of reciprocity, pointing to a disturbance of central gait cycle timing as a trigger for FOG. Recent work has associated the development of FOG also with abnormal synchronization between left and right leg stepping as well as with the deterioration in executive functions.

The risk of developing freezing in PD is increased with disease progression, but is generally more common among patients who have abnormal gait and postural instability with only little tremor. FOG also often occurs in other parkinsonian syndromes. It is frequent and disabling in PSP, multiple-system atrophy parkinsonian type (MSA-P), vascular parkinsonism and HLGD.

As PD progresses, FOG becomes a major cause of disability and falls with subsequent loss of independency. FOG has been shown to have a major effect on quality of life, over and above its effect on gait and mobility. Therefore, it deserves special attention and aggressive treatment.

Festinating Gait

Festinating gait is another episodic disturbance of locomotion in parkinsonism. It may be part of the onset or termination of freezing, as described above, but can be observed by itself. Its frequency is undetermined, but it is known to be more common in older patients and in those with more advanced PD. It consists of rapid small steps taken in an attempt to keep the center of gravity (COG) above the feet while the trunk leans forward involuntarily and shifts the COG forward. Festination and freezing are related phenomena and may also share a common etiology.

Assessment of Gait

The importance of gait deficits in PD warrants a thorough gait assessment as part of the basic clinical evaluation. Two timed tests of gait can be used: (1) the 10-m walk test and (2) the timed 'up-and-go' (TUG) test. In the 10-m walk test the patient is asked to perform straight-line walking, enabling the measurement of gait speed, step length, and step frequency. For the TUG, the patient is asked to get up from a chair, walk for 3 m in a comfortable speed, turn around, walk back to the chair and return to a sitting position. These are two informative bed side tests, providing an opportunity to evaluate general motor function, comprehension as well as the quality of gait initiation, locomotion, turning, and gait termination. In both tests the patient should be asked to walk at whatever speed feels most comfortable. Such an examination should be performed in an open space free of obstacles to allow for the patient's best performance. If the patient is complaining about freezing, the examiner should try to provoke freezing episodes by testing the patient 'Off' drugs and asking to perform turns, walk through narrow spaces, and step up and down stairs to differentiate between freezing (locomotion gait disturbance only) and akinesia (which also effects stairs climbing in addition to walking). Also, for assessment of gait in general it is of special importance to distinguish between performance in 'On' or 'Off' state. Various instrumental gait assessment systems allow for measuring cadence, stride length, velocity, and double limb support phase objectively. For the assessment of the dynamic aspects of gait, like stride-to-stride variation, left/right leg synchronization, the use of cues and the effect of dual tasking, locomotion should be assessed over a longer period of time (2–6 m) and over multiple steps. Ambulatory monitors are now used for quantifying walking and general mobility over 24-h period in daily life.

The clinical evaluation and quantification of FOG is difficult because of the highly variable and transitory nature of this motor disturbance. Two FOG questionnaires (FOG-Qs) have been validated; the original one which assesses FOG but also general mobility; and the New FOG-Q which includes a video to ensure uniformity, has a screening part to define freezers, assesses FOG severity and disability separately and is validated against care givers perception.

Treatment of Parkinsonian Gait

Levodopa, the most effective and commonly used antiparkinsonian drug, has significant and long-lasting effects on parkinsonian gait. Its use leads to improvements in stride length, velocity, and synchronization of movements, double-support time, and control of foot landing. The addition of external cueing to enhance motivational or arousal processes will yield further improvements in stride length. The effect of levodopa on locomotion occurs mainly through mechanisms involved in control of force and amplitude, as it has smaller effects on stride-to-stride time variation. The symptomatic benefit of levodopa is greater in younger patients, suggesting that gait disturbances in the older PD population are more profoundly related to nondopaminergic mechanisms. However, the motor complications of long-term treatment with levodopa also have to be considered. Especially dyskinesias (dystonia and chorea) have serious implications with regard to gait. These hyperkinetic complications are much more common in younger patients. Severe painful foot or leg dystonia as well as violent generalized or crural chorea/ballism, frequently aggravated by walking, can form a major problem in advanced PD patients. Patients often have to choose between an akinetic 'Off' state with freezing or an 'On' state with disabling dyskinesias.

Dopamine agonists, amantadine, monoamine oxidase type B(MAO-B) inhibitors, and C-*O*-methyltransferase (COMT) inhibitors are all known for their symptomatic benefits on almost all parkinsonian parameters, including gait disturbances. However, there have been no prospective, double blind, placebo-controlled studies

to assess the effect of any of these drugs on parkinsonian gait as the primary outcome. In addition to medication, it is generally agreed that nonpharmacologic treatment and, in particular, physiotherapy can improve parkinsonian gait disturbances.

Treatment of FOG

Freezing is considered to be among the more therapy-resistant symptoms in PD. 'Off' freezing may respond to dopaminergic treatment, whereas 'On' freezing sometimes improves by lowering the dosage of dopaminergic medications.

One of the most characteristic features of freezing is its response to cueing. Cueing may heighten attention to the motor task and can be used in addition to a variety of behavioral and attentional strategies. These strategies are of immediate help to overcome a freezing episode and because of their effectiveness, noninvasiveness and availability can be recommended. However, whether training with such strategies is also effective in reducing the occurrence of freezing episodes needs further investigation.

Levodopa and MAO-B inhibitors are the two classes of drugs which have been shown to have special effects on FOG in prospective double blind, placebo controlled studies. However, any dopaminomimetic treatment that will decrease the severity or duration of the 'Off' phase will decrease FOG. The effect of dopamine agonist drugs on FOG is not clear, but it has been suggested that they might increase its prevalence. In contrast, apomorphine injections have been reported to produce a good symptomatic effect on severe freezing episodes where other antiparkinsonian agents failed. L-Threo-3,4-dihydroxyphenylserine (DOPS) (a chemical precursor of norepinephrine) has been proposed to have a unique symptomatic effect on FOG especially in the 'Pure freezing syndrome' but further studies are needed.

Rehabilitation Treatments of Gait Disturbances

Physiotherapy for gait disorders in PD can be of benefit, especially by improving the speed of walking through a variety of training methods. Treadmill training has been shown to have symptomatic benefit on gait speed, especially after intensive practice. In addition, walking on a treadmill can be used as an external pacemaker, improving the timing variability of gait.

To overcome the typical problem of automatic maintenance of the appropriate scale and timing of gait, cues have been used for immediate gait correction and as a training method with demonstrated benefits. As stated before, external cues (temporal or spatial stimuli) as well as attentional strategies have been successful in overcoming episodic gait disturbances.

Functional Neurosurgery for Gait Disturbances

Stereotactic neurosurgery is an increasingly common approach for treating patients with advanced PD. Bilateral high-frequency, deep brain stimulation (DBS) of the globus pallidus internus (GPi) or the subthalamic nucleus (STN) have shown significant beneficial effects on parkinsonian gait. It is most effective for patients with a clear response to levodopa even if short lasting. STN stimulation improves levodopa-responsive FOG in most patients but less consistently than levodopa itself and in some cases it may aggravate gait disturbance. Preliminary data suggests that unilateral or bilateral stimulation of the pedunculopontine nucleus (PPN) in the upper brainstem can be an alternative approach for the treatment of levodopa-resistant gait and postural disturbances.

Gait Ignition Failure

J G Nutt, Oregon Health and Science University, Portland, OR, USA

Glossary

Gait pattern – The cadence, base of support, and limb and body trajectories that characterize a patient's walking pattern while starting to walk, walking in a straight line, turning, and tandem walking. Gait patterns are neurological signs that generate a differential diagnosis as no gait pattern is pathognomonic of a single disease.
Locomotor networks – The spinal and brainstem neural circuits that can generate stepping adequate for walking forward without input from the brain hemispheres.

Definition and History

Gait ignition failure was a term invented by Professor David Marsden to describe freezing of gait. The term captured the apparent impairment of engaging the lower locomotor networks of the brainstem and the spinal cord crucial for stepping that characterize freezing of gait. Gait ignition failure was first used in a paper describing higher-level gait disorders, gait patterns that could not be explained by motor, and sensory and coordination signs that are elicited by the neurological examination.

Freezing of gait is a dramatic neurological sign that has caught the attention of many clinicians who have used a variety of terms for the clinical phenomenon. It has been described with various terms that (1) describe the phenomena such as freezing, primary progressive freezing, gait ignition failure, trepidant abasia, or magnetic gait; (2) imply types of neurological dysfunction such as gait apraxia; or (3) describe pathology with which freezing is associated such as vascular parkinsonism or lower-half parkinsonism.

Freezing of gait is the most widely accepted term for describing the difficulties in initiating gait or maintaining gait. Freezing is not a perfect term for the phenomenon, as it implies no movement, while freezing of gait is often associated with the trembling of the legs. However, until we understand the origin of this neurological sign, it seems that this term should be used in preference to gait ignition failure and the other synonyms described earlier.

Gaucher's Disease

A Rosenberg and N Giladi, Tel-Aviv University, Tel-Aviv, Israel

Glossary

Gaucer's disease – The most common lysosomal storage disease.
GBA associated parkinsonism – Mutations in the GBA gene have been associated with the late development of parkinsonism.
***GBA* gene** – The gene located on chromosome 1q21 and is coding the synthesis of glucocerebrosidase.
Glucocerebrosidase (GBA) – The enzyme responsible for the degradation of the Glucocerebroside (a glycolipid component of the cell membrane) which is affected in Gaucher's disease due to mutation in the *GBA* gene.

Pathogenesis/Epidemiology

Glucocerebroside is a basic glycolipid component of the cell membrane, which is degraded by the enzyme glucocerebrosidase (GBA) to glucose and lipid, with saposin c acting as a cofactor protein in the reaction. The gene responsible for the synthesis of GBA is 7 kb in size and is sited on chromosome 1q21. More than 200 mutations have been described in the GBA gene; however, the mutations N370S (the commonest one), L444P, and 84GG are found in about 80% of mutation carriers. Among Ashkenazi Jews, the prevalence of those three mutations is even higher, reaching over 90%.

Gaucher's disease (GD) has a diverse dispersion worldwide with a carrier prevalence of 1% or about 1 out of 40 000 births in western countries. The frequency is lower in Asian countries: for example, the incidence is 1 out of 330 000 births in Japan. There are several ethnic groups with higher prevalence in the general population, among them Ashkenazi Jews who have a carrier frequency of 1 out of 15 people and an incidence of 1 out of 450–500 people. The second ethnic group with especially high frequency lives in the Norrbotten region of northern Sweden, with a higher frequency of Type 3 GD (see below) and an incidence of 1 out of 50 000 people.

Clinical Presentation

GD is a lysosomal storage disease. Because of mutations in the GBA gene, the activity of the enzyme is reduced or absent and glucocerebroside accumulates in the macrophages which constitute the Gaucher cell. The main areas where glucocerebroside accumulations are found in the senescent leukocytes and erythrocytes that are phagocytized and degraded by macrophages. Other areas where glucocerebrosides accumulate are the bone marrow, liver, spleen, lungs, and brain, all of which are classically involved in the clinical picture.

There are three forms of the clinical expression of GD:

Type 1 – nonneuronopathic
Type 2 – acute neuronopathic
Type 3 – chronic neuronopathic

All three forms are inherited in a recessive mode. There are several typical clinical features which are seen in most GD cases. Splenomegaly, hepatomegaly, anemia, thrombocytopenia, osteopenia, bone pain, and pathologic fractures can be observed in most Type 1 and in some of Types 2 and 3 cases. Neurological involvement is responsible for the clinical manifestations in Types 2 and 3.

Type 1 GD

This is the most common form of GD, with a prevalence of 1 out of 40 000 among the general Caucasian population. There is significant diversity in the age at diagnosis of patients with Type 1 GD, but two-thirds of the patients will have been diagnosed by 20 years of age. The most prevalent sign detected on clinical examination is splenomegaly, which can be an incidental finding on a medical examination in asymptomatic people or the cause of abdominal discomfort that motivates the individual to seek medical counseling. There are several symptoms associated with splenomegaly, including excessive energy expenditure and growth delay, as well as the trapping of thrombocytes in the spleen, which result in easy bruising. Hepatomegaly with different degrees of liver dysfunction is the next most common clinical presentation of GD Type 1. Another common clinical presentation is skeletal changes which can manifest as painful episodes that are the result of bone ischemia. Other skeletal changes include a lower than the average level of bone mineral density and pathological fractures or progression into avascular necrosis. The cortical thinning and widening of the medullary cavity of the metaphysis and adjacent diaphysis is a typical radiological finding of Erlenmeyer flask deformity of the distal femur. Other less common features include puberty delay, interstitial lung disease,

malignancies in the hematopoietic system (especially multiple myeloma) and a high level of angiotensin-converting enzyme (ACE) in the blood.

The natural history of GD is varies greatly, from the individual's being able to live a normal life in the milder form to death within the first decade of life in the severe form if untreated. Death is the result of complications such as severe thrombocytopenia with bleeding, severe asthenia and complications of infections due to splenectomy or from severe bone disease. With currently available treatment, Type 1 GD patients can expect to live an almost normal life with a life expectancy of 60–90 years.

Type 2 GD

The second type of GD has a very poor prognosis, with no clinical benefit of the new treatment on the disease course. The acute neuronopathic form is characterized by a rapidly progressive, early onset disease with severe neuroectodermal manifestation and death in the first few years of life. The clinical syndrome includes ichthyosis, disruption of the epidermal layers, oculomotor dysfunction, disruption of saccadic eye movements, bulbar palsy, hypertonia, rigidity, swallowing disturbance, seizures, strabismus, and eventually a failure to thrive, progressive psychomotor deterioration and death.

Type 2 GD can also be manifested in the uterus, affecting the embryo by causing nonimmune hydrops with or without ichthyosis. Pathologic examination of the brains of those embryos demonstrated extensive neuronal loss, especially in the frontal cortex, thalamus, cerebellum, the basal ganglia, and pons.

Type 3 GD

The third type of GD has a diverse course but most of the patients die in their second decade of life because of progressive neurological manifestations. The only available long-term prospective follow-up study was conducted in the Norrbotten region of Sweden: the mean life expectancy was 11 years before the advent of modern enzyme replacement therapy, but has now been extended to the third and even to the fifth decade of life.

The chronic neuronopathic form has slower rate of progression compared to the galloping form. There are two major types: the one typically reported from the Norrbotten region of Sweden has a mutation at L444P location and is associated with extensive involvement of visceral organs, oculomotor disturbance, seizures, and cognitive impairment. The second type is associated with mutation at D409H location with the development of early corneal opacities and calcifications of the aortic and mitral valves.

The Gaucher Gene and Parkinsonism

The last 10 years have witnessed an increasing interest in GD and several lines of evidence for an association between Type 1 GD and parkinsonism have recently emerged. Some GD patients manifest the disease very late in the form of parkinsonism of the akinetic-rigid type with manifestation of the first symptoms during the fifth or sixth decade of life. However, the introduction of genetic screening of patients with Parkinson's disease (PD) for mutations in the Gaucher gene has revealed cases of typical PD who were found to be homozygote or compound heterozygote for the Gaucher mutations. The relationships between GD and PD have a third potential level of association. Recent studies have demonstrated that healthy people who are heterozygotes, that is, carrying only one of the GD-related mutations, are at higher risk to develop classical PD. About 17% of Ashkenazi Jews with PD carry mutations on the GD gene, and being heterozygote for the Gaucher's mutations, significantly increases the risk of developing classical PD between the fifth and seventh decade of life. The exact mechanism that links those two diseases is still unclear but an association was observed between the presence of mutations which are known to cause more sever GD and an earlier age of PD onset as well as higher risk to develop PD among asymptomatic carriers.

Diagnosing GD

The first steps in diagnosing GD depend on the clinical history of the patient, the physical examination and the laboratory results (including cell blood count, ACE, and liver function enzyme). The appropriate imaging studies include abdominal ultrasound for evaluation of organomegaly, magnetic resonance imaging for evaluation of the involvement of the bone marrow, radiography for identification of skeletal manifestations, and diagnostic bone marrow aspiration for the demonstration of Gaucher cells. The results of a biochemical assessment of the GBA activity in peripheral leukocytes and DNA analysis for the common mutations in the Gaucher gene can strongly support the diagnosis, but both should be considered with the clinical syndrome.

Treatment

The most important therapeutic modality is enzyme replacement therapy with a recombinant GBA that replaces the production of the enzyme from the human placenta. This treatment has led to a revolution in the way patients with GD live and develop. The main disadvantage of this treatment is the high production cost which

Table 1 Gaucher Types

	Type 1 – nonneuronopathic form	*Type 2 – acute neuronopathic form*	*Type 3 – chronic neuronopathic form*	
Common mutation	*N370S*	L444P	*L444P*	*D409H*
Ethnic predilection	Ashkenazi Jews	None	Norrbottenians (Northern Sweden)	Palestinian Arabs, Japanese
Prevalence	1/40 000	1/100 000	1/50 000–100 000	Rare
Clinical manifestation	Organomegaly, easily bruising bone pain	Neuroectodermal manifestation	CNS involvement	CNS involvement
Special feature	None	None	None	Corneal opacities and calcifications of the aortic and mitral valves
CNS involvement	Parkinsonism	Oculomotor dysfunction, bulbar palsy, hypertonia, rigidity, strabismus	Oculomotor disturbance, seizures, and cognitive impairment	Oculomotor disturbance
Enzyme replacement therapy	Indicated for symptomatic patients	Not indicated	Indicated for visceral involvement	Indicated for visceral involvement
Life expectancy	60–90 years	2 years	20–40 years	Adolescence

limits its use for the symptomatic nonneuronopathic type as well as the use for patients with Type 3 GD who have severe manifestation of skeletal disease and a significantly abnormal blood count or organomegaly.

The recommended dose of the recombinant enzyme ranges between 30 and 60 unit kg^{-1}, with the first signs of improvement being seen in the laboratory results followed by decrease in the organomegaly and then improvement in skeletal disturbances. This pattern of recovery can last several years and a gradual decrease in dosages can be considered but only when there is a significant improvement in all measures.

This treatment has a disadvantage in the neuronopathic types (Types 2 and 3) because of the very low penetrance of the recombinant enzyme through the blood–brain barrier. As a result, the effect of the treatment and the damage to the CNS are inconclusive.

If enzyme replacement therapy is not effective or available, the next option is a substrate reduction therapy that involves inhibiting glucosylceramide synthase, which has a limited negative effect on glucocerebroside production and has a main influence with improvement on the blood count as well as on organomegaly.

Other treatments, which are less medically accepted include splenectomy. Due to the serious negative effects associated with this procedure, it is limited to cases of uncontrolled thrombocytopenia, severe pulmonary disease, and inferior vena cava syndrome.

Bone marrow transplants have a high mortality rate and are used sparingly for the severe neurological form before the onset of disease manifestation.

There is a wide difference in therapeutic results between each of the three forms of GD. While the acute neuronopathic form has a gloomy outcome, we can be optimistic about the final outcome of the other types as a result of the continuously improving treatment modalities.

GDNF (including Nurturin)

D M Gash and G A Gerhardt, University of Kentucky, Lexington, KY, USA
John T Slevin, Department of Veterans Affairs & UK Medical Centers, Lexington, KY, USA

Glossary

AAV2 – Adeno-associated virus serotype 2; a viral vector used to deliver genetic material into the brain by transfecting the host cells.
GDNF – Glial cell line-derived neurotrophic factor, the first discovered member of a novel family of neurotrophic factors composing a subgroup of the transforming growth factor β superfamily.
GFRα-1 – GDNF family receptor α-1, the preferred cell surface receptor for GDNF. It can also be activated by NTRN.
GFRα-2 – GDNF family receptor α-2, the preferred cell surface receptor for NTRN. It can also be activated by GDNF.
NTRN – Neurturin, a member of the GDNF family of neurotrophic factors composing a subgroup of the transforming growth factor β superfamily.
RET – A component of a cell surface receptor complex for GDNF family trophic factors. RET is a receptor tyrosine kinase activated by binding to GDNF (and other family members) in combination with GDNF family receptors like GFRα-1 and GFRα-2.

Definition and History

Glial cell line-derived neurotrophic factor (GDNF) and the related proteins neurturin (NTRN), persephin, and artemin define a novel family of neurotrophic factors composing a subgroup of the transforming growth factor β superfamily. Both GDNF and NTRN have undergone testing in clinical trials for treating Parkinson's disease and are being actively studied for possible use in treating movement disorders. The receptors for GDNF and NTRN are also promising candidates for drug therapy.

GDNF, the first member of this family, was described in 1993 by a research team working at Synergen (a Biotechnology Company in Boulder, CO) searching for trophic factors for dopamine neurons. They identified a 211 amino acid protein proGDNF, which is processed by endoproteolytic enzymes into the 134 amino acid mature trophic factor. This biologically active form of GDNF is composed of two monomers (a homodimer) that migrate in gels with an apparent molecular weight in the 33–45 kDa range. Two additional splice variants of GDNF have been identified, the biological importance of which have not been determined.

NTRN, a related protein with a 42% amino acid homology with GDNF and conserved GDNF-like molecular structural features, was discovered by an academic research team at Washington University, St Louis, in 1996, while searching for other members of the GDNF family. Human PreproNTRN is a 197 amino acid protein that is also processed by endoproteolytic enzymes into a 102 amino acid mature protein.

Unlike other members of the TGFβ superfamily, which signal through the receptor serine–threonine kinases, GDNF family ligands activate intracellular signaling cascades via receptor tyrosine kinases. The receptors of the GDNF family ligands have multiple components. They include a signaling unit, the membrane-spanning receptor tyrosine kinase (RET) and a high-affinity GDNF family receptor (GFR) ligand-binding protein. It is posited that ligand–receptor interactions begin when the dimer binds to its preferred receptor, in the case of GDNF to GFRα-1. Then, the ligand–GFRα-1 complex binds to and stimulates autophosphorylation of RET. The preferred receptor for NTRN is GFRα-2, but both GDNF and NTRN can bind to and activate the other's receptors. Evidence has emerged for another multicomponent receptor complex consisting of GFRα-1 and neural cell adhesion molecule (NCAM), that can be activated by GDNF and NTRN.

Trophic Effects

GDNF exerts both short-term (minutes to hours) and long-term effects (weeks to months) on dopamine

neurons that that have the potential to slow the progression of Parkinson's disease and promote the regeneration of injured neurons. If this therapeutic potential is realized, it would represent an important advance in Parkinson's disease treatment. Consistent results from a number of laboratories suggest that GDNF exerts at least three general trophic actions on dopamine neurons in the substantia nigra: pharmacological, restorative, and neuroprotective.

Pharmacological

GDNF can increase the phosphorylation of tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine synthesis. Increased invoked release of dopamine is also found. These actions can effectively increase neuronal levels of dopamine and increase dopamine metabolism in the nigrostriatal pathway that undergoes degeneration in Parkinson's disease and the synaptic release of dopamine in the normal, aged, and parkinsonian brain.

Restoration

A long-term effect of GDNF that can last for over a month following a single administration is to increase the number of neurons expressing the dopamine markers TH and the dopamine transporter in the substantia nigra. This suggests that one trophic action is to stimulate recovery of injured/quiescent nigral neurons. Supporting this interpretation is the consistent observation that GDNF promotes increases in dopamine neuron perikaryal size and the number of neurites. In addition, intraputamenal (IP) GDNF administration promotes restoration of dopamine axons in the nigrostriatal pathway of parkinsonian nonhuman primates and, based on increased [^{18}F] dopamine uptake in PET scans, in patients with Parkinson's disease.

Neuroprotection

Nigrostriatal administration of GDNF either shortly before or following a neurotoxic challenge (e.g., 6-hydroxydopamine, MPTP, or methamphetamine) protects dopamine neurons from injury in rodents and nonhuman primates. In part, this action appears to be related to its effects on modulating cell signaling pathways. While the pharmacological effects of NTRN on dopamine neurons are not clear, treatment with NTRN is neuroprotective and restorative for dopamine neurons in rodent and nonhuman primate models of Parkinson's disease.

GDNF and NTRN Therapy for Parkinson's Disease

Following its discovery as the first member of the GDNF family, intensive efforts by a number of research groups were focused on developing GDNF for the clinical treatment of Parkinson's disease. More recently, patent issues have dictated that the other members of the GDNF family also be considered. NTRN, like GDNF, is also a ligand for the GFRα-1 receptor. As mentioned earlier, in animal models of parkinsonism, NTRN shows neuroprotective and neurorestorative actions similar to GDNF. Because GDNF and NTRN demonstrated safe toxicological profiles (with exceptions that will be discussed later) and consistent efficacy in animal models, five clinical trials have been conducted to evaluate their safety and efficacy in treating Parkinson's disease (see **Table 1**).

Efficacy

Significant functional improvements were reported in three of the five clinical trials: Bristol Phase 1 GDNF Trial, Kentucky Phase 1 GDNF Trial, and the Ceregene Phase 1 AAV2-NTRN Trial. In the first year of treatment, all three trials reported significant improvements averaging from 36% to 45% in the off medication motor subscore (Part III) on the Unified Parkinson's Disease Rating Scale (UPDRS), the gold standard for judging efficacy. The two GDNF Phase 1 studies also showed significant improvements in total UPDRS scores both on and off medication.

In contrast to open label Phase 1 trials, Phase 2 trials have a vehicle control arm and are double-blinded. Thus, a placebo component to the striking differences between the Phase 1 and Phase 2 trials cannot be ruled out. However, the placebo effects are typically sporadic and longitudinally inconsistent for individual patients. The consistent improvements in the UPDRS III off medication in the Bristol and Kentucky GDNF trials and the Ceregene NTRN trial strongly suggests that efficacious trophic factor effects in patients are possibly matching those demonstrated in animal models.

Why did the two Phase 2 trials fail? Insuring adequate trophic factor availability to dopamine neurons in the substantia nigra and their axons and synapses in the putamen is critical for achieving the efficacy. There is evidence that the delivery systems used in both Phase 2 studies failed to do this. The first Phase 2 trial used an implanted intracerebroventricular catheter to deliver bolus injections of GDNF monthly. In all likelihood, sufficient GDNF failed to penetrate through the ventricular wall into the parenchyma of the target tissue, the principal components of the nigrostriatal dopaminergic system consisting of the putamen and substantia nigra. The second Phase 2 trial used a catheter implanted in the putamen to continuously infuse GDNF. However, a different catheter and infusion parameters were used than those utilized in the Phase 1 studies. It has been calculated that GDNF bioavailability was limited to only 2–9% of the human putamen with the point source Phase 2 IP catheter.

Table 1 GDNF and neurturin clinical trials

Study/phase	*Start date*	*Delivery*	*Dose range*	*Patient number*	*Treatment duration*	*Results*
Amgen ICV GDNF/ Phase 1/2	1996	Monthly bolus ICV	25–4000 μg per month	50	Up to 28 months	Side effects, not efficacious
Bristol IP GDNF/ Phase 1	2001	Continuous IP infusion	14.4–42.4 μg day per putamen	5	Up to 42 months	Safe, efficacious
Kentucky IP GDNF/ Phase 1	2002	Continuous IP infusion	3–30 μg day per putamen	10	Up to 26 months	Safe, efficacious
Amgen IP GDNF/ Phase 2	2003	Continuous IP infusion	15μg day per putamen	34	6 months	Safe (?), not efficacious
Ceregene AAV2 NRTN/Phase 1	2005	AAV2-NRTN IP injection	$1{\cdot}3\times10^{11} - 5{\cdot}4\times10^{11}$ Vector genomes	12	12 months	Safe, efficacious

Four clinical trials have been conducted testing GDNF. The first employed an implanted intracerebroventricular (ICV) catheter and subcutaneous access port to deliver bolus GDNF injections monthly. Significant side effects were found and the treatment regime was not efficacious. The next two studies (Bristol and Kentucky) used subcutaneously implanted programmable pumps connected to intraputamenal (IP)-implanted catheters to continuously deliver GDNF into the putamen. Both studies reported that the procedures were safe and promoted significant functional improvements. The Phase 2 Amgen IP GDNF trial that followed did not achieve its primary endpoint of a statistically significant improvement in the UPDRS III off medication score. There were also two safety issues raised during the trial: cerebellar toxicity was seen in high-dose GDNF-treated rhesus monkeys and some patients developed binding antibodies to GDNF. The most recent clinical trial tested the safety and efficacy of using adeno-associated virus serotype 2 (AAV2) to transfect cells in the putamen with a hybrid gene construct consisting of the prepro sequence of Nerve Growth Factor linked to the gene sequence for mature NTRN. The initial report from the trial indicated that both the low and high doses were safe, with functional improvements in four of six patients in both treatment groups.

Side Effects

The most significant side effects were noted following intracerebroventricular delivery of GDNF in the first Amgen Phase 1/2 trial. Hyponatremia, weight loss, paresthesias, and nausea were the most common problems. The two Phase 1 GDNF IP infusion studies and the Phase 1 NTRN trial have not reported serious clinical side effects. Surgical complications with the delivery system were encountered in three patients in the Amgen Phase 2 IP GDNF study, requiring surgical intervention in all three individuals, and in one case the device removal.

Safety Issues

Two significant safety concerns have arisen with IP infusion of GDNF. The first, seen in 6 of 32 patients receiving GDNF and 46 of 52 nonhuman primates in a toxicology study, is the expression of binding antibodies to GDNF. It is not atypical to find in patients antibodies to endogenous proteins used therapeutically (e.g., β-interferon and insulin): this does not prohibit continued use of the drug. To date, there have not been any clinical consequences in humans or animals that have developed GDNF antibodies.

The second safety issue, cerebellar toxicity, has only been found in one study in nonhuman primates receiving high doses (100 μg per day) of continuous GDNF infusion into the putamen. Four monkeys were found to have multifocal lesions involving the loss of cerebellar Purkinje cells, and in some instances, associated loss of underlying granule cells. GDNF-associated cerebellar toxicity has not been seen in other toxicology studies in rodents or nonhuman primates, nor is there any evidence that GDNF therapy has induced cerebellar injury in patients. Autopsies on patients who participated in the clinical trials may help to resolve this question, but high-resolution MRI scans conducted on 10 patients and the one published autopsy report conducted to date are negative. The apparent restriction of cerebellar toxicity to one animal study, raises the possibility that it was idiosyncratic, due to some peculiar combination of physiology, surgery, anesthesia, or other treatment in that group of nonhuman primates.

While the published reports on AAV2-NTRN indicate that this approach is safe, there remains a concern that there is no way to control the expression of NTRN in transfected cells in the brain. Overexpression of NTRN eventually causing serious side-effects from leakage into the ventricular system (see below) or leading to the accumulation of large deposits of protein in brain regions would prove challenging to manage medically in patients. Another possible side-effect could be aberrant sprouting and TH downregulation of the nigrostriatal dopaminergic pathway, which has been reported in rats exposed to high GDNF levels from viral vector gene transfer.

Effective Therapy: The Challenges are Delivery and Regulation

Analysis of the clinical trials conducted to date and supporting studies in animal models strongly indicate that successful GDNF or NTRN therapy requires site-specific delivery. Oral delivery of either trophic factor

or a mimetic drug would produce side-effects from actions on the GDNF-responsive neurons composing the enteric nervous system. In addition, the blood–brain barrier effectively blocks entry of blood-borne proteins and many drugs preventing systemic delivery. In addition to focal delivery into the appropriate site, distribution of GDNF or NTRN must be tightly regulated regardless of the method used (e.g., direct infusion, stem cells, encapsulated cells, gene therapy). This is because allowing either trophic factor to persist in brain sites outside of the target area significantly increases the risk for major side effects, such as the hyponatremia, anorexia, nausea, and paresthesias seen with GDNF infusion into the cerebrospinal fluid in the first Phase 1/2 trial. Both GDNF and NTRN have strong heparin-binding domains, which help to control their distribution by limiting their free diffusion in brain parenchyma.

The two leading methods for delivering GDNF and NTRN into the brain are by direct infusion through catheters connected to programmable pumps and via gene therapy. As previously discussed, both methods have been tested clinically; both approaches are well suited for site-specific delivery. Regulation of drug delivery is straightforward using programmable pumps where the flow is adjustable and dosing can be varied as needed. If necessary, the pump can be turned off, stopping drug infusion. The challenge with programmable pump/implanted catheter delivery is with optimizing target tissue distribution of the trophic factor. High concentrations of the infused protein build up at the catheter tip and drug concentration can drop precipitously with increasing distance from the catheter site. Convection-enhanced delivery can partially correct this problem by increasing the bulk flow rate of large molecules promoting tissue penetration and distribution over larger volumes of the brain. In contrast, tissue distribution using gene therapy is easily managed, while regulation of trophic factor levels is problematic. Creative approaches for regulating transfected genes are currently in preclinical testing including drug-dependent regulatory systems to induce transient gene expression. However, none has reached a level of safety and reliability suitable for clinical use.

Summary

GDNF and NTRN therapies have the potential to revolutionize the treatment of Parkinson's disease and other neurodegenerative disorders. The field is now in a challenging era, where three Phase 1 clinical trials have yielded encouraging results, while two Phase 2 studies have been disappointing. Analysis of the differences between the successful and unsuccessful trials strongly suggests that efficacious therapeutic approaches require controlled, site-specific delivery of trophic factors using methodology to optimize the target tissue distribution. The next generation of clinical and preclinical studies is underway to understand and build upon the hard-won lessons from the five clinical trials conducted to date. Achieving efficacy will depend upon the progress made in regulating trophic factor delivery and distribution.

Gene Microarrays

S D Ginsberg, Nathan Kline Institute, New York University, Langone Medical Center, Orangeburg, NY, USA

Introduction

Analytical and experimental developments in high-throughput genomic methods enable the assessment of dozens to hundreds to thousands of genes simultaneously in a coordinated manner. Expression data is increasingly available for many diverse organs and tissues throughout the body, allowing for exciting hypothesis testing of critical concepts such as normative function, development, senescence, and ultimately, disease pathogenesis. For example, microarray analysis has been performed from RNA extracted from the midbrain and discretely within the substantia nigra pars compacta (SNPC) using animal models of Parkinson's disease (PD) as well as human brains obtained postmortem from subjects with PD and age-matched normal controls. Expression profiling studies have revealed downregulation of genes critical to mitochondrial function and energetic homeostasis, suggesting that experimental perturbations such as mitochondrial poisons and complex I inhibitors of the respiratory chain result in a PD-like pathology in the SNPC. Moreover, microarray analysis of postmortem SNPC tissue from PD patients identified increases within the ubiquitin–proteosomal system compared to age-matched controls. These observations suggest that a final common pathway for neutralizing and removing misfolded proteins contributing to the electron transport chain may be dysfunctional in PD.

CNS Expression Profiling

Microarray analysis is a useful, reproducible, and fairly cost-effective tool to assess transcript levels in a wide variety of experimental paradigms. A disadvantage is a requirement for high-quality and abundant input sources of RNA. Whole organism studies can generate significant input amounts of RNA, but do not allow regional or cellular specificity. Regional gene expression analysis is used widely with RNA extracted from cultured cells, animal model tissues, as well as postmortem human brain tissues. However, expression profiles garnered from regional dissections cannot discriminate molecular signatures from admixed neuronal and nonneuronal populations within the region of interest.

Microaspiration

Several techniques are used to aspirate individual cells or populations of cells (termed population cell analysis), including single-cell microaspiration and laser capture microdissection (LCM). Single-cell microaspiration entails visualizing and manually removing an individual cell (or cells) using an inverted microscope connected to a micromanipulator, vacuum source, and an imaging workstation on an air table. This method yields very precise accrual of cells, but can be labor intensive and is dependent on the experience level of the end user. LCM enables rapid accession of single cells and homogeneous populations, and is generally available at genomics core facilities and some individual functional genomics laboratories. Positive LCM extraction entails pulsing an infrared laser source onto thermoplastic film embedded in a specialized microfuge cap, effectively adhering the matrix to target cells. Lifting the thermoplastic cap separates targeted cells from surrounding undisturbed tissue. Negative LCM extraction (or noncontact laser extraction) procedures employ a near-infrared laser source to cut around the area of interest within a tissue section, and the microdissected material is catapulted into a microfuge tube. RNA, DNA, and protein extraction methods can be performed on microdissected cells for downstream genomic and proteomic applications.

Microarray Platforms

Microarrays can be considered as a nanotechnology derivative of conventional dot blots, as they are effectively miniaturized probe–target platforms that exploit the complementary hybridization between nucleic acids. Synthesis of cDNA microarrays entails adhering cDNAs or expressed sequence-tagged cDNAs (ESTs) to a material support such as glass slides or nylon membranes. Similarly, photolithography can be employed to synthesize oligonucleotides directly onto a desired array media. The anchored sequence is commonly called the microarray target. Target length varies from short oligonucleotides to large chromosomal fragments. Probe generation is typically performed via reverse transcription, and a detection moiety is incorporated directly into the transcribed strand. If input RNA is amplified through an RNA amplification methodology, then the amplified material is labeled and used to probe a microarray. Arrays are washed to remove nonspecific hybridization, and imaged using a laser scanner for biotinylated/fluorescently labeled probes a phosphor imager for radioactively labeled probes. A target-labeled probe complex emits a quantifiable signal that is proportional to the abundance of the labeled probe in the sample. Quantification of hybridization signal

intensity is performed to evaluate relative expression levels of each cDNA, EST, or oligonucleotide feature on the array platform. Gene expression is then assessed using informatics software. Computational analysis is a key aspect for adequate array quantitation due to the massive number of data points that can be generated from a single assay.

RNA Amplification Strategies

An RNA amplification technique is often required when using small sample inputs as starting material. PCR-based amplification methods are not optimal, as exponential amplification can skew the original quantitative relationships between genes. Linear RNA amplification is another approach used to generate input RNA for microarrays. For example, the amplified antisense (aRNA) amplification method utilizes a T7 RNA polymerase-based amplification procedure. aRNA maintains a proportional representation of the size and complexity of the initial mRNAs. Modifications of the initial aRNA procedure have been utilized, and several aRNA-based kits are available commercially. A new RNA amplification procedure has been developed in our laboratory that utilizes a method of terminal continuation (TC). Specifically, synthesis of the first strand cDNA complementary to template mRNA is performed by two oligonucleotide primers, a poly d(T) primer and a TC primer. RNA is then amplified via in vitro transcription procedure using the newly formed cDNA as template. The poly d(T) primer is similar to conventional primers that anneal to the poly(A)+ sequence present on most mRNAs. Therefore, transcript orientation can be in an antisense orientation (similar to conventional aRNA methods) when the bacteriophage promoter sequence is placed on the poly d(T) primer or in a sense orientation when the promoter sequence is attached to the TC primer, depending upon the experimental design. TC RNA amplification enables quantitative assessment of a large proportion of genes as evidenced by bioanalysis and microarray analysis in animal model and human postmortem brain tissues, including single cells and populations of homogeneous neurons.

Microarray Considerations

The application of microarray technology towards understanding the pathophysiology of PD and related movement disorders is in its early stages. There are many concerns regarding the actual handling of tissues, fixation, and cutting of sections for RNA accession, especially in the case of human postmortem material. The decision to microdissect specific cell type(s) of interest via LCM or a related technology still depends on the skill level of the operator and the availability of expensive equipment that requires significant maintenance. Moreover, the choice of microarray platforms (i.e., high-density versus moderate density; single use glass arrays versus reusable nylon membrane arrays), probe labeling procedures (e.g., direct or indirect fluorochrome incorporation and radioactive labeling), and amplification procedures (including PCR-based amplification, T7-based RNA amplification, isothermal amplification, and microRNA amplification), and a dizzying array of hybridization procedures make standardization a significant issue. Each of these procedural and technical variables may have substantial effects on the subsequent microarray datasets. As a result of these potential pitfalls, negative findings on any array platform must be interpreted cautiously. Importantly, independent validation methods of transcript analysis (including real-time quantitative PCR (qPCR), Northern hybridization, RNase protection assay, and in situ hybridization, among others) are essential components to a rigorous study that employs high-throughput transcription profiling technologies. Another caveat of microarray analysis is that coordinate changes in respective proteins encoded by the genes of interest are often found, but are not an absolute feature.

Conclusions

Functional genomics advances have led to the development of high-throughput techniques that enable expression profiling within discrete brain regions and specific cell types. These exciting technologies, when combined with solid experimental design and validation using alternative molecular- and cellular-based strategies, comprise a paradigm that is useful for assessing mechanisms underlying the pathophysiology of PD. Specifically, individual genes and classes of transcripts that comprise discrete signaling pathways can be evaluated in vitro as well as in the midbrain, SNPC, and/or striatum of relevant animal models of PD and human postmortem brains of subjects afflicted with PD.

Generalized Primary Torsion Dystonia

Lawrence Severt and Rachel Saunders-Pullman, Albert Einstein College of Medicine, Beth Israel Medical Center, New York, NY, USA

Definition and Classification

Dystonia is a syndrome characterized by sustained, twisting involuntary contractions of muscles, producing abnormal postures and movements. The movements are usually directional in nature, and may be action specific. Dystonia is classified in several ways: (1) by etiology, (2) by age of onset, (3) by the site in the body where dystonia begins, or (4) by the final distribution of the body parts affected by dystonia. These classifications are not mutually exclusive, as most early onset dystonia starts on a limb, and most leg-onset dystonia is early onset.

When separated by etiology, dystonia is classified as primary or secondary, with an intermediary form, dystonia-plus, which straddles both categories, but usually considered as a form of secondary dystonia. Primary torsion dystonia (PTD) is defined when dystonia is the only abnormality on neurological exam, with the exception of tremor, and when there is no known metabolic, structural, or toxic etiology and a dramatic and sustained response to levodopa is absent. When an etiology is identified, such as an exposure to dopamine-blocking medications (tardive syndromes), perinatal brain injury (germinal matrix hemorrhage, hypoxic brain injury, kernicterus) or dystonia is a component of heredodegenerative diseases (Parkinson disease, Wilson disease) or when brain imaging abnormalities are present, the dystonia is then considered secondary. Primary dystonias were previously labeled 'idiopathic,' but as genetic etiologies for some forms of 'idiopathic' dystonias have been elucidated, they have been renamed as 'primary.'

There are three genetic disorders where dystonia is not the sole neurological feature, but in which no imaging or structural abnormalities are identified, and these are classified as dystonia-plus syndromes. They include dopa-responsive dystonia (DRD), myoclonus-dystonia (M-D), and rapid-onset dystonia parkinsonism (RDP). Parkinsonism and hyperreflexia may be present in DRD, myoclonus is prominent in M-D, and parkinsonism and spasticity are features of RDP. Particularly in DRD and MD, some family members may present with isolated primary appearing dystonia; therefore, these conditions should be considered in the differential.

Dystonia may also be defined by the age at onset, with <27 or <22 usually being the cut-off for early onset dystonia. Age of onset may be helpful in determining the etiology; almost all DYT1 dystonia, for example, is early onset. In contrast, in other conditions such as DYT6, there is a mixed age of onset disorder with the majority of cases starting before the age of 25 (earliest age 5 years), but some starting as late as 49 years of age.

Dystonia may also be separated into the muscles involved first, such as leg or neck, and this has utility in predicting spread, as rostral onset dystonia (such as blepharospasm) is much less likely to spread to other sites than more caudal onset dystonia such as leg onset. The most useful clinical classification is by the distribution of sites involved at last exam in combination with and the etiology and the age at onset. Focal dystonias present in specific body regions (such as the arm in writer's cramp, and the muscles of eye closure in blepharospasm). Segmental dystonias affect adjacent areas of the body (e.g., blepharospasm with other lower cranial involvement in segmental cranial dystonia, and cervical dystonia with writer's cramp in segmental cervical-brachial). Generalized dystonia involves multiple body regions, usually defined as one or both legs, the trunk, and one other part of the body.

This section focuses on dystonias which are primary in etiology and which are generalized in distribution.

History

Some of the first reports of primary generalized dystonia were from Schwalbe and Oppenheim in 1908 and 1911, respectively. Schwalbe described generalized PTD in his essay "*Tonic Cramps with Hysterical Symptoms*" and his reference to hysteria led to the misunderstanding that dystonia was a psychiatric disorder. This is probably based in the misinterpretation of the unusual and sometimes bizarre abnormal postures of dystonia, and the fact that the postures can be action specific, as well as the Freudian influence in Europe at the time. Oppenheim described classic primary generalized dystonia in his treatise in 1911 entitled "About an unusual cramping syndrome in children and adolescents" which he named dystonia musculorum deformans. In hindsight, because the cases Oppenheim described were of Jewish background, it is likely that they had mutations in the first dystonia gene to be identified, DYT1. However, it took over 70 years to understand that although DYT1 is familial, and may skip generations, it is an autosomal dominant disorder with reduced penetrance (and not autosomal recessive), and that even though there is a founder effect in the Ashkenazi population, it occurs worldwide, and in people of varied ethnicities.

While ethnic background plays a role in determining the likelihood that generalized PTD is due to certain mutations, not all cases of primary generalized dystonia in the Ashkenazim can be attributed to DYT1 mutations, and not all cases of primary generalized dystonia in the Amish-Mennonites can be attributed to DYT6 mutations. In individuals of Ashkenazi background, DYT1 mutations account for 80–90% of early onset PTD; however, in those not of Ashkenazi descent, DYT1 mutations only account for approximately 30–60% of early onset PTD. Recently, the DYT6 gene was cloned, and while a founder was initially demonstrated in the Amish-Mennonites, mutations in this gene are responsible for PTD in people of other backgrounds as well. Conversely, a de novo DYT1 mutation was reported in a Mennonite man with early onset generalized PTD.

Unlike DYT1, DYT6 less classically begins as leg-onset dystonia, although onset in the arm is common. While DYT6 may be an important cause of PTD, it is unlikely to account for most of the generalized PTD in non-Ashkenazim or in the Ashkenazim without DYT1 mutations. Another gene, DYT13, has been reported to cause generalized dystonia, but the gene has not yet been identified. Further, it has been seen in only one Italian family, and infrequently causes generalized dystonia.

Therefore, while this entry will focus on the three identified etiologies of generalized PTD, *there is still a large amount of generalized PTD whose etiology must be elucidated*. We will discuss overall features of primary generalized dystonia, followed by the specific genetic etiologies, DYT1, DYT6 and DYT13, differential diagnosis, genetic counseling and testing and treatment.

Epidemiology

Primary generalized dystonias occur with a reported prevalence of 34–50 per 1 million persons of the population in the United States and Western Europe, although the prevalence may be much higher in certain ethnic groups. Early-onset primary generalized dystonia in the Ashkenazi Jewish population occurs with a prevalence of more than 100 per 1 million persons.

Clinical Features

During normal muscular activity, antagonist muscles relax when the agonist muscles contract, and vice versa. Dystonic patients often experience simultaneous contraction of the agonist and antagonist muscles. Usually one set of muscles will dominate; this often produces movements with a dominant directional vector. The directionality of the movements can help distinguish cervical and brachial dystonias from essential tremor of the head or arm, for example. Careful examination and positioning of an affected limb will often reveal a null point, at which the dystonic movement is minimized, again differentiating this disorder from other tremors, myoclonus, or tics. Movements in dystonia are often task specific and usually show kinetic exacerbation or overflow, for example, muscles of the hand and forearm will display little activity at rest, but contract dramatically with handwriting in the patient with writer's cramp. In generalized PTD, the task specific phenomenon may be observed when patients may have pronounced dystonia walking forward, but not walking backwards or running. Dystonic movements disappear during sleep and anesthesia, although over time contractures may appear which then do not abate.

One of the most intriguing characteristics of dystonias is the sensory 'trick' or *geste antagoniste*. Tactile stimulation of a specific site within the dystonic region of the body can ameliorate the abnormal movement; for example, touching the chin or the back of the head may temporarily straighten the neck of the patient with cervical dystonia, and holding a toothpick or orthodontic device within the mouth may provide relief from oral movements. In certain patients, simply visualizing the 'trick' may also provide relief. The effect of sensory afferent input on dystonic movements provided some of the first clues that the disorder encompasses abnormal sensory processing as well as abnormal movements; more recent investigations with functional and detailed anatomical imaging, as well

as studies of motor learning have confirmed the complex pathophysiology of the disease.

Primary generalized dystonias often present with focal onset during childhood, usually in the foot or leg in the cases of DYT1 or in an arm in cases of DYT6. Spread to the other leg and trunk then occurs. The "dromedary gait" described by Oppenheim with trunk flexion and hip elevation during walking is classic for generalized PTD. There is tremendous heterogeneity among generalized PTD with regards to the disability associated with the dystonia, and this depends on the severity of the trunk and leg posturing. As discussed below, not all cases of DYT1 and DYT6 dystonia will spread to become generalized.

DYT1 Dystonia

DYT1 dystonia, also known as Oppenheim dystonia, or dystonia musculorum deformans is the most common known genetic etiology of generalized PTD. It is caused by a three base pair (GAG) deletion in exon 5 of the *DYT1* gene on chromosome 9q34. This common deletion is found in almost all patients with this disease regardless of ethnic background, and the relevance of other reported mutations is not yet clear. Therefore genetic screening is limited to screening for the GAG deletion.

Pathophysiology

DYT1 encodes a nuclear envelope heat shock protein in the AAA+ family of ATPases known as torsinA. The protein is widely expressed in the brain, including in the basal ganglia, cerebral cortex, hippocampus, and cerebellum. The intracellular localization of torsinA changes as a result of the GAG deletion, and the mutant form of the human protein shows decreased ATPase activity when expressed in bacterial cultures. Animal and cell culture models have also demonstrated a redistribution of the mutant protein from the endoplasmic reticulum to the nuclear envelope. A single copy of the gene can cause this redistribution; hence the mutation acts in a dominant negative fashion. The role of torsinA in cellular functioning remains unknown, but it may play a role in interactions between the nucleus and the cytoskeleton, trafficking of vesicles along the microtubular components of the cytoskeleton, extension of neurites during development, or regulated exocytosis of synaptic vesicles. The possible link to exocytosis of vesicles containing neurotransmitters is particularly intriguing in light of other evidence demonstrating increased dopamine turnover in the striatum in transgenic mice expressing mutant human DYT1. Transgenic mice also manifest dopamine D2 receptor abnormalities associated with altered GABAergic neurotransmission, as well as abnormal responses of cholinergic interneurons to dopaminergic afferent activity.

Genetics, Penetrance, and Expression

The higher frequency of disease in patients of known Ashkenazi ancestry is attributed to a founder mutation that likely occurred in Byelorussia over 400 years ago. The disorder occurs in 1 out of 3000–9000 Ashkenazi Jews and in 1 out of 9000–27 000 non-Jews. About 90% of primary generalized dystonia in the Ashkenazi group results from the DYT1 founder mutation, and about 50% of the primary generalized dystonia in non-Jewish populations can be attributed to DYT1. The mutation is dominant, but there is both reduced penetrance and variable expression. Only approximately 30–40% of individuals who harbor the mutation will ever develop disease, and the type of disease they develop (expression) may vary from severe generalized to mild focal even among family members. Opal et al. reported a family with one member with severe dystonic storm and another with mild writer's cramp. A polymorphism at residue 216 of the codon has been demonstrated to decrease penetrance of the mutation; however, as it is rare, it only accounts for a small proportion of the reduced penetrance. As this is an early onset disorder, there is a window of vulnerability, with most individuals developing symptoms by the age of 26 or not at all. Late onset cases (up to the age of 64 with oromandibular dystonia) are rare. Among carriers of the DYT1 mutation who have not developed dystonia, there may be an endophenotype with functional imaging abnormalities as well as slowness in motor learning tests, and a higher prevalence of affective disorders than control subjects without the mutation.

Clinical Features

DYT1 dystonia almost always (95%) involves a limb initially, and two-thirds of cases will progress to generalized or multifocal dystonia, usually within 5–10 years. Onset is almost always by age of 26. A minority of cases will remain as focal or segmental dystonias, usually writer's cramp or bibrachial dystonia. Focal neck or cranial muscle involvement is rare. A study of early onset cervical dystonia did not identify any DYT1 cases, and it is highly unusual for DYT1 to be the cause of adult onset focal dystonia, overall the most common form of dystonia. Early involvement of the cranial structures in patients with DYT1 dystonia is unusual; this distinguishes these patients from other forms of primary generalized dystonia that may show early (younger than 21 years of age) cranial symptoms, particularly DYT6 dystonia where cranial features are common and usually more disabling than leg dystonia. Later in the disease, about 15–20% of individuals may have cranial muscle involvement. The trunk and cervical muscles may also be involved in 25–35% of cases. As the dystonia may be jerky, or myoclonic, it is infrequently mistaken for essential tremor (ET) or

myoclonus-dystonia. DYT1 dystonia can be distinguished from ET by the directionality and posturing of the limbs in certain movements, and often a null-point of the tremor. Further, unlike myoclonus-dystonia where there are separate jerks of myoclonus, the myoclonic jerks superimposed on the dystonia in DYT1 are usually slightly slower.

As alluded to, unusual cases of DYT1 dystonia have been documented with clinical presentations as late as seventh decade of life, although most older onset cases do not present for medical attention and are usually identified through an affected family member. Because writer's cramp may never come to medical attention, in some individuals dating the onset of the dystonia may be difficult.

Imaging and Neurophysiology

Although clinical magnetic resonance imaging of the brains of patients with DYT1 dystonia is usually normal, multiple studies have found abnormalities on positron emission tomography (PET) scanning, functional MRI, and specific sequences of (e.g., diffusion tensor imaging/DTI) of MRI scans. Fluorodeoxyglucose PET scanning of persons with DYT1 dystonia, as well as of nonmanifesting carriers of the mutation, shows increased glucose metabolism in the putamen, globus pallidus, cerebellum, supplementary motor area, and parietal cortex association regions. Similar patterns have been noted across variable clinical phenotypes of dystonia: regional metabolic patterns are distinct between manifesting and nonmanifesting carriers of DYT1 and DYT6 mutations. During the performance of a motor task, differences in metabolic activity emerge on glucose PET scans of manifesting carriers of the DYT1 mutation and nonmanifesting carriers or control subjects. All carriers of the DYT1 mutation showed increased metabolic activity in primary motor cortex, whereas manifesting carriers showed greater activation in sensorimotor cortex, supplementary motor area, parietal association regions, and the cerebellum; nonmanifesting carriers showed increased activity compared to controls, but not as great as the levels seen in manifesting carriers. As a functional correlate, both manifesting and nonmanifesting carriers of the DYT1 deletion show impairment in learning sequential motor tasks. Further, DTI scans of the brains of manifesting and nonmanifesting carriers of DYT1 show abnormalities in white matter tracts in primary sensorimotor cortex and in the lentiform nucleus, suggesting structural abnormalities.

Imaging with the dopamine D2 receptor ligand, raclopride, shows decreased binding in carriers of the DYT1 and DYT6 mutations in the caudate and putamen. These abnormalities in striatal dopaminergic tone occur both in manifesting and in nonmanifesting carriers of the mutations. The well-known occurrence of acute-onset of focal dystonias after exposure to D2 receptor blocking agents (metaclopramide, haloperidol), and development of dystonia as a result of a number of mutations in the biosynthetic pathway for dopamine, illustrate the clinical relevance of this finding.

Transcranial magnetic stimulation (TMS) of the cortex in manifesting and non-manifesting carriers of DYT1 reveals abnormal cortical electrical activity; specifically intracortical inhibition is decreased in carriers of the DYT1 deletion. Transgenic mouse models of DYT1 dystonia show abnormal inhibition in the globus pallidus externa (GPE) and interna (GPI) after stimulation of the cortex.

Possible Affective and Cognitive Features

Nonmotor symptoms have emerged as possible features of primary generalized dystonias. In one study, major depression occurred more commonly in carriers of DYT1 mutations, even if they did not have motor manifestations of the disease, than in family members who did not carry the mutation. Further supporting that the depression was related to the gene, the age of onset for major depression in the nonmanifesting carriers was younger than that seen in family members with depression who did not carry the mutation. Interestingly, patients with DYT1 dystonia perform better on tests of semantic verbal fluency than age-matched controls. This occurs in spite of retroactive memory interference (the adverse effect of learning new material on the retention of material learned in the past) seen in patients with DYT1 dystonia.

DYT6

Until recently, only one gene for primary dystonia, DYT1, had been discovered. There is now a second gene, DYT6, which causes a phenotype deemed 'mixed' due to its overlap with both early onset generalized dystonia and late onset localized cervical or cranial dystonia. Like DYT1, DYT6 dystonia tends to begin early and to spread to multiple body regions. On the other hand, DYT6 is more likely than DYT1 to involve cervical or cranial muscles, with less disabling leg and gait abnormalities.

The DYT6 gene was originally mapped to chromosome 8p21–q22 in two Amish-Mennonite families who shared a haplotype of marker alleles across a 40 cM linked region, and common ancestral pairs were later identified through genealogical records. In these families, dystonia was characterized by a relatively early but broad age at onset (mean 18 years, with range 5–38 years). The body regions first affected included the cranial muscles, neck, arm, and rarely the leg; almost all had some degree of progression of dystonia to other body regions, but this varied widely. More recently, three additional dystonia families of Amish-Mennonite ancestry have been identified. In one of them, the DYT6 haplotype was identified but it was excluded in the other two, suggesting genetic

heterogeneity in the etiology of PTD in the Amish-Mennonite population. In early 2009, a mutation in the THAP1 gene was identified as responsible for DYT6 dystonia in the above mentioned families carrying the common haplotype. Since then, mutations in DYT6 have been shown to be responsible for mixed age onset PTD in non-Amish-Mennonite families as well.

Genetics, Pathogenesis, and Pathophysiology

DYT6 is inherited in an autosomal dominant manner with reduced penetrance (~60%) and variable expressivity. Although more cases of DYT6 mutations in women are reported, initial penetrance studies have not demonstrated that gender affects penetrance.

The founder mutation found in the three initial families of Amish-Mennonite origin and the subsequent one represented a 5 bp insertion/3 bp deletion resulting in premature termination of the THAP1 protein. A different mutation, representing a missense mutation in exon 2 of the *THAP1* gene was identified in a German family without Amish-Mennonite ancestry.

The mechanism for which mutations in *THAP1* result in primary dystonia is not clear. THAP1 regulates endothelial cell proliferation through its DNA binding domain. Both known mutations are likely to be sufficient to abolish its DNA binding activity and this loss it is hypothesized to potentially cause transcriptional dysregulation effecting downstream targets. An alternative pathway involving programmed cell death has also been proposed as a possible etiologic mechanism, as THAP1 is known to function also as a proapoptotic factor.

Clinical Features and Diagnostic Criteria

From the families described, it is known that the disease onset is broad; however, in more than of half of the affected members, PTD began in midadolescence. The most common site of onset was the arm, followed by cranial muscles and neck. Most affected individuals had some but varying degree of progression to other body regions. It is notable that in contrast to DYT1, very few patients required assistive aids for ambulation despite involvement of leg in half of the affected subjects. Most had arm involvement and more than half had speech impairment. The greatest source of disability was cervical and lower cranial dystonia.

The phenotype of DYT6 may expand in the near future as we learn that DYT6 mutations are present in pedigrees of non-Amish-Mennonite descent and other mutations are described in *THAP1*.

DYT13

Generalized PTD has also been identified in a single Italian family, although leg involvement was present in only 2 of 11 family members with dystonia, supporting that generalized dystonia may be present, but is not the predominant phenotype. Dystonia was mapped to the DYT13 locus on chromosome 1p, although the gene has not yet been identified. Age of onset in DYT13 is early (mean age 15.6 years, range 5–43) with a range that is strikingly similar age range to DYT6 (5–58 years). Body regions first affected in DYT13 include the neck, cranial muscles, and arms. Only 2 out of 11 individuals developed leg dystonia, but like DYT6, the disability from leg dystonia was relatively mild.

Diagnostic Work-up/Tests and Differential Diagnosis

First, as is the case for other types of dystonia, a careful and detailed history and examination should be performed to determine whether the dystonia is primary or secondary. This includes a careful medication history, including current and past exposure to neuroleptics and antiemetics to elucidate medication induced tardive dystonia. Imaging of the brain with MRI should be considered in cases without DYT1 mutations (see Genetic Testing section). The differential diagnosis for primary generalized dystonia includes DYT1 dystonia, DYT6 dystonia, DYT13 dystonia, dopa-responsive-dystonia and myoclonus-dystonia. Secondary causes of dystonia are less likely in dystonia without other neurological features and normal imaging; however, Wilson disease should always be considered in the differential as it is a highly treatable disorder. Evaluation for Wilson includes serum ceruloplasmin and slit lamp examination, and may include 24 h urine collection for copper levels. Incomplete history-taking or unfamiliarity with the diagnosis may result in the misdiagnosis of 'cerebral palsy' in these children or even in young adults. Dopa-responsive-dystonia is an early onset dystonia plus disorder, which usually presents in childhood with generalized dystonia. This may be accompanied by spasticity, toe walking, hyperreflexia, and or parkinsonian features. However, dystonia may be the sole presenting finding; therefore, a diagnostic and therapeutic trial of levodopa-dopa should be considered in all patients presenting with primary generalized dystonia who do not harbor a DYT1 mutation, or whose status is unknown.

DYT1 and DYT6 differ in their overall clinical presentation, although in individual cases there may be overlap: in DYT6 there is a prominence of cervical and cranial muscle involvement and high frequency of speech abnormalities compared to the greater leg and gait abnormalities characteristic of DYT1. Also, in contrast to most early onset dystonia, there is a high preponderance of cervical and cranial onset disease in DYT6. Even when DYT6 dystonia is generalized, the walking disability is usually less severe than in DYT1 dystonia. However, as noted, DYT1 may also be mild. In the case of the Mennonite man with de novo DYT1 dystonia, the

clinical picture was suggestive of DYT1 rather than DYT6 because of the crural, trunk, bibrachial, and cervical involvement with prominent gait impairment. He did not have cranial dystonia or speech impairment.

Further, while the DYT6 phenotype also shares many features with DYT13, there is more prominent cranial and laryngeal dystonia in DYT6 than DYT13. The differential for DYT6 dystonia also includes inherited dystonia with prominent cervical involvement (DYT13, DYT7), as well as focal cervical dystonia and focal and segmental cranial dystonia.

Genetic Testing

In patients younger than 26 years of age who present with idiopathic generalized dystonia, genetic counseling should be offered together with DYT1 mutation testing. Genetic counseling serves a particularly important function with this disease because the inheritance pattern is complex and patients and family members need to be educated that even if a DYT1 mutation is found, there is only 30–40% chance that symptoms will develop, and even then the phenotype is variable. Presymptomatic testing is available in adults, as is preimplantation diagnostic testing. At this time there is no clinical testing to assess for the polymorphism associated with decreased risk of disease. As the DYT6 gene was recently elucidated, no commercial clinical genetic testing is yet available; however, it is anticipated that it will be available soon. In contrast to DYT1 where one mutation, the GAG deletion is responsible for dystonia, many different DYT6 mutations across the three exons are likely to cause DYT6. Therefore interpretation of a negative result will be more difficult, as until complete screening for all mutations and deletions is available, one cannot definitively state that an individual is not a DYT6 carrier. Genetic testing for DRD is discussed in the section on dopa-responsive-dystonia.

Treatment

Treatment of primary generalized dystonias currently involves a combination of medical (either oral or injectable with botulinum toxin), and/or surgical and nonpharmacological strategies. Current dilemmas in treatment of generalized PTD revolve around whether and when to refer individuals for deep brain stimulation (DBS) surgery. This decision must include weighing risks and benefits of surgery compared to the ones of medical therapies. Important factors in consideration of surgery include whether the genetic form of dystonia plays a role in (a) responsiveness to surgery, for example, DYT1 patients have dramatic improvement in DBS in the GPi, although some have argued that response depends more on duration to timing of surgery than the genetic etiology, and (b) the targets chosen, as pallidal DBS appears ideal for DYT1 but may not necessarily be for other genetic etiologies of generalized PTD.

Medical treatment of dystonia often involves a combination of oral medications and injections of botulinum toxin. Primary oral treatment options include: anticholinergics (e.g., trihexyphenidyl), benzodiazepines (e.g., clonazepam), baclofen or tizanidine. Others include levodopa, tetrabenazine, topiramate, gabapentin and pregabalin, and levetiracetam.

Anticholinergic medications have long been a mainstay of medical treatment for dystonia, and often are the initial medication employed. Trihexyphenidyl is probably the most commonly used anticholinergic drug; others include benztropine, biperiden, and ethopropazine. The anithistaminergic drug, diphenhydramine, also has significant anticholinergic actions, which may account for its mild benefit to some patients. Anticholinergic drugs may prove effective when generalized dystonias first manifest, and the effects may be dramatic in some individuals, although others may be refractory. If patients require higher doses of the agent, side effects may prevent further dose escalations. Side effects include pupillary dilation and blurred vision, dry mouth and eyes, urinary retention, decreased gastric motility, and cognitive impairment; children tend to tolerate higher doses of anticholinergic agents better than adults, but impaired eyesight and memory can affect academic performance. Simultaneous administration of pyridostigmine may ameliorate the ophthalmologic side and other peripheral side effects and enable the patient to tolerate higher doses of these drugs.

Benzodiazepines likely ameliorate dystonia directly through GABAergic effects on the impaired cortical inhibition found in the dystonic brain, and secondarily by their anxiolytic benefit. Doses are again limited by side effects, notably sedation and amnesia, although children may paradoxically become agitated or irritable. Clonazepam is the commonly used agent in this class, due to its relatively long half-life and somewhat lower sedating capability. Diazepam may be used as well. Shorter-acting agents, such as alprazolam and lorazepam are usually less helpful.

Oral baclofen may benefit patients with generalized and focal dystonias, most likely by increasing GABAergic tone. Side effects include sedation, and in the elderly, hallucinations or other psychotic symptoms. Intrathecal baclofen pumps allow delivery of the drug directly into the cerebrospinal fluid, and may provide higher effective doses to reach the brain directly, with fewer systemic side effects. However, baclofen pumps carry considerably morbidity and have been most useful in cases of secondary dystonia with associated spasticity. Currently, if a baclofen pump is considered, the patient is usually considered a surgical candidate for deep brain stimulation.

Other drugs with significant GABAergic properties, such as gabapentin and pregabalin, are generally well-tolerated, but less efficacious in the treatment of primary

generalized dystonia. They may lessen pain, however, and can play an important role in adjunctive therapy. The anticonvulsant topiramate, commonly used in the treatment of essential tremor and migraine, may also improve symptoms in dystonia. Cognitive impairment may preclude the use of high doses.

Most patients with primary generalized dystonia will not respond dramatically to levodopa therapy, but small doses of the drug are well-tolerated and have been reported to produce improvement in a minority of patients, even those with genetically proven DYT1 disease. Significant response to especially low doses of levodopa should immediately raise the diagnostic possibility of dopa-responsive dystonia, or a secondary dystonia due to an underlying disorder such as Parkinson disease.

Conversely, the dopa-depleting agents (tetrabenazine, reserpine, and α-methyl-para-tyrosine), which are often effective oral agents for treating tardive dystonias, have also been reported to improve symptoms in primary generalized dystonia, particularly in combination with anticholinergics and benzodiazepines. The occurrence of severe depression in patients on dopa-depleting drugs necessitates vigilant monitoring of mood. If severe depression occurs, the dopa-depleting agent usually must be withdrawn; if this is required, the depression will often improve within days if due to tetrabenazine, but may persist for weeks in patients treated with reserpine.

Injections of botulinum toxin are the treatment of choice for isolated blepharospasm or cervical dystonia, and can greatly improve either of these symptoms in patients with primary generalized dystonia, sometimes reducing the need for higher doses of oral medications. Injections to the limbs may also improve dystonic movements, but great care must be exercised, especially in children. Deaths have occurred in children with cerebral palsy who received large doses of botulinum toxin for relief of spasticity in the limbs. Limb and cervical injections are often done with electromyographic guidance in order to target affected muscles more accurately and lessen the chance of side effects.

Botulinum toxin type A inhibits the release of vesicles containing acetylcholine in motor neurons, by binding and cleaving the protein SNAP-25 at the presynaptic site of neurotransmitter vesicle docking. This results in a failure of neuromuscular transmission and weakens muscle contraction. Botulinum toxin also inhibits the release of neuropeptide transmitters, such as substance P and calcitonin gene-related peptide in sensory neurons; it may also modulate the activity of vanilloid receptors in patients with chronic pain. This antinociceptive property may explain why the toxin may lessen pain in patients with dystonia even more significantly than it improves the dystonic posture or movement.

Three formulations of botulinum toxin A are available for therapeutic use (Botox, Dysport, and Xeomin), although only Botox is currently available in the United States. Myobloc is the only commercially available form of botulinum toxin B, and is available in the United States and other countries. The remaining serotypes of the toxin (C-G) are not used clinically.

Surgical Treatment

Deep Brain Stimulation

Deep brain stimulation (DBS) has replaced earlier neurosurgical practices of lesioning the brain by freezing or chemical ablation; the placement of electrodes into the globus pallidus interna (GPi) allows delivery of electrical stimulation of precisely controlled amplitude and frequency into an area of the brain responsible for a major motor efferent pathway from the basal ganglia. Patients with primary generalized dystonia also show abnormal inhibition within the globus pallidus, and the GPI is the target for electrode placement in the treatment of DYT1 dystonia with deep brain stimulation. Current theory holds that DBS blocks abnormal electrical overactivity in this pathway and symptomatically improves dystonia. For the treatment of primary generalized dystonia, electrodes are usually implanted bilaterally. Programming of the stimulators must be done by a neurologist with experience in the field, and parameters such as amplitude, pulse width, and frequency must be adjusted for individual patients. Improvement of dystonic tremor may occur relatively quickly (in hours to days), but sustained dystonic postures may not improve for weeks or even months. DYT1 dystonia may respond particularly well to DBS, and children who show rapid progression of their symptoms, or who develop intolerable side effects from oral medications or from botulinum toxin should undergo evaluation by a neurologist and neurosurgeon with expertise in this therapy. Although the neurostimulator can be turned off completely, and the electrodes may be removed surgically if necessary, some patients have experienced irreversible dysarthria after the procedure. Reports of cognitive impairment and impulsivity after the procedure also reinforce the value of careful neuropsychological testing before surgery.

Denervation

Selective denervation has been employed for focal dystonias, such as blepharospasm or cervical dystonia. If these sites represent the major location of disability or pain in a patient with generalized dystonia, and the patient fails to respond to botulinum toxin and oral medications, denervation may be considered. However, clinical improvement after denervation has been inconsistent, and significant, non-reversible side effects may occur. For generalized dystonia, DBS is usually considered before denervation treatment.

Nonpharmacological Treatment

Nonpharmacological treatment includes physical therapy to retain range of motion, and support in the school and at work, with accommodations not only for assistive devices, but also in allowing people to sit/stand in positions that accommodate their particular postures, and having a scribe or personal computer in the classroom or workplace. Psychological stress exacerbates dystonia, and stress-reduction techniques can therefore form an important therapeutic function. Proposed entities include acupuncture, massage, relaxation techniques, yoga, and tai ji quan. Although the effect of these therapies on the underlying disease is not well-known, many patients report subjective improvement, reduction in pain, and better quality of life. Finally, affective disorders are known to occur at higher rates both in patients with DYT-1 dystonia and in nonmanifesting carriers, when compared to control groups. Effective treatment of these symptoms can improve psychiatric health as well as the severity of the involuntary movements and pain. If anxiety or depression emerges as a disabling symptom, the expertise of a psychiatrist familiar with movement disorders will benefit the patient, and may avoid complications of psychopharmacotherapy, such as tardive syndromes.

Geste Antagonistique

B I Karp, National Institutes of Health, Bethesda, MD, USA

Glossary

Geste antagoniste – A maneuver that can temporarily improve dystonia.

Introduction

Gestes antagonistes, also called 'sensory tricks,' are maneuvers that can temporarily ameliorate dystonic postures and spasm. Gestes are especially likely in idiopathic dystonia and are particularly characteristic of cervical dystonia.

Clinical Features

Typical gestes in cervical dystonia (CD) include touching the cheek, face, back of the head or chin. Gestes can be effective whether applied contralaterally or ipsilaterally to the direction of the dystonia. Other maneuvers include resting the back of the head, shoulders, or neck against a support, bending the trunk forward, or yawning.

The duration of relief of symptoms from a geste varies widely. In 42% of patients reported by Muller, the effect on head position lasted less than a minute, sometimes only seconds. However, in 1/3 of patients, normal head posture could be sustained as long as the touch or geste was maintained. About half of patients have several geste

techniques that vary by either using the other hand or touching different areas of the face.

Gestes do not rely on simple pressure to push the head to a normal position, and often do not even require touch or contact. In many patients, the head begins moving towards a neutral position before contact is made and some patients can elicit dystonic relief by simply thinking about or imagining the geste. In CD, relief of dystonia is not elicited as effectively by passive maneuvers such as having someone else manipulate the arm or touch the face.

The prevalence of effective gestes appears to vary with CD pattern. While 64–89% of CD patients overall report having a geste, they are present in 85% of those with rotational torticollis and in 55% of those with retrocollis, but only in 36–38% of those with laterocollis or complex CD.

The utility of gestes is not affected by sex, age, the severity of dystonia, presence of pain, or presence of coexistent tremor, although there may be a relationship to the age at dystonia onset and the duration of dystonia. Gestes may be more likely in those with a younger age of dystonia onset and in those who have had dystonia for a shorter period of time. Most patients cannot describe how they discovered their geste, but some patients uncover the geste while actively seeking a way to obtain relief or when questioned about gestes by a clinician.

Patients consider gestes that maintain relief for long periods of time more beneficial than those that bring the head closer to midline but are not sustained. 82% of CD patients have at least 30% improvement in head posture with geste. With the most effective geste, dystonic head deviation can be reduced by 60–100%. However, an individual geste may not be consistently effective every time it is applied. Gestes are usually more effective in correcting abnormal head position than in reducing abnormal movements or in relief of pain. While the degree of benefit from the geste can be greater than that obtained by botulinum toxin injection, the brief nature of relief makes gestes less useful therapeutically.

Gestes remain effective for years in some patients, but many others lose benefit over the years with a shorter duration of geste effect and a need for more forceful sensory stimulation. In some cases, gestes entirely lose efficacy. Interestingly, three patients reported by Muller whose gestes ceased being effective, regained benefit from the gestes for 4–6 weeks following botulinum toxin treatment, although Filipovic reported patients whose gestes became weaker or disappeared after starting botulinum toxin injections.

Sensory tricks can also relieve blepharospasm and oromandibular dystonia. In blepharospasm, a light touch to the cheek or near the eyes is commonly used. Gestes reported for oromandibular include a light touch to the face, humming, singing, yawning, pulling an eyelid, pinching the neck, chewing gum, sucking on candies, bending the neck forward or talking. Although external supports and devices are not generally helpful in cervical dystonia, placing objects in the mouth or between the teeth often ameliorates oromandibular dystonia. Thus, various reports describe relief from custom dental or oral prosthetics. Similar to cervical dystonia, oromandibular dystonia in some patients can be relieved by thinking about the geste.

EMG has been used to characterize the modulation of dystonic muscle activity by gestes. Two distinct patterns of neck muscle surface EMG during performance of an effective geste have been reported. Two-thirds of patients have a decrease in EMG amplitude and in recruitment in at least one dystonic muscle. One-third of patients, and only those with phasic CD, have an increase in tonic muscle activation in at least one dystonic muscle. Four percent of subjects have no change in EMG pattern during the geste. Gestes can suppress burst, tremorous, and continuous dystonic EMG activity. Wissel et al. confirmed that touch is not necessary to elicit dystonia relief. They found a decrease in EMG activity that was movement related, starting before the finger actually made contact with the face, in 52% of patients. EMG activity decreased again when the geste was released. In 28% of patients, the EMG activity did not decrease until contact was made. Decreased EMG activity was not sustained during touch in all cases, and outlasted the touch in 28% of patients. The role of the geste itself in mediating a decrease in muscle activity is not certain since moving towards and maintaining the head in midposition causes a similar decrease in cervical muscle EMG activity in patients without gestes.

On PET scanning, Naumann et al. demonstrated increased activation of the postcentral gyrus and other parietal areas ipsilateral to the direction of head rotation with a decrease in the activity of the contralateral supplementary motor area and primary sensorimotor cortex during performance of an effective geste. Clinical observation and physiological studies thus suggest that the mechanism by which geste maneuvers decrease dystonic posture involves somatosensory or proprioceptive feedback modulating neuronal activity in the basal ganglia-thalamo-cortical circuits implicated in the generation of dystonia.

Thus, when present, gestes provide temporary dystonic relief for some individuals and can provide insight into the pathophysiology of dystonia.

Glabellar Reflex

R C Shah, Rush University Medical Center, Chicago, IL, USA

Glossary

Glabellar reflex – A primitive reflex elicited by tapping a person's forehead (between the nose and eyebrows) with an index finger and observing that the eyes blink.

Habituation – A decrease in a response to a stimulus after exposure to repeated stimuli over a duration of time.

Myerson's sign – The lack of habituation of the glabellar reflex.

Primitive reflex – Reflex originating from the central nervous system normally present in infancy and early childhood that disappears in the mature brain. Presence of a primitive reflex in adulthood is viewed as a physical finding associated with brain pathology.

The glabellar reflex is one of the primitive reflexes. Primitive reflexes originate in the central nervous system, are present in infancy and early childhood, and disappear as the brain matures. If they are present in a neurologically intact adult, they are felt to represent central nervous system pathology.

The glabellar reflex is elicited by tapping the forehead in between the eyebrows and nose (known as the glabella) with the index finger of the examiner. While the subject will blink in response to the first several taps, blinking ceases with additional taps. If the blinking persists in an adult (sometimes termed Myerson's sign), the finding is considered abnormal.

Physiologically, the glabellar reflex occurs via transmission of afferent sensory signals by the trigeminal nerve to the brainstem bulbopontine level. The efferent signals conducted by the facial nerve cause contraction of the orbicularis oculi muscle and result in the blinking of the eyes. Influences on the reflex come mainly from the cerebral cortex and basal ganglia. In a study of children from ages 2 days to 18 years and adults from 18 to 50 years, the mean number of glabellar taps required for habituation of the blink reflex increased from ~3 at 0–2 months of age to a peak of 13 at ages 3–4 and remained at more than 10 until age 6. Then, a rapid decline occurred reaching an adult level of 2–5 blinks to habituation by age 12.

The abnormal glabellar reflex has been examined as a diagnostic sign in many conditions, especially in older persons. While an abnormal glabellar reflex may be present in the pediatric population with conditions such as mental retardation, it commonly has been examined in

geriatric populations as a sign of cognitive and/or movement disorders.

Some of the difficulty in associating an abnormal glabellar reflex with a specific age-related condition lies in the fact that the abnormal glabellar reflex increases in prevalence with aging. In normal aging Dutch individuals from age 25 to 75, the prevalence of the glabellar reflex increased from about 10% between ages 25 and 45 to 22% between ages 66 and 82 with no significant difference between men and women. In a Japanese brain imaging study of 68 normal aged volunteers, 50% of all subjects had one primitive reflex (glabellar, snout, or palmomental). Individuals with a primitive reflex had more incidental cerebral lesions with no differences in mean regional blood flow and brain atrophy.

In the limited prospective studies examining the relationship between an abnormal glabellar reflex and cognition, an abnormal glabellar reflex was not found to be a marker of cognitive decline in older persons. However, a higher prevalence of an abnormal glabellar reflexes in individuals with dementia (including Alzheimer's disease) and with movement disorders (mainly Parkinson's disease) has been noted in longitudinal cohort studies and in case-control studies.

While the finding of an abnormal glabellar sign may not be a sensitive or specific physical exam finding for dementia and/or a movement disorder, it may be a more useful marker of disease severity, especially if it is present with other primitive reflexes. Also, habituation to the glabellar reflex may change in response to therapy. In Parkinson's disease, small studies have pointed to reduction of the abnormal glabellar reflex during the 'on' period of treatment with dopamine replacement agents. However, at least one study has found that the presence of the glabellar reflex in Parkinson's disease did not vary with plasma dopamine levels and that the presence of the glabellar reflex may reflect extrapyramidal disease.

In conclusion, while an abnormal glabellar reflex is common in older persons, it may be a better sign of severity of a given disease entity (such as dementia or a movement disorder) rather than as a diagnostic sign. Further work is needed to elucidate the underlying pathways resulting in the abnormal habituation of the glabellar reflex in the context of certain neurodegenerative diseases.

Glial Cell Activation in PD

K Wakabayashi, Hirosaki University Graduate School of Medicine, Hirosaki, Japan

Glossary

6-Hydroxydopamine – A dopaminergic neurotoxin inducing parkinsonism in rodents.

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) – A dopaminergic neurotoxin inducing parkinsonism in humans, nonhuman primate, and

other species of animals. MPTP is oxidized by monoamine oxidase to produce 1-methyl-4-phenylpyridinium ion (MPP^+), which is a more potent and true neurotoxin than MPTP itself.
Rotenone – A lipophilic pesticide causing highly selective nigrostriatal dopaminergic degeneration in rodents.
α-Synuclein – A presynaptic nerve terminal protein originally identified as the precursor protein of the non-Aβ component of Alzheimer's disease amyloid. α-synuclein is now known to be a major component of Lewy bodies.

Definition and History

Microglia, the antigen presenting immune cells in the brain, were discovered independently by Nissl (1899) and Robertson 1900, and first studied in detail by Rio-Hortega. Regarding the origin of microglia, the most widely accepted hypothesis is that they are bone marrow-derived cells. Microglia constitute ~10% of all glial cells. Under normal conditions, microglia display a ramified morphology, but rapidly transform into an activated state displaying a plastic ameboid morphology in response to invading pathogens, the presence of foreign substances, or neuronal injuries inflicted by trauma, ischemia, or neurodegeneration. Activation of microglia begins within minutes after the insult and precedes the morphologically detectable neuronal damage. Activated microglia can destroy invading microorganisms and remove potentially deleterious debris by phagocytosis.

Pathogenesis/Pathophysiology

Markers of neuroinflammation, including activated microglia and increased levels of circulating proinflammatory cytokines, have been observed in the brains and cerebrospinal fluid of patients with Parkinson's disease (PD). Activated microglia and reactive astrocytes are prominent in the substantia nigra in PD. The presence of activated microglia in the substantia nigra is also observed in animal models of PD. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), rotenone, and 6-hydroxydopamine (6-OHDA) all cause selective degeneration of nigrostriatal system.

In addition to the dramatic morphological changes, activation of microglia results in the upregulation of surface molecules. Furthermore, activation of microglia leads to an increase in the production of cytokines such as tumor necrosis factor-α (TNFα), interleukin-1β (IL-1β), IL-2, IL-4, IL-6, interferon-γ (IFNγ), the induction of inducible nitric oxide synthase (iNOS), cyclooxygenase-1 (COX-1), COX-2, and the activation of enzymes such as NADPH oxidase. These proinflammatory and neurotoxic factors and related enzymes are upregulated in human PD brains and experimental animal models of PD. Furthermore, studies of postmortem of PD brains and various cellular and animal models of PD strongly suggest that the generation of proinflammatory and neurotoxic factors by microglia plays a prominent role in mediating the progressive neurodegenerative process. The proinflammatory cytokines TNFα and IL-1β can trigger direct toxicity in neurons and potentiate an ongoing inflammatory response by enhancing microglial NO production. Mice deficient in TNFα receptors are completely resistant to MPTP toxicity. Several groups have shown an association of IL-1β gene polymorphism with increased risk of PD. IFNγ has been demonstrated to induce the expression of major histocompatibility complex class II molecules in microglia in vitro. Mice lacking *iNOS* gene are less sensitive to MPTP-induced loss of dopaminergic neurons in the substantia nigra. Microglia upregulate the levels of COX-2, a key enzyme responsible for the synthesis of inflammation-related prostaglandins. The prostaglandins can be directly toxic to neurons through activation of caspase 3, or indirectly through the release of glutamate by astrocytes leading to excitotoxicity. Mice lacking COX-2 gene, but not COX-1 gene, are significantly less vulnerable to MPTP-induced nigral degeneration. NADPH oxidase is one of the major sources for production of reactive oxygen species or related reactive nitric species in activated microglia. In mice lacking a functional NADPH oxidase, significant protection against MPTP-induced nigral degeneration is observed. Thus, activation of microglia is associated with the induction of neuronal cell death in PD, causing the vicious cycle of neurodegeneration. This is in line with the autopsy finding that activated microglia were present in the substantia nigra in human subjects decades after MPTP exposure, suggesting that even a brief pathogenic insult can induce an ongoing inflammatory response.

Astrocytes can produce various proinflammatory and neurotoxic factors, and may play a role in modulating microglial activity. Intercellular adhesion molecule-1 (ICAM-1) is overexpressed in reactive astrocytes in the substantia nigra in PD cases. Additionally, its counter receptor lymphocyte function-associated antigen 1 (LFA-1) is overexpressed in activated microglia. Astrocytes also secrete a number of neurotrophic factors. These include glial cell line-derived neurotrophic factor (GDNF), brain-derived neurotrophic factor (BDNF), and mesencephalic astrocyte-derived neurotrophic factor (MANF). Overexpression of NF-E2-related factor 2 (Nrf2) in astrocytes is also reported to protect against 6-OHDA damage in mice. Furthermore, astrocytes may suppress microglial activation by releasing transforming growth factor-β or IL-10. Astrocytes may play dual roles in neurodegeneration in PD.

Pathological Feature

The discovery of point mutations of the α-synuclein gene and amplification of the gene in some familial forms of PD, and the identification of α-synuclein protein as a major component of Lewy bodies, the histological hallmark of PD, in sporadic and familial PD, have emphasized interest in the role of α-synuclein in the pathomechanisms in PD. Lewy body formation has been considered to be a marker for neuronal degeneration, because neuronal loss is found in the predilection sites for Lewy bodies. To date, more than 70 molecules have been identified in Lewy bodies, in which α-synuclein is a major constituent of the inclusions. α-Synuclein is a potent activator of microglia and induces microglial expression of both IL-1 and TNFα. Microglia stimulated by a combination of α-synuclein and IFNγ are neurotoxic in vitro. Aggregated extracellular α-synuclein activates microglia in culture. This α-synuclein-induced microglial activation leads to dopaminergic neurotoxicity in a midbrain neuron/microglia mixed cell culture. However, the α-synuclein treatment does not produce the neurotoxic affect in the absence of microglia. α-Synuclein can stimulate the expression of ICAM-1 and the secretion of IL-6 in human astrocytes in vitro. Nigral neuronal damage may release aggregated α-synuclein that activates microglia with the production of proinflammatory mediators, thereby, leading to persistent and progressive nigral neurodegeneration in PD. Although α-synuclein is concentrated in the presynaptic nerve terminals in the normal brain, in vitro studies have shown that α-synuclein mRNA and protein are also expressed in both astrocytes and oligodendrocytes. Fibrillary aggregates of α-synuclein have been reported in astrocytes in PD. α-Synuclein expression in astrocytes increases in response to stimulation with the proinflammatory cytokine IL-1β. Although α-synuclein inclusions have also been reported in oligodendrocytes, they do not seem to play a role in promoting inflammation. Conversely, α-synuclein inclusions have never been described in microglia.

Epidemiology/Management

Nonsteroidal antiinflammatory drugs are effective inhibitors of COX enzymes that block the production of prostaglandins. Epidemiological studies suggest that chronic use of nonsteroidal antiinflammatory drugs such as aspirin and ibuprofen reduce the risk of PD. Evidence is accumulating that anti-inflammatory agents may have a place in PD therapy.

Prognosis

Activation of microglia is a double-edged sword in PD pathogenesis. Microglia produce several protective factors including antioxidants, growth factors, and signals to astrocytes that can secrete neuroprotective factors. Microglia also play an important role in the disposal of extracellular α-synuclein aggregates. However, microglial activation induces cell death in the substantia nigra through increasing oxidative stress and through producing noxious compounds including proinflammatory cytokines.

Glial Cytoplasmic Inclusions

K Wakabayashi, Hirosaki University Graduate School of Medicine, Hirosaki, Japan

Glossary

αB-crystallin – A lens protein which has homology with the small heat-shock proteins and is also expressed in nonlenticular tissues.

α-Synuclein – A presynaptic nerve terminal protein originally identified as the precursor protein of the non-Aβ component of Alzheimer's disease amyloid. α-Synuclein is now known to be a major component of Lewy bodies and glial cytoplasmic inclusions.

Definition and History

Glial cytoplasmic inclusion (GCI) is a histopathological hallmark of multiple system atrophy (MSA), a sporadic neurodegenerative disorder characterized clinically by combinations of parkinsonism, cerebellar signs, autonomic failure, and pyramidal signs. MSA was previously thought to be three separate diseases known as striatonigral degeneration, olivopontocerebellar atrophy, and Shy–Drager syndrome. Graham and Oppenheimer (1969) first proposed the term MSA based on the finding that sporadic striatonigral degeneration, olivopontocerebellar atrophy and Shy-Drager syndrome can coexist both clinically and pathologically. GCIs are consistently found in the brain of patients with MSA regardless of clinical presentation. The discovery of GCIs confirmed that MSA is a single clinicopathological entity.

Cellular Pathology

GCIs are argyrophilic and oligodendroglial in origin. They are triangular, sickle, half-moon, oval, or conical in shape. The nuclei of the GCI-bearing cells appear to be slightly larger and lighter than those of normal-looking oligodendrocytes. Immunohistochemical studies have shown that GCIs contain many substances, including α-synuclein, ubiquitin, tubulin, and αB-crystallin. The cells containing GCIs also give positive staining with oligodendroglial markers, including carbonic anhydrase isoenzyme II, transferrin, Leu-7, and heat-stable tubulin polymerization promoting protein. Gallyas-Braak impregnation method and α-synuclein immunohistochemistry are the most sensitive techniques to demonstrate GCIs. Ultrastructurally, GCIs consist of randomly arranged, loosely packed, granule-coated fibrils ~25–40 nm in diameter. Filamentous inclusions are also found in the nuclei of GCI-bearing oligodendrocytes.

Distribution

GCIs are widely distributed throughout the central nervous system. Although GCIs are more numerous in the areas showing neuronal loss and gliosis, as well as their targets, they are distributed even in regions in which neuropathological changes (neuronal depletion, loss of myelin and axons, or reactive astrocytosis) seem minimal or negligible. High GCI density is seen in the motor and supplementary motor cortical areas, white matter subjacent to the motor cortical areas, caudate nucleus, putamen, globus pallidus, internal capsule, external capsule, pontine base, middle cerebellar peduncle, cerebellar white matter, and reticular formation of the brainstem. GCIs are also present in the spinal cord and olfactory bulbs.

Pathogenesis/Pathophysiology

The most important recent development in the characterization of GCIs has been the discovery of α-synuclein in MSA. α-Synuclein was originally identified as a presynaptic nerve terminal protein. In Parkinson's disease and dementia with Lewy bodies, α-synuclein is deposited in neuronal cell bodies and processes as Lewy bodies and Lewy neurites, whereas filamentous aggregates of α-synuclein are predominantly found in oligodendrocytes as GCIs in MSA. α-synuclein deposited in α-synucleinopathy lesions was phosphorylated at Serine129; anti-phosphorylated α-synuclein antibody intensely immunolabeled Lewy bodies and Lewy neurites in Parkinson's disease and dementia with Lewy bodies, as well as GCIs in MSA. Moreover, the phosphorylated α-synuclein is ubiquitinated. Lewy bodies and GCIs are also immunopositive for synphilin-1, an α-synuclein-associated protein.

Although α-synuclein is abundantly expressed in neurons, α-synuclein mRNA and protein have been reported to be expressed by cultured rat oligodendrocytes. α-synuclein immunoreactivity has been detected in the neuronal perikarya and axons as well as in the cytoplasm of oligodendrocytes in proteinase K- or formic acid-treated

sections of normal human brain. Therefore, it is possible to consider that overexpression of α-synuclein in oligodendrocytes can cause GCI formation.

In addition to GCIs, neuronal inclusions have also been observed in MSA. Neuronal cytoplasmic inclusions (NCIs) were first described in the pontine and arcuate nuclei of patients with olivopontocerebellar atrophy, using silver impregnation techniques such as Bielschowsky and Bodian staining. Subsequently, several investigators revealed that NCIs were also found in the putamen, substantia nigra, inferior olivary nucleus, motor cortex, and dentate gyrus. The NCIs in the pontine nucleus are visible as round or ovoid inclusions, whereas those in the inferior olivary nucleus are reniform, crescent-shaped, or coarse granular in shape. The NCIs in the dentate granule cells are ring-like or C-shaped inclusions. Moreover, neuronal nuclear inclusions are found in the same populations as the NCIs. The neuronal nuclear inclusions consist of fibrillary or thread-like structures, irregularly arranged near to the nuclear membrane, and are occasionally seen to fill the whole karyoplasm.

The occurrence of GCIs precedes neuronal degeneration in MSA. This notion is supported by some cases of 'minimal change' MSA in which neuronal loss was restricted to the striatonigral and olivopontocerebellar systems, but GCIs were widely distributed in the central nervous system. The incidence of GCIs is correlated with the severity of neuronal loss in the olivopontocerebellar system as well as in the striatonigral system. Apoptosis occurs almost exclusively in oligodendrocytes, and extensive myelin damage is present in the MSA brain. Moreover, loss of myelin is much more severe than that of axons in the pontine base (transverse fibers), suggesting that loss of myelin precedes loss of axons in the disease process of MSA. Thus, widespread occurrence of GCIs may cause oligodendroglia–myelin degeneration (oligodendrogliopathy) in the central nervous system in MSA.

Since the discovery of α-synuclein as a major component of glial and neuronal inclusions in MSA, two neurodegenerative processes have been considered in this disease; one is due to the widespread occurrence of GCIs associated with oligodendrogliopathy in the central nervous system, and the other is due to the filamentous aggregation of α-synuclein in neurons in several brain regions. These two degenerative processes might synergistically cause neuronal depletion in MSA.

Animal Models

In order to study the consequence of α-synuclein expression in oligodendrocytes, transgenic mouse models were generated in which human α-synuclein was driven by oligodendrocyte-specific promoters. MSA-like pathology has been reported in transgenic mice with oligodendroglial α-synuclein overexpression combined with mitochondrial inhibition by 3-nitropropionic acid. In a transgenic mouse model that expresses human wild-type α-synuclein in oligodendrocytes of the mouse central nervous system under the control of the 2′,3′-cyclic nucleotide 3′-phosphodiesterase promoter, they developed slowly progressive motor impairments, filamentous aggregates of human α-synuclein in oligodendrocytes, but not in neurons, linked to the autophagocytosis of myelin, and loss of oligodendrocytes and neurons. Several investigators have generated transgenic mouse lines expressing human α-synuclein under the control of the murine myelin basic protein promoter. These mice displayed severe neurological alterations, accumulation of phosphorylated human α-synuclein in oligodendrocytes, loss of dopaminergic fibers in the basal ganglia, and myelin pallor in the white matte. These findings suggest that oligodendrocytic degeneration is a consequence of α-synuclein aggregates and that GCIs cause secondary neuronal degeneration.

Glucocerebrosidase Gene Mutations and Parkinsonism

J Aharon-Peretz, Rambam Medical Campus, Haifa, Israel

Glossary

Glycosphingolipids – A subtype of glycolipids (carbohydrate-attached lipids whose role is to provide energy and serve as markers for cellular recognition) containing the amino alcohol sphingosine. In Gaucher's disease, glucocerebroside (a type of glycosphingolipid) accumulates in lysosomes and macrophages resulting in multiorgan involvement.

Lewy body – An eosinophilic cytoplasmic inclusion whose primary structural component is α-synuclein; considered the pathological hallmark of Parkinson's disease.

Lewy body dementia, Lewy body disease, dementia with Lewy bodies – A disease characterized by dementia and parkinsonism.

Lipid (fats) storage disorders – A group of inherited metabolic disorders in which abnormal lipids accumulate in some of the body's cells resulting in cellular and organ failure. People with these disorders either do not produce enough of one of the enzymes needed to metabolize lipids or they produce enzymes that do not work properly. The nervous system, spleen, and bone marrow are usually affected.

LRRK2 – A gene that encodes a cytoplasmatic protein. Mutations in this gene have been associated with autosomal dominant Parkinson's disease, previously known as *PARK8,* but also with sporadic cases.

Lysosomes – Intracellular organelles that contain digestive enzymes (acid hydrolases), and digest excess or worn-out organelles, misfolded proteins, food particles, and engulfed viruses or bacteria.

Ubiquitin–proteosome system – An intracellular system by which misfolded proteins are tagged with polymeric ubiquitin for subsequent degradation by the proteasome.

α-Synuclein – α-Synuclein is a soluble protein that can aggregate to form insoluble fibrils in pathological conditions characterized by Lewy bodies such as in Parkinson's disease, dementia with Lewy bodies and multiple system atrophy.

Definition and History

The Glucocerebrosidase Gene and Gaucher Disease

The glucocerebrosidase gene, located on 1q21, encodes for the lysosomal enzyme glucocerebrosidase, which normally hydrolyzes glucocerebroside to glucose and ceramide. Deficiency of the glucocerebrosidase enzyme leads to the accumulation of glucocerebroside in lysosomes and macrophages resulting in multiorgan involvement. The ensuing clinical condition, named Gaucher disease, is the most prevalent, recessively inherited lysosomal lipid storage disease. The clinical manifestations include hepatosplenomegaly, anemia, thrombocytopenia, and easy bleeding. Bone and pulmonary involvement may also be present. Gaucher disease is classified into three subtypes based on the absence (type 1), presence of neurological involvement during childhood (type 2), or adolescence (type 3). Type 1 Gaucher disease, the most common form, is not associated with neurological manifestations, by definition. Type 1 is panethnic, but is especially prevalent among individuals of Ashkenazi Jewish descent. The carrier frequency for the glucocerebrosidase gene mutation is estimated at 0.0343 in the Ashkenazi Jewish population, and at 0.006 in the general population. In recent years, a subset of type 1 Gaucher patients who developed parkinsonism has been described.

Parkinsonism in Gaucher Type 1 Patients

Initial case reports indicating the existence of an association between Gaucher disease and parkinsonism described Gaucher patients with early onset, treatment refractory parkinsonism. Subsequently, Gaucher patients manifesting parkinsonism characterized by asymmetric onset of rigidity, resting tremor, bradykinesia, and favorable response to levodopa, as well as atypical, levodopa resistant disease were reported. Furthermore, an increased incidence of parkinsonism was reported in obligate heterozygotes, relatives of patients with Gaucher disease.

Epidemiology

Glucocerebrosidase Gene Mutations in Patients with Parkinson's Disease

Glucocerebrosidase gene mutations have been described in pathological samples and in clinical cohorts of patients with Parkinson's disease and Lewy body dementia. Sequencing of the glucocerebrosidase gene from 57 DNA samples

collected from brain bank material of patients diagnosed pathologically with idiopathic Parkinson's disease identified mutant glucocerebrosidase in 14% versus 4.6% mutant glucocerebrosidase in brain samples without pathological evidence of Parkinson's disease. In clinically diagnosed Parkinson's patients, mutant glucocerebrosidase was repeatedly detected more often than expected, in patients from various ethnic groups, with frequencies varying several folds among studies, and even within cohorts of similar ancestry. In a clinic based Ashkenazi cohort from Israel, 31% of 99 Parkinson's disease patients carried a mutant glucocerebrosidase as compared to 4.1% of 74 Alzheimer's patients and 6.2% of 1543 controls composed of healthy individuals undergoing testing to identify recessive disorders. An additional Israeli cohort identified a glucocerebrosidase carrier frequency of 17.9% in patients with Parkinson's disease versus 4.2% in elderly and 6.35% in young controls. A study in New York City revealed that 13.7% of 278 Parkinson's patients carried a glucocerebrosidase gene mutation compared to 4.5% of controls. The frequency of the glucocerebrosidase gene mutations was higher in a subset of 178 patients of Ashkenazi descent (16.9%). In Toronto, Canada, investigators reported a glucocerebrosidase gene mutation frequency of 5.6% of 88 Caucasian Parkinson's patients with early age of onset parkinsonism compared to 0.8% of controls. An increased number of Parkinson's disease patients presenting a mutation in the glucocerebrosidase gene as compared to controls was reported in Portugal (6.1% vs. 0.7%), Taiwan (12.9% of patients with early onset parkinsonism vs. 1.8% of controls), Brazil (3% of patients with early onset parkinsonism vs. 0% of controls), Venezuela (12% of patients with early onset parkinsonism vs. 3.2% of controls), Singapore (3% vs. o%), and Southern Italy (2.8% vs. 0.2%), but not in patients of Norwegian descent. The number of the glucocerebrosidase gene mutations studied varied among studies, from only two (N370S and L444P, the two most prevalent mutations) to comprehensive screening of the entire coding region. Parkinsonism was found to be associated with multiple allelic variants of the glucocerebrosidase gene.

The glucocerebrosidase mutations were not found to be associated with the G2019S mutation in the leucine-rich repeat kinase 2 gene which encodes the protein dardarin, and has been associated with autosomal dominant, late onset Parkinson's disease in both Askhenazi Jewish and non-Jewish subjects.

Clinical Features

Phenotypic Spectrum of Parkinson's Patients Carrying Glucocerebrosidase Mutations

The clinical features encountered among subjects with parkinsonism and glucocerebrosidase mutations include a wide spectrum of clinical manifestations. Patients with early age of onset, and refractory to levodopa therapy have been described along with patients with a classic presentation, including asymmetric onset of rigidity, tremor, and bradykinesia, favorable response to levodopa and clinical course that does not differ from patients with Parkinson's disease without glucocerebrosidase mutations. Recent analyses have suggested a high incidence of glucocerebrosidase mutations in patients diagnosed clinically and pathologically with Lewy body dementia. Treatment trials in a few subjects with Gaucher disease and parkinsonism with enzyme replacement therapy using recombinant human glucocerebrosidase did not show improvement or slowing of the parkinsonian symptoms.

Pathogenesis/Pathophysiology

Neuropathology

The neuropathological characteristics of the glucocerebrosidase related parkinsonism include loss of dopaminergic neurons in the substatnia nigra, synuclein positive Lewy bodies in the CA2–4 layers of the hippocampus or distributed all over the cortex and in the substantia nigra, and focal regions of gliosis especially in the hippocampal CA2–4 region and calcarine cortex. Biochemical cerebrospinal fluid studies show a decreased activity in several lysosomal hydrolases, beyond the expected decreased activity of β-glucocerebrosidase. The parkinsonism may be caused by a presynaptic dopaminergic dysfunction as substantiated in a [^{11}C] CFT and [^{11}C] raclopride PET study of a type 3 Gaucher patient and his heterozygous father, both presenting with treatment responsive parkinsonism. Nevertheless, as numerous studies report levodopa resistant parkinsonism, it would be premature to assume that all glucocerebrosidase related cases of parkinsonism represent a presynaptic hypodopaminergic state.

Pathogenic Mechanisms

The pathogenic mechanism causing parkinsonism in glucocerebrosidase gene mutation carriers remains elusive. Several hypotheses have been suggested. Since processing of α-synuclein occurs in lysosomes, glucocerebrosidase mutations might cause lysosomal dysfunction or interfere with the binding of α-synuclein at the lysosomal membrane. In addition, the aggregation of proteins in Lewy bodies suggests protein mishandling and subsequent proteolytic stress that might overwhelm the ability of the ubiquitin–proteasome system to degrade abnormally accumulated proteins, including α-synuclein. The functional form of α-synuclein is a lipid-bound state, and involves an interaction with lipid membranes. Glucocerebroside accumulation may perturb the affinity of the α-synuclein to lipid surfaces. The recent observation that α-synuclein binds to glucocerebroside-containing glycosphingolipids

which are elevated in glucocerebrosidase gene mutation carriers, supports this scenario.

Thus, a possible Parkinson–Gaucher intersection would involve a toxic gain of function related to aberrant α-synuclein accumulation, degradation, or a combination of both processes.

Summary

The association between Parkinson's disease and the glucocerebrosidase gene indicates that glucocerebrosidase mutations increase susceptibility to parkinsonism in heterozygotes from diverse ethnicities. Carriage of mutant glucocerebrosidase is one of the most significant risk factors for parkinsonism, identified to date. However, since the vast majority of patients with Gaucher disease never develop Parkinson's disease, it is likely that additional genetic and environmental factors interact with the glucocerebrosidase gene mutation's impact, resulting in the variety of clinical manifestations and responsiveness to levodopa therapy.

Gluten Ataxia

M Hadjivassiliou, The Royal Hallamshire Hospital, Sheffield, UK

Glossary

Ataxia – Disorder of coordination and balance that frequently affects limb movement, gait, eye movements, speech, and swallowing.

Autoimmunity – Lack of recognition by an organism of its own constituent parts as self, may result in an immune response against the organism's own cells and tissues; autoimmune diseases include celiac disease, systemic lupus erythematosus, Hashimoto's thyroiditis, rheumatoid arthritis among others.

Celiac disease (CD) – Celiac disease or gluten sensitive enteropathy, classically a disease characterized by gastrointestinal signs and symptoms.

Gluten ataxia (GA) – An immune-mediated disease triggered by dietary intake of gluten, associated with cerebellar signs and symptoms, often related to genetic susceptibility.

Definition and History

Celiac disease (CD) was first described in 100 AD. Classic CD (also known as gluten-sensitive enteropathy), was thought to be exclusively a disease of the small bowel and characterized by weight loss, diarrhea, abdominal bloating, and malabsorption. Gluten sensitivity (GS) refers to the whole spectrum of clinical manifestations,

including extraintestinal ones. Such manifestations can occur independently of the presence of the classic small bowel enteropathy. Cerebellar involvement, in the context of GS, also known as gluten ataxia (GA), is one of such extraintestinal manifestations that have only been recognized in the last decade. Currently-GA is defined as sporadic cerebellar ataxia associated with the presence of serological evidence of GS.

Pathogenesis/Pathophysiology

Postmortem examination from patients with GA demonstrates patchy loss of Purkinje cells throughout the cerebellar cortex. There is marked perivascular cuffing with inflammatory cells, mainly T lymphocytes within the cerebellar white matter. These findings are in favor of an immune-mediated pathogenesis.

Experimental evidence suggests that there is antibody cross-reactivity between antigenic epitopes on Purkinje cells and gluten peptides as well as tissue transglutaminase (the autoantigen in CD). Support for an antibody-mediated pathogenesis comes from the fact that intraventricular injection of serum from patients with GA can induce ataxia in mice. The role of transglutaminases in GA appears to be very important. Immune response targeting different types of transglutaminases (TG2 in CD, TG3 in dermatitis herpetiformis, TG6 in GA) may dictate the primary manifestation (e.g., bowel vs. skin vs. cerebellum involvement, respectively). The structural similarity among these transglutaminases may also explain the considerable overlap of these manifestations.

Epidemiology/Risk Factors

GA is probably one of the commonest causes of idiopathic sporadic ataxia (10–45%). A number of studies looking at the prevalence of antigliadin antibodies in patients with ataxia have been published. The common finding in all of these studies is the consistently high prevalence of these antibodies in sporadic ataxias when compared to healthy controls. Some have found a high prevalence of these antibodies in patients with genetically determined ataxias and in patients with Huntington's disease. This finding, if confirmed by larger studies, should not necessarily challenge the existence of GA as a disease entity, but rather should stimulate interest on the possible mechanism by which a genetically determined ataxia or other neurodegenerative process can result in the generation of antibodies against gluten. Variations in prevalence may relate to differences in the antigliadin assays used, geographical differences, and methodology including inadequate population size to extract meaningful prevalence information. Like CD, GA is associated with the HLA DQ2 and DQ8, which represent risk factors for the development of both CD and GA.

Clinical Features

There are no unique features that distinguish GA from other ataxias. The following clinical characteristics are based on 160 patients diagnosed and followed over the last 12 years. GA is characterized by insidious onset of predominantly gait ataxia, often associated with symptoms and signs suggestive of peripheral neuropathy (60%). The mean age at onset is 53 years. It affects both sexes equally. Evidence of limb ataxia is seen in up to 90% of patients with lower limbs more often affected than upper limbs. Gaze-evoked nystagmus and other ocular signs of cerebellar dysfunction are seen in up to 80% of cases. Additional movement disorders encountered in GA include myoclonus, chorea, palatal tremor, and opsoclonus myoclonus. As with CD, patients with GA are often found to have an increased prevalence of additional autoimmune diseases. Gastrointestinal symptoms are seldom seen and are not a reliable indicator of the presence or absence of enteropathy. In this respect, GA resembles dermatitis herpetiformis where gastrointestinal symptoms are not prominent despite the presence of an enteropathy.

Differential Diagnosis

The differential diagnosis includes all late onset acquired sporadic ataxias: cerebellar variant of multiple system atrophy (often associated with autonomic dysfunction), paraneoplastic cerebellar degeneration (usually a rapidly progressive course), immune-mediated cerebellar ataxia (organ-specific autoimmune disease), and idiopathic sporadic ataxia.

Diagnostic Work-up/Tests

By definition, all patients will have positive IgG and/or IgA antigliadin antibodies. Antiendomysium antibodies are present in only 22% of patients. Tissue transglutaminase antibodies are positive in up to 56% of patients with GA, often at lower titers than those seen in patients with CD. The HLA type DQ2 is seen in 70% of these patients (seen in 90% of patients with CD) with the remaining 30% having the HLA DQ8 (10%) and HLA DQ1 (20%). As some of these serological markers may not be 100% specific or sensitive, it is advisable that all these tests are done in all patients suspected of having GA. New markers are emerging such as tissue transglutaminase antibodies against TG6. TG6 may well be the

autoantigen in the neurological manifestations and ultimately prove to be the best marker for GA.

Up to 60% of patients with GA have evidence of cerebellar atrophy on magnetic resonance imaging (MRI). Some patients, in addition, will have evidence of white matter abnormalities which are often extensive and confluent. Even in those patients with GA who have no evidence of cerebellar atrophy on MRI, proton MR spectroscopy of the cerebellum reveals abnormalities, supporting the hypothesis that cerebellar neuronal physiology is abnormal.

Management

The benefits of a gluten-free diet in the treatment of patients with CD and dermatitis herpetiformis have long been established. There are very few studies, mainly case reports, of the effect of gluten-free diet on the neurological manifestations of GS. All but one of these reports primarily concern patients with established CD who then develop neurological symptoms. In the majority of these case reports, adherence to the gluten-free diet is assumed or assessed by improvement of gastrointestinal symptoms. Such an approach is inadequate if partial adherence to the diet is insufficient for neurological improvement to occur. The best marker of strict adherence to a gluten-free diet is serological evidence of elimination of circulating antigliadin antibodies. A small, uncontrolled study looked at the use of intravenous immunoglobulins in the treatment of four patients with GA without enteropathy. All four patients improved. All of these case reports and small studies suggest variable but overall favorable response to gluten-free diet.

Only one systematic study of the effect of gluten-free diet on a cohort of patients presenting with neurological dysfunction, with or without an enteropathy, has been published. Forty-three patients with GA were enrolled. There was significant improvement in performance in all the ataxia tests and in the subjective global clinical impression scale, in the treatment group when compared to the control group. The significant improvement in all the tests when comparing treatment and control groups was apparent even after excluding patients with an enteropathy. The study concluded that a gluten-free diet appeared to be an effective treatment for GA. It was suggested, however, that close monitoring should be undertaken using regular antigliadin antibody estimation and dietetic review to ensure strict adherence to the gluten-free diet.

Prognosis

As the end result of prolonged exposure to gluten in patients with GA is the loss of Purkinje cells, early diagnosis and treatment are imperative to prevent permanent disability. Strict gluten-free diet results in stabilization of the ataxia. It is important to monitor adherence to the diet by regular (e.g., every 6 months) serological testing for GS related antibodies.

GM1 Type 3 Gangliosidosis

E Roze and M Vidailhet, Fédération de neurologie, hôpital Pitié-Salpêtrière, Paris, France
C Flamand-Rouvière, Service de neurologie, Hôpital Kremlin-Bicêtre, Le Kremlin Bicêtre, France

Glossary

Athetosis – Involuntary slow continuous distal writhing movements.
Chemical chaperone therapy – Therapy based on chemicals that enhance enzyme activity by stabilizing the mutant protein.
Chorea – Irregular, unpredictable, brief involuntary movements that flow from one part of the body to another in nonstereotyped fashion.
Dystonia – Movement disorder characterized by involuntary twisting movement or abnormal postures resulting from simultaneous contraction of agonist and antagonist muscles.
Gangliosides – Components of the outer leaflet of plasma membranes. They are highly concentrated in neuronal plasma membranes but their function in neurons is unknown.
Gene therapy – Correction of an enzyme deficiency by insertion of a normal gene into the genome to replace an abnormal, disease-causing gene.
A carrier (vector) is used to deliver the therapeutic gene to the patient's target cells.
Hyperkinetic dysarthria – Speech disorder associated with hyperkinetic diseases, mainly characterized by aprosodia, imprecise articulation, abnormal orofacial movements, and vocal forcing.
Speech apraxia – Disorder of speech motor programming, mainly characterized by effortful groping for articulatory gestures, difficulties with the initiation of utterances, dysprosodia, and context-dependent variability of speech performance.
Substrate reduction therapy – Therapy aimed at relieving a deficient enzyme of an excessive substrate burden by pharmacological inhibition of substrate biosynthesis, thereby reducing substrate accumulation.

Definition and History

GM1 gangliosidosis (GM1-g) is an autosomal recessive metabolic disorder due to β-galactosidase deficiency. The gene that encodes this enzyme is located on chromosome arm 3p21.33. β-galactosidase catalyzes glycoconjugates with a terminal β-galactose, including ganglioside GM1, oligosaccharides and keratan sulfate (**Figure 1**). Deficient enzyme activity leads to the accumulation of these substrates, particularly in neurons. Following the first reports from Norman and Craig in 1959, GM1 gangliosidosis was proposed as a new inborn metabolic disorder in the early 1960s by Landing and O'Brien, and β-galactosidase deficiency was first demonstrated by Okada and O'Brien in 1968.

β-Galactosidase deficiency can manifest clinically as either Morquio B disease or GM1 gangliosidosis. Morquio B disease mainly involves generalized skeletal dysplasia without CNS involvement. GM1 gangliosidosis is classified into three clinical subtypes according to the degree of residual enzyme activity and substrate accumulation, which correlates with clinical severity. Type 1 is the most severe form, with rapidly progressive diffuse neurological deterioration, facial and skeletal abnormalities, and visceromegaly; death occurs during the first years of life. Patients with type 2 have less severe skeletal changes and slower neurological deterioration but usually die during childhood. Type 3 (GM1-3g) is characterized by later onset with only mild skeletal abnormalities, a protracted clinical course with survival into adulthood, predominant movement disorders, and selective accumulation of GM1 gangliosides in the striatum.

Genotype–Phenotype Correlation and Pathophysiology

The main substrates that accumulate in β-galactosidase deficiencies are keratan sulfate in Morquio B disease and ganglioside GM1 in GM1 ganglisosidosis, partly explaining the different clinical phenotypes. More than 100 mutations have now been identified in the *GLB1* gene in patients with Morquio B disease and GM1 ganglisosidosis. Neither the type nor the location of mutations has been clearly linked to the clinical phenotype. In GM1-3g, non-Japanese patients usually have heterozygous mutations located throughout the gene, whereas most Japanese patients are homozygous for the I51T mutation.

Altered intracellular signaling and neurotransmission, increased autophagia, and mitochondrial dysfunction have been reported in animal models of GM1 gangliosidosis. Postmortem analysis of the brains of GM1-3g GM1 patients shows abnormalities largely restricted to the striatum, including accumulation of ganglioside GM1 and its

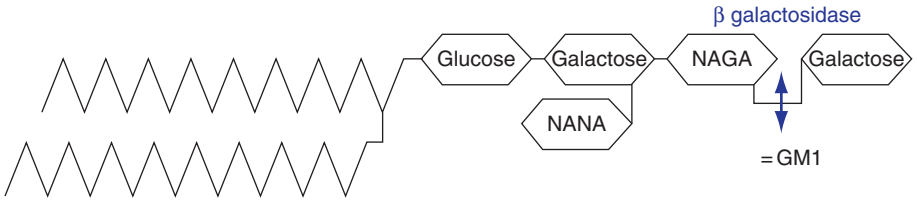

Figure 1 Biochemical defect in GM1 gangliosidosis. β-galactosidase deficiency prevents hydrolysis of the terminal β-galactosyl residues of GM1 gangliosides, leading to massive accumulation.

derivatives, neuronal loss, morphological abnormalities of neurites, and gliosis. Although the precise pathogenesis of the neurological disorders is unknown, it likely involves the metabolic and morphological effects of GM1 ganglioside accumulation. The residual enzyme activity present in GM1-3g patients may protect the brain from these effects, with the exception of the striatum, where GM1 ganglioside turnover may be higher.

Epidemiology

The incidence of GM1 gangliosidosis could be estimated at about 1 in 200 000 births. GM1 gangliosidosis seems to exist worldwide but a higher incidence has been reported in Malta, Cyprus, southern Brazil, and in Bulgarian gypsies. Type 3 accounts for about one-third of cases, and Japanese patients are overrepresented. It is not clear whether it reflects or not a higher incidence of this form in this country.

Clinical Features

Movement disorders are almost always present in the GM1-3g clinical subtype. These patients' initial psychomotor development is usually normal. Onset occurs at a median age of 6 years, and before age 20 years in 85% of cases. Most patients gradually develop generalized dystonia and related gait and speech disorders. Dystonia is an early manifestation and remains prominent throughout the disease course. Major facial involvement with facial grimacing, suggestive of symptomatic dystonia, is particularly significant, as associated swallowing disorders can be life-threatening. Speech disorders can progress to anarthria, leading to severe problems of communication. Patients typically have complex speech alterations consistent with combined hyperkinetic dysarthria and speech apraxia. Dystonia is often associated with akinetic-rigid parkinsonism that also gradually worsens with aging, giving the patients a 'stuck in glue' appearance. Choreoathetoid movements can also be present, mostly in the early stages of the disease. A pyramidal syndrome and mental retardation can be observed and are usually mild when present. Short stature, likely related to skeletal dysplasia, is frequent and can be a good, albeit nonspecific diagnostic clue. Scoliosis and musculo-tendinous retractions are frequent during the course of the disease, most likely secondary to chronic dystonia.

Diagnostic Work-up

Bone radiography can frequently detect minor bone dysplasia, which is a good diagnostic clue to GM1-3g. In particular, flattening or anterior beaking of the vertebral bodies, flattening of the femoral head and acetabular hypoplasia are suggestive of the diagnosis in patients with generalized dystonia. Brain MRI can show hyperintensities of the posterior putamina on T2-weighted images. To confirm the diagnosis, β-galactosidase deficiency has to be established by measuring its activity in leukocytes or skin fibroblasts; values range from 2% to 10% of normal. Molecular analysis of the *GLB1* gene can be performed later, as a basis for reliable genetic counseling and prenatal diagnosis.

Treatment and Prenatal Diagnosis

There is currently no way of preventing or even slowing the progression of the neurological disorders associated with GM1-g. The development of several animal models has made it possible to test new therapeutic approaches, some of which warrant evaluation in clinical trials. In mice, substrate reduction therapy by pharmacological inhibition of gangliosides biosynthesis, and restoration of enzyme activity by gene therapy or chemical chaperone therapy can reduce brain ganglioside accumulation and/or improve the neurological phenotype. Chemical chaperone therapy may be particularly interesting for GM1-3g patients, who usually have some residual β-galactosidase expression. Symptomatic drug therapy of generalized secondary dystonia is usually disappointing but GM1-3g patients can derive some benefit from anticholinergic drugs or benzodiazepines. Deep brain stimulation is also a therapeutic option in this setting, although the improvement is less marked and less predictable than in patients with primary dystonia. Finally, physiotherapy, speech rehabilitation, and swallowing rehabilitation are crucial in improving these patients' quality of life and prognosis. As each subsequent sibling has a 25% risk of being affected and there is no effective

therapy, prenatal diagnosis should be discussed with affected families. It can be based on β-galactosidase assay in fetal amniotic cells, or on the detection of previously identified mutations in trophoblast biopsy specimens.

Prognosis

Clinical severity and the rate of progression both vary widely from one patient to the next, ranging from severe disability in adolescence to mild symptoms and normal social interaction with slow deterioration and survival into old age. The survival of severely disabled patients depends on their swallowing function (risk of respiratory infections and acute respiratory failure), and on their overall management, especially the prevention of decubitus complications.

GM2 Gangliosidosis

E Roze, C Ewenczyk, and F Sedel, Fédération de neurologie, hôpital Pitié-Salpêtrière, Paris, France

Glossary

Ataxic dysarthria – Speech disorder associated with a cerebellar syndrome and mainly characterized by dysprosodia, imprecise articulation, and poor coordination of respiration with speech.
Athetosis – Involuntary slow continuous distal writhing movements.
Chorea – Irregular, unpredictable and brief involuntary movements that flow from one part of the body to another in non stereotyped fashion.
Dystonia – Movement disorder characterized by involuntary twisting movement or abnormal postures resulting from simultaneous contraction of agonist and antagonist muscles.
Gangliosides – Components of the outer leaflet of plasma membranes. They are highly concentrated in neuronal plasma membranes but their function in neurons is unknown.
Gene therapy – Correction of an enzyme deficiency by insertion of a normal gene into the genome to replace an abnormal, disease-causing gene. A carrier (vector) is used to deliver the therapeutic gene to the patient's target cells.
Hyperkinetic dysarthria – Speech disorders associated with hyperkinetic diseases mainly characterized by aprosodia, imprecise articulation, and abnormal orofacial movements.
Pharmacological chaperone therapy – Therapy based on pharmacological compounds that enhance enzyme activity by stabilizing a mutant protein.

Substrate reduction therapy – Therapy aimed at relieving a deficient enzyme of an excessive substrate burden by pharmacological inhibition of substrate biosynthesis, thereby reducing substrate accumulation.

Definition and History

GM2 gangliosidosis (GM2-g) is an autosomal recessive metabolic disorder due to β-hexosaminidase deficiency (**Figure 1**). The enzyme is composed of a dimer of two subunits α and β encoded by genes *HEXA* and *HEXB* and two isoforms do exist: hexosaminidase A formed by the hetero dimer αβ and hexosaminidase B formed by the homo dimer ββ. GM2 gangliosidosis can be caused by defects in the genes *HEXA* (Tays–Sachs disease, where only the isoform A is deficient), *HEXB* (Sandhoff disease, where both isoforms are involved) or *GM2A*, an activator required for both isoforms activity. These three genes are located on chromosome 15q23–q24, 5q13, and 5q31.3–33.1, respectively. The normal products of these three genes are required to hydrolyze GM2 ganglioside; deficient activity results in GM2 ganglioside accumulation, particularly in neurons. Tay first identified the cherry-red macular spot observed in the infantile form in 1881, and Sachs, in 1887, identified characteristic neuropathological abnormalities (neurons with distended cytoplasm and ballooning dendrites). They initially called the disease amaurotic idiocy. In 1962, Svennerholm found that ganglioside GM2 is the main neuronal storage compound in GM2-g, and hexosaminidase A deficiency was first demonstrated by Okada and O'Brien in 1969. At the same time, Sandhoff reported that some patients were missing both hexosaminidase A and B.

GM2 gangliosidosis is divided into three clinical subtypes according to the age at onset. In general, the later the disease occurs, the more slowly it progresses. Type 1 (infantile type) begins in the first year of life with rapidly progressive diffuse neurological deterioration and death before 4 years of age. Type 2 (juvenile type with onset between 2 and 10 years) and type 3 (adult type with onset after age 10 years) are more slowly progressive neurological disorders in which the clinical manifestations depend on which parts of the central nervous system are affected. Although rarely prominent, movement disorders can occur in these later-onset forms.

Genotype–Phenotype Correlation and Pathophysiology

The degree of residual enzyme activity partly determines the clinical severity. Mutations that lead to the production of no mRNA, or highly instable mRNA, result in a complete lack of enzyme activity and cause the most severe infantile forms of GM2-g. Late-onset forms are due to less severe point mutations within the coding region, resulting in stable mRNA and residual enzyme activity. In heterozygous patients, disease severity is determined by the less severe of the mutated alleles. For example, at least one G269S or W474C mutation in the *HEXA* gene may be associated with a milder phenotype.

The pathogenesis of the neurological disorders in GM2-g patients, although poorly understood, is primarily due to GM2 and GA2 ganglioside accumulation in neurons. This progressive storage leads to neuronal dysfunction that has been attributed to the disruption of intracellular structures, impaired axonal transport and neurite outgrowth, altered intracellular signaling and neurotransmission, and an abnormal inflammatory response. The residual enzyme activity present in late-onset forms may protect neurons that have a low rate of ganglioside biosynthesis.

Epidemiology

The incidence of GM2 gangliosidosis has been estimated at about 1 in 150 000 births. GM2 gangliosidosis seems to occur worldwide but a higher incidence has been reported in Switzerland, Japan and eastern Quebec, in Louisiana Cajuns, Ashkenazi Jews (Tay–Sachs disease); Lebanese and Lebanese-Canadians, Creoles from northern Argentina, Metis Indians from Saskatchewan, and Maronites from Cyprus (Sandhoff disease). The incidence of Tay–Sachs disease among Ashkenazi Jews was as high as 1 in 3000 births before a screening and genetic counseling program led to a 90% reduction.

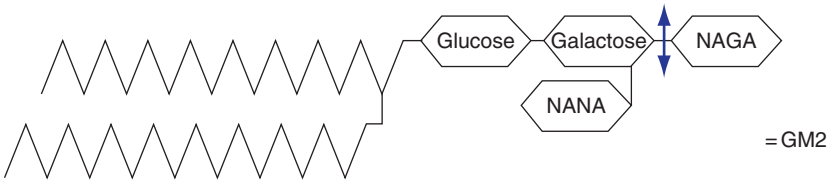

Figure 1 The biochemical deficiency in GM2 gangliosidosis. β-Hexosaminidase deficiency results in an inability to remove the terminal *N*-acetyl-galactosamine residue from GM2 ganglioside, leading to massive GM2 ganglioside accumulation.

Clinical Features

Movement disorders can occur in both the juvenile and adult forms of late-onset GM2 gangliosidosis. Type 2 patients usually have progressive tetraparesis, epilepsy, and dementia. Visual disturbances including optic atrophy and macular cherry-red spot can be present. In addition, rare patients with a less severe juvenile mono-symptomatic forms characterized by pure generalized dystonia have been reported. These pure dystonic forms with a more protracted course are probably underdiagnosed. In type 3 patients, movement disorders are frequent usually in association with more complex neurological disorders. The combination of movement disorders with more common features resulting from cerebellar and motor neuron dysfunction is suggestive of late-onset GM2-g. Psychotic symptoms, mild pyramidal signs, painful sensory polyneuropathy, dysautonomia, vertical supranuclear palsy can also be observed. Movement disorders are occasionally the predominant clinical abnormality. They are observed in 30–50% of patients and include tremor, generalized or focal dystonia, chorea, and parkinsonism. Most patients gradually develop severe gait disorders and become wheelchair-bound within about 20 years after disease onset. Dementia and visual disturbances are very unusual in this form. Progressive speech disorders, mainly consisting of ataxic and/or hyperkinetic dysarthria, are almost always present and gradually result in severe communication difficulties. Swallowing disorders can become life-threatening later in the disease.

Diagnostic Work-up

In late-onset GM1-g, brain MRI can show cerebellar atrophy, either in isolation or associated with mild overall brain atrophy. Neurophysiological examination can reveal abnormalities consistent with anterior horn cell disease or axonal sensory polyneuropathy. Ophthalmological examination is usually normal but some cases of optic atrophy or macular cherry-red spots similar to those seen in the infantile form have been reported in the type 2 form. Rectal biopsy can show membranous cytoplasmic bodies in ganglionic cells from the mesenteric plexus, similar to those observed in the brain. To confirm the diagnosis, β-hexosaminidase deficiency has to be established by measuring its activity in leukocytes or skin fibroblasts. Molecular analysis of the *HEXA*, *HEXB*, or *GM2A* genes can be performed later, as a basis for reliable genetic counseling and prenatal diagnosis.

Treatment and Prenatal Diagnosis

There is currently no way of preventing or even slowing the progression of the neurological disorders associated with GM1-g. The development of several animal models has made it possible to test new therapeutic approaches, some of which warrant evaluation in clinical trials. In mice, substrate reduction therapy based on pharmacological inhibition of ganglioside biosynthesis with miglustat and restoration of enzyme activity by gene therapy have both been found to reduce brain accumulation of gangliosides and/or to improve the phenotype. However, in human, miglustat failed to stop the neurological deterioration in clinical trials. Pharmacological chaperone therapy can increase enzymatic activity in vitro and may be particularly interesting for patients with late-onset disease, who usually have residual β-hexosaminidase expression. Drug therapy of movement disorders associated with GM2-g is usually disappointing. Patients with dystonia and/or choreoathetosis may benefit from treatment with anticholinergic drugs, benzodiazepines or low-dose tetrabenazine. The associated parkinsonism is occasionally dopa-responsive. Psychiatric disorders associated with GM2-g are difficult to treat, and the drugs used (particularly phenothiazines) can lead to neurological deterioration. Physiotherapy, speech rehabilitation, and swallowing rehabilitation are crucial for these patients' quality of life and prognosis. Prenatal diagnosis should be proposed to affected families, as each subsequent sibling has about a 25% risk of being affected. It can be based on β-hexosaminidase assay in fetal amniotic cells, or on the detection of previously identified mutations in trophoblast biopsy specimens.

Prognosis

In type 2 and type 3 GM2-g, severity and the rate of progression both vary widely, ranging from severe disability in adolescence to mild symptoms and normal social interaction with slow deterioration and survival into old age. The survival of severely disabled patients depends mostly on swallowing function (risk of respiratory infections and acute respiratory failure) and on overall management, especially the prevention of decubiti complications.

H

Hallervorden–Spatz Syndrome (PKAN)

S J Hayflick, Oregon Health & Science University, Portland, OR, USA

Glossary

Autosomal recessive – A mode of inheritance of a disease where two copies of an abnormal gene must be present in order for the disease to develop.
Dystonia – Movement disorder producing muscle contractions with characteristic postures.
Pigmentary retinopathy – A disorder of the retina characterized by deposits of pigment and increasing loss of vision, present in many neurodegenerative diseases.

Definition and History

Hallervorden–Spatz syndrome is an autosomal recessive neurodegenerative disorder. Mutations in the gene encoding pantothenate kinase 2 cause the disorder, which includes abnormal movements, vision defects, and psychiatric problems. The disorder is now referred to as pantothenate kinase-associated neurodegeneration or PKAN.

First described in 1922 by Julius Hallervorden and Hugo Spatz, the eponym for this disorder is no longer favored. These two German neuropathologists participated in objectionable Nazi-era programs. To discredit Hallervorden and Spatz, the medical community sought to abandon the eponym in favor of a rational moniker. Following the discovery of its genetic basis, Hallervorden–Spatz syndrome became known as pantothenate kinase-associated neurodegeneration (PKAN).

Historically, the term Hallervorden–Spatz syndrome encompassed any neurodegenerative disorder associated with high brain iron. Now, the overarching term for this heterogeneous group of disorders is neurodegeneration with brain iron accumulation, or NBIA, of which PKAN is one form.

Pathogenesis/Pathophysiology

PKAN is caused by mutations in *PANK2*, which encodes the mitochondrial form of pantothenate kinase. This key regulatory enzyme phosphorylates vitamin B5, or pantothenate, and commits it to the biosynthesis of coenzyme A. While the precise cascade of metabolic perturbations arising from defective *PANK2* is uncertain, PKAN is an inborn error of coenzyme A metabolism.

PANK2 is one of four homologous genes to encode a pantothenate kinase. Such redundancy at the level of the genome suggests a specific role for each member of this enzyme family. PANK2 is associated with mitochondria, and its unique biochemical features suggest a possible localization to the intermembranous space. There, PANK2 is proposed to function as an indirect sensor of matrix coenzyme A levels, signaling to the cytoplasmic pantothenate kinases 1 and 3.

Defects in PANK2 are predicted to lead to aberrant levels of mitochondrial coenzyme A. However, the limited tissue vulnerability (brain, retina, testis) in PKAN suggests that most cells can overcome this defect. Possible reasons include a relative predominance of PANK2 versus PANK1 and PANK3, high energy demands, or high oxidative stressors. Regardless, the cascade of changes lead to tissue damage, and in the brain, iron accumulation. Clearly, the primary defect precedes accumulation of high amounts of iron. However, abundant iron almost certainly contributes to disease pathogenesis, and it remains the best recognized feature of this rare disorder.

Epidemiology/Risk Factors

PKAN is a rare autosomal recessive disorder. Incidence is estimated to be in the range of 1 in 250–500 000 worldwide. There is no ethnic predilection for mutations in *PANK2*, although specific mutations may be more commonly associated with certain ethnicities. For rare recessive disorders in general, consanguinity increases risk.

Clinical Features and Diagnostic Criteria

PKAN can be generally divided into two phenotypic groups: classic and atypical. Classic disease is clinically homogeneous and is characterized by onset in the first 5 years, with a rapid progression to loss of ambulation by age 15 years. The most common presenting feature is gait abnormality due to limb dystonia, with frequent falls from poor balance. The dystonia worsens with time and progresses to involve more body parts. Dysarthria is common as well. Pigmentary retinopathy occurs in most patients with classic disease, although clinical compromise is generally limited by the more significant neurologic impairment.

Atypical PKAN includes all patients with *PANK2* mutations who do not fit into the classic category. Atypical disease is later in onset, ranging from late childhood to early adulthood. Also, progression is slower, with a loss of ambulation often not until well into adulthood. Furthermore, although patients with atypical disease eventually develop disabling dystonia, the presenting features are more commonly neuropsychiatric disturbances. These may include impulsivity, obsessive-compulsive disorder, depression, and tics. Some patients will carry a diagnosis of Tourette syndrome prior to being diagnosed with PKAN. As a general rule for atypical PKAN, later onset is associated with a slower progression.

For the majority of PKAN patients, characteristic MRI findings lead to the correct diagnosis. The eye-of-the-tiger sign refers to the characteristic MRI pattern found PKAN. Specifically, the sign describes hypointense signal in the globus pallidus in conjunction with a region of central or anteromedial hyperintensity on T_2-weighted imaging. PKAN can be confirmed by direct DNA testing for mutations in *PANK2*.

Differential Diagnosis

The eye-of-the-tiger sign is considered to be virtually pathognomic for PKAN (**Figure 1**). Rare reports have offered evidence to refute this notion; however, none of these has provided sufficient data to challenge this robust association. Therefore, especially in the context of supporting clinical data, the eye-of-the-tiger sign indicates PKAN.

NBIA encompasses a heterogeneous group of disorders that includes PKAN, as well as neuroferritinopathy, aceruloplasminemia, infantile and atypical neuroaxonal dystrophy and idiopathic NBIA. The specific MRI patterns associated with these disorders differ from that of PKAN, though all include high regional iron in the basal ganglia.

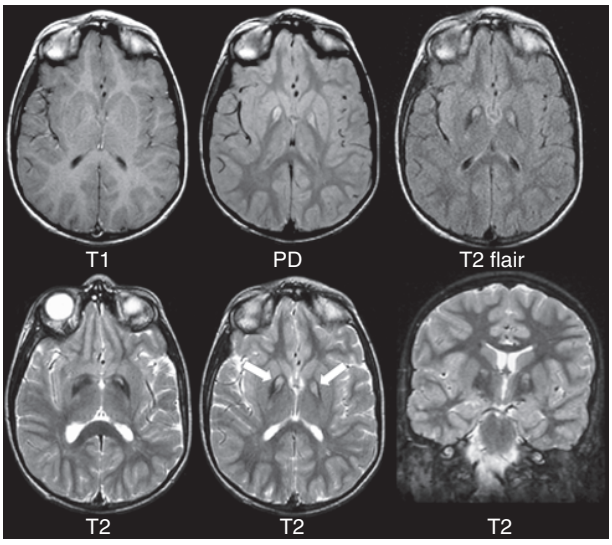

Figure 1 ''Eye of the tiger'' abnormality, T2-weighted imaging shows hypointense signal in the globus pallidus with a region of central or anteromedial hyperintensity (white arrows).

Diagnostic Workup/Tests

When the MRI shows the eye-of-the-tiger sign, diagnostic studies for PKAN are indicated. Blood may be sent for DNA sequencing of *PANK2* in order to confirm the diagnosis. Laboratories currently offering clinical testing can be found at GeneTests. The sensitivity of current screening tests is >98%.

Management

Efforts are underway to develop rational therapies for PKAN. Currently, treatment remains palliative. The two drugs most commonly beneficial in both classic and atypical PKAN are baclofen and trihexyphenidyl. L-DOPA is not beneficial in PKAN, although it may be useful in non-PKAN forms of NBIA. Transient benefit has been reported in some PKAN patients from deep brain stimulation with bilateral electrodes placed in the globus pallidus interna. Newer formulations of CNS-acting chelators may also have a role in limiting the secondary iron accumulation in PKAN. Risks of systemic iron deficiency, especially in children, remain of concern.

Prognosis

PKAN is a relentlessly progressive neurodegenerative disorder. Currently available interventions do not alter the course of disease. In classic disease, the rate of progression typically leads to a loss of ambulation by age 15 years and commonly as early as 5–10 years of age.

Progression is characterized by periods of rapid decline interspersed with plateaus. The factors leading to these episodes of exacerbation remain unknown but seem not to be simple catabolic stress. Once lost, skills are not usually regained.

In contrast to classic disease, atypical PKAN varies with onset from adolescence to adulthood. For these less severe forms, the rate of progression typically is slower.

Hallucinations and Movement Disorders

G Fénelon, AP-HP, Hôpital Henri Mondor, Service de neurologie, Créteil, France; INSERM U955, Equipe 1, Neuropsychologie interventionnelle, Créteil, France

Glossary

Delusion – False beliefs based on incorrect inference about external reality that is firmly sustained despite what almost everyone else believes and despite what constitutes incontrovertible and obvious proof of evidence to the contrary.

Hallucination – Sensory perception that has the compelling sense of reality of a true perception but that occurs without external stimulation of the relevant sensory organ. Hallucinations may be visual, auditory, olfactory, gustatory, somatic, or tactile.

Illusion – Misperception or misinterpretation of a real external stimulus.

Presence (sense of presence, hallucination of presence) – Vivid sensation that somebody is present nearby, when no one is there and no one is seen.

Psychosis – Applied to PD or other neurodegenerative diseases, this term usually refers to a mental state characterized by hallucinations and/or delusions.

Simple/complex visual hallucinations (VH) – Simple VH consist of elementary visual phenomena such as geometrical patterns, shadows, or flashes. Complex, or formed, VH consist of people, animals, or objects.

History

Movement disorders and hallucinations coexist in a number of conditions, especially in Parkinson's disease (PD) and dementia with Lewy bodies (DLB). An early detailed description of hallucinations in the course of PD was provided by Victor Parant, a French psychiatrist, in 1883. Since the end of the nineteenth century, views on hallucinations and PD have evolved in three stages: in the first stage, they were considered coincidental or end-stage nonspecific phenomena; they were later viewed as a side effect of an antiparkinsonian treatment mainly using dopaminergic agents; more recently, they are viewed as the product of complex interactions of treatment and disease-related factors. Hallucinations and delusion emerged as common and typical features of DLB in the early 1990s.

Clinical Features

The typical hallucinatory syndrome of PD and DLB appears in patients with a clear sensorium and recurs in short sequences (seconds or minutes). Hallucinations may occur at any moment, but are more frequent in the evening and during the night. Complex visual hallucinations (VH) are the most common type, and mostly consist of persons, who may or may not be familiar, and less often animals or objects. The hallucinated figures are usually single or few, and may be relatively stereotyped in a given patient. Hallucinations appear and vanish suddenly, sometimes when the patient tries to check their reality by approaching or touching them. Hallucinatory images are seen superimposed on the normal background scene. Simple VH are uncommon. Auditory hallucinations may be elementary (ringing, knocks, etc.), or more often, complex. When auditory verbal hallucinations are present, they are neutral and clearly different from the pejorative or threatening auditory hallucinations characteristic of schizophrenia. Tactile hallucinations, in most cases, involve contact with small animals or the feeling of being touched by someone. Olfactory, and less often, gustatory hallucinations have been reported in series and case reports. Related 'minor' phenomena include visual illusions (typically seeing an inanimate object as a living being) and a sense of presence. Hallucinatory phenomena may also accompany: for instance, the patient may hear the conversation of unreal persons, or see the small animal he feels creeping on his legs. In a minority of cases, especially in patients with cognitive impairment, delusions may accompany hallucinations.

Patients who are free of cognitive impairment realize the hallucinatory nature of their hallucinations. Demented patients commonly lose this insight. Some patients with cognitive impairment may have partial and (or) fluctuating insight.

Epidemiology

Frequency

In PD, as shown by most cross-sectional prospective studies, VH are present in one quarter to one third of PD patients. Auditory hallucinations are rarer. Hallucinations in other modalities were not systematically sought in most studies, so their prevalence may be underestimated. If illusions and minor forms of hallucinations (e.g., a sense of presence) are taken into account, the prevalence is higher, reaching 40–75% of chronically treated PD patients. Lifetime prevalence of hallucinations is higher than in point prevalence studies, reaching at least 50%. Finally, the prevalence of hallucinations is higher in PD patients with dementia, with figures (50–70%) similar to those observed in the course of DLB.

Studies of hallucinations in other parkinsonian disorders (multiple system atrophy, progressive supranuclear palsy, corticobasal degeneration) are infrequent, so it is difficult to estimate their occurrence in these conditions. However, the available data suggest that hallucinations are rarely present in patients with parkinsonism associated with non-Lewy body parkinsonism.

Risk Factors

In PD, the role of dopaminergic treatment has been considered critical. However, disease-related factors also play an important part. In clinical studies, the main disease-related factor is severe cognitive impairment and/or dementia. Other significant concomitants of hallucinations or psychosis are older age, a longer PD duration, a greater severity of PD, altered dream phenomena (vivid dreams, nightmares, rapid eye movement (REM) associated behavioral disorder), daytime somnolence, and abnormalities of visual input due either to coincident ocular disease or to specific retinal dysfunction affecting contrast sensitivity and color discrimination. A facilitating role for depression is suggested by some, but not all, studies.

Pathophysiology

Imaging or biological studies provide information on the pathophysiology of VH, but no single integrated mechanism has been identified. Neuroimaging studies of PD yielded heterogeneous results, but suggested a decreased visual input ('bottom-up' processes) and a disinhibition of 'top-down' cortical processing. In PD and DLB, pathological studies have shown an association between VH and higher densities of Lewy bodies in the temporal lobe and in the amygdala as well as in other cortical areas. The involvement of dopaminergic, serotoninergic, and/or cholinergic widespread projection pathways in the genesis of hallucinations has been postulated mainly on the basis of indirect pharmacological evidence or more theoretical considerations. The core dopaminergic hypothesis postulates that hallucinations result from the overstimulation of the mesocorticolimbic dopaminergic receptors. Variants of this model focus on several neurotransmitter systems through a cascade of activations and inhibitions. Among these, researchers have advocated both a serotoninergic–dopaminergic imbalance and a monoaminergic–cholinergic imbalance.

Finally, hallucinations may constitute a common end pathway of different, and possibly combined, underlying mechanisms. No simple model can account for the full diversity and heterogeneity of the factors associated with hallucinations in PD. Diederich et al. proposed an integrated model based on Hobson's work on factors

regulating consciousness. A more general model of complex VH involves cognitive and psychology-based models of scene perception.

Diagnostic Work-Up

As hallucinations are not witnessed by physicians, they cannot be directly studied or quantified with ease. The examiner is dependent on what the patient or his/her caregiver reports. When the patient is cognitively impaired, one may assume that only striking hallucinations or those associated with behavioral disorders will be recorded by the caregiver. Prospective studies devoted to the prevalence and/or phenomenology of hallucinations in PD or DLB have used structured or semistructured questionnaires. Other studies and therapeutic trials used various specific or nonspecific scales, the latter being derived from the fields of dementia or psychiatry. The impact of hallucinations must be carefully evaluated. Most hallucinations are nonthreatening, but they may induce anxiety and/or behavioral disorders in some patients. The consequences should also be evaluated in the caregiver, as hallucinations are often poorly understood and accepted.

Management

Nonpharmacological approaches are recommended in all cases. They include providing information on hallucinations to the patient and his/her caregiver; promoting coping strategies; identifying depression or other comorbid psychiatric conditions; checking visual acuity; and evaluating cognition by brief bedside tests. Reducing doses of antiparkinsonian drugs, psychopharmaceuticals, analgesics, and/or anticholinergics given for indications other than those of PD should be considered. If cognitive impairment is present, cholinesterase inhibitors may be added to the regimen. However, evidence that these drugs reduce hallucinations or other psychotic symptoms relies on open-labeled studies. Finally, if hallucinations are responsible for severe anxiety and/or behavioral distress, an antipsychotic drug can be used. According to a 2007 meta-analysis, clozapine is the only atypical antipsychotic fully recommended in this setting. This drug has demonstrated safety and efficacy in controlled trials, but requires blood cell count monitoring for potential agranulocytosis.

Prognosis

Once they occur, hallucinations become a recurrent and chronic problem in most patients with PD. Patients with mild hallucinations and retained insight tend to have more severe hallucinations and lose insight as the disease progresses. Hallucinations are associated with the development and progression of dementia in both cross-sectional and longitudinal studies. Even though prognosis has improved with the use of atypical antipsychotics, hallucinations are associated with an increased risk of nursing home placement and mortality.

Hand-reach Task

V Joers, A Haertel, S L Loerch, and M E Emborg, University of Wisconsin, Madison, WI, USA

Glossary

6-OHDA – 6-Hydroxydopamine (6-OHDA) is a neurotoxin that targets catecholamine neurons and is commonly used to model of Parkinson's disease in animals.
Basal ganglia – A group of subcortical nuclei that is anatomically located between the cerebral cortex and the thalamus. The nuclei consist of the striatum (caudate and putamen), globus pallidus, the subthalamic nucleus, and the substantia nigra.
Bradykinesia – One of the cardinal symptoms of Parkinson's disease and prevalent in a range of movement disorders, bradykinesia refers to the slowness of movements. Difficulty in initiating movement, completing repetitive tasks, and performing simultaneous movements are other noted manifestations.
Dystonia – A group of movement disorders that present involuntary movements and sustained muscle contractions generating twisting movements and abnormal postures. Dystonias can be functional or result from brain injury or other neurodegeneration.
Essential tremor – This progressive, adult-onset disease exhibits characteristic tremors that are rhythmic and exacerbated by voluntary actions. It is the most ordinary tremor and frequently misdiagnosed as Parkinson's disease. Emerging views propose that essential tremor might be a family of diseases unified by the presence of kinetic tremor.
Huntington's disease – An inherited progressive neurodegenerative disorder associated to the genetic mutation of the IT15 gene. The disease presents motor and cognitive dysfunction associated to striatal and cortical neurodegeneration.
Hypokinesia – The reduction of desired movements associated with a decrease in muscle activity. This includes the speed and size of movements.
MPTP – 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is a human neurotoxin that inhibits the mitochondrial complex I. It affects dopaminergic nigral neurons and induces parkinsonian syndrome. MPTP is used to model Parkinson's disease in mice and monkeys.
Parkinson's disease – A progressive neurodegenerative disease of unknown origin that affects 1% of the population over the age of 55. Typical symptoms include tremor, rigidity, bradykinesia, and postural instability. The morphological hallmarks of the disease are dopaminergic nigral cell death and intracytoplasmic aggregations called Lewy bodies.
Tourette's syndrome – A childhood-onset movement disorder that presents involuntary, sudden, and repetitive tics in motor activity or vocalizations. This disease of unclear etiology is often considered a comorbid syndrome since there is high prevalence of Tourette's patients experiencing psychiatric disorders, such as obsessive-compulsive disorder, depression and attention deficit/hyperactivity disorder.

Defining 'Hand Reach Task'

A hand reach task (HRT) is usually defined as a test to assess the gross and fine motor skills of a subject. Gross motor skills are defined as larger movements of the body as sitting up. Fine motor skills refer to the use of small muscle groups to manipulate petite objects, such as to hold a pen between the thumb and a finger. The HRT implies ability to plan, initiate, coordinate hand–eye movement, and execute dexterity.

Anatomy of a Successful HRT

Successful completion of a HRT requires voluntary movements that incorporate neural commands to different muscle groups and input from sensory systems in order to create accurate and well-executed motor actions (**Figure 1**). The pyramidal system or the corticospinal tract directly controls the distal muscles that are responsible for voluntary action. Axons from the motor areas of the cerebral cortex project through the internal capsule to the midbrain and continue down the brainstem into the medullary pyramids where the descending fibers cross to the opposite side, known as the pyramidal decussation. At this point, the pathway is referred to as the lateral corticospinal tract. The fibers synapse in the spinal cord to a lower motor neuron that will travel to a motor neuron pool that activates the limb and hand muscles.

The HRT relies on the sensory system to provide information on the location and trajectory of the object,

the force and sensitivity required to pick up the object, and orientation and balance of other body parts. This information is part of the feedback and a feedforward system that is mediated by the thalamus to produce a successful HRT. The thalamus translates sensory input into a form readable by the cerebral cortex. Furthermore, the thalamus supports the accuracy and planning of the HRT by delivering information from the cerebellum and the basal ganglia to the motor areas of the cortex. The cerebellum, in turn, helps to regulate the execution of the movements by processing information from the sensorimotor areas of the cortex via the pons and sending it back to the system by output connections to the thalamus and from there to the motor areas of the cortex. The basal ganglia have a key role in higher-order planning, and seem to be responsible for the initiation and control of movement. These nuclei regulate motor cortex function through their thalamocortical projections. They receive massive inputs from the cortex and their output pathways connect back to specific motor areas (directly or indirectly via the thalamus) along with the prefrontal cortex. The basal ganglia also relay information to the cerebellum and have direct access to motor areas in the brain stem reticular formation.

Who Can Present Difficulties Performing a HRT?

As the HRT requires a system that includes grasp tool (hand), output information (corticospinal nerves), input information (sensory system), and central control (prefrontal cortex, basal ganglia, cerebellum, thalamus), a 'malfunction' on any part of this system will affect the successful completion of this task. Due to the highly coordinated action required to initiate and perform HRTs, these tasks are widely used to evaluate diseases that affect

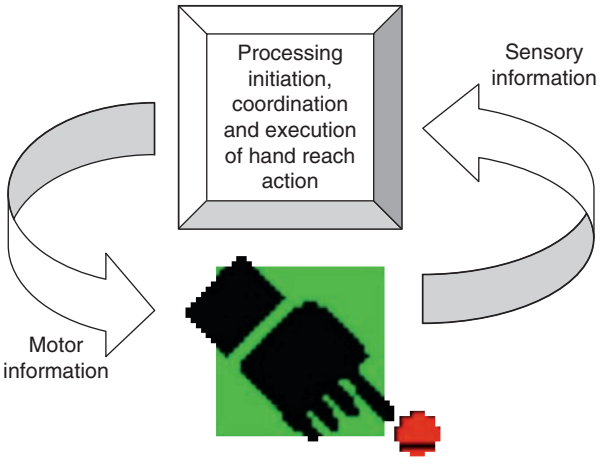

Figure 1 Elements needed for successful completion of a hand reach task.

'central control,' such as movement disorders. Typically, movement disorders are defined as affecting the ability to generate and control movements, by disturbing basal ganglia function. Decreased inhibitory output from the basal ganglia to frontocortical areas has been associated to hyperkinetic activity and increased inhibitory output with hypokinesia. Some common movement disorders are Parkinson's and Huntington's disease, essential tremor, Tourette's syndrome, and dystonia. As Parkinson's disease is the second most common neurodegenerative disease, many HRTs have originally been developed and used to assess this disease.

Using HRTs as Preclinical and Clinical Evaluation Tools

Evaluation of hand reach ability can be used as a diagnostic tool, to evaluate disease progression and to assess therapies (**Table 1**). As such, HRTs have been developed and adapted to assess patients and animal models of disease. HRTs can provide key information on manual dexterity on their own or as part of a battery of tests, including electrophysiological and imaging analysis to understand in vivo the functional components of the system. Equivalent tests could be transferred from the lab to the clinic and back in order to understand the disease and the limitations of a treatment.

HRTs for Laboratory Animals

Animal testing for HRT usually requires training and commitment of time and resources. These issues have been a limiting factor for their application, yet there is increased awareness of their importance to provide unbiased, more sensitive quantification of motor skills. **Table 2** lists key tests used to evaluate HRT in different species. HRTs for rodents are not widely used. The typical test is the 'staircase test' that evaluates the animals' ability to grasp and retrieve food from wells in two staircases with steps positioned downward and bidirectional from the animal. Variations of this test include placing two staircases side by side, or two staircases arranged in an upside-down V where the highest steps are placed side by side.

In comparison to rodents, monkey studies have frequently used HRTs to evaluate primate's complex motor planning and execution skills. There is a range of tests that evaluate the grasping action (reach and grasp and conveyor

	Reach and Grasp	Castiello and Bennett
	3D virtual reality	Messier et al.

Within each species category, tests are organized from the most simple to more complex, requiring more extensive training.

belt), handedness (reach with alternating hands), planning (object retrieval detour task), or spatial hemineglect (lateralized reward retrieval task). Tests can be manually operated (reach in to tubes, recessed wells) or take advantage of automated computerized systems (movement assessment panel). Different variations of the tests can be used to increase the difficulty level (movement assessment panel). Complex tests usually require extensive training for acclimation of a restraining device, as well as comprehension of the proposed challenge (extinction with double simultaneous stimulation, response to a moving target, operant task, level pulling, and free-reach device). When selecting a test, it is important to match it to the scientific question and to the experimental conditions (e.g., combination of a HRT with electrophysiological measures requires animal restraining).

HRTs for Humans

HRTs are a simple, noninvasive method to evaluate movement disorders in humans that have the potential of being combined with functional imaging or electrophysiology. HRTs include evaluation of overall activity, initiation, reaction time (drinking action, look and point, and reach and grasp) and speed and strength (pinch grip task). New computerized systems create a virtually distorted environment to assess patient's learning speed of a new task (3D virtual reality).

Conclusions

As our understanding of movement disorders increases, the use of a battery of tests to evaluate different components of these disorders becomes more important. Biomarkers of disease progression are intensely searched for. In that regard, the movement disorder field will benefit from the systematic application of HRTs to compare novel therapies aiming to improve function, induce neuroprotection (e.g., trophic factors), or circuit repair (e.g., transplants for cell replacement). Unbiased quantifications of HRTs deficits and improvements have the potential to shed light on disease progression or disease modifying strategies. In that context, the use of HRTs in the lab that has a clinical equivalent will be key to predict future successful therapies.

Harmaline Tremor Model

Adrian Handforth, Veterans Affairs Greater Los Angeles Healthcare System, Los Angles, CA, USA

Glossary

β-Carboline – A structure in which the ethylamine side chain of two-ring tryptamine has been reconnected to the indole ring with a carbon atom. β-Carbolines vary according to side chains and the saturation of the third ring.
Conductance – The flow of ions through an open ion channel so as to produce a membrane voltage change.
Deep cerebellar nuclei – These include the fastigial, interpositus, and dentate nuclei and are the sole output neurons of the cerebellum.
Gap junctions – Where the surfaces of specific neurons fuse and form pores composed of connexin proteins, so that electrical and cytosolic coupling occurs.
Inferior olive – A collection of neurons in the ventral medulla that receives signals from the spinal cord and cerebral cortex and projects climbing fibers to Purkinje neurons.
Preclinical model – An animal model of a human disease that has predicted whether therapies tested on it will show efficacy in patients.
Purkinje cells – Very large neurons that integrate multiple inputs to the cerebellum and are the sole output neurons of the cerebellar cortex, projecting to the deep cerebellar nuclei.
Synchrony – Refers to the state in which a population of neurons share membrane voltage changes or fire action potentials at precisely the same time.

Harmaline-Induced Tremor in Animals

Among β-carbolines, the 7-methoxy compounds harmaline and harmine are tremorogenic (see **Figure 1**). Within minutes of administration, each produces a whole-body postural and kinetic tremor in mammals with a peak frequency ranging from 8–10 Hz in monkeys to 10–16 Hz in mice (see **Figure 2**), that lasts as long as several hours. Experimentally, such tremor is assessed with rating scales, electromyography, or motion detection systems.

Harmaline/harmine doses of 10–20 mg/kg are often used in rats, with mice requiring twice as much. Repeated dosing causes a loss of the tremor response (tolerance), suggested to result from physiological changes such as the failure of the expected harmaline-induced rhythmic inferior olivary (IO) and Purkinje neuron firing to occur.

Neuronal damage occurs after harmaline, but rats and mice show differences. Strips of cerebellar cortex display Purkinje cell loss and microgliosis in rats, whereas mice show no such changes but instead exhibit microgliosis in accessory IO subnuclei without cell loss.

The Anatomy of Harmaline Tremor

IO neurons project climbing fibers to Purkinje cell dendrites, releasing glutamate, aspartate, and peptides to produce complex spikes. On systemic harmaline administration, IO neurons of the medial accessory (MAO) and dorsal accessory (DAO) nuclei fire rhythmically and synchronously, generating rhythmic Purkinje cell complex spikes in the vermis and paravermis; these cortical regions project to the fastigial and interpositus deep cerebellar nuclei (DCN), which also

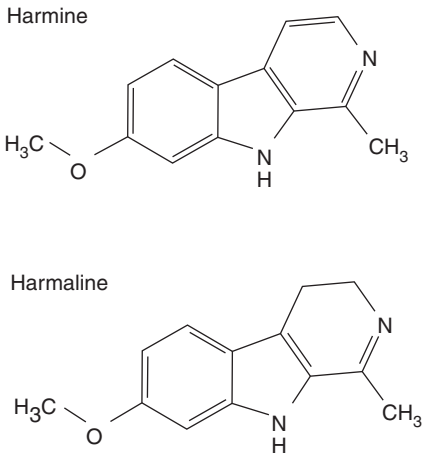

Figure 1 Chemical structures of harmine and harmaline.

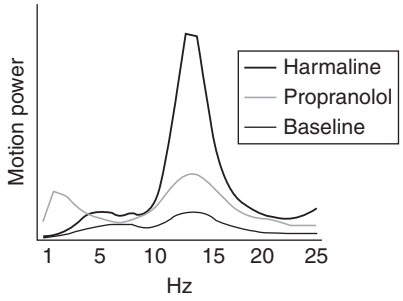

Figure 2 Motion power frequency spectrographs of a sample mouse. During baseline, motion power is mainly represented at low frequencies. After subcutaneous harmaline, 20 mg kg^{-1}, a 10–16 Hz motion power peak emerges, corresponding to visible whole-body tremor. The magnitude of the tremor peak is reduced by intraperitoneal propranolol, 20 mg kg^{-1}.

receive collaterals from MAO and DAO. The DCN send projections to brainstem nuclei and thalamus, as well as a reciprocating inhibitory projection back to the IO subnuclei. The end result is a rhythmic activation of bulbar reticular nuclei and spinal motoneurons, expressed behaviorally as tremor.

Selective IO destruction by systemic 3-acetylpyridine eliminates harmaline tremor. Cutting the climbing fibers does not affect harmaline-induced IO bursting, but eliminates Purkinje cell and fastigial nucleus bursting. Moreover, harmaline-induced bulbar reticular nuclei bursting, but not IO bursting, is eliminated by the removal of the cerebellum including the DCN. Llinás and Volkind observed that cooling of the cerebellar cortex does not abolish harmaline-induced motoneuron firing, and suggested that the olivo-nuclear loop is sufficient to sustain tremor. Supporting this notion, mice with complete Purkinje cell degeneration, but intact olivo-nuclear climbing fibers, can manifest harmaline tremor. Neither cooling the motor cerebral cortex, lesions of the ventrolateral thalamus or globus pallidus, or intercollicular transections abolish tremor in cats or monkeys. Harmaline thus activates IO, with enlistment of the DCN, brainstem, and spinal cord as minimum requirements for tremor expression.

Physiology of Harmaline Tremor

IO rhythmic subthreshold oscillations involve a high-threshold calcium conductance that is terminated by a calcium-dependent potassium conductance, creating an after-hyperpolarization that deinactivates a low-threshold calcium current. That causes a rebound spike that triggers the high-threshold calcium spike and may or may not be enough to trigger a sodium spike. The subthreshold oscillation frequency is approximately 10 Hz, whereas individual IO cells usually fire at 1 Hz. These oscillations are tightly synchronized among ensembles of IO neurons via electrical coupling that is mediated by connexin-36 gap junctions. Purkinje cell complex spike firing is synchronized within small vertical cortical bands, due to their control by the projection of an electrically coupled IO ensemble.

Through an unexplained mechanism, harmaline hyperpolarizes IO neurons, thereby increasing the rebound low-threshold calcium spike. Each rebound discharge is then associated with bursts of sodium action potentials. Thus the IO neurons are made more excitable by harmaline and convert to rhythmic 8–16 Hz burst-firing that upon network propagation is expressed as tremor.

Connexin 36-null mice lack IO or Purkinje cell synchrony, yet unexpectedly mount a relatively normal harmaline tremor response. On the other hand, the broad-spectrum gap junction blocker carbenoxolone suppresses harmaline tremor. Conceivably, harmaline tremor requires synchrony that can be mediated at another level, for example in DCN, by other gap junctions.

Effect of Drugs on Harmaline Tremor

Serotonin

Lesions of serotonin fibers to the IO or drugs that reduce serotonin receptor activation (methysergide, *para*-chlorophenylalanine, low-dose trazodone) attenuate harmine- or harmaline-induced tremor, whereas drugs with the opposite effect (5-hydroxytryptophan, citalopram, imipramine) exacerbate tremor.

Norepinephrine (NE) and Dopamine (DA)

Systemic or intraventricular injection of the NE precursor L-threo-3,4-dihydroxyphenylserine suppresses harmaline tremor in rats, whereas blockade of NE synthesis with α-methyl-*p*-tyrosine exacerbates tremor. Electrical

stimulation of locus ceruleus also suppresses harmaline tremor; lesions have the opposite effect. Harmaline tremor is suppressed by β1- and β2-adrenergic antagonists, but the latter appear more effective. Evidence indicates that propranolol acts both peripherally and by directly counteracting harmaline's physiological effects on IO neurons. Levodopa and DA receptor agonists (apomorphine, piribedil) reduce harmine tremor in rodents.

Glutamate

Dizocilpine, an antagonist of the *N*-methyl-D-aspartate (NMDA) receptor channel, and competitive NMDA receptor antagonists (CPPene, 2-amino-5-phosphonovalerate) each suppress harmaline tremor in rodents, indicating a role for this receptor in tremor expression.

Alcohol

Suppression of harmaline tremor by ethanol has been well replicated, but the mechanism is unclear. Contrary to expectation, a moderate dose of ethanol induces increased rhythmicity and synchrony of vermal Purkinje cell complex spikes, and by inference, IO ensemble activity. Moreover, ethanol fails to affect harmaline-induced rhythmic complex spike activity. These observations suggest that alcohol acts elsewhere other than IO to mask tremor expression.

Antiepileptic Drugs (AEDs)

Recent studies have shown harmaline tremor suppression by zonisamide and lacosamide, the latter with efficacy comparing favorably with propranolol and primidone. De Ryck and colleagues surveyed AEDs and found that levetiracetam had little effect on tremor, whereas the derivative brivaracetam was effective without producing sedation. Primidone and clonazepam were effective but sedating. Carbamazepine and gabapentin also reduced tremor. In brainstem slices, brivaracetam counteracts harmaline's effects on IO physiology, suggesting a direct action on IO.

Harmaline Tremor as a Preclinical Model of Essential Tremor (ET)

ET and the harmaline animal model differ in a number of respects, and the evaluation of its predictive success awaits further testing of compounds in both animals and humans. **Table 1** summarizes a comparison of harmaline and ET tremor.

Harmaline tremor is drug-induced, acute, and self-limited, whereas ET is a nonremitting progressive condition. Harmaline acts on the IO to produce tremor; in ET, IO's role is less certain. Eye-blink conditioning, which depends on the olivo-cerebellar pathway, is impaired in ET patients. Cerebellar cortical hypermetabolism is present in both ET and the harmaline model; in the latter, it is known to depend on climbing fiber activation. Interestingly, alcohol increases IO blood flow in ET but not control subjects, suggesting that IO physiology differs in ET.

On comparing the tremor response to drugs in **Table 1**, it should be noted that ET is likely biochemically heterogeneous, which may limit the predictive validity of the harmaline model. Another problem is uncertainty about

Table 1 Comparison of harmaline rodent tremor model and essential tremor

Feature	*Harmaline tremor*	*Essential tremor*
Clinical		
Action tremor	Yes	Yes
Time course	Acute	Chronic
Inducing agent	Pharmacologic	Probably neurodegenerative
Role of inferior olive	Definite	Uncertain
Cerebellar hypermetabolism	Yes	Yes
Role of thalamus	Not essential	Essential
Response to drugs		
Primidone	Suppresses	Suppresses in some
Clonazepam, diazepam	Suppresses	Suppresses in some
Gabapentin	Suppresses	Suppresses in some
Carbamazepine	Suppresses	Does not suppress
Levetiracetam	Does not suppress	Does not suppress
Propranolol	Suppresses	Suppresses in some
L-dopa, DA agonists	Suppresses	Do not suppress
Anticholinergics	Do not suppress	Do not suppress
Ethanol	Suppresses	Suppresses in some
γ-Hydroxybutyrate	Suppresses	Suppresses in some
Caffeine	Worsens	Worsens in some
Citalopram, imipramine	Worsens	Worsens in some
1-Octanol	Suppresses	Suppresses in some

the extent to which reported harmaline tremor suppression represents nonspecific motor activity reductions. Potential remedies are to employ tremor measures that are insensitive to locomotor activity levels and to select doses shown in independent tests not to cause sedation or impair motor performance.

Of 13 agents listed in **Table 1**, correspondence prevails in 11/13. Carbamazepine and dopaminergic drugs suppress harmaline tremor, representing false positives as these are not effective for ET. To date, the model has been employed to predict clinical efficacy for just one compound that has been in published clinical trials: 1-octanol. Encouragingly, pilot trials indicate that 1-octanol has clinical efficacy.

Hemiatrophy Hemiparkinsonism

M F Facheris and P P Pramstaller, Institute of Genetic Medicine, EURAC & Central Hospital of Bolzano, Bolzano, Italy

Glossary

Dystonia – An uncommon disorder characterized by involuntary muscle contractions that cause uncontrollable, often painful, twisting of the affected body parts, which interferes with the performance of many day-to-day tasks.

Parkin (also known as *PRKN*, or *PARK2*) – A gene implicated in autosomal recessive juvenile parkinsonism. Mutations in the *parkin* gene might be involved in the accumulation of defective proteins in the cells, leading to nigral neuronal degeneration.

Perinatal – Pertaining to or occurring in the period shortly before and after birth, variously defined as beginning with completion of the 20–28 week of gestation and ending 7–28 days after birth.

Striatum – Part of the basal ganglia of the brain that is involved in the planning and modulation of movement pathways but also in cognitive processes that require executive function. It includes the caudate nucleus and the putamen.

Definition and History

Hemiatrophy hemiparkinsonism (HAHP) is a rare neurological condition initially proposed as a distinct syndrome in 1981 by Klawans. He described four cases characterized by the occurrence of body hemiatrophy and ipsilateral

hemiparkinsonism. This syndrome differs from a unilateral presentation of idiopathic Parkinson's disease (IPD) by early age of onset, clinical evidence of hemiatrophy, unilateral parkinsonism on the same side of hemiatrophy, action-provoked dystonia that occurs prior to the introduction of levodopa therapy, and slow progression.

Although a minimal asymmetry of body size is considered normal, marked asymmetry (2–3 cm in limb length or asymmetry of the face and chest) is rare. In order of frequency, the body parts affected in hemiatrophy are hands, feet, and face. No right- or left-sided predominance has been reported in HAHP. The asymmetry is often recognized early in life (e.g., shoe and glove size discrepancies), suggesting that the atrophy is a result of a developmental failure rather than a process occurring later in life, as seen in conditions such as the Parry–Romberg syndrome. Parkinsonism presents with rest tremor, bradykinesia, and rigidity predominating on the same side of hemiatrophy, although very minor signs can sometimes be detected on the other side of the body. Some individuals eventually develop progressive, contralateral parkinsonism, but the main signs remain predominantly on the hemiatrophic side of the body. Pyramidal tract dysfunction, such as exaggerated tendon reflexes and Babinski sign, is commonly seen in HAHP patients. Dystonia is an often-reported early sign in HAHP. It normally begins several years before the introduction of levodopa therapy, and before other parkinsonian signs develop. It is usually confined to the foot, although the arm, face, and neck can also be involved. Frequently, dystonic movements occur only with the movement of the involved body part (action-induced dystonia) and there is no dystonia at rest.

Pathogenesis

The average age of onset of parkinsonian symptoms in HAHP is ~40 years, and no gender prevalence has been reported. The presence of corticospinal signs suggests that motor areas can also be involved, and cases of hemiatrophy related to brain injuries involving the postcentral frontal lobe have been reported. HAHP has been frequently associated with abnormal pre- and perinatal injuries, including prolonged or traumatic labor or delivery, premature delivery, breech presentation, or neonatal hypoxia. Perinatal stress may underlie brain injuries and subsequent development of HAHP, as supported by studies in which experimental animals were exposed in utero to toxins such as lipopolysaccharide, eventually leading to reduced dopaminergic neurons at birth. Perinatal injuries can also explain the early onset of symptoms and might support the reason for slow school learning in some of the described individuals. In addition, although early life insults often cause asymmetric neurological findings, they may be associated with whole brain injury, potentially explaining why parkinsonian signs sometimes evolve over years to include the contralateral side. However, perinatal complications have not been found in all HAHP patients, leading some authors to dispute whether to include this association as a criterion to differentially diagnose HAHP from IPD. Similarly, dystonia has been frequently reported as a presenting symptom of IPD, especially of early onset PD (EOPD) and in monogenic forms of PD (*PARK2*); however, other features of parkinsonism usually develop within few months in these latter cases. A diagnosis of IPD should always be considered in cases of adult-onset foot or leg dystonia.

Diagnostic Evaluation

Conventional neuroradiological examinations are inconstantly informative. Some studies show no cerebral, cortical, or ventricular asymmetry at CT or MRI scans, while others show hemicalvarial thickening, paranasal sinus enlargement, or frank hemiatrophy of the brain with cortical, subcortical, ventricular, and basal ganglia atrophy. Functional studies have provided more information; both fluorodopa (FDP)- and fluorodeoxyglucose (FDG)-PET scans show a decrease in striatal FDP uptake and striatal glucose metabolism on the side of the brain opposite the hemiatrophic part of the body. The dopamine transporter activity seems accordingly reduced when beta-CIT SPECT is employed. Notably, fluoroethylspiperone (FESP)-PET, which assesses dopamine D2 receptor binding capacity, does not show any binding reduction, suggesting a nonreceptor mechanism for the striatal dysfunction in HAHP. Unlike FDP-PET, which highlights the dysfunction along the nigrostriatal pathway, but is not capable of separating HAHP from IPD, FDG-PET shows a metabolism reduction exclusively in the striatum, supporting the theory of isolated dysfunction of striatal neurons. EEG anomalies, such as paroxysmal polyspike activity in the frontal area, and CSF abnormalities, that is, a homovanillic acid concentration of less than one third of the normal level, have been described only once. Similarly, genetic mutations have been reported only by a study that performed an extensive analysis of the *parkin* gene on a HAHP patient and found a duplication of exon 7. The presence of *parkin* mutations could justify, in some HAHP individuals (in addition to global perinatal brain damage), the clinical involvement of the contralateral side, and explain why some researchers could not find any side-to-side differences with FDP-PET scanning. Heredity for HAHP has never been reported, even though the occurrence of HAHP has been described in one pair of twin brothers, and few cases confirmed familiality for IPD. No mention of genetic mutations was provided in this latter report.

Treatment

To date, only two main treatments for HAHP have been reported: pharmacological and surgical. Levodopa treatment has given inconsistent results. The original report by Klawans showed no response to either dopaminergic or cholinergic drugs. Other studies, however, reported a sustained response to levodopa. These observations suggest that different types of lesions may cause HAHP. Parkinsonism is normally seen as a condition characterized by dopamine depletion due to nigral degeneration. However, a primary dysfunction of the striatum could also lead to parkinsonism. In cases of HAHP with striatal dysfunction as a consequence of postcentral brain injuries, a low or absent response to dopaminergic drugs might be anticipated. To date, there have been no postmortem examinations of HAHP brains to test this hypothesis. In addition, in all published studies, inclusion criteria for HAHP patients have been highly variable in terms of drug response to levodopa and other dopaminergic drugs, making treatment conclusions difficult to draw.

Only five patients have been reported after surgical treatment: three with thalamotomy and two with deep brain stimulation (DBS) directed to the ventral intermediate nucleus (VIM) of the thalamus and to the subthalamic nucleus (STN) respectively. Thalamotomy was not successful and only the patient who received STN DBS improved.

Prognosis

Despite the reduced response to conventional treatments, HAHP has a slow progression and a better prognosis compared with IPD.

Hemiballismus

N Hermanowicz, University of California, Irvine, USA; Eisenhower Medical Center, Rancho Mirage, CA, USA

Glossary

Ballism – Large amplitude involuntary movements with jerking, irregular, flailing, flinging, and exhausting qualities.
Hemiballismus, hemiballism – Ballism affecting one side of the body.

History and Clinical Presentation

Ballism is derived from the Greek verb meaning *to throw.* This movement disorder involves large-amplitude involuntary jerking, irregular flailing, flinging, and exhausting movements. They are among the more distressing of the hyperkinetic disorders for patients to endure and for their families and clinical practitioners to observe. The term

ballism or ballismus is variably credited, in its initial use, to Plouequet, Pfefferkorn, Kussmaul, and von Economo and probably dates back to the early 1800s. Ballismus is similar to chorea because of the unpredictable and random character of movements, but in ballism, the movements are more severe and proximal, whereas in chorea, the movements are distal. When ballism occurs on only one side of the body, the cause is usually a cerebrovascular accident and the condition is termed hemiballismus.

Pathophysiology

Although hemiballismus has been associated with damage to the contralateral subthalamic nucleus (STN), especially by hemorrhage, it has long been recognized that lesions in other locations may contribute to the appearance of these movements. In fact, an STN lesion is only rarely found in isolation.

In a report of 22 cases of patients with hemiballismus who had either CT or MRI, the STN was abnormal in only 6, and only 1 had the STN as the sole site of identified pathology. Other sites combined with the STN included the pons, midbrain, thalamus, and caudate. Notably, some cases have structural abnormalities identified only in the parietal, parietotemporal, or temporal lobes, and 7 of the 22 had no abnormalities detected at all on imaging. It is possible that conventional imaging is insufficiently sensitive to detect all the sites of pathology in hemiballismus.

Models of the basal ganglia network, involving cortical motor areas, the caudate and putamen, the globus pallidus, substantia nigra, STN, and thalamus, are under continuous refinement to explain the motor phenomena associated with diseases. It is known that the STN is functionally important to these basal gangliar circuits. The concept of hemiballism and its pathophysiology has shifted from a focus on this nucleus to the appreciation that lesions within a larger and more complex circuitry are likely responsible for the movement disorder.

Differential Diagnosis

The single most common cause of hemiballismus is a vascular lesion created either by stenosis or hemorrhage. Recently, several cases in association with hyperglycemia and opportunistic central nervous system infections in HIV patients have been reported. Other etiologies for hemiballismus include trauma, systemic lupus erythematosis, metastatic neoplasm, multiple sclerosis, tuberous sclerosis, tuberculoma, hypocalcemia with hypoparathyroidism, hypoglycemia, and vascular malformations (**Table 1**).

Table 1 Causes of hemiballismus

Brain hemorrhage or ischemic infarction
Hyperglycemia
Toxoplasmosis or other opportunistic infection in immunocompromised patient
Metastatic neoplasm
Multiple sclerosis
Tuberous sclerosis
Head trauma
Tuberculoma
Vascular malformation
Hypocalcemia with hypoparathyroidism
Hypoglycemia

Many of these causes provoke hemiballismus through vascular complications associated with the underlying diagnosis. In one case of hemiballismus associated with hyperglycemia, MRI T1-weighted images demonstrating hyperintense signals in the putamen were associated with petechial hemorrhages detected on postmortem examination. The majority of cases of hemiballismus associated with hyperglycemia have been among Asian patients, although no explanation for this has yet been identified. Rarely, hemiballismus can be seen in multiple sclerosis, and in one reported case, a plaque was identified in the STN.

Examination

Hemiballismus is so striking that the examiner must take care to focus on the remainder of the neurological examination to detect more subtle signs that may yield clues to the underlying cause. Generally, both the arm and leg are affected by large-amplitude movements that are jerking or flailing in appearance. They may cause patients to slide out of their chair or abrade and bruise their limbs. As is true with involuntary movements in general, hemiballismus increases with heightened emotional states. When the patient is relaxed and unstimulated, the movements may reduce in amplitude and resemble chorea. Similarly, the chorea of Huntington's disease or that induced by dopaminergic medication in Parkinson's disease may, in some circumstances, appear to become ballistic, but in these cases, the movements involve both sides of the body. However, patients with Parkinson's disease are typically asymmetric in both their parkinsonism and their dyskinesia. Therefore, both sides of the body must be observed carefully in all cases of seeming hemiballism.

The majority of cases of hemiballismus are due to a vascular event, hyperglycemia, or an opportunistic infection in an immune-compromised patient, and therefore, the history and examination should be directed to these etiologies. The primary process causing hemiballismus can cause additional problems in the central or peripheral nervous system, and hence a thorough examination is

essential, even though the dramatic hemiballism may compromise the detection of subtle findings. Considering that even in vascular cases of hemiballismus, a minority had lesions restricted to the STN, the patient must be assessed for evidence of infarction elsewhere.

Testing should include brain imaging on an urgent basis, since some of the known processes causing hemiballismus, such as hemorrhage, ischemic infarction, or mass lesions, require prompt attention. MRI is preferable for most conditions, but may require sedation or anesthesia in order to allow the patient to be scanned. For patients with recent onset of hemiballismus, urgent hospitalization is reasonable. A rapid assessment of the serum glucose level should be accomplished for all patients with hemiballismus. Other blood tests, particularly regarding an ischemic etiology, include a complete blood count, including platelets, PT, and PTT and an evaluation for hypercoagulability syndromes. A complete chemistry panel, including calcium levels, should also be obtained. Low calcium should be investigated by assessing the parathyroid hormone. The erythrocyte sedimentation rate at minimum should be checked as a screen for lupus, vasculitis, or other autoimmune disorders.

Prognosis and Treatment

Despite early descriptions of dire outcomes, more recent series of cases indicates a favorable prognosis with spontaneous resolution or substantive improvement of movements within weeks or months for the majority of cases. The provocative underlying disease and its severity are likely the principal determinants of outcome.

In the acute period, when the movements are most disruptive and potentially injurious, some cases will require treatment. Neuroleptic medications have long been established as being effective and remain the first choice among most clinicians, although no one specific medication has been identified to be superior to others. Clozapine has been reported to be helpful where other neuroleptics have failed. The presynaptic, dopamine-depleting medications reserpine and tetrabenazine have also been reported to be beneficial. Other medications reported to be helpful include valproic acid, gabapentin, topiramate, sertraline, and combinations of a neuroleptic with reserpine, tetrabenazine, or diazepam.

For patients in whom hemiballismus persists and medications have not been helpful, functional neurosurgery may be an option. Pallidotomy, thalamotomy, and deep brain stimulation of the thalamus have been reported to be effective. However, for the majority of patients, given the natural history of spontaneous resolution of hemiballismus within weeks, it is prudent to allow sufficient time to pass before considering surgical treatment.

Hemifacial Spasm

W H Jost, Deutsche Klinik für Diagnostik, Wiesbaden, Germany

Definition and History

Hemifacial spasm (HFS) is characterized by unilateral, involuntary, irregular clonic twitches or tonic (rarely) contractions of the muscles of the face innervated by cranial nerve VII. Patients complain of involuntary twitching of the facial muscles, with the initial symptoms usually involving the lower lid and the orbicular muscle of one eye. The spasms may progress in severity and may spread to the lower face on the same side. Some patients will have intermittent or mild symptoms with intervals during which they are asymptomatic.

These contractions involve the mimetic muscles; patients may have both tonic and clonic activity in these muscles. The symptoms may be exacerbated by specific movements of the face, changes in head posture, physical or emotional strain (anxieties, upset, stress), and fatigue. Remissions rarely occur.

Involuntary contractions may also be observed during sleep in ~80% of patients. A familial history is seldom obtained although some families have been described.

HFS occurring in conjunction with trigeminal neuralgia is termed tic convulsif.

HFS is not dystonia, although some of the treatments used may overlap with those used for blepharospasm.

Pathogenesis/Pathophysiology

For a long time, this disorder was considered a psychogenic disorder. Over the last 40 years, however, the organic basis of HFS has been firmly established.

There have been many proposed mechanisms for HFS, an issue that remains unresolved. Lesions and/or disinhibition of the nucleus of the facial nerve have been speculated. More recently, HFS has been attributed to compression of the facial nerve by blood vessels or ectopic structures in the region of the nerve. The vulnerability of the nerve to compressive injury is thought to relate to the fact that upon emergence into the cerebellar angle, the facial nerve is not myelinated and merely ensheathed by a thin arachnoidal membrane. In addition, the facial nerve may be at increased risk of compression at the point of exit from the brainstem and entrance into the internal auditory canal.

How the compression of the nerve by a blood vessel leads to contractions of the facial muscles has not been clearly established. Compression of the nerve and consequent demyelination may lead to ectopic excitation and axonoaxonal ephaptic transmission between the demyelinated fibers. In addition, the root exit zone may act as a trigger zone. The antidromic impulses can excite the facial nucleus and produce a kindling effect rendering the facial nucleus hyperexcitable, which, in turn generates impulses down the facial nerve eliciting the muscular contractions.

Compression of the nerve may occur in different regions. The vulnerability of the root exit zone alone has been proposed to be one of the primary mechanisms. This zone is a transition zone that is 2–3 mm in length between the central and peripheral axonal myelination and is located at the nerve's exit from the pons. However, studies have shown that only one-fourth of HFS patients have a demonstrable nerve compression at this particular site. Compressions in the attached segment (i.e., an area between root exit point and the root detachment point) are much more common and occur in nearly two-thirds of the patients. Hence, atypical HFS is more common than compression to the posterior or rostral side of the nerve with compression at the brainstem. The site of each region compressed presumably impacts on the clinically picture. Moreover, it is felt that the severity of compression correlates with the severity of HFS symptoms. There is still controversy as to whether HFS is more typically caused by more distally located compressions.

The AICA (anterior inferior cerebellar artery) is the primary blood vessel thought to cause facial nerve compression. The posterior inferior cerebellar artery and vertebral artery (tortuosity) are frequently involved as well. Multiple compressing vessels were found in about one-third of the cases. Rarely, aneurysms of these vessels may cause HFS. Bilateral compression resulting in bilateral HFS is an exception. Although compression of the facial nerve is considered to be one mechanism, ~25% of normal controls will show vascular loops that are compressing the facial nerve, suggesting that this phenomenon alone is not enough to produce HFS.

Space-occupying lesions such as meningioma, acoustic neuroma, schwannoma, bony abnormalities of the skull, parotid gland tumor, and pilocytic astrocytoma of the fourth ventricle are believed to be nonvascular origins of HFS. Lacunar pontine infarction may be another rare cause. Bilateral HFS has been reported in association with multiple sclerosis.

Epidemiology/Risk Factors

HFS is a very common disease with an overall prevalence of about 10/100 000 – and is even more prevalent in Asia. HFS usually begins in the fifth decade, and increases with advancing years. It is very seldom seen in childhood or adolescence. Some patients may be genetically predisposed to developing HFS, but most cases are sporadic. Risk factors include arterial hypertension (in up to two-thirds of the patients), vascular diseases, and smoking. Women are afflicted approximately twice as often as men.

Clinical Features and Diagnostic Criteria

HFS is marked by synchronous unilateral contractions of muscles innervated by the facial nerve. There is variable involvement of the muscles of the lower face. Symptoms will typically originate in the area of the orbicularis oculi muscle of the eye and may spread in a caudal or cranial direction. There is a lot of variability in the pattern and temporal course of the disorder. Some cases are characterized by onset in the orbicularis oris muscle of the mouth and the buccinator muscles. The frontalis and stapedius muscles are much less involved, although rhythmic clicking may sometimes be a symptom of the latter. These symptoms are enhanced by fatigue, emotional strain, and light. HFS is not associated with pain or other sensory changes in the face. Corneal reflexes should be normal. Although patients with HFS may have mild facial asymmetry, there is no paralysis of facial muscles in untreated HFS. If there are additional neurological deficits, then a consideration of other possible etiologies included space-occupying lesions should be excluded.

Bilateral HFS is very rare. When it occurs, the spasms are usually independent of each other and not synchronous on both sides of the face. It is postulated that in bilateral HFS there is bilateral compression of the facial nerve.

HFS may seriously impact the patients' quality of life. This arises from the sensations of the muscular contractions, involuntary eyelid closure that appears like winking, visual impairment, and sometimes speech involvement or lack of control of salivation. The continuous contractions may also interfere with sleep. In addition, the symptoms may be socially disabling. The winking of the eye and grimacing of the face may attract attention, making patients feel stigmatized and misunderstood. In some cases, muscle contractions can also become esthetically disfiguring. In severe cases, HFS may be functionally and socially disabling.

Differential Diagnosis

Differential diagnosis include local processes that may involve the region close to the exit of the facial nerve from the brainstem. Unilateral blepharospasm is the most important differential diagnosis at the onset of the disease (involving solely the orbicular muscle of the eye). In contrast to HFS, blepharospasm typically involves both eyes and does not have the synchronous, simultaneous rapid contractions of the muscles. However, there have been cases when both disorders may be present in a single patient.

Meige's syndrome, which is the combination of blepharospasm and oromandibular dystonia or lower facial dystonia involves muscles supplied by the facial nerve, but may also involve muscles innervated by other nerves, including cranial nerve V. Similar to blepharospasm, the muscle contractions may be more irregular, and bilateral in comparison to the synchronous muscle contractions of HFS (**Figure 1**). In contrast to HFS, oromandibular dystonia affects only the lower face and jaw and does not involve the upper face, as in HFS.

Synkinesias following facial paralysis (post-Bell's palsy synkinesis) may clinically resemble HFS. Synkinesias do not occur at rest but on activation of the muscles innervated by the facial nerve, such as eye blinks or smiling.

Eye and facial tics, occurring either a simple motor tic or as a part of Gille de la Tourette syndrome may sometimes be a part of the differential of HFS. However, motor tics involving the eyes are often bilateral, associated with eye rolling, and arise secondary to an 'urge' to move. In addition, motor tics are typically suppressible, whereas HFS is not. Other disorders that can be included in the differential diagnosis are myokymia (in brainstem lesions), tardive dyskinesia, epilepsia partialis continua, and psychogenic facial spasm.

Diagnostic Work-up/Tests

The diagnosis of HFS is based on history and clinical findings. Neuroimaging of the brain and brainstem with magnetic resonance imaging (MRI) will rule out structural lesions, including space-occupying lesions of the brain/cerebellar pontine angle. In many cases, MRI/magnetic resonance tomographic angiography can help us identify pathologic neurovascular contact at the root entry zone or more distally, especially when the anterior inferior cerebellar, posterior cerebellar, or vertebral artery is involved. Parotid tumors – a very rare cause of HFS – should also be considered in the appropriate patient.

In most patients, if imaging studies are normal, no further diagnostic work-up is necessary. However, in some patients in whom the movements are not typical, electromyography may be helpful. In HFS, the EMG of muscles innervated by the facial nerve shows typical high-frequency and short-duration bursts occurring synchronously in all muscles involved, aside from frequent signs of peripheral neurogenic lesion with abnormal spontaneous

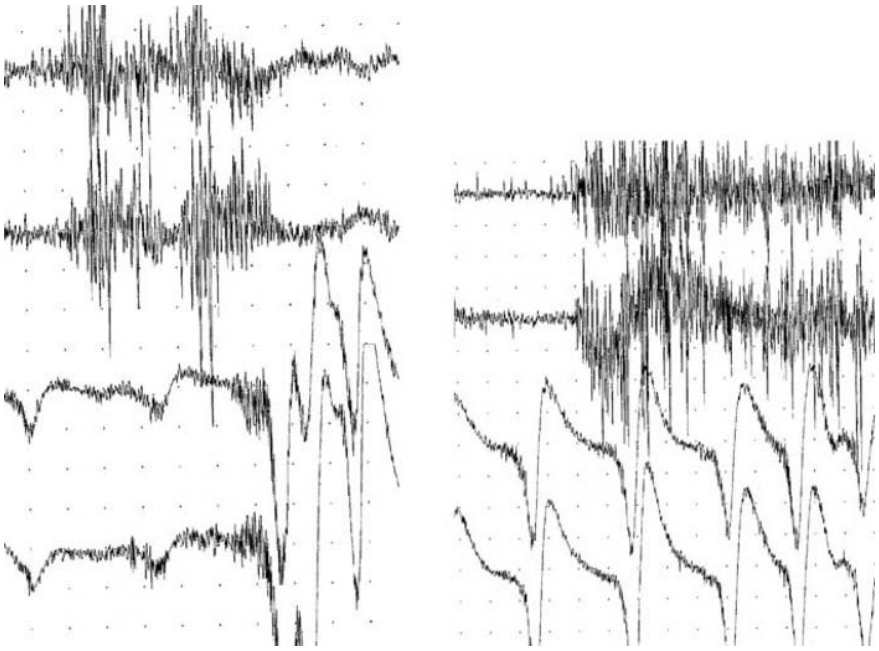

Figure 1 EMG in a patient with Meige's syndrome: Involuntary, asynchronous contractions of the orbicularis oris muscle (track 1 and 2) and the orbicularis oculi muscle (track 3 and 4).

activity, and motor unit potential change even. The blink reflex (e.g., R1/R2-junction, contralateral early R1-component) and magnetic evoked potentials (prolonged latencies) are may also be useful in particular patients.

Management

Many pharmacologic treatments and surgical procedures have been used for the treatment of HFS. Some of these are still in use today. Membrane-stabilizing agents – anticonvulsants in particular – are oral medication. Medications reported to improve HFS include carbamazepine, clonazepam, phenytoin, gababentine, and baclofen. The benefit from these drugs have been modest and often not sustained. The use of the oral medications may be somewhat limited by the occurrence of adverse effects. Injections of neurolytic agents, such as doxorubicin, have been considered as a treatment option but there are inadequate studies of these agents, and the potential adverse effects may outweigh the benefit.

Injections of botulinum neurotoxin (BoNT) to the tonically or clonically activated musculature is considered a safe and effective treatment for HFS. Many consider the treatment of choice. Injections of BoNT have been shown to be beneficial in controlling the HFS, and the adverse effects are usually mild and reversible.

The success rates of various studies range between 76% and 100%.

Dosage and injection sites may substantially vary and clearly depend on the clinical picture. The orbicularis oculi muscle of the eye and platysma muscle if involved are the most common muscles injected for HFS. Although there are no comparative studies assessing different techniques for injection, most investigators target the pretarsal segment of the orbicularis oculi muscle rather than the preseptal area. Injections of the lower face are avoided because of the weakness that may occur, causing sagging of the angle of the mouth, speech problems, difficulty with forming a seal for drinking, and drooling.

The doses of BoNT used for HFS are very small. Injections are given subdermally, and EMG guidance is not usually needed. The dose is frequently lower than what would be needed in blepharospasm. The injection sites are chosen according to the clinical picture. Possible injection sites are demonstrated in the illustration below. Undesired effects include incomplete paralysis of the injected muscles, or weakness of adjacent muscles. Ptosis and local hematomas may occur in up to 10%. The effect of injections begins ~2–3 days following injection and maximizes up to 2 weeks following injection. The effect of BoNT injections lasts from 2 to 6 months with most patients seeking retreatment after 3–4 months. A few patients have a sustained benefit and may only require injections on an annual basis.

Most patients will require continued treatment to maintain benefit.

The primary surgical procedure for HFS is a decompressive intervention (surgical vascular decompression of the facial nerve, Janetta's technique). This operation aims at eliminating the pathologic contact of nerve and vessel by interposition of muscles, surgical gauze, or use of fibrin

glue. Success rates are quoted between 80% and 97%, with relapse rates up to 25%. Microsurgical vascular decompression is proposed to act by separating the artery from the facial nerve and can provide sustained improvement. However, this procedure is associated with a potential for serious complications including facial paralysis, deafness/hearing loss, excessive bleeding, and even death. The recurrence rate is about 20%.

Prognosis

HFS is usually a chronic disorder. Spontaneous remissions have been described but are rare. Facial weakness can occur in some patients, involving the orbicularis oris muscle of the mouth and resulting in sagging of the labial angle with disordered speech and sialorrhea. This mild paralysis must be distinguished from the possible untoward effects of treatment.

HIV Infection and Movement Disorders

A Di Rocco, New York University School of Medicine, New York, NY, USA

Glossary

Chorea – From Greek: circle dance. Irregular and usually fast involuntary movements affecting one or more body segments or generalized to the entire body. When generalized, these movements appear to flow randomly from one body part to the next.
Dystonia – Involuntary and persistent muscle contractions affecting one or more muscle groups that can lead to involuntary, repetitive movements and postures of body segments.
Hemiballismus – Large amplitude, irregular involuntary movements affecting the proximal extremities on one half of the body (movements may resemble kicking or throwing).
Movement disorders – General term that refers to abnormal execution of movements or presence of abnormal involuntary movements.
Parkinsonism – A term used to describe a constellation of symptoms typical of Parkinson's disease and similar disorders (Parkinson-like diseases) that include bradykinesia (slowing of movements), rigidity (increased muscle tone, usually with the typical 'cog-wheel' phenomena), and tremor.
Tremor – Rhythmic involuntary oscillatory movement of a body part. Tremors are classified on the basis of clinical setting (resting, postural, kinetic), frequency (high or low), and intensity.

Definition and History

Movement disorders are common among human immunodeficiency virus (HIV)-infected individuals, with both hypokinetic and hyperkinetic syndromes that may manifest themselves at all stages of the disease and occasionally appear as the first clinical manifestations of HIV infection. HIV-infected individuals are also exquisitely prone to developing movement disorders after exposure to dopamine-blocking drugs.

Since the early stages of the epidemic, a variety of movement disorders have been recognized in HIV-infected subjects. While most movement disorders observed before the introduction of highly active antiretroviral therapy (HAART) were due to opportunistic infections or neoplasms affecting the basal ganglia, with the widespread use of HAART, most of the movement abnormalities are now observed in subjects with HIV dementia (HAD) and are thought to be a clinical consequence of dopaminergic and basal ganglia dysfunction caused by chronic HIV infection. The basal ganglia are in fact one of the brain regions that preferentially hosts the virus and in more advanced stages of HIV infection neuronal loss and other neuropathological changes are observed in the substantia nigra and the striatum. Nigral dopaminergic cells seem particularly vulnerable to the viral envelope protein glycoprotein (gp) 120, which reduces dopamine uptake and can cause apoptosis. Another HIV protein, Tat, produces mitochondrial dysfunction and excitotoxicity and may contribute to

the cascade of events responsible for the dopaminergic neuronal loss.

A number of abnormalities in the structure of pre- and postsynaptic striatal dopaminergic synapses have also been described, providing further explanation to the vulnerability of HIV-infected individuals to developing motor dysfunction and movement disorders.

Clinical Syndromes

Parkinsonism in HIV-Associated Dementia

Since its first historical descriptions, motor slowing and other motor abnormalities were recognized as an integral part of HAD. With evolving knowledge of the underlying mechanism of the disease, and renewed clinical categorization, motor dysfunction, and particularly extrapyramidal signs became one of the essential diagnostic criteria of HIV 'minor cognitive motor disorder,' a possible early stage of HAD. Motor abnormalities remain an important component of the syndrome even in the HAART era. Most of the motor abnormalities in the early stages of the disease are limited to mild bradykinesia and psychomotor slowing that can manifest before other cognitive changes become apparent. Interestingly, most of the neuropsychological abnormalities that characterize HAD are also reminiscent of those observed in Parkinson's disease, with prominent attention problems and executive dysfunction, that at least in part correlate with abnormal dopaminergic tone. In later stages, HAD is often accompanied by frank hypomimia, dysarthria, hypophonia, bradykinesia, loss of manual dexterity, and gait and balance problems. As the disease progresses, some patients become clinically indistinguishable from individuals with advanced idiopathic Parkinson's disease and dementia.

Subclinical motor dysfunction attributable to abnormal basal ganglia function, including prolonged reaction time and subtle abnormalities in rapid alternating movements can be demonstrated in asymptomatic individuals, and may predict patients at risk for HAD.

A rare, predominantly parkinsonian syndrome associated with neurological problems and cognitive changes has also been described in HIV-infected children. It is unclear whether this syndrome is a pediatric equivalent of the motor-cognitive syndrome of HAD, or is a distinct clinical and pathological entity.

Other Forms of Parkinsonism in HIV

In addition to parkinsonism associated with HAD, a rapidly progressing pure parkinsonian syndrome can develop in the course of HIV infection. In rare cases, a Parkinson-like disorder may be the presenting manifestation of HIV infection, without concomitant systemic or neurologic abnormalities. As discussed in one of the following sections, many cases of Parkinsonism in HIV are drug-induced.

As the use of HAART has transformed HIV into a chronic infection, there is growing evidence suggesting an increased vulnerability to developing parkinsonism in older chronically infected subjects. The reason for this presumed vulnerability remains unclear, but it is possible that subjects already predisposed to Parkinson's disease may develop early and more severe signs of Parkinsonism due to the concomitant chronic dopaminergic dysfunction produced by HIV.

Tremor and Other Movement Disorders in HIV-Associated Dementia

A low-frequency, predominantly resting tremor is often observed in HAD as part of an accompanying parkinsonian syndrome. A predominantly postural and symmetrical tremor, occasionally with a kinetic component, is also a frequent finding in HAD.

Hyperkinetic movement disorders, including chorea, dystonia, and myoclonus, are also occasionally observed in HAD, often as a part of a mixed hypokinetic-hyperkinetic complex motor disorder.

Other Forms of Tremor

Postural tremor in HIV infection can also be present in isolation, without evidence of concomitant HAD. A coarse postural and kinetic tremor may also be consequent to opportunistic infections involving the midbrain.

More often, tremor in HIV is caused by drugs that interfere with the dopaminergic system, such as neuroleptics or antiemetics, or as a complication of antidepressants. Rarely, tremor is observed as a side effect of preventive treatment of pneumocystis carinii pneumonia with trimethoprim-sulfamethoxazole.

Hyperkinetic Movement Disorders

The majority of hyperkinetic movement disorders are related to discreet lesions affecting the basal ganglia and the related motor pathway projections. Virtually, all movement disorders have been described in HIV infection, including focal, segmental, and generalized dystonia, myoclonus, chorea, and choreo-atethosis, hemiballismus, and tremors.

Before the introduction of HAART, chorea, often in the form of hemichorea-hemiballismus was s a common complication of AIDS, usually consequent to toxoplasmic abscess or other opportunistic infections. With the introduction of HAART, chorea has become uncommon, although choreic movements may, in rare occasions, manifest themselves in patients with HAD without any other obvious lesion affecting the basal ganglia.

Dystonia is also an uncommon neurological complication of HIV infection, and although it may be due to an underlying opportunistic infection or other lesions affecting the basal ganglia, it is often caused by exposure

to drugs that interfere with dopaminergic transmission. In rare instances, dystonia may be a manifestation or a complication of HIV encephalopathy.

Myoclonus is another uncommon complication of HIV, usually observed as part of the clinical constellation of HAD.

Up to a third of patients with chronic HIV infection controlled with HARRT have also been reported to have symptoms consistent with restless legs syndrome.

Drug-Induced Movement Disorders

Many movement disorders in HIV are caused, unmasked, or worsened by drugs that interfere with the dopaminergic system. The neuronal loss in the substantia nigra, the pathological changes in the basal ganglia, and the consequent dopaminergic dysfunction, in HIV-infected individuals, are likely explanations for their vulnerability to extrapyramidal side effects. These side effects may develop even after limited exposure to low doses of neuroleptics or after treatment with drugs with a lower potency for inducing extrapyramidal complications, such as metoclopromide and prochlorperazine. It has been estimated that in HIV-infected individuals, exposure to neuroleptics in general and haloperidol in particular are respectively associated with a 2.4- and 3.4-fold greater risk of developing extrapyramidal side effects.

Although parkinsonism is the most common drug-induced movement disorder, dystonia, tremor, and chorea have all been reported as side effects of dopamine-blocking agents.

Among drug-induced movements, a rare Parkinsonian syndrome induced by ritonavir and other antiretroviral agents deserves special mentioning. These antiretroviral agents in patients with concomitant Parkinson's disease may increase the effect of L-dopa and cause uncontrollable dyskinesias.

Therapeutic Strategies

There are no specific treatments for HIV-associated movement disorders, and most symptomatic treatments used in the general population are also utilized in HIV-infected individuals. Since the introduction of HAART, most neurological complications, including movement disorders, have become less common and less severe, and it is not uncommon that in HAART naïve patients, neurological manifestations improve solely as a result of effective antiretroviral treatment.

Parkinsonism is empirically treated with dopamine agonists, monamine oxidase inhibitors (MAO-I), and L-dopa, with variable results. In general, however, the response to treatment is less robust than in idiopathic Parkinson's disease, and it is not uncommon that the treatment proves ineffective. Side effects from dopaminergic mediations are also more common and more severe in HIV-infected patients. Individuals who respond well to L-dopa treatment may also have a higher risk of developing early and severe L-dopa motor complications, especially dyskinesias.

Treatment of hyperkinetic movements also relies on symptomatic agents, with no clear evidence of a different response to treatment among HIV-infected subjects. When the involuntary movements are caused by an opportunistic infection or other lesions affecting the basal ganglia, resolution of the underlying problem leads to amelioration of the movement abnormality.

While there is no known preventive treatment, there are reasonable hopes that an ever more effective control of HIV infection with HAART may maintain neurological health and prevent the onset of neurological complications, including Parkinsonism and other movement disorders. There is however increasing concern that an aging population with an underlying dopaminergic dysfunction may be more prone to developing Parkisnons's disease and other neurodegenerative disorders of ageing.

Hoehn and Yahr Staging Scale

P Martinez-Martin, National Center for Epidemiology, Madrid, Spain

Glossary

Construct – Any conceptual or abstract attribute that is not directly observable (e.g., intelligence).
Convergent validity – Correlation with other measures used to evaluate the same or related constructs.
Dopaminergic – Relating to the neurotransmitter known as dopamine.
Known-groups validity – A scale's ability to detect differences among groups.
Ordinal – Level of measurement which classifies attributes by order of rank.

Parametric – Statistical tests for continuous variables with normal distribution.
Parkinsonism – Syndrome that includes hypokinesia, rigidity, and tremor.
Reliability – Extent to which a scale is free of random error.

History

The Hoehn and Yahr staging scale (HY) was published in 1967, exactly 150 years after James Parkinson's seminal description of Parkinson's disease. The paper, in which Margaret M. Hoehn and Melvin D. Yahr included the first description of the scale, sought to display information about the course of 'Parkinsonism,' so that the potential effect of new treatments could be determined. Prior to its publication, some evaluative instruments, such as those by Schwab (1960), Canter et al. (1961), and Petrinovich and Hardyck (1964), had been published. None of these, however, gained the wide recognition and importance accorded to the HY.

Immediately after its introduction, the HY became, and indeed continues to be, the most commonly applied tool for the classification of Parkinson's disease (PD) patients. Its simplicity and ease of use make this scale attractive and useful for clinical practice and research. As a consequence of the HY's relevance, a Movement Disorder Society Task Force reviewed this instrument and published its conclusions in an overall laudatory critique in 2004.

Description

The HY was described by its authors as 'an arbitrary scale based on the level of clinical disability.' It is a five-level measure consisting of: stage I – unilateral involvement only, usually with minimal or no functional impairment; stage II – bilateral or midline involvement, without impairment of balance; stage III – first sign of impaired righting reflexes; stage IV – fully developed, severely disabling disease; and stage V – confinement to bed or wheelchair unless aided. The most relevant modification of the HY was introduced in 1987 by the Unified Parkinson's Disease Rating Scale (UPDRS) Development Committee. This version includes stages 1.5 (unilateral plus axial involvement) and 2.5 (mild bilateral disease with recovery on pull test). In addition, stage 0 (no signs of disease) was added to the original scale. These later adaptations have not been clinimetrically tested. The HY furnishes a global assessment of PD severity based on a combination of clinical features and disability.

Applications

In consonance with the original intention of its authors, the HY has been applied to a diversity of studies on the natural history of PD and its course relative to the effects of the diverse treatments. HY staging provides an overall description of the patient's condition vis-à-vis PD, allowing for a generally accepted clinical translation to mild (stages I and II), moderate (stage III), and severe (stages IV and V) levels. As an indicator of PD progression, change in HY stage is an important feature in the course of the disease and influences its management.

Not only is the scale commonly used to select patients for clinical trials and other types of applied research, but it is also used to stratify samples for data analysis in epidemiological studies and outcomes research. It has been incorporated into other composite rating scales such as the MDS-UPDRS and the Core Assessment Programs for Surgical Interventional Therapies in PD (CAPIT and CAPSIT-PD). Correlation between disease stage and dopaminergic-activity markers in neuroimaging has been demonstrated in longitudinal and in cross-sectional studies. Lastly, the HY is a benchmark for testing and developing newer rater and patient-based PD measures.

The Hoehn and Yahr Scale as a Measure

HY is an ordinal scale, since it ranks disease severity according to an order that ranges from the mildest (stages I or II) to the most severe disease stages (stage V). Hence, steps in this scale cannot be presumed to be equal, and parametric statistical methods should not be applied for the purpose of HY data-analysis. The HY conceptual and measurement model is beset by some problems, namely: (1) the combination of impairment and disability, which often renders stage assignment difficult in cases where there are discrepancies between these two aspects of disease assessment; (2) the lack of consistency between disease onset and lowest scale rank for a proportion of patients who apparently begin PD in stage II; (3) the absence of strict relationship between increment in stage and increasing disability, something that mainly affects stages I–III; (4) the possibility of wide variability in severity within each stage, due to the small number of categories; (5) the emphasis on balance and bilateral involvement does not specifically focus attention on upper limb function, motor complications, and nonmotor symptoms of PD all of which may play important overall roles in the final severity of PD.

As an outcome measure, HY is valuable for charting clinical disease progression. At present, however, without a restorative therapy for PD, improvement in HY should be interpreted, not as a regression to earlier phases of the disease, but rather as a symptomatic effect on

manifestations that influence stage assignment. Furthermore, due to the great gap between stages (scant precision), the scale is poorly responsive to current interventions. The application of the HY is not standardized and therefore, the scale is prone to spurious variability in the assignment of scores. Furthermore, modifications (see earlier text) have been introduced without clinimetric validation.

Psychometric Attributes

Due to the scale's structure, only some properties can be tested. With regard to reliability, several studies performed on the original version of the HY have reported a moderate-to-substantial level of interrater agreement (κ values, 0.44–0.71). Test–retest has not been examined. Convergent validity with other PD rating scales has been extensively tested against other measures, including the Schwab and England, UPDRS subscales, Intermediate Scale for Assessment of PD, Rating Scale for Gait Evaluation, Freezing of Gait Questionnaire, and the Short Parkinson's Evaluation Scale/Scales for Outcomes in Parkinson's Disease-Motor (SPES/SCOPA-Motor). These evaluations have yielded the following correlation coefficients: 0.26–0.84 with functional scales; 0.62–0.87 with motor examination scales; 0.44–0.67 with motor complications. Additional correlation has been determined with: SCOPA-autonomic, 0.35–0.60; SCOPA-Cognition, −0.39 to 0.66; and nonmotor symptoms questionnaire, and scale, 0.31 and 0.33, respectively. Low/moderate or nonsignificant correlations (always <0.40) have been found between HY and the following PD-specific scales: Parkinson's Disease Sleep, SCOPA-Sleep, and Parkinson Psychosis Rating Scales.

Both generic and specific health-related quality of life (HRQoL) measures have been used in PD, and the HY has been frequently used as the global severity benchmark. These studies showed a variable, largely moderate association between HY and summary indices of generic HRQoL measures, and a moderate-to-high correlation between specific HRQoL instruments (PDQ-39, PDQL, and PDQUALIF) and HY. While dimensions relating to physical aspects, such as mobility and functional status, generally displayed a close association with HY staging, other domains (such as emotional role, mental health, pain, social support) showed a less robust correlation. Disease severity has a global effect on most determinants of and factors associated with HRQoL. For most of the clinical scales and HRQoL instruments, known-groups (discriminative) validity has been demonstrated on the basis of sample stratification by HY stage or severity level.

Conclusions

Over 40 years after its introduction, the HY continues to be a reference for classification of patients in relation to the evolutionary phases and global severity of PD. The ad hoc Movement Disorder Society Task Force recommends that the original version be used until such time as clinimetric testing of the modified version, that includes 0.5, 1.5, and 2.5 designations, has been completed. Despite ambiguities and lack of standardization, HY staging is the most widely used instrument for assessment of PD patients and the primary benchmark for other types of measures.

Hot-Cross Bun Sign

A Schrag, University College London, London, UK

The Hot-Cross Bun Sign

The hot-cross bun sign (**Figure 1**) is the neuroradiological finding of cross-shaped abnormal hyperintensity in the pons, resembling a hot-cross bun (a pastry bearing a white cross traditionally eaten in the UK at Easter). The hot-cross bun sign was first described in patients with multiple system atrophy, as a differentiating feature in comparison with findings of normal pontine structures in patients with Parkinson's disease. The underlying pathological feature is thought to be the degeneration and gliosis of the transverse pontocerebellar fibers and raphe pontis, which stand out against a background of intact tegmentum and pyramidal tracts. On T2-weighted images and proton density weighted sequences, the vertical and horizontal fibers give the appearance of a white cross. The sensitivity of the signs is 40–50% in patients fulfilling the criteria for probable multiple system atrophy (higher in MSA with predominant cerebellar ataxia and lower in MSA with predominant parkinsonism), and it is typically associated with pontine atrophy and hyperintensities in the middle cerebellar peduncles on T2-weighted images. The hot-cross bun sign is absent in patients with Parkinson's disease and progressive supranuclear palsy, making this a specific finding in the context of differentiating these syndromes. However, the hot-cross bun sign has been reported in patients with other disorders associated with olivopontocerebellar atrophy, including SCA 2- and SCA 3-associated disorders and vasculitis. The hot-cross bun sign has been incorporated in the diagnostic criteria for multiple system atrophy.

H-reflex

J A Robichaud, University of Illinois at Chicago, Chicago, IL, USA

Glossary

H/M ratio – This ratio represents the percentage of the motoneuron pool that is active at any particular time. This ratio is between the amplitude of the maximum M-wave and the amplitude of the tested H-reflex.

M-wave – This is the electrically stimulated direct motor response. The M-wave elicited by supramaximal stimulation is used for motor nerve conduction studies. The maximum M-wave represents 100% of the activity of the specified muscle's motoneuron pool.

Parkinson's disease – A neurodegenerative disorder that causes motor symptoms such as tremor, rigidity, and bradykinesia.

Introduction

The H-reflex can be used to assess changes in motoneuron pool reflex excitability. This reflex, also known as the Hoffmann reflex, is an electrically stimulated reflex that excites the muscle spindles Ia afferents. When electrical stimulation is applied over a nerve, this causes action potentials to be transmitted to the spinal cord where monosynaptic or polysynaptic connections cause motoneurons to reach threshold, thereby, causing the extrafusal muscle to contract. The overall level of reflex excitability may be influenced by excitation of Ib afferents from Golgi tendon organs, group II afferents from muscle spindles, and larger cutaneous afferents. While the H-reflex was originally suggested to be analogous to the tendon jerk, the central timing of the H-reflex is shorter than the tendon response, allowing for the possibility that more spinal processing occurs with the tendon response. Therefore, it is possible that both responses use slightly different pathways, and hence, it may not be appropriate to directly compare these responses.

The H-reflex can be evaluated either through the latency of the response or the reflex size (peak to peak amplitude). While there are established values for the latency of this response (time from stimulus application until initial deflection from baseline), this is not the case for the amplitude. The validity and reliability of the H-reflex amplitude have been evaluated by Crayton and King and Hugon et al. Because of the variability of the amplitude of the H-reflex, one test measurement should consist of the average of at least 5–7 (and up to 20) H-reflex measurements. The amplitude of the H-reflex also exhibits a wide intersubject variability in reflex recording; however, there is small test/retest variability within each subject. Because of this variability, changes in the amplitude of the H-reflex should only be analyzed relative to each subject's baseline H-reflex value.

Several methods, which evaluate H-reflex amplitude changes, have been used to assess spinal reflex excitability. One method assesses the percentage change of the test H-reflex amplitude in comparison to a control (baseline) H-reflex amplitude. However, this method of analysis requires an understanding of how changes in stimulus intensity can influence the amplitude of the H-reflex. At low stimulation intensities, Ia afferents are activated first which causes activation of the muscle's motoneurons eliciting a small amplitude H-reflex. As stimulation intensity further increases, the amplitude of the H-reflex increases which activates alpha motoneurons, and the direct muscle response (M-wave) is now observed. As the stimulation intensity further increases, the amplitude of the H-reflex becomes progressively larger up to a critical point, after which the amplitude of the H-reflex becomes progressively smaller until the H-reflex is no longer present. Therefore, test H-reflex alterations elicited by a given conditioning stimulus depend not only on the conditioning volley, but also on the amplitude of the control H-reflex. This aspect of H-reflex recruitment makes it difficult to determine the 'true' amount of reflex facilitation or inhibition. For instance, a small control H-reflex could result in a large amount of facilitation, while a larger control H-reflex would result in a smaller amount of facilitation. Therefore, using percentage change may make it difficult to estimate the real amount of either facilitation or inhibition of the motoneuron pool.

The H/M ratio, which is the ratio of the size of the H-reflex to the size of the M-wave, is an alternate method of analyzing changes in motoneuron reflex excitability. The H/M ratio represents the percentage of the motoneuron pool that may be considered to be active at any particular time. The maximum M-wave represents 100% of the activity of the specified muscle's motoneuron pool. The H/M ratio allows a quantification of the percentage of the active motoneuron pool. This interpretation enhances the ability to compare changes in the H-reflex between subjects. Crone and colleagues established that regardless of differences in the maximum H-reflex, the

change in sensitivity to facilitation followed the same pattern as long as the control reflex sizes are explored.

The H-reflex recovery curve, which is a variation of the H-reflex, can also be used to assess motoneuron pool reflex excitability. The recovery curve is elicited by stimulating a nerve with paired stimuli at intervals from 1 ms to 10 s. The magnitude of the recovery curve at a given interstimulus interval refers to the percentage ratio of the test H-reflex amplitude to the unconditioned H-reflex amplitude, with these amplitudes being plotted as a function of the intervals between the reflexes. The recovery curve in healthy subjects consists of several phases. The first phase occurs with interstimulus intervals from 3 to 10 ms with the test reflex varying in size with simulation intensity. Next, there is an inhibition phase which is then followed by a facilitatory phase which occurs at stimulus intervals between 50 and 400 ms (peaks at 200–300 ms). Finally there is another inhibition phase which can last from 5 to 10 s.

In addition to changes in motoneuron reflex excitability, changes in the H-reflex have also been used to evaluate reciprocal Ia inhibition, Ib inhibition/facilitation, and presynaptic inhibition. Reciprocal Ia inhibition is evaluated by using a test H-reflex and a conditioning response (paired stimulus paradigm). The H-reflex is elicited with a low intensity stimulus (designed to stimulate primarily the muscle spindle Ia afferents) supplying the antagonist muscle. If the antagonist stimulation is given at the appropriate time, the test H-reflex in the agonist can be inhibited. Ib inhibition/facilitation is also assessed using a paired stimulus paradigm. However, unlike Ia inhibition, Ib inhibition/facilitation can be measured in the antagonist or synergists muscles acting at different joints within a limb. Finally, several techniques have been established whereby the H-reflex can be used to assess presynaptic inhibition. One method assesses H-reflex amplitude changes after vibration has been applied to either the tested muscle or a different muscle. In this method, the amount of inhibition is assessed by analyzing the amplitude change between the amplitude of the H-reflex prior to, and then after vibration. Presynaptic inhibition can also be assessed while testing for reciprocal inhibition between extensors and flexors in the forearm. Finally, Hultborn and colleagues showed a more difficult, but more specific method of analyzing presynaptic inhibition. In this method, the amount of H-reflex facilitation in one muscle is assessed while a monosynaptic heteronymous Ia volley is being applied to another muscle.

H-reflex changes have been evaluated in individuals with neurological disorders. It is known that slowing down of the H-reflex latency can be detected long before nerve degeneration in hereditary and acquired demyelinating neuropathies are observed. However, the scientific and clinical implication related to changes in the H-reflex amplitude is not as clear. For instance, Angel and Hoffmann observed that the H_{max}/M_{max} ratio was higher in individuals with spasticity. In contrast, other studies have concluded that changes in the H_{max}/M_{max} ratio were not a good measurement tool to quantify changes in spasticity. The literature is also mixed regarding the H-reflex changes when assessing rigidity. While no difference was shown in the H-reflex recovery curve when Parkinson's disease (PD) subjects with rigidity were compared to healthy subjects, other studies showed that rigid PD subjects exhibited an abnormal H-reflex recovery curve. Along this line, changes in the H-reflex behavior correlated with the level of rigidity in PD subjects. Studies are also mixed regarding changes in presynaptic inhibition in individuals with neurological disorders. While studies have shown a decrease in presynaptic inhibition in subjects with upper motoneuron lesions, others researchers have shown no change in presynaptic inhibition in the same type of subjects. While changes in the amplitude of the H-reflex can be used to measure several different parameters related to changes in spinal reflex excitability, it is clear that more research is needed in order to determine the clinical relevance of H-reflex changes in individuals with neurological disorders.

Huntington, George

D J Lanska, Veterans Affairs Medical Center, Tomah, WI, USA

Glossary

George Huntington (1850–1916) – American general practitioner, who gave the classic description of hereditary chorea (Huntington's disease) in 1872.
Huntington's disease – Neurodegenerative disease transmitted as an autosomal dominant trait and characterized by adult onset, chorea, dementia, psychiatric disturbances, and a tendency to suicide, as characterized by George Huntington in his classic description in 1872.

Although genealogical studies suggest that Huntington's disease has existed since at least the seventeenth century, it had not been differentiated from other forms of chorea until the nineteenth century. The rarity of the disease, confusion with other more common neurologic conditions, inadequate appreciation of the role of heredity in the etiology of disease, and publication of some early clinical reports in inaccessible places without identification of cases all contributed to the delay in recognition. Although clinical descriptions of hereditary chorea were given by several authors from 1841 to 1868, there had been no general recognition of the disorder until the description by George Huntington (1850–1916) in 1872.

George Huntington (**Figure 1**) grew up in the 'drowsy, secluded village' of East Hampton on the eastern end of Long Island, where both his grandfather and his father practiced medicine. Huntington in later years stated that his grandfather, Dr. Abel Huntington, came to Long Island from Connecticut in 1797 and found hereditary chorea well established there. From years of contact with patients afflicted with hereditary chorea, Huntington's grandfather, and later his father, began to recognize the clinical features of the disorder.

George Huntington first encountered victims of 'that disorder' at the age of 8 while riding with his father on his professional rounds. As Huntington recalled in 1910, 'Driving with my father through a wooded road leading from East Hampton to Amagansett, we suddenly came upon two women, mother and daughter, both bowing, twisting, grimacing. I stared in wonderment, almost in fear. What could it mean? My father paused to speak with them, and we passed on . . . . From this point, my interest in the disease has never wholly ceased.'

Around 18, Huntington began preliminary medical studies under his father's guidance, prior to matriculation at the College of Physicians and Surgeons of Columbia University, New York. After graduation in 1871, Huntington returned to East Hampton and for several months assisted his father in practice. He was particularly interested in the cases of hereditary chorea still living in the area, and studied the clinical notes of cases treated previously by his father and grandfather. Huntington incorporated this material in an essay entitled 'On chorea,' which was carefully edited by his father.

Late in 1871, Huntington took the advice of a relative and moved to Pomeroy, Ohio to set up a general medical practice. Huntington brought his unpublished paper with him and at the age of 21 presented it before the Meigs and Mason Academy of Medicine at Middleport, Ohio on February 15, 1872. In his presentation, Huntington noted that. . .

> The hereditary chorea . . . is spoken of by those in whose veins the seeds of the disease are known to exist, with a kind of horror, and not at all alluded to except through dire

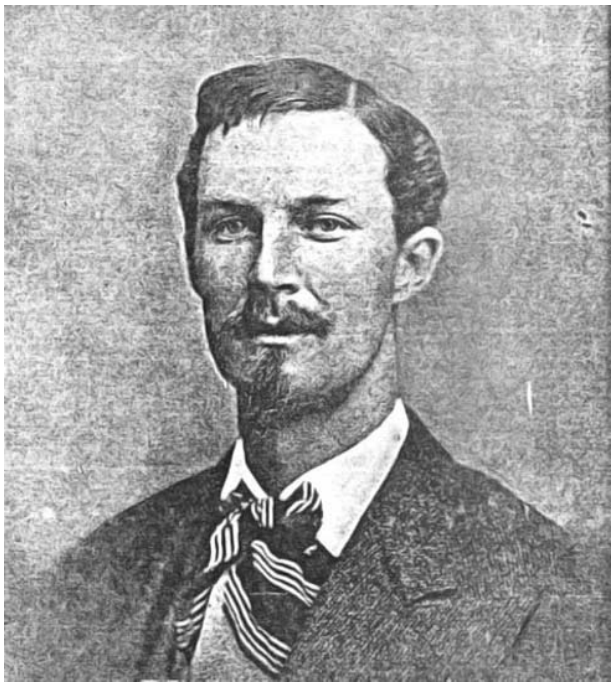

Figure 1 George Huntington in 1872 around the time of publication of his classic paper, 'On chorea.' Photograph from 'the Huntington number' of Neurographs.

> necessity, when it is mentioned as 'that disorder.' It is attended generally by all the symptoms of common chorea, only in an aggravated degree, hardly ever manifesting itself until adult or middle life, and then coming on gradually but surely, increasing by degrees, and often occupying years in its development, until the hapless sufferer is but a quivering wreck of his former self... There are three marked peculiarities in this disease: 1. Its hereditary nature. 2. A tendency to insanity and suicide. 3. Its manifesting itself as a grave disease only in adult life... When either or both the parents have shown manifestations of the disease, and more especially when these manifestations have been of a serious nature, one or more of the offspring almost invariably suffer from the disease, if they live to adult age. But if by any chance these children go through life without it, the thread is broken and the grandchildren and great-grandchildren of the original shakers may rest assured that they are free from the disease... It begins as an ordinary chorea might begin, by the irregular and spasmodic action of certain muscles, as of the face, arms, etc. These movements gradually increase, when muscles hitherto unaffected take on the spasmodic action, until every muscle in the body becomes affected (excepting the involuntary ones), and the poor patient presents a spectacle which is anything but pleasing to witness. I have never known a recovery or even an amelioration of symptoms in this form of chorea; when once it begins it clings to the bitter end. No treatment seems to be of any avail, and indeed nowadays its end is so well known to the sufferer and his friends, that medical advice is seldom sought. It seems at least to be one of the incurables.

As his presentation was well received, Huntington submitted his manuscript to the editors of the Medical and Surgical Reporter of Philadelphia, where it was published on April 13, 1872. Although Huntington's article had been published almost three decades before Mendel's laws were simultaneously rediscovered and made known by DeVries, Correns, and Tschermak von Seysenegg in 1900, there was already growing interest in hereditary neurodegenerative diseases, especially in light of Friedreich's work on hereditary ataxia. Huntington's description of hereditary chorea was considered particularly important by his contemporaries, because of his clear and concise description, and because it demonstrated that hereditary conditions could have their clinical onset in adulthood. Huntington's paper was abstracted for international yearbooks, widely discussed, and published verbatim in scholarly texts. Because of this attention, by the late 1880s authors began referring to hereditary chorea as 'Huntington's chorea,' as did Huntington himself after about 1895.

In 1903, in a presentation in Columbia, South Carolina, to the Tri-State Medical Society (i.e., Virginia and the Carolinas), Huntington expanded upon his original description of the clinical features:

> Of very gradual onset, the symptoms are progressive, and seldom commence suddenly... [Whole] groups of muscles are put into action as if by voluntary effort, as if the patient were posturing or making grimaces. He has a dancing or swaying movement of legs and body, and the mouth and other facial muscles are drawn and twisted into the most ludicrous shapes; the tongue is protruded and then suddenly withdrawn, the head nodding and neck twisting at the same time. The contortions are never localized to one muscle or set of muscles, but the whole muscular system seems to be involved. The facial muscles seem to be usually the ones first involved, then the arms, trunk and legs, and occasionally all simultaneously. The voice is changed to a thick nasal tone and sentences are spoken in a jerky way. It is not a stammer, but jerky, as one would expect from the irregular contraction of the vocal muscles, the lips, tongue, etc... Voluntary muscular efforts are often interrupted and impeded on account of imperfect co-ordination, so that if the patient desired to shake hands with another, he would go through quite a rigamarole of movements before accomplishing his object... Some patients are very irritable and easily provoked, occasionally wildly maniacal. Some become gradually helpless and demented, while others show but little mental impairment to the end.
>
> The diagnosis is made upon the family history largely; upon the period of life at which the disease manifests itself, seldom, if ever, occurring before adult life, and most

> frequently between 25 and 40; the character of the spasmodic movements being slower and of larger range than those of ordinary chorea... [The] general progress of both mental and physical symptoms, ever tending onward and downward to the end, point decidedly to this form of the disease... The patients are born with nerve cells not having the capacity of living but for a limited time, and when the cells begin to degenerate, the symptoms of chorea commence to show themselves... No treatment that is of any effect has yet been found.

In 1908, Dr. William Browning of Brooklyn, New York edited a special edition of 'Neurographs,' in honor of Huntington in which Huntington's work was applauded by many, including Osler. While accepting that Huntington was not the first to describe hereditary chorea, Osler noted in regard to Huntington's description that 'In the history of medicine there are few instances in which a disease has been more accurately, more graphically, or more briefly described.'

Huntington spoke on hereditary chorea at the New York Neurological Society on December 7, 1909, with Drs. William Browning (1856–1941), Smith Ely Jelliffe (1866–1945), and Charles Loomis Dana (1852–1935) among those in attendance. A modest man, Huntington readily credited the contributions of his grandfather and father:

> It must also be remembered that, without the facts and observations handed down to me by my grandfather, Dr. Abel Huntington, and my father, Dr. George Lee Huntington, the medical lives of whom both were spent in East Hampton, Long Island, and whose memory is still cherished there by the few remaining who once knew them – I never could have formulated a picture of the salient characteristics of the disease so true and so complete as to make of it a so-called classic. As in old Greece the pupil sat at the feet of his teacher, so your essayist sat at the feet of these two, and whatever of honour, whatever of praise, whatever of scientific worth there is, is due much more to them, than to him to whom has come this unsought, unlooked for honour.

The characteristics of Huntington's disease recognized by George Huntington in 1872 and by his father and grandfather before him – the distinct clinical profile, midlife onset, and inheritance pattern – made the disease ideal for investigation by genetic linkage analysis a century after Huntington's description.

Huntington's Disease: Genetics

E Berry-Kravis, Rush University Medical Center, Chicago, IL, USA

Glossary

Genetic anticipation – Worsening and/or earlier onset of disease over generations, usually due to increasing size trinucleotide repeat expansion mutation over the generations.

Huntingtin – The protein product of IT15 contains polyglutamine repeat expansion mutation in HD.

Huntington's disease (HD) – Progressive neurodegenerative disease associated with chorea, psychiatric disturbance, and dementia.

***IT15* – Huntington's disease gene** – The gene mutated with CAG repeat expansion in Huntington's disease.

Trinucleotide repeat expansion mutation – Increase in length of a normally occurring DNA sequence containing repeat units of three nucleotides.

History of Huntington's Disease Genetics

Huntington's disease (HD) is a progressive movement disorder characterized by major features of chorea, psychiatric disease, and dementia. In the 1840s, HD was first described in the medical literature as 'chronic hereditary chorea' when several physicians described accounts of people with involuntary movements and mental disturbances that were inherited from a similarly affected parent. In 1872, George Huntington wrote what is considered as the classic description of HD in his landmark paper '*On Chorea*,' in which he also clearly described the genetic nature of the condition, stating, 'When either or both the parents have shown manifestations of the disease, one or more of the offspring invariably suffer from the condition. It never skips a generation to again manifest itself in another. Once having yielded its claims, it never regains them.'

In 1955, Americo Negrette described communities in Lake Maracaibo, Venezuela with an unusually large fraction of the population affected by HD. Nancy Wexler began work in that community in 1981, which eventually led, in 1983, to the identification of a genetic marker linked to HD at the end of the short arm of chromosome 4. Predictive linkage testing was implemented as a way of assessing the likelihood that individuals at risk for HD had inherited the disease. After much work attempting to identify the disease-defining linked gene, the causative mutation in HD was identified in 1993 as a trinucleotide (CAG) repeat expansion mutation in the *IT15* gene at chromosomal location 4p16.3.

The HD Mutation and Inheritance

The gene responsible for HD, *IT15* (also called *HTT*), encodes a ubiquitously expressed 350 KDa protein termed huntingtin. The causative mutation, an expansion of a tract of uninterrupted CAG repeats, is located within the coding sequence of the gene, 17 codons downstream of the ATG translation initiation codon in exon 1. The expanded CAG repeat in the mutation codes for an expanded polyglutamine tract in huntingtin. This mutational mechanism occurs in nine other diseases, known to be caused by abnormal expanded polyglutamine tracts, including many of the dominantly inherited spinocerebellar ataxias.

Identification of the disease-associated mutation led rapidly to a large number of studies characterizing the population distributions of normal and disease allele sizes and genotype–phenotype interactions. Based on these studies, current consensus is that normal alleles have 9–26 CAG repeats, with 17–20 repeats found most commonly and representing the majority of the alleles in the population. Intermediate or 'premutation' alleles of 27–35 repeats are not associated with clinical symptoms but can be meiotically unstable and expand to disease-causing mutations of 36 repeats or more when passed on to offspring. Alleles that have 36–40 repeats exhibit incomplete penetrance in that they are associated with disease in some individuals but not in all, although the penetrance disease at each of these mutation sizes is not well-defined. Alleles with 41 or more repeats are thought to always cause HD if the individual lives long enough.

There is earlier onset and more severe disease with increasing length of the CAG repeat sequence. There is, however, a wide variation in the age of onset observed with any given repeat number and thus CAG repeat number has poor specific predictive value for the age of onset for a given individual. The number of CAG repeats, in fact, accounts for about 60–70% of the variation in the age of onset, with the remainder of variation contributed by modifying genes and environmental factors. Survival models have been developed to predict the probability of neurological (motor) disease onset of HD at different ages based on CAG repeat length. Several reports have identified genes that modify the age of onset of HD in one or several cohorts, including polymorphisms in Huntingtin-associated protein-1 (HAP1), transcription factor p53 (TP53), human caspase activated DNase (hCAD), ubiquitin C-terminal hydrolase L1 (UCHL1), GluR6 kainate glutamate receptor (GRIK2), glutamate receptor subunits NR2a, and NR2B (GRIN2A and GRIN2B), but some of these have failed to be replicated or have not yet been studied in sufficient independent cohorts.

Inheritance of HD is autosomal dominant with anticipation, a phenomenon in which the age of onset becomes earlier and disease severity increases in successive generations. In HD, the molecular basis for this phenomenon is explained by the meiotic instability in the number of CAG repeats passed on from parent to child. The repeat mutation may increase or decrease in size when passed from parent to offspring, although expansion is more common (73% of transmissions) than contraction (23% of transmissions). There is a gender bias for the expansion of the HD CAG repeat mutation, such that paternally inherited alleles carry a much higher risk of significant further expansion when passed on to a child, due to large size increases that occur in spermatogenesis relative to

oogenesis. Thus, large expansions of the CAG repeat mutation during replication happen almost exclusively in males, and likewise, severe, early-onset juvenile HD, which typically results from alleles of >50 repeats, is almost always inherited from the father. Thus, the characteristics of the mutational instability in the CAG repeat mutation explain the prior clinical observation of genetic anticipation in HD when the mutation was inherited paternally. Similarly, new onset cases of HD, for which there is no family history, are now known to arise because of expansion of an intermediate allele in the 'premutation' range (27–35 repeats) into the disease-causing range, generally when inherited through the paternal line. No cases of expansion of alleles in this size range to disease-causing alleles on maternal transmission have yet been reported.

Somatic instability of the HD mutation can be seen such that there may be some mosaicism for slightly different mutation sizes in different tissues of the body. Although this finding may contribute to selective vulnerability in the CNS, it does not typically confuse genetic testing results.

Genetic Testing for Diagnosis of HD

Genetic diagnosis of HD can now be accomplished through a simple PCR assay, which determines the size of the CAG repeat sequence and can be performed by most molecular diagnostics laboratories. DNA testing to confirm diagnosis in symptomatic cases is the current standard of care.

While genetic testing for asymptomatic cases is also now easy to accomplish, care must be taken to make sure that the individual being tested wants the test done, understands the implications of the result, and is not depressed or suicidal, particularly when receiving positive test results. Despite the ease of obtaining the test, current data suggest that only about 5% of individuals at risk choose to pursue testing. Those who do have testing generally utilize the result to help to make career and family choices. Currently, protocols are typically used to exclude suicidal individuals from testing, inform the person seeking testing about the implications of the test results for themselves and others in the family, identify potential sources of support for the person receiving the result, and to ensure protection of confidentiality. Individuals who undergo recommended pretest assessment and counseling protocols generally feel that their overall experience with the testing process is positive. Although anxiety and stress increase immediately after receiving a positive result, this returns to baseline and within 2 years, stress levels are lower than pretest, irrespective of the outcome. Persons with a negative result can experience stress from the so-called 'survivor guilt,' which can be handled with counseling.

Prenatal testing is only infrequently done, due predominantly to the resistance to abortion for a relatively late-onset disease. Preimplantation testing, although expensive, is becoming increasingly utilized to avoid pregnancies with HD-affected fetuses. Elderly individuals who are asymptomatic may undergo exclusionary testing to allay fears that children or grandchildren may be at risk for HD. Experience with issues arising in association with genetic testing for HD has provided a model for approaches to testing in other late-onset disorders.

Epidemiology of HD

The prevalence of genetically diagnosed HD in Caucasian populations is about 5–7 affected individuals per 100 000. Higher frequencies exist in genetically isolated populations with a few founders, such as the population at Lake Maracaibo. Prevalence in Asian and African populations is less than 10% that of Caucasian populations (<0.5 affecteds/100 000). This is largely due to the higher frequency of borderline alleles of 27–35 repeats in Caucasian populations, although reasons for the increased prevalence have not been discovered.

Animal Models of HD

Transgenic animal models of HD have been created in mice, *Drosophila*, and *Caenorhabditis elegans*. The fly and mouse models show neuronal polyglutamate inclusions, progressive late-onset motor dysfunction, and neuronal dysfunction followed by neuronal death, with pathology dependent on polyglutamine length. Of note, when the transgene is switched off in clinically symptomatic mice, the clinical symptoms and inclusions resolved, suggesting that treatment to limit toxicity could be helpful even later in the course of the disease. The animal models have continued and will continue to provide an extremely valuable resource for understanding the pathogenesis of the disease and for testing new potential treatments targeted to the underlying mechanism of disease.

Cellular and Molecular Pathogenesis of HD

Huntingtin is expressed in all human cells, with highest concentrations in the brain and testis. The function of the normal protein is still incompletely understood as are the specifics of the underlying mechanisms active in HD.

One possible mechanism of disease that could occur in an autosomal dominant disease like HD is haploinsufficiency, in which the genetic defect leads to the reduction of a vital protein to half the normal levels resulting in disease

due to inadequate amounts of the protein for normal function. This mechanism is unlikely in HD for a number of reasons: (1) the CAG repeat expansion is the only mutation in *IT15* that causes HD – if haploinsufficiency caused HD, there would likely be other disease-associated mutations; (2) carriers of a balanced translocation that transects the *IT15* gene on one chromosome and render it inactive do not develop HD; (3) individuals with a terminal deletion of 4p and who are missing one copy of *IT15* do not develop HD; (4) the absence of one copy of the HD gene does not cause a disease phenotype in mice; and (5) although homozygous deletion of the gene in mice is associated with embryonic lethality, individuals homozygous for an HD-associated CAG expansion develop normally. Taken together, this data suggest that the CAG repeat mutation does not work through a loss-of-function mechanism and that haploinsufficiency of *IT15* is probably not associated with specific clinical manifestations.

Rather, the CAG repeat mutation appears to be inherited dominantly because it operates through a gain-of-function mechanism, generating a new toxic function not intrinsic to the normal huntingtin protein, and likely resulting from cellular toxicity of the polyglutamine expansion. In support of this concept, homozygous cases of HD show similar age of onset (although perhaps more rapid progression) to heterozygous cases with an allele size similar to the larger allele in the homozygous case. The best lines of evidence supporting the gain-of-function mechanism for HD include the demonstration that expression of expanded polyglutamine peptides alone in Drosophila causes neurodegeneration. Further, a mouse model with the CAG repeat sequence inserted into the *Hprt* gene developed a late-onset neurological disease that progressed eventually to death. Transgenic overexpression of polyglutamine expansions, introduced either into the full-length huntingtin protein or just in exon 1, also results in neurodegeneration in mice and *Drosophila*.

As in other diseases (such as dominant spinocerebellar ataxias), the HD-associated expanded CAG repeat is transcribed into mRNA and translated into a polyglutamine stretch the Huntingtin protein. Since such expanded polyglutamine sequences result in selective neurodegeneration in nine other conditions, all the nine diseases show neuronal inclusions containing aggregates of polyglutamines, and all the nine diseases show correlation of the age of onset and the length of the polyglutamine repeat, it seems highly likely that the polyglutamine expansion confers a toxic effect.

Another line of evidence in support of a gain-of-function mechanism in HD is the tendency for polyglutamine strands to aggregate after 37 consecutive glutamine residues. This process has a time lag before initiation and proceeds faster with longer glutamine repeat sequences, findings that could help to account for the delayed onset of the disease in HD, the strong correlation of onset with repeat length, and the size of repeat (36–40 repeats) at which humans begin to show the disease phenotype.

Wild-type huntingtin is found mostly in the cytoplasm, with a small portion intranuclear. The protein is known to be associated with the plasma membrane, endocytic and autophagic vesicles, the ER, the Golgi apparatus, mitochondria, and microtubules. The huntingtin protein contains 28–36 HEAT repeat sequences distributed along the entire length of the huntingtin protein. HEAT repeats are degenerate 50 amino acid sequences comprising two antiparallel α-helices forming a hairpin. These motifs are usually involved in protein–protein interactions and are found in proteins that play roles in intracellular transport, microtubule dynamics, and chromosome segregation.

Huntingtin contains an NES (nuclear export signal) near the C-terminal and it is also thought that the N-terminal 17 amino acid sequence may serve as an NES due to its binding with the nuclear exporter protein, Tpr (translocated promoter region). The polyglutamine expansion mutation appears to interfere with the huntingtin–Tpr interaction, resulting in an accumulation of mutant huntingtin in the nucleus. The N-terminal 17 amino acids also, in conjunction with the first three HEAT repeats and the region surrounding them, appear to play a role in targeting huntingtin to multiple membrane-bound organelles in the cell. The 17 amino acid N terminal sequence also contains several lysine residues that compete for SUMOylation and ubiquitination, and thus are potentially involved in the regulation of half-life, localization, and nuclear export of wild-type huntingtin and may modify the toxicity of the expanded polyglutamine mutant huntingtin. Huntingtin also undergoes palmitoylation for the regulation of trafficking and function and this process is disturbed in mutant huntingtin. Both wild-type and mutant huntingtin undergo cleavage by various intracellular proteases, including caspases, calpain, and an aspartic protease. It is not known what role proteolytic cleavage plays in normal function and metabolism of huntingtin but it is known that cleavage of mutant huntingtin plays an important role in disease pathogenesis as the intact mutant huntingtin shows significantly less cellular toxicity than the cleaved N-terminal fragments.

There has been an enormous research effort put forth to understand the normal functions of huntingtin over the past 15 years. However, these functions have been difficult to pinpoint due to lack of similarity to other proteins, localization everywhere in the cell, and interactions with so many other cellular proteins (over 200) that a specific area of impact is impossible to define. Evidence is beginning to accumulate that huntingtin is a scaffold protein that may act as a master regulator of converging pathways for intracellular trafficking and signaling. Presumably through such a mechanism, there is support for roles of huntingtin in iron homeostasis, regulation of apoptosis (through caspase interactions), nucleocytoplasmic

shuttling of transcriptional regulators and mRNA, binding and sequestration of transcription factors (particularly restrictive element transcription factor (REST), which regulates transcription of brain-derived neurotrophic factor (BDNF), vesicle trafficking, long- and short-range transport along microtubules (including transport of vesicles containing BDNF), and negative regulation of glutamate receptor *N*-methyl-*D*-aspartic acid (NMDA) and mGluR1) activity at the synapse (through interactions with PSD-95 and optineurin). Support for these diverse roles of huntingtin is predominantly based on defects that occur in huntingtin knockdown models.

It has become fairly clear that the mechanism of disease induction by mutant huntingtin involves proteolytic cleavage, resulting in an N-terminal fragment containing the polyglutamine expansion. In animal models, N-terminal huntingtin fragments are sufficient to produce clinical disease and intranuclear inclusions, and recent data suggest that inhibition of caspase 6 cleavage of mutant huntingtin rescues both behavioral symptoms and neuropathological abnormalities in mice expressing a full-length mutant huntingtin transgene. Thus, proteolytic cleavage likely converts a relatively nontoxic full-length mutant huntingtin into toxic N-terminal fragments.

Intranuclear and intracytoplasmic inclusions of mutant huntingtin are pathological hallmarks of the CNS disease in HD, and these kinds of aggregates are also seen in all known polyglutamine diseases. It is unclear whether the inclusions are toxic, protective, or just represent an epiphenomenon. The density of inclusions in human brain correlates with CAG repeat length but not with areas of the brain most affected. In cell culture, there is a correlation between aggregate formation and cell death. Overexpression of heat shock proteins that reduce aggregation also reduces cell death in cellular and mouse models of HD. However, reduction in aggregates may be due to reduction of oligomeric precursors, which could be the actual toxic species. Inclusion formation has not seemed related to disease in a number of studies. Overexpression of certain proteins like the transcription factor CA150, or crossing the HD mouse with a tissue transglutaminase deficient mouse, has resulted in partial rescue of clinical features and neuronal toxicity, while increasing inclusions. One study demonstrated that HD cells with large inclusions were less compromised than those with diffuse mutant huningtin.

Mutant huntingtin does appear to interfere with numerous cellular processes, even if this is not primarily mediated by aggregate formation. Mutant huntingtin interacts with cAMP response element binding (CREB)-binding protein and Sp1 transcriptional regulators, altering the levels of downstream products of genes regulated by these transcription factors. An example of this effect includes the alteration of BDNF regulation by mutant huntingtin, which shows abolished binding and regulation of REST/NRSF (neuron-restrictive silencer factor), a transcription factor normally regulated by the wild-type protein. The lack of binding by mutant huntingtin leads to an accumulation of REST/NRSF in the nucleus, with resultant excessive transcriptional repression of regulated genes, including BDNF. Other examples of results of proposed aberrant transcriptional regulation by mutant huntingtin include decreased D2 receptor expression, and decreased premordial germ cell (PGC)-1α leading to decreased mitochondrial biogenesis and energy deficit.

There have been numerous reports linking various forms of mitochondrial dysfunction and deficits in energy production to HD. A decrease in ATP production with increasing CAG repeat number has been demonstrated, both in the normal and disease-causing range and this was linked to enhanced calcium influx through NMDA receptors. Mutant huntingtin appears to impair the motility of mitochondria, with aggregates potentially impairing the physical passage of mitochondria along neural processes, and causing them to accumulate adjacent to aggregates.

It has been proposed that mutant huntingtin impairs the ubiquitin–proteasome system (UPS) in HD and this alters protein turnover and processing, thus contributing to the disease mechanism. There are, however, conflicting data derived from various HD-affected tissues, and cell culture and transgenic models. Although the majority of data seem to support impairment of the UPS at some level, including the recent data showing an increased amount of polyubiquitin chains in HD transgenic mice, HD knock-in mice, and human HD brain, all possible explanations for this finding have not been evaluated, explanations for conflicting findings in prior studies have not been identified, and thus definitive evidence of impairment of the UPS in HD remains elusive.

In any case, it seems clear that mutant huntingtin interactions may compromise a diffuse array of cellular processes, including transcriptional regulation, apoptosis pathways, mitochondrial function, neurotransmitter release, and axonal transport. This has led to many potential pathways to investigate for targeted treatment of HD. Yeast two-hybrid screens, aggregate retardation assays, genome-wide RNAi screens, and cell-based assays have been utilized to identify potential HD interacting proteins that might serve as treatment targets and might act as genetic modifiers of disease expression. Numerous candidates have emerged and are in the process of being evaluated.

Huntington-Like Disease Genetics

Huntington-like (HDL) conditions have a clinical picture indistinguishable from HD, chorea is prominent, and onset ranges from young adult to middle age. Inheritance is autosomal dominant for HDL1, 2, 4, and autosomal

recessive for HDL3. The mechanism for HDL1, 2, and 4 is gain of function and there is polyglutamine toxicity with intranuclear inclusions in HDL2 and HDL4, although the genetic mechanism is unknown for HDL3. HDL1 results from a mutation consisting of extra octapeptide repeats in the *PrP* gene. HDL2 is caused by a CTGCAG repeat expansion in the *junctophilin-3* gene. It is the most common of the HD phenocopies and is particularly prevalent in populations of African origin. Of affected patients, 10% have acanthocytes. Normal *junctophilin-3* alleles have 6–28 repeat units, while HDL2 alleles have 44–57 repeats. The age of onset correlates with the repeat length, but unlike HD, the gender bias for expansion is maternal. The mechanism of disease is thought to be mRNA toxicity with inclusions. HDL3 has been described in one family and neither the genetics nor mechanism of disease is known. HDL4 is also SCA17, with mutations in a TATA box binding protein and most individuals with a mutation in this gene have ataxia but the condition can present as an HD phenocopy. This condition results from an expansion of a CAACAG repeat with normal alleles having 25–42 repeats, intermediate alleles 43–48 repeats, and disease-causing alleles more than 48 repeats.

Other autosomal dominant disorders that can mimic HD are dentato-rubro-pallidal-luysian atrophy (DRPLA) and neuroferritinopathy, which results from FTL gene mutations and resultant mutant ferritin light protein. Affected patients have low blood ferritin, iron deposition on MRI, and mitochondrial respiratory chain dysfunction. Other autosomal recessive disorders that can resemble HD include Wilson's disease, chorea-acanthocytosis (VPS13A gene), pantothenate kinase-associated neurodegeneration (PKAN, Hallarvorden–Spatz disease), although PKAN usually presents with more dystonia and there is iron deposition in the basal ganglia. Mutations in PANK2 and PLA2G6 cause diseases similar to PKAN that may mimic HD. X-linked McLeod syndrome has a phenotype similar to chorea-acanthocytosis, although it has absent Kx antigens on erythrocytes. Diagnostic evaluation of a patient with HD-like symptoms, but negative for an HD-associated *IT15* CAG repeat expansion mutation, would include acanthocytes, copper level, ceruloplasmin, ferritin levels, an MRI for iron deposition, and then if these are normal, DRPLA DNA and if African American, HDL2. If these are negative, then an SCA17 DNA test could be done, followed by other gene sequencing based on clinical data. As not all causes of HD phenocopies are yet known, a specific genetic etiology will not be identified for some patients.

Huntington's Disease-like 2

R L Margolis, D D Rudnicki, and S E Holmes, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Glossary

Acanthocyte – Abnormally spiculated red blood cell.
Endoplasmic reticulum – A cellular organelle with multiple functions, including protein processing and calcium storage.
Open reading frame – A section of DNA that has the potential of being encoded into protein, based on the presence and spacing of start and stop signals.
Transcript – The RNA molecule transcribed from the DNA of a gene.

The Differential Diagnosis of Huntington's Disease

Individuals with a progressive, adult onset, autosomal dominant disorder characterized by chorea with concomitant abnormalities of voluntary movement, cognition, and psychiatric status most likely have Huntington's disease (HD). Indeed, in carefully examined individuals with an HD-like syndrome or pathology in Europe and North America, as low as 1% do not have the *HD* mutation. Diagnosis is less certain in cases in which either the family history is unknown or the presentation is atypical. Once HD is considered in the differential diagnosis, HD genetic testing can quickly establish the disease as HD, or exclude HD from the list of differential diagnoses.

If HD is excluded, the differential diagnosis of an HD-like presentation becomes more challenging and largely depends on family history. With no known family history, almost any process that can affect the basal ganglia must be considered: infections (e.g., HIV, neurosyphilis), autoimmune (e.g., systemic lupus erythematosis), metabolic syndromes, tumors, strokes, trauma, and drugs. Probably, the single most common disorder considered along with HD is tardive dyskinesia, the movement disorder associated with long-term antipsychotic medicines. These individuals typically have chronic psychiatric diseases and may have movement abnormalities intrinsic to their psychiatric disorder, complicating diagnosis.

For individuals with the HD phenotype, but not the HD mutation, a family history of a nondominant disorder raises the possibility of Wilson's disease (a recessive disorder of copper metabolism): important to consider because of the availability of specific treatments. Other possible recessive disorders include pantothenate kinase-associated neurodegeneration (characterized by childhood onset and iron accumulation), chorea-acanthocytosis (characterized by abnormal morphology of red blood cells), some forms of ceroid neuronal lipofuscinosis, and unusual presentations of Friedreich's ataxia. X-linked familial inheritance pattern may be indicative of McLeod neuroacanthocytosis, while maternal transmission suggests a mitochondrial disease.

HDL2 Clinical Presentation

Huntington's disease-like 2 (HDL2) is an autosomal dominant disorder first detected in a family followed at Johns Hopkins in which affected individuals had an HD presentation but did not have the HD mutation. Affected members of the HDL2 family first identified at Johns Hopkins, as well as affected members of at least one other well-documented family, develop prominent weight loss, poor coordination, rigidity, dysarthria, hyperreflexia, bradykinesia, dystonia, and tremor, with minimal chorea or eye movement abnormalities and no cerebellar signs, by the age of 40. Depression, irritability, and apathy are common. The disease progresses to profound dementia and rigidity over 10–15 years. A second and apparently more common presentation of HDL2 resembles classic HD, with a somewhat older age of onset, more prominent chorea and dysmetric saccades, and less dystonia and other parkinsonian features. Familial factors, potentially including longer repeat expansion, appear to influence the type of presentation. Overall, HDL2 and HD cannot be clinically distinguished.

HDL2 Neuropathology

The neuropathology of HDL2, based on the published findings in eight brains, closely resembles HD. On gross examination, this pattern of degeneration was evident, with diffuse cortical atrophy, no evidence of white matter demyelination, severe atrophy of the caudate and the putamen, mild atrophy of the globus pallidum, and little evidence of abnormality in other structures. Microscopically, a dorsal-to-ventral gradient loss of small neurons was apparent in the striatum. Other than one case, there were no neurofibrillary tangles or unusual number of β-amyloid deposits. Lewy bodies have not been detected. On electron microscopy, numerous neurons showed features of autophagy, including autophagic vacuoles, as well as intranuclear fibrillar aggregations resembling those seen in HD. As in HD, HDL2 brains have prominent intranuclear inclusions, stained by antiubiquitin antibodies and antibodies thought to be specific to long polyglutamine repeats. The inclusions also stain for torsinA and TATA-binding protein (TBP), but not for huntingtin. Unlike in HD, inclusions have not been detected in neuropil. Recently, small RNA inclusions have also been detected in HDL2 brain (see the following section).

HDL2 Mutation, Genetics, and Laboratory Findings

The causative mutation of HDL2 was determined to be a CTG/CAG repeat expansion on chromosome 16q24.3, in the gene *junctophilin-3*. The presence of the mutation is established using a simple polymerase chain reaction (PCR) assay similar to that used for other repeat expansion diseases. This has facilitated the detection of >40 HDL2 pedigrees around the world. The highest frequency is in South Africa, where individuals of African descent with an HD presentation are almost as likely to have HDL2 as HD. Most other individuals with HDL2 are of African ancestry. Other laboratory findings, including MRI scans showing striatal and cortical atrophy, are

nonspecific. Interestingly, acanthocytes have been detected in some individuals; the implications of this finding are unclear.

The range of the *JPH3* repeat length in the normal population is 6–28 triplets, while in HDL2 the range is 40–58 triplets, with potential decreased penetrance of alleles of 40–45 triplets. This is remarkably similar to the huntingtin repeat, which has a normal range of 4–35 triplets, a range of incomplete penetrance of 36–39 triplets, and is fully penetrant with > 39 triplets. Like HD, longer repeats are correlated with a younger age of disease onset. Repeat length is modestly unstable during vertical transmission, with insufficient data yet available to establish a propensity for expansion.

HDL2 Pathogenesis

The pathogenic mechanism of HDL2 is intriguing and may shed light on HD pathogenesis. The original hypothesis, based on the clinical, genetic, and neuropathological similarity to HD, was that neurotoxicity was a result of polyglutamine toxicity, as is the case in HD and other CAG repeat expansion diseases. An open reading frame exists at the HDL2 locus in which the repeat is in-frame to encode polyglutamine, but thus far there has been no evidence that a protein containing an expanded glutamine repeat is generated from this site in HDL2. The only gene at the HD locus, *JPH3*, is on the reverse strand. The repeat, in the CTG orientation, falls within a variably spliced exon. Preliminary evidence suggests that in HDL2 *JPH3* transcripts containing the expanded repeat forms small aggregates (RNA foci, noted above) and that neurotoxicity may in part arise from toxic properties of the RNA transcript, similar to those observed in myotonic dystrophy type 1 and 2. In addition, there is a loss of expression of the *JPH3* protein product in HDL2, perhaps because the *JPH3* transcript with an expanded repeat is sequestered and unavailable for translation. Since *JPH3* protein appears to form part of the structural connection between plasma membrane and endoplasmic reticulum, loss of expression may contribute to neurotoxicity via dysregulation of calcium-mediated signaling pathways.

HDL2 Prognosis and Management

Like HD, there is currently no treatment to stop the progression of HDL2 to total debilitation and death. However, symptomatic care of the type provided to HD patients can be of great value to patients and their family. This effort should include education, occupational and physical therapy, support and respite for families, assistance with financial and legal planning, and vigorous treatment of psychiatric disorders. Treatment options that emerge from current clinical trials in HD may prove applicable to HDL2.

Acknowledgments

The authors thank Drs. Nancy Sachs, Ruth Walker, Amanda Krause, Adam Rosenblatt, and Mark Moliver for valuable insight and guidance; and the individuals with HDL2 and their families for their patience and cooperation. This work was supported by the Hereditary Disease Foundation, NIH NS016375, and NIH NS38054.

Huntington's Disease

L C Seeberger, Idaho Elks Rehabilitation Hospital, Boise, ID, USA

Glossary

Apraxia – Inability to perform purposeful movements or to imitate gestures when motor strength and sensation are intact.
Dystonia – Abnormal contractions of muscle leading to sustained, twisting postures.
Genotype – The genetic makeup of an individual.
Neurodegenerative disease – A neurological disorder characterized by the loss of neurons and other brain cells causing decline in function and ability.
PHAROS (Prospective Huntington At Risk Observational Study) – A large, prospective trial to study the natural history of adults at risk for Huntington's disease who do not know their gene status.
Phenoconversion – The change from an asymptomatic state to manifesting the underlying genetic abnormality phenotype. In HD, the emergence of unequivocal motor signs in those at risk for the disease.
Phenotype – The physical or biochemical expressions of the genetic makeup of the individual as influenced by the environment.
PREDICT (Neurobiological Predictors of Huntington's Disease) – A large, prospective trial.
Presymptomatic HD (preHD) – Gene carriers of the HD gene mutation who do not show overt clinical signs or symptoms of the disease.
Striatum – Part of the basal ganglia nuclei consisting of the caudate and the putamen, the region of selective nerve cell loss in HD.
Total functional capacity (TFC) – A rating scale of function in HD used to assess the capabilities in several areas and determine the stage of disease.
Trinucleotide – A series of three of the building blocks (nucleotides) of DNA required to code a specific amino acid.
UHDRS (Unified Huntington's Disease Rating Scale) – A rating scale for the uniform assessment of clinical features of HD with components including: motor, behavioral, cognitive, and functional assessments, independence scale and total functional capacity.

Definition and History

Huntington's disease (HD) is a dominantly inherited, neurologically degenerative disease with typical onset in the mid- to late-1930s. It is caused by an unstable trinucleotide expansion in the huntingtin (Htt) protein gene coding region on chromosome 4 (4p16.3). The repeated trinucleotide sequence, cytosine–adenine–guanine (CAG), codes for glutamine and the mutation produces a polyglutamine expansion within the Htt protein. Disease manifestations include a characteristic choreiform movement disorder, progressive disturbance of gait and balance, worsening cognition and, in many, marked psychiatric symptoms. The disease process is relentless resulting in death 20–25 years after onset.

History

The term chorea (Greek: to dance) used to describe writhing, dance-like movements dates back to the 1500s. Although mostly seen in epidemics probably related to infectious diseases, clinicians noted that some forms of chorea occurred within families. HD was first recognized in Norway by Lund, in 1860, as a familial chorea associated with dementia. The disease was probably brought to the United States by people of northern European origin during migration in the early 1600s. It was best described by George Huntington in 1872, his first year after medical school, as a medical curiosity likely of little importance to his colleagues. The vivid, succinct description included a longitudinal perspective gathered by George Huntington based on his family of physicians' lengthy observation of the affected families on Long Island, New York. He described a tendency to insanity, a high risk of suicide, a choreic movement disorder of adult onset, and its hereditary nature. These are salient features of the disease to this day. His contribution led to the eponymous designation but the newer term 'Huntington's disease' is preferred over 'Huntington's chorea,' as chorea is not the only manifestation.

In the early 1970s, attention focused on a region near Lake Maracaibo in Venezuela where there was a very high prevalence of HD. Scientists studying this population discovered a genetic marker linked to HD on the short arm of chromosome 4. Predictive genetic linkage testing allowed better definition of risk for disease in HD families and paved the way for the definitive gene discovery on chromosome 4 in 1993.

Pathogenesis/Pathophysiology

Gross Pathology/Macrostructure

The pathology of HD was first correlated with chorea by Jelgersma and Alzheimer at the turn of the twentieth century. There is generalized atrophy of the entire brain at autopsy with corresponding decrease in brain weight. Gross gyral atrophy is most prominent over the frontal lobes and marked focal atrophy of the striatum occurs along with enlargement of the lateral ventricles. A neuropathological staging system of disease, grades 0 (none) through 4 (severe striatal pathology), is based on the pattern of atrophy and loss of neurons by gross and microscopic examination. Those with later stage disease show more shrinkage of the brain. Cortical ribbon thinning may be seen by on visual inspection and with magnetic resonance imaging (MRI).

Morphological assessments using MRI in patients with manifested HD and presymptomatic HD (preHD) demonstrate relative sparing of cortical gray matter with great reductions in cerebral white matter and striatal volumes. This differential effect on the gray and white matter occurs despite the microscopic evidence of neuronal loss in the cerebral gray matter. Some investigators have postulated a neurodevelopmental role of mutant Htt (mHtt), possibly causing increases of the gray matter, during embryogenesis. Quantitative MRI of the whole brain in preHD patients support this theory revealing larger cortical gray matter volumes compared with controls. These differences lessen as the preHD patients come closer to disease onset although still remain above the volume of controls.

Microscopic Pathology

The pathological hallmark of HD is the degeneration of the caudate and putamen, starting in the caudal regions. Postmortem microscopic examination of the HD brain reveals up to 95% loss of striatal neurons. The selective loss of medium-sized, spiny, cholinergic neurons of the caudate and putamen is associated with an increase in reactive astrocytes. There are also activated microglia found postmortem. Early pathological grades, grade 1 or 2 HD, have little involvement outside the striatum. By grade 3–4, there is a spread of pathological changes to include the paleostriatum, neocortex, thalamus, substantia nigra pars reticulata, subthalamic nucleus, and the cerebellum. No reactive gliosis is found in these nonstriatal parts of the brain. In the globus pallidus (GP), the projecting spiny enkephalin neurons of the GP externa are more vulnerable to cell death than the substance P containing medium, spiny neurons projecting to the GP interna. There is also loss of the cerebral cortex neurons in the third and fourth layers. Although the white matter is atrophic, it is not microscopically abnormal indicating probable loss of fiber passage and neuropil. PreHD and HD patients have pathologic evidence for increased density of oligodendrocytes that seems independent from the degenerative process.

Although the abnormal gene and gene product are present in all cell types, degeneration is confined to the central nervous system. Higher neuropathological grade at autopsy is positively correlated to an increase in neuronal loss and worse clinical motor impairment. There is greater nerve cell death seen with longer CAG repeat lengths and with younger age at onset. CAG repeat length dictates the rate of development of neuropathology, probably linearly from birth.

Intracellular Pathology

The development of transgenic models has provided a powerful tool to understand the pathogenesis of HD. Transgenic mice R6/1 and R6/2 lines have a stable CAG expansion in exon 1 of the HD gene. These mice develop a motor and cognitive disorder with underlying striatal and cortical degeneration. The discovery of intranuclear inclusions in the HD mouse model led to similar findings in autopsied HD patients. The inclusions or aggregates contain not only mutant huntingtin proteins but also a number of other proteins, including transcription regulating proteins, chaperones, proteasome subunits, and ubiquitin. Inclusions are identified by labeled antibodies against mHtt or ubiquitin and are found in vulnerable nerve cell populations long before the onset of disease. It is currently unknown why striatal neurons die as most cells and neurons with the same mutation are unaffected.

Huntingtin Protein

Wild type huntingtin (Htt) is expressed in all mammalian cells with highest amounts produced in brain and testes. It is highly conserved through evolution. Htt has 67 exons with the human gene mutation present in the first exon. The protein has a molecular mass of 349 kDa and the normal (wild type) protein has 3140 amino acids. It bears no homologies to other proteins but has a region that is similar to a protein motif involved in cytoplasmic transport. In the brain, Htt is found in neurons rather than glial cells and is seen throughout neurogenesis. Interestingly, knockout mice embryos that are genetically engineered without *Htt* genes die at gestational age 8–10 weeks. In those with the HD mutation, mutant gene product is also expressed throughout brain development. Although the function of wild type *Htt* is not completely known, it is believed to have a role in brain development. *Htt* is known to increase the production of brain-derived neurotrophic

Table 1 Number of CAG repeats and expression of Huntington disease

Less than 27 repeats	*27–34 CAG repeats*	*35–39 CAG repeats 'intermediate'*	*≥40 CAG repeats*
No HD	Very rarely express HD (based on recent clinical and pathological data)	May or may not express HD 'reduced penetrance'	Always express HD 'full penetrance' in time
No transmission to children	Increased risk for further CAG repeat expansion into intermediate or disease causing length in children	May transmit an expanded 'disease causing' mutation to children	50% chance of transmitting expanded mutation to children

factor through upregulation. As well, findings suggest *Htt* functions in cell vesicle trafficking, fast axonal transport, and mature cell gene expression.

HD patients express 'normal' wild type huntingtin protein as well as mutated Htt. Intracellular cleavage of the mutated Htt protein results in N-terminal fragments containing the enlarged polyglutamine tract. Abnormal processing of the protein forms dimers, oligomers, and eventually intracellular protein aggregation. It is not known whether the aggregation is protective or toxic to the nerve cell. The expanded polyglutamine tract leads to conformational changes that alter the cellular interactions of the protein. Neuronal dysfunction may be due to these abnormal protein–protein interactions that occur, possibly before aggregation, with cytoplasmic, proteasomal, and nuclear transcription proteins.

Most features of the disease result from a 'gain in function' within the cell nucleus due to the mutated gene product as it takes on new actions with known and unknown proteins. It is unlikely that disease is due to loss of function of *Htt* because disruption of the gene does not cause HD. However, new research also shows an effect from the loss of wild type *Htt* function, particularly, its effect on brain-derived neurotrophic factor (BDNF) production and cortical-striatal protein trafficking.

Ubiquitinated, intranuclear, neuronal inclusions are common to the inherited polyglutamine diseases but their role in causing disease is debated.

Epidemiology and Risk Factors

HD is present worldwide with the highest prevalence in western European nations. Global average estimates are 5–10 cases per 100 000 persons. Its prevalence is lowest among African and Asian populations. The average age at disease onset is 35–44 years old, although ranges of onset as early as 2 years old and as late as 80 years old have been described. HD can be found in members of any socioeconomic class and demonstrates an autosomal dominant transmission pattern within families. Autosomal dominance means each child of a gene carrier has a 50% chance of inheriting the abnormal gene.

The most reliable risk factor for disease is the presence of the gene mutation containing greater than 40 CAG repeats (**Table 1**). HD is then fully penetrant depending on life span. The age at onset is predicated on the CAG repeat length. Higher repeat length is associated with an earlier onset and more rapid progression of disease. Those with 35–39 CAG repeats may or may not express the disease but can pass an expanded mutation (into the definite disease-causing range) to their children. Those with 28–34 CAG repeats more rarely express the disease and are less likely to pass a disease-causing expansion than those with the longer repeats. People who have less than 27 repeats never have the disease.

There are several candidate genes that may modify age at onset including, transcription factor 53, human caspase activated DNAse, glutamate receptor 6 subunit (GluR6) of kainate receptor, MSX1 polymorphism, and NMDA receptor subunit 2B. Earlier age at onset is seen in the best described of these genes, GluR6, and also in those with a YY polymorphism in the UCHL1 gene regulating proteolysis.

In R6/1 and R6/2 mouse models of HD, environmental enrichment has been found to delay the onset of motor symptoms in affected mice but it is unknown how this impacts human onset of disease.

Clinical Features and Diagnostic Criteria in HD

The clinical features of HD are motor, psychiatric, and cognitive in origin. Typically, there is the gradual onset of a motor disorder starting with early eye movement abnormalities, fine dexterity loss, and then the evolution of twitchy choreiform movements. Some patients will have cognitive or psychiatric symptoms prior to the motor disorder.

Motor

Eye movement abnormalities start with slowing of visual saccades. There is progressive difficulty in initiating saccades and further slowing of voluntary saccades. These findings are easily demonstrated by asking the patient to follow an object that is moved in horizontal and vertical fields for testing extraocular movements and also by

asking the patient to quickly shift gaze between two objects when one object is moved. Later-stage patients have obviously abnormal, slow, jerky eye movements, and large head thrusting movements to initiate the saccades. Patients are poorly able to suppress eye movements toward a stimulus in the environment despite being so instructed.

An early finding in HD is impairment of fine motor movements of the hands as examination of finger taps and alternating movements reveals. There are initial small-amplitude distal choreic movements of the hands and feet that can be seen with the patient upon a table with legs dangling and arms in outstretched posture. Chorea increases to involve facial, neck, and trunk muscles, and more proximal limb movements emerge. Patients may demonstrate eyebrow raises, lip pursing, as well as involuntary inhalations. The chorea can cause trunkal extensions making the person appear to sit up taller or rock backwards. Larger amplitude chorea interferes with the performance of voluntary, accurate movements. There are greater deviations in performance because of effects upon the accuracy and speed of the movements. Chorea is variable through the disease and may significantly lessen in later stages replaced by a more rigid and bradykinetic motor disorder.

Independent of chorea is another classic motor feature of the disease, motor impersistence. The patient is unable to maintain a constant level of voluntary motor contraction that leads to a breakdown in sustained movements. Motor impersistence can be demonstrated by asking the HD patient to forcefully close their eyes. There will be breaks in the tightness of eye closure as witnessed by smoothing of the muscle folds. This can also be shown by asking the patient to lightly hold your hands and feeling the intermittently squeezing pressure. Motor impersistence worsens progressively with disease severity.

There is loss of balance, increased trunkal sway, and abnormal gait mechanics in HD. Gait testing using a long corridor walk will show increased stance time, tendency to lean back on the heels, decreased velocity, and variability of stridelength. Gait disturbance is independent of chorea and is not improved with the use of neuroleptics. Verbal cues and increased attention while walking may help to improve velocity but not variability of the gait pattern. Postural balance is maintained primarily by proprioception rather than visually. Falling occurs more frequently during progression. Patients with more advanced disease have worse balance and declining gait mechanics, ultimately resulting in a nonambulatory state.

Weight loss is seen despite adequate calories and increased appetite. This may be due to a higher energy expenditure described in HD, not just attributable to involuntary movements. Metabolic studies indicate a more catabolic state in people with HD. Compared with controls, there is more muscle wastage, particularly in larger proximal muscles, and hence patients with HD have less muscle strength.

Psychiatric

The spectrum of psychiatric disturbances in HD includes mood disorders, anxiety, apathy, obsessive–compulsive disorders, irritability, aggression, impulsiveness, and, sometimes, psychosis. There is no evidence for an early psychiatric personality that readily identifies which person in a family is more likely to develop the disease. In fact, personality disorders are sometimes found in unaffected members of the family, likely from environmental factors. Depression is the most common psychiatric manifestation of HD in any stage of illness. It presents in some cases prior to motor signs. The prevalence of depression is ~40–50% and is not correlated with cognitive impairment, CAG length, or motor symptoms. Depression can lead to a rapid decline in the patient's function. Suicide rates are four to five times higher than the general population.

Obsessive–compulsive disorder is also more prevalent in the HD population than in the general population. The tendency to obsessive–compulsive disorder can present in preHD patients as excessive worrying and checking behaviors. Other psychiatric manifestations similarly present at any stage do not typically parallel the progression of disease. For some, substance abuse and other pathological behaviors have origins in poor impulse control. The patient with HD can be very challenging to manage for psychiatric reasons.

Cognitive

People with the HD gene mutation are found to have normal intelligence prior to disease onset. There are no differences in levels of academic achievement in those with adult onset disease. Beginning early in disease, there are impairments of executive functioning with a decrease in working memory, planning, and attentional control. Patients have trouble in multitasking and shifting from one task to another. They tend to continue to follow old rules for task even when given entirely new tasks, showing limited flexibility in thinking.

Several expressions of deranged perception can be found. HD patients have impaired recognition of whole body angry postures and facial expressions of surprise, disgust, anger, or fear. Lack of understanding these nonverbal cues causes interpersonal conflicts through miscommunication. Patients may have decreased kinesthetic awareness and ideomotor limb apraxia when trying to mimic postures, gestures, and pantomime tool use. As well, patients have a poor awareness of self that can lead to minimizing or denying disease features that may be blatant to others.

Sleep disturbance is common in HD patients with reports of sleep fragmentation, decrease in slow wave sleep, and alterations in the circadian rhythm.

Diagnosis

The diagnosis is made based on a clinical examination showing typical choreiform movements in the setting of a known family history of HD. At the time of diagnosis, there are usually eye movement abnormalities, motor impersistence, and possible cognitive or behavioral changes. Recent intensive study on gene-positive presymptomatic persons has shown that many subtle abnormalities may precede the onset of the movement disorder. These include neuropsychological abnormalities on testing and very early changes in eye movements noted years prior to onset of chorea.

For systematic study of affected and at-risk persons, a rating scale was developed and validated by the Huntington Study Group. The Unified Huntington's Disease Rating Scale is a standardized rating scale that assesses motor, cognitive, behavioral, and functional capacity changes in HD. The motor subscale measures eye movements, motor control and fluency, muscle tone, slowness in movement, dystonia, chorea, balance, and gait. The cognitive portion includes verbal fluency testing, Stroop Interference testing, and the Symbol Digit Modalities test. The behavioral section queries 11 different psychiatric symptoms.

Also used to assess the patient is the total functional capacity scale (TFC). This scale consists of five items including occupational level, ability to handle financial affairs, ability to handle domestic (housekeeping/management) tasks, ability to perform activities of daily living, and the type of residence appropriate for the patient (home or nursing care). Scores range from 0 to 13; lower scores indicate lessened abilities and more advanced disease. These scores consistently decline over time. Clinical stages of disease have been defined based on the TFC score (see **Table 2**).

No specific biochemical abnormalities have been found in the blood or urine of HD patients. In longstanding HD, some studies report greater likelihood of glucose intolerance and abnormal response to challenge testing of insulin secretion. There may be reduced levels of testosterone found in males with HD.

In children at risk for HD, most common presenting features are decline in school performance, gait disorder, rigidity, bradykinesia, oral motor dysfunction, and/or seizures. Chorea is not common in children. The juvenile form of HD was described by Westphal, in 1905, as a progressive Parkinsonian syndrome. It occurs in ~8–10% of all cases of HD and is defined by manifestation of disease symptoms prior to age 20. Furthermore, 1–2% of juveniles have onset of symptoms prior to age 10. These individuals usually have very elongated CAG repeats expansions, from 70–250 repeats. Juvenile HD is much more likely to have been inherited through paternal transmission. There is an inherent instability of the expanded CAG mutation during germline mitotic divisions tending toward further expansion. The resulting longer CAG repeats in the child versus parent causes earlier onset of disease in the offspring known as 'genetic anticipation.' This most often happens in the paternal line during spermatogenesis as the 'mean increased change in length' is proportional to the 'increased number of CAG repeats.' Not all paternal sperm will have these marked expansions. Juvenile patients have more extensive symptoms and more rapid progression than adults. Disease manifestations include bradykinesia, rigidity, dystonia, seizures, ataxia, and intellectual deterioration.

Some younger adults, in their 20s, can present with clinical motor features more closely akin to juvenile onset showing profound bradykinesia, bradyphrenia, and dystonia rather than chorea. These patients do not necessarily inherit through the paternal line and other siblings commonly present in the same manner.

Presymptomatic Markers

Currently, we rely on nonspecific motor features, family, or patient reports of behavioral or other changes to herald

Table 2 Total functional capacity and stages of HD

Total functional capacity	*Engagement in occupation*	*Capacity to handle financial affairs*	*Capacity to manage domestic responsibilities*	*Capacity to perform activities of daily living*	*Care can be provided at*
Stage I	Usual level	Full	Full	Full	Home
Stage II	Lower level	Requires slight assistance	Full	Full	Home
Stage III	Marginal	Requires major assistance	Impaired	Mildly impaired	Home
Stage IV	Unable	Unable	Unable	Moderately impaired	Home or extended care facility
Stage V	Unable	Unable	Unable	Severely impaired	Total care facility only

the onset of disease. A complicated formula, based on thousands of HD cases, has been created to predict the number of years to disease onset. This allows the study of asymptomatic people, who are closer or further from disease onset, for any differences using a battery of tools, including neurological examination, cognitive testing, psychiatric assessments, and brain imaging.

Most studies show evidence of oculomotor and cognitive deficits prior to definite onset of clinical disease. Investigations in psychiatric functioning in preHD patients have been more equivocal. Some show higher rates of hostility, irritability, psychological distress, and others have found no differences in the prevalence of psychiatric disorders in those with and without the gene mutation for HD. Psychiatric symptoms seem to be more common in those predicted to be near to disease onset but may be reported by patient and caregiver even far from onset. PreHD patients have a decreased ability to identify a 'disgusted' facial and verbal expressions. Similarly, those with HD express less disgust to unpleasant smell or food combinations.

The most promising biological markers for onset of disease are imaging tools. Positron emission tomography (PET) and functional MRI (fMRI) have shown changes in those with preHD before symptoms begin. PET imaging reveals in vivo activation of microglia in HD and preHD. On the basis of fMRI and MR spectroscopy studies, it is found that the changes in brain may precede the disease onset by decades. MR spectroscopy shows marked glutamate activity in juveniles, preHD-, and HD-manifested adults. MRI morphological volumetric assessments of the cortex, putamen, and the caudate also define changes years before estimated clinical onset. There is mounting support that the ongoing neuronal modulation, nerve cell dysfunction, or death begin more than a decade before diagnosis.

There is upregulation of immune system markers in HD. Interestingly, monocytes, peripheral white blood cells that aid in the immunological response of the human body, share a common precursor with brain microglia. The monocytes, like microglia, express mHtt protein and should show similar cellular reactions perhaps offering a biomarker of central nervous system pathology through studying easily obtained peripheral cells.

Differential Diagnosis

The differential diagnosis of HD includes several other inherited diseases, such as dentatorubral pallidoluysian atrophy, HD like-2 illness, SCAs 1, 3, and 17, neuroferritinopathy, and neuroacanthocytosis. Infectious, toxic-metabolic causes of chorea have a different time course and other associated features. These cases will lack family history and should not have eye movement abnormalities, motor impersistence, or progressive cognitive decline. If the presentation is primarily dystonic in nature, consider Wilson's disease.

Diagnostic Workup

The diagnosis is made on neurological examination, based on the presence of a typical movement disorder and other features in a person at risk for the disease. Confirmatory gene testing can be undertaken if there is clinical suspicion of disease with or without a family history. It is more cost-effective to check the gene status in a person with a family history of HD or typical clinical features of HD than to embark on a full workup of causes of chorea. A positive test is confirmatory for the diagnosis in the symptomatic person.

There are no other laboratory evaluations required for diagnostic workup. Brain imaging is not necessary as it is usually normal in early disease. In those with more advanced disease, there is enlargement of the lateral ventricles and bilateral atrophy of the caudate nucleus on imaging. As imaging modalities improve, they may provide a diagnostically important biological marker for onset of disease. Currently, the genetic mutation for HD determines that the person will have the disease but not precisely when its onset.

An electroencephalogram may be useful in childhood onset HD if seizure activity is suspected. Routine EMG/NCV is unhelpful.

Protocols have been developed for testing those at risk for HD, who are not yet symptomatic with illness. Presymptomatic testing includes psychological evaluation, counseling, and an assessment of readiness for testing. It identifies support people and networks to help with the testing process and in dealing with the results. Patients undergo a neurological examination to look for signs of the disease prior to testing. If there are obvious features and the patient is ready, most physicians will discuss the findings with the patient who may then decide to have confirmatory testing. The overwhelming majority of those at risk do not undertake presymptomatic testing. Many reasons underlie this decision including fear of knowing, fear of financial repercussions, and the possibility of genetic discrimination. All patients need support and confidentiality. Those who do test usually do so around marriage, childbearing, and during other life decisions.

Testing is not recommended for those with active, unstable psychiatric disease or suicidal ideation. Testing is not done in children at risk for HD unless there are definite and compelling symptoms such as bradykinesia, dystonia, cognitive decline, or seizures. It is not recommended to test an individual if it means the nonintended disclosure of another's gene status, such as a child testing before their parent or in the case of identical twins. Many

times, an older family member at risk but not symptomatic will choose to test to define the risk for their offspring.

Prenatal testing is available though rarely do patients choose this option.

Clinical Course

The progression of HD is divided into five stages based on the level of functional capabilities as assessed using the TFC (**Table 2**). The scale regards the working and domestic abilities, financial management, activities of daily living, and need for long-term care. Full capability in all realms equals 13 points. Most patients lose, on average, one point per year on their assessment. Other known markers of disease progression include total striatal volume on MRI (calculated), CAG repeat length, and Digit Symbol Modalities. More sensitive scales for following early and preHD patients are being developed.

Herein, because of overlap in this progressive disease, the disease course will be divided into early, middle, and late stage disease.

Early Course

Through observing the phenoconversion of gene-positive individuals to overt expression of HD, it is recognized that many patients have the onset of mild behavioral abnormalities or cognitive disruption before the motor disorder. Personality changes may be seen with a tendency to become easily irritated or aggressive. Outbursts and impulsive actions can occur. Depression is worse in the earlier stages of disease, peaking in stage 2 (see **Table 2**), then decreasing. Suicide is also more common in early disease, especially in those with a family history of suicide. The range of mood disorders may occur in this and any stage of HD. It is only apathy that directly correlates with disease progression, growing worse with the duration of disease.

Cognitive decline usually begins with a loss of organizational skills. Patients have difficulty following through with planning and attention to task. They have more concrete thinking and difficulty in learning new skills. This may lead to problems at work, especially if required to learn new skills on the job or if the job requires mental flexibility and changing tasks. Patients can become difficult to redirect and do not express themselves as well due to a decrease in verbal fluency.

The onset of chorea is insidious with initial finger flicking or piano playing movements. Chorea can increase to a movement disorder of variable amplitude and severity usually in the early to middle stages of disease. Restless movements of the limbs are seen with some attempt by the patient to blend the movements into normal actions. Early eye movement abnormalities are found with a delayed initiation of voluntary saccades and inability to suppress involuntary eye movements to a new stimulus. Motor features include slowed rapid alternating movements, motor impersistence, and decline in visual motor performance that all gradually worsen with progression of disease. A decrease in crispness of speech articulation begins and worsens significantly over time.

Midcourse

In the middle stages of disease, there is a more classical expression of chorea, seen in most HD patients, along with the development of balance disturbance. Movements are present throughout the waking day and the patient may be described as restless in bed at night. Choreiform movements are worsened by excitement, stress, and anxiety and lessened with relaxation. Ballistic movements of the limbs afflict those with severe chorea. The flinging motions can be misinterpreted as intentional hitting by others and can interfere with care. Patients have progressive worsening of clumsiness that they describe as difficulty holding onto objects or they knock things over by involuntary limb motions. Speed and dexterity of fine movements decline as does handwriting ability. More significant slowing of eye movement saccades makes the patient blink or turn their head to initiate and complete the saccade giving a peculiar lagging eye movement. On examination, abnormal opticokinetic response is seen and there is impairment in fixation of gaze.

All affected aspects of cognitive failing are worsened during this stage. Patients with HD tend to have preservation of language skills even in later disease. Worsening dysarthria compromises communication. Poor self-awareness consequently affects self-care and can lead to lack of acknowledgment of the disease manifestations. Situational apathy causes the HD patient to be less interested in their environment, less interactive, and show less motivation. Little suicide occurs in this stage. Psychiatric manifestations are likely but variable in presentation and patients can be very challenging to treat because of their loss of insight and impulsive nature. Many loss issues occur during this stage as patients face possible job loss and termination of driving privileges. Psychomotor abilities are most affected by the changes in cognition.

Advanced Course

The patient loses the ability to safely ambulate in this stage of disease due to severe imbalance and very frequent falling. Muscle mass is markedly decreased and strength lessens given the level of debilitation. Cognition steadily declines and the patients are demented. There is little reasoning ability and the patient is less able to respond to behavioral intervention. Changes in the environment or caretakers are not as well tolerated. Patients may rock,

grunt, and make other noises especially while eating. Appetite usually remains very good until late stages. There is severe dysphagia and dysarthria. Speech content decreases in complexity and prolonged pauses occur in responding. Studies have shown that the ability to understand, semantic knowledge, is largely intact. Psychiatric and behavioral problems are present. More severe eye movement slowness and dysfunction are seen. Ballistic or choreiform movements can be present but patients are more likely to be rigid and dystonic with time. The terminal rigid state resembles Parkinsonism.

Many will be placed in a nursing care facility due to their families' inability to manage advanced disease issues, such as incontinence of bowel and bladder. End of life discussions are held with the family. Death is due to complications and secondary illness from dysphagia, poor mobility, bedbound state, or injury from falling.

Weight loss of unknown cause occurs in HD patients, prior to overt symptoms in some, despite adequate nutrition. This unintended weight loss is seen in HD patients and in the murine animal model of HD. Loss worsens with advanced disease even without the presence of chorea. Although weight loss does not correlate to motor features it does correlate to CAG length, thus, those with longer CAG expansions show increased weight loss. There is speculation that a change in cell-based energy homeostasis or another metabolic process is guided by the length of CAG causing weight loss.

Variations in Age at Manifestation and Course

It is estimated that CAG length alone is responsible for ~70% of the variability in age at onset. The rest of the variability also seems to be genetically based rather than environmental. Generally, those with longer CAG repeat lengths have an earlier onset of disease. A longer CAG repeat is also directly associated with a faster rate of progression in motor, cognitive, and functional domains. Still, there is wide variability in rates of progression in HD. Those with shorter expansions have the most favorable prognosis. Heterogeneity in clinical presentation is not related to age at onset or to CAG length.

CAG Affect on Course

Longer CAG repeat length expansion is associated with greater rate of weight loss, younger age at onset, more severe CNS pathology, and faster progression of disease.

Juvenile HD Course

Juvenile onset HD has more extensive symptoms and more rapid progression of disease. Bradykinesia, rigidity, and ataxia occur much earlier than seen in adults. Almost half will develop epilepsy. The duration of disease is about 10 years to death.

Management

The ultimate goal in management of the disease is the prevention of onset and modulation of course progression. Such an intervention, aimed at the pathogenesis of disease, should be safe for long-term administration and would be best started as early as possible. Large, observational trials (PHAROS, PREDICT) are underway to delineate the subclinical state and signs definite enough to warrant diagnosis and biomarker studies. These trials will aid in design of neuroprotective trials based on the type of early symptoms and time to phenoconversion in gene carriers. There is no cure for HD, currently.

Numerous exciting therapies are being explored for prevention of disease onset and aim to enhance neurotrophic factors, nerve cell replacement, mutant gene silencing, and binding expression or splicing of mHtt to mitigate aggregation formation.

Many compounds used in the therapeutic trials of HD, thus far, have not shown slowing of functional decline, including idebenone, creatine, vitamin E, cysteamine, ethyl-EPA, riluzole, lamotrigine, and remacemide. A large multicenter study of high-dose coenzyme Q 10 is underway as an earlier trial indicated a trend for slower functional decline with 600 mg day^{-1} dose. Other trials aimed at efficacy in modulating disease progression in HD are evaluating creatine, phenylbutyrate, and minocycline. Studies, particularly of preHD, are limited by insensitivity of the assessment tools. There is no single biomarker to date that can be used to determine the onset and reliably track the progression of disease but several trials will use biomarkers along with clinical endpoints attempting to discover a more sensitive measure.

Symptomatic Therapy

Despite many multicenter, randomized, controlled trials in HD, there are no standard treatment recommendations that can be given. Recently, members of the Huntington Study Group were surveyed about treatment preferences for a number of symptoms in HD in an effort to develop a consensus of care statement based on expertise in the treatment of HD. Data suggest most patients with HD receive symptomatic treatment primarily for depression or other psychiatric manifestations. Individual management of the HD patient is based on the symptoms displayed over time and a knowledgeable team approach is invaluable. The team ideally consists of a physician, genetic counselor, psychologist or neuropsychologist, social worker, physical therapist, occupational therapist, speech therapist, and dietician. The patient then has a network of support as they struggle through diagnosis,

connecting with medical and social services, coping with family changes and job loss, as well as loss issues surrounding their own decline in function and loss of autonomy. The use of symptomatic treatments is largely based on clinical experience.

Motor

Chorea

Chorea should only be treated if bothersome to the patient or if it interferes with care or seating. Tetrabenazine, a dopamine depleting agent, is the first agent FDA approved to treat chorea in HD. There are good long-term benefits of the medication with dose adjustments. Titration should be done slowly as it takes several weeks for tetrabenazine to exert its full effect. Treating chorea may improve the accuracy of motor movements. Excessive dopamine depletion or blocking can dampen the personality, motivation, or worsen swallow function. The patient should be carefully monitored for behavioral changes, particularly for depression and suicidal ideation. Atypical and typical neuroleptics can also control choreiform movements and some aspects of the psychiatric disease; for example, severe anxiety, aggression, and psychosis. Clozapine has been well studied in HD but therapeutic dosages cause intolerable side effects. Olanzapine, risperidone, ziprasidone, and quetiapine have been reported to have some positive effects on movements and behaviors. Older typical neuroleptics are less expensive to use and less likely to cause weight gain or metabolic syndrome. Neuroleptic malignant syndrome has been reported with tetrabenazine and typical and atypical neuroleptics. It is recommended to treat with the lowest effective dose and decrease or stop treatment if chorea subsides. Dopamine 'stabilizers,' such as ACR 16, are being studied for their role in mood and movement.

Parkinsonism

Parkinsonism and bradykinesia may respond to levodopa or dopamine agonist therapy. Patients have to be observed for increased agitation, aggression, hallucinations, compulsions, and hypersexuality. Anticholinergic agents aggravate chorea and cause confusion, so they are generally not used.

Dystonia

Dystonia occurs mostly in younger onset disease and in those with longstanding HD. Physical therapy is used to relax muscle tone, to reduce secondary muscle contracture, to maintain muscle length through stretching, and to fit adaptive equipment. For focal dystonia causing discomfort or decreased functional use, botulinum toxin can be injected to reduce abnormal posturing and pain, improving the use in some cases. Generalized dystonia is best treated with medications, such as baclofen, tizanidine, or benzodiazepines.

Myoclonus

Some patients with HD have overwhelming myoclonic jerking. The movements interfere with all purposeful movements greatly hampering self-care and activities of daily life. Valproic acid, levetiracetam, carbamazepine, and benzodiazepines are the preferred agents to control this movement disorder.

Bruxism

Rarely, patients may show jaw clenching or teeth grinding present during the waking hours as well as at night. This is highly destructive to the teeth further compromising effective chewing and safe swallow. At times, there is a decrease in jaw opening excursion that further hampers efforts to feed the advanced patient. Botulinum toxin injections into the masseter muscles bilaterally relax the muscles generally without adverse effects on swallowing function.

Gait Dysfunction

The ataxia and gait abnormalities in HD are not responsive to medications. Patients are treated through physical therapy interventions, such as cueing and balance training. Gait safety is better with a wheeled walker than a cane. There comes a point that the patient must be confined to the wheelchair to prevent injury.

Psychiatric Disease

Identification of abnormal thought processes or behaviors is very important in management. It is advised to have a caregiver come with the patient to the office visit for a well-rounded discussion of how each is doing. At times, they must be interviewed separately to prevent repercussions for the caregiver. Obtain psychiatric and social work input for situations of possible neglect or abuse and do not hesitate to contact government social services to protect the patient and family. The practitioner should be familiar with emergency psychiatric services and suicide prevention hotlines in their community so that they can act quickly in times of crisis.

Depression is treated through counseling when the patient has insight as well as pharmacological medications. Most specialists prescribe selective serotonin reuptake inhibitors for mild to moderate depression. It is of great interest that in recent studies both sertraline and paroxetine have been found to prolong survival and increase brain-derived neurotrophic factor in the transgenic mouse model. Anxiety, panic, obsessive

compulsive disorders, irritability, and mania are treated with selective serotonin reuptake inhibitors or other mood stabilizing medications, including valproate, carbamazepine, lamotrigine, or lithium. If more severe manifestations of these disorders are accompanied by delusional thinking or psychosis, then neuroleptics should be used. Behavioral modification therapy can be successful in some patients with hostility, aggression, or compulsions.

Cognitive Disease

There are no medications that have reliably improved cognition in HD. A recent safety trial of dimebon gave hope for possible cognitive stabilization and a phase-3 trial is being planned. Treating behavioral and psychiatric problems should maximize the patient's capacity for cognitive performance.

Other Features

Start by treating sleep disturbance with lessons on good sleep hygiene practices and over the counter sleep aids. Rule out any psychiatric disturbance interfering with sleep onset or maintenance before using prescription sleep medications. Short-acting sedative hypnotics, such as eszopiclone, or zaleplon, are effective. The longer acting benzodiazepines (clonazepam) or sedating antidepressants (trazodone, nortriptyline) are also used. Clinicians can attempt regulation of the disturbance of circadian rhythm with a sleeping aid at night and a wake-promoting agent, like modafinil, in the morning.

An active lifestyle can improve sleep and may have long-term benefit in HD.

Special Situations

Endstage

Most patients ultimately require institutionalization to manage their care. It is harder to assess the advanced patient due to dementia and considerable difficulties in communication. The advanced stages of HD have particular management challenges either from excessive movement or too little movement. Special floor beds and Broda chairs have been developed to confine and pad flailing limbs. Lipped plates and trays on sticky mats prevent inadvertent scooting away during clumsy attempts at self-feeding. Because of significant weight loss, frequent meals and snacks should be offered. Ultimately, they require pureed foods and full assistance to feed. Patients continue to lose weight but usually do not choose to have a percutaneous gastrostomy tube placed for nutrition.

HD patients often refuse to use a bathtub or shower but will usually submit to a sponge bath. Patients may scream, hit, and be very unpredictable in behavior. Sometimes, a source of agitation can be found, as the patients do best with a routine accompanied by simple repeated explanation and the same caregivers. The secondary complications of an immobile state (pneumonia, urinary tract infections, venous thrombosis) are a common cause of death.

Juvenile HD

Juvenile HD, like adult onset HD, is treated using supportive care and symptom management. For generalized epilepsy, use typical anticonvulsant therapy in monotherapy, if possible. Rigidity, spasticity, and dystonia may be treated with antispasmolytics, such as baclofen, tizanidine, or benzodiazepines, or with antiparkinson medications, that is, levodopa or dopamine agonists. Depression, anxiety, oppositional behavior, and irritability are treated with standard medical and behavioral therapies. School failure can worsen feelings of isolation, and individualized educational plans for the children are helpful in dealing with schoolwork and adopting a 'no fail' strategy. Some parents will decide to home-school their children. A simple communication device can be very helpful as dysarthria grows severe to allow the child to express the needs. Timely discussion should be held about end of life issues and palliative care as children progress more rapidly with dysphagia and decline in mobility.

Prognosis

Prognosis is affected by many factors including age at onset, rate of disease progression, other genetic factors, weight, environment, and attentive care. Despite the advancements in research, survival is unchanged. Most patients require care in a long-term nursing facility at end stage of disease. The average duration of disease until death is estimated as 15–20 years after onset of chorea. The actual duration of disease is likely much longer as based upon biomarker studies and the clinical observations during phenoconversion into disease state.

Hydrocarbons

E Cubo, Complejo Hospitalario Burgos, Burgos, Spain

Glossary

Cytochromes – Membrane-bound hemoproteins that contain heme groups and carry out electron transport. They are found either as monomeric proteins (e.g., cytochrome *c*) or as subunits of bigger enzymatic complexes that catalyze redox reactions. They are found in the mitochondrial inner membrane and endoplasmic reticulum of eukaryotes, in the chloroplasts of plants, in photosynthetic microorganisms, and in bacteria.
Dopamine – A neurotransmitter occurring in a wide variety of animals, including both vertebrates and invertebrates. In the brain, this catecholamine functions as a neurotransmitter, activating the five types of dopamine receptors – D1, D2, D3, D4, and D5, and their variants. Dopamine is produced in several areas of the brain, including the substantia nigra and the ventral tegmental area.
Dyskinesia – Abnormal, involuntary movements. In the context of Parkinson's disease, dyskinesias are often the result of chronic levodopa (L-dopa) therapy.
Leukoencephalopathy – A disease, often due to degenerative, inflammatory, or toxic causes, that affects myelin (white matter) of the brain.
Neurotoxin – A toxin that acts specifically on the peripheral or central nervous system usually by interacting with membrane proteins such as ion channels.

Chemical Structure

Hydrocarbons are a heterogeneous group of organic substances that are primarily composed of carbon and hydrogen molecules and can be derived from either petroleum or wood. Petroleum distillates include kerosene, gasoline, and naphtha. *n*-Hexane and its derivates are common environmental contaminants, as they are also a constituent of many petroleum-derived products. However, *n*-hexane is present also in the human body as by-products of lipid peroxidation, independently of environmental pollution. Physiologically, *n*-hexane is converted by cytochrome P-450-dependent monooxygenases, mainly CYP2E1 and CYP 2B6 isomers, and by alcohol dehydrogenases into 2-hexanone, and subsequently, into 2,5 hexanedione and finally 2,5-dimethylpyrrole. Wood-derived hydrocarbons

include turpentine and pine oil. While most are liquids, some (e.g., butane) are gases, and others (e.g., waxes) are solids at room temperature. Hydrocarbons are quite abundant in modern society; their use includes fuels, paints, paint and stain removers, dry cleaning solutions, lamp oil, lubricants, rubber cement, and solvents. In addition, many volatile substances that contain hydrocarbons (e.g., glue, propellants) are commonly abused for their euphoric effects.

Hydrocarbons can be classified as being aliphatic or aromatic. Halogenated hydrocarbons are a subgroup of aromatic hydrocarbons, with one of the hydrogen molecules substituted by a halogen group. The most important halogenated hydrocarbons include carbon tetrachloride, trichloroethylene, tetrachloroethylene, trichloroethane, chloroform, and methylene chloride. Cigarettes contain large quantities of aromatic and aliphatic hydrocarbons, including *n*-hexane.

Environmental Exposures

Hydrocarbon exposure can be divided into the following four broad categories: Accidental ingestion, especially in children; recreational ingestion, where inhaling of hydrocarbons or other volatile solvents for the purpose of producing a transient state of euphoria; accidental exposure, more often industrial, where a worker gets either a dermal exposure to the liquid or an inhalational exposure to the vapors; and intentional. The toxicity of hydrocarbons is directly related to their physical properties, specifically the viscosity, volatility, surface tension, and chemical activity of the side chains. Many of the hydrocarbons that directly affect the central nervous system are able to cross the blood–brain barrier, because certain hydrocarbons are highly lipophilic. In addition, for individuals who deep breathe ('huffing') or rebreathe ('bagging'), hypercarbia can occur as well, contributing to a decreased level of arousal, and in severe cases, hypoxia or simple asphyxiation. In order to predict the intensity of inhalation, exposure to aromatic solvents among commercial painters, an exposure model for measurements that could be used as a tool in the historical exposure assessment in a health surveillance program has been developed. In this regard, toluene has been selected as a marker for solvent exposure, since hydrocarbon exposures appeared to be strongly correlated.

Clinical Signs of Intoxication

The most common CNS symptoms include headache, lethargy, and decreased mental status. Acute intoxication has been reported, and in such cases, has been associated with gait ataxia, tremor, dysarthria, limb weakness, myoclonus, and bradyphrenia, in various combinations. Treatment after acute hydrocarbon exposure consists in removing any contaminated clothing and washing the skin. Gastric emptying, which increases the risk of aspiration, is contraindicated. Patients who have symptoms are admitted and treated supportively.

There are several studies, albeit controversial, that suggest that hydrocarbons may be involved in the pathogenesis of neurodegenerative diseases. Exposure recall bias and other methodological issues make the extrapolation of epidemiologic studies difficult. However, prolonged abuse of hydrocarbons can result in white matter degeneration (leukoencephalopathy). Cases of parkinsonism have been repeatedly attributed to various hydrocarbons, mainly aliphatic and halogenated compounds. It has been demonstrated that ketonated compounds, such as 2,5-hexanedione, are able to bind neurofilaments selectively, forming accumulations of ubiquitin-positive material that resembles those found in many neurodegenerative diseases. Moreover, it has been suggested that the susceptibility to the development of Parkinson's disease (PD) may involve an isoform of cytochrome P450, CYP2E1, which metabolizes the hydrocarbon *n*-hexane, leading to the formation of its neurotoxic metabolite 2,5-hexanedione. In the only case reported in the literature with neuropathological findings, the nature of the lesions was intermediate between PD and multiple system atrophy, so that the neuropathologic picture did not clearly correspond to either diagnosis; no Lewy body inclusions were found. Neuronal loss was also observed in the periaqueductal gray matter, locus ceruleus, and pedunculopontine nucleus. These changes, if combined with moderate anemia due to marrow suppression, and a mild axonal neuropathy are suggestive of a hydrocarbon toxic insult.

In animal models, hydrocarbon exposure may induce parkinsonism and damage to the central nervous system characterized by an increase in lipid peroxidation and cytoskeleton alterations associated with accumulation of neurofilaments. Similar lesions have been described in PD and other neurodegenerative disorders. Compared with control mice, mice intoxicated with trichloroethylene presented significant dopaminergic neuronal death measured by the tyrosine hydroxylase inmnunoreactivity in the substantia nigra pars compacta.

A survey in elderly Canadians showed that patients with PD had been more exposed to resins, paints, and petroleum derivates, all containing hydrocarbon solvent compounds, compared to a healthy group. Furthermore, the incidence of PD is much higher among residents of Kibbutzim, where large quantities of chemical pollutants are present in drinking water and used in agriculture. Other studies have also found that the exposure to hydrocarbon-containing solvents was higher in parkinsonian patients compared to healthy controls or to any other patient population. McDonnell et al. investigated whether occupational exposure to metals or solvents was associated with an increased risk of death from or with PD. They found a significant exposure–response relationship for solvents and a nearly fourfold increase in the risk for employees exposed

for 30 years or more, suggesting a sustained cumulative exposure or stricter industrial environmental controls later in the twentieth century or exposure to older solvents such as trichloroethylene. Neurotoxic actions of trichloroethylene have been demonstrated in animal models showing that oral administration of such solvent for 6 weeks instigated selective complex 1 mitochondrial impairment in the midbrain with concomitant striatonigral degeneration and loss of dopamine neurons. Pezzoli et al. studied the exposure to hydrocarbon solvents and derivatives on PD symptoms in a cohort study of 990 patients with PD, using neuropharmacologic tests and imaging techniques. They found that exposure to hydrocarbon-containing solvents was detected in almost 20% of all patients. The exposed group was younger, and the length of the latency period inversely correlated with the degree of exposure to hydrocarbons. Further, the severity of PD symptoms was directly proportional to the duration and intensity of exposure. In addition, exposed patients had a poorer response to dopaminergic agents compared to nonexposed. This poorer response to dopaminergic agents could be due to pharmacodynamic differences between receptors in the two populations of patients following damage induced by hydrocarbon solvents. As a result, exposed patients with PD seems to have an earlier onset of disease, reduced response to treatment and greater immobility, and less levodopa-induced dyskinesias, although the mean dosage of levodopa was higher in exposed subjects.

Another distinguishing feature between exposed and nonexposed patients with PD is the MRI picture, with a higher number of focal lesions in the white matter on T2 among subjects exposed to hydrocarbons. The relatively circumscribed focal white matter alterations have been associated with chronic solvent exposure rather than heavier abuse. Different patterns of striatal dopamine transporter binding have also been documented in PD patients exposed or not exposed to hydrocarbons. In patients exposed to hydrocarbons, significantly decreased striatal uptake occurred compared with healthy controls and nonexposed PD patients, suggesting that exposure to hydrocarbons may modify the disease course and ultimately accelerate nigrostriatal denervation. Imaging and spectroscopic data have shown that, compared to normal subjects with no previous exposure to hydrocarbon-solvents, in PD patients exposed to hydrocarbons, *N*-acetylaspartate levels, as a marker of neuronal damage/loss, were normal in the lentiform nucleus of patients with low exposure as well as in patients with no exposure, whereas it was decreased in PD patients with higher exposure. According to these authors, clinical expression may be more severe in PD patients with a previous high level of solvent exposure, because of the associated postsynaptic damage of the nigrostriatal pathway, suggesting that dopaminergic neurons and their projections are particularly susceptible to organic solvents.

It has been hypothesized that metabolic changes may be seen in individuals with particular genotypes that can cause difficulties in metabolizing one or more environmental toxins and this 'poor metabolizer' status could make them more susceptible to developing PD following exposure of such toxins. In one study, the urinary levels of the main metabolites of *n*-hexane (2,5-hexanedione and 2,5-dimethylpyrroles) were measured in 108 patients and 108 healthy controls, matched by age and sex. Metabolite urinary excretion was significantly reduced in PD patients compared with controls and was inversely related to age in both groups, suggesting that aging and PD may be associated with a reduction in the capacity to eliminate the hydrocarbon *n*-hexane.

Hyperekplexia

M A J Tijssen and M J Bakker, University of Amsterdam, Amsterdam, The Netherlands

Glossary

GLRA1 gene – α1 subunit of the glycine receptor.
Glycine receptor – Widely distributed inhibitory receptor in the central nervous system, especially in the spinal cord and brain stem.
Head-retraction reflex – The examiner applies a reflex hammer downward to the middle of the upper lip or the nose in order to effect a brisk bending of the head. When this reflex is positive, the patient answers with a quick retraction of the head.
Major form hyperekplexia – Combination of excessive startle reflexes, generalized stiffness at birth and stiffness related to the startle reflex.
Minor form hyperekplexia – Excessive startle responses without signs of stiffness.
SLC6A5 gene – Presynaptic glycine transporter-2 (GLYT2).

Definition and History

In 1958, the first family with exaggerated startle reflexes and unexpected violent falls was reported. In 1963, in a large Dutch family, this autosomal dominantly inherited disorder was named 'hyperekplexia' (HPX). The combination of the Greek words 'υπερ' and 'εκ-πλησσώ' means 'to startle excessively.'

In HPX or startle disease, two clinical forms have been recognized: the major and the minor form. For the diagnosis of the major form HPX, three features are required: excessive startle reflexes, generalized stiffness at birth, and stiffness related to the startle reflex. Patients with the minor form suffer from excessive startle responses without signs of stiffness.

In the major form HPX, the excessive startle reflexes to unexpected, especially auditory stimuli are present from birth. The frequency of startle responses can increase with emotional tension, nervousness, and fatigue, and can decrease while holding objects or drinking alcohol. The second cardinal feature is the generalized stiffness immediately after birth, normalizing during the first years of life. Handling increases the stiffness, and during sleep, it disappears. The third feature is a short period (seconds) of generalized stiffness after the startle response, making it impossible to stretch out arms and causes patients to fall while fully conscious. The stiff-baby syndrome, congenital stiff-person syndrome, and 'Kok disease' are other names for the major form HPX.

Neurological examination in newborns reveals a generalized stiffness and marked hypokinesia. Held horizontally, the child is as 'stiff as a stick.' In adults, in a clinical setting, startle reflexes are difficult to elicit as unexpected stimuli are required. A stiff-legged, mildly wide-based gait can be observed, but the most evident abnormality is an exaggerated head-retraction reflex elicited by tapping on the nose. It has been suggested as the hallmark of HPX.

Patients with the minor form HPX suffer from excessive startle reactions without stiffness. These exaggerated startle reflexes never start in the neonatal period, but the age of onset ranges from early infancy to adulthood. Neurological examination shows normal.

Genetics in HPX

The *GLRA1* gene is the major gene for the major form HPX. The *GLRA1* gene is located on chromosome 5q33–q35 and encodes for α-1 subunit of the inhibitory glycine receptor, located in the postsynaptic membrane of glycinergic and mixed γ-aminobutyric acid (GABA)ergic/glycinergic neurons. Dominant, recessive, and compound heterozygote mutations are identified in many individuals with the familial major form HPX and occasionally in sporadic cases. Glycine receptors are ligand-gated chloride channels causing postsynaptic hyperpolarization and synaptic inhibition in the brainstem and spinal cord. Glycine receptors are assembled into pentameric complexes and consist of combinations of α and β subunits. The combinations depend on the developmental stage and the brain region. The mutations in the gene often lead to compromised channel dynamics and impair the efficiency of glycinergic inhibition in the brainstem and spinal cord.

A second gene is the presynaptic glycine neurotransmitter transporter Glyt2 or *SLC6A5* gene (2006). Compound heterozygote inheritance of recessive alleles has mainly been described. The phenotype of Glyt2 patients closely resembles the phenotype of patients with the GLRA1 genotype except for a higher frequency of life-threatening neonatal apnea episodes in the Glyt2 positive patients. The *SLC6A5* gene codes for one of the glycine transporters (GlyTs), members of the Na^+/Cl^--dependent neurotransmitter transporter superfamily. GlyT2 is found in glycinergic axons, and the transporter functions are knocked out by

a process of nonsense mediated decay, the disruption of the glycine uptake or the inhibition of Na^+ ion coactivation.

Mutations in three other genes, encoding subunits, or binding proteins of GlyR complexes mutations have been reported. In each gene, single patients were identified: one had a compound heterozygous mutation in the GlyR β-subunit (GLRB); one showed a mutation in the *gephyrin* gene (GPHN); and the last one had an X-linked mutation in the collybistin gene (*ARHGEF9*). These three sporadic patients showed the classical major form HPX except for the patient with the *ARHGEF9* gene mutation, who died at the age of 4 and suffered from severe epilepsy and mental retardation.

In patients with the hereditary minor form HPX, no genetic cause has been detected until now. The minor form HPX patients have mainly been described in pedigrees also exhibiting the major form HPX. In a large Dutch family, all patients with the major form HPX carried a mutation of the *GLRA1* gene, but no patients with the minor form did. Only in a few small pedigrees with concisely described symptoms, *GLRA1* mutations were found in members who may possibly have had the minor form.

Several animal models display HPX-like phenotypes with autosomal recessive inheritance, indicating loss-of-function effects for these mutations. The *spasmodic (spd)* and the *oscillator* (spd^{ot}) harbor mutations in the *GLRA1* gene, whereas the *spastic (spa)* has a mutation in the β subunit. *Spd, spa*, and spd^{ot} have overlapping phenotypes with striking similarities to human HPX. Transgenic mutants resemble the human HPX phenotype even better. The targeted deletion of *gephyrin* (*Geph*) and glycine transporter subtype 2 (*GlyT2*) also resulted in HPX-like phenotypes in mice. A congenital recessive startle syndrome in Poll Hereford cattle has been described with mutations in the *GLRA1* gene and more recently, cattle with congenital muscular dystonia type 2 showed mutations in the Glyt2 gene.

Pathophysiology

The startle reflex is interpreted as the rapid accomplishment of a defensive stance with maximum postural stability. It consists of bilaterally synchronous shock-like movements, especially in the face and the upper part of the body. For the physiological details of the startle reflex.

In the major form HPX, the pattern of the startle reflex was identical with those of the normal startle reflex, although the latencies were shorter. Compared with controls, the motor response was more frequent and larger with repetitive stimuli and the auditory threshold was lower.

The abnormal startle reflex in HPX is suggested to originate in the brainstem. Arguments for this are that symptomatic HPX usually concerns brainstem damage. Furthermore, latencies of startle EMG responses point toward a brainstem origin as do eye movement recordings in HPX. Another argument is that glycine receptors in humans are concentrated in the brainstem and spinal cord.

Little is known about the background of stiffness in HPX. In the major form HPX with a proven GLRA-1 mutation, disynaptic reciprocal inhibition was absent similar to abnormalities in patients with pyramidal tract lesions. However, transcranial magnetic stimulation testing the pyramidal pathways was normal.

Startle responses in the minor form HPX differ substantially from those in the major form. EMG latencies are prolonged and habituation is lacking. Furthermore, the reciprocal inhibition of H-reflexes was found normal in the minor form HPX, consistent with their lack of stiffness.

Several hypotheses have been raised to explain how cases with the minor form HPX without a mutation in the *GLRA1* gene can occur in the same pedigrees as patients with the major form HPX with a mutation in the gene. One hypothesis is that the minor form startle response represents a learned behavior in subjects subjected to family members with organic startle reflexes. The prolonged EMG latencies can be an indication of a psychiatric or psychogenic origin of the exaggerated startle reflex, although the jerks do not have all characteristics of a psychogenic startle response. Alternatively, a polymorphism or a nonpenetrance of the *GLRA1* gene may underly the disorder. Finally, excessive startling may be much more common in the general population than previously thought, and the minor form HPX represents a common variant coincidentally found in some HPX families.

Epidemiology

The prevalence of hereditary HPX is low; over 70 pedigrees in many different nationalities have been described. The major form HPX mainly occurred in these pedigrees; occasionally the minor form was described. Sporadic HPX has been published in over 120 cases representing both the major and minor form HPX.

Clinical Features and Diagnostic Criteria

For the diagnosis of the major form HPX, three features are required: (1) generalized stiffness immediately after birth, normalizing during the first years of life, (2) an excessive startle reflex particularly to auditory stimuli that is present from birth, and (3) a short period (seconds) of generalized stiffness following the startle reflex. Patients with the hereditary minor form HPX suffer from an excessive startle response without signs of stiffness. Associated features are exaggerated head-retraction reflex, periodic limb movements in sleep, abdominal herniation, congenital dislocations of the hip, and sudden infant death.

Differential Diagnosis

In the following sections, a differential diagnosis of HPX is tabulated for each of the three main clinical features of hereditary HPX: excessive startle responses to unexpected stimuli, transient stiffness in relation to unexpected stimuli, and continuous stiffness in the neonatal period. A detailed discussion of all differential diagnoses is beyond the scope of this article.

Excessive Startle Responses to Unexpected Stimuli

Clinical observation alone is not sufficient to discriminate between excessive startle responses and startle-induced disorders. Still, Fwe divide the differential diagnosis of excessive startle reflexes into HPX, that is, defined as startle reflexes (**Table 1**), subsequently the differential diagnosis of the neuropsychiatric startle disorders (**Table 2**), and finally a group of stimulus-induced disorders (**Table 3**).

Excessive startle reflexes (HPX)

The most important discriminative factor among the three forms of HPX (hereditary, sporadic, and symptomatic) is the family history. HPX is usually hereditary, and a positive family history points toward this form. In sporadic HPX, the phenotype is similar to hereditary HPX, but a positive family history is lacking. In sporadic HPX, attacks of tonic neonatal cyanosis have frequently been described that can be stopped by the 'Vigevano' maneuver (forced flexion of the head and legs toward the trunk). Patients with a sporadic minor form HPX usually have an adult onset without other neurological signs. In these patients, a psychogenic etiology can be considered (see the following section). In symptomatic HPX, excessive startle responses are usually accompanied by other neurological signs arising especially from the brainstem. Causes of symptomatic HPX include cerebral or brainstem damage and encephalitis due to several causes (see **Table 1**). The symptomatic HPX cases have late-onset HPX without stiffness in the neonatal period. The discrimination between sporadic and symptomatic HPX is based on medical history and additional clinical and radiological information.

Table 1 Molecular genetic testing in hyperexplexia

Test method(s)	*Mutation detection rate*	*Inheritance pattern*
Sequencing of all exons and flanking introns	In familial: ±90% In sporadic: ±10%	
GLRA1 gene	>40 cases	AD, AR
GLRA1 deletions	6 cases	
SLC6A5 gene	>10 cases	AR
GLRB gene	Single case	AR
GPHN gene	Single case	
ARHGEF9 gene	Single case	X-linked

Table 2 Excessive startle reflexes (HPX)

Hereditary HPX	Major form
	Minor form
Sporadic HPX	Major form
	Minor form
Symptomatic HPX	Children with cerebral palsy
	Postanoxic encephalopathy
	Encephalomyelitis with rigidity
	Multiple sclerosis
	Gilles de la Tourette's syndrome
	Posttraumatic
	Paraneoplastic
	Cerebral abscess with encephalitis
	Brainstem infarct or haemorrhage
	Brainstem encephalopathy
	Creutzfeldt–Jakob's disease
	Subacute sclerosing panencephalitis
	Paraneoplastic syndromes

Neuropsychiatric startle syndromes

The main differential symptoms of the minor form HPX are the neuropsychiatric disorders, including the culture-specific syndromes, such as the 'Jumping Frenchman of Maine,' 'Latah,' and 'Myarichit,' startle neurosis, and hysterical jumps. Although startle responses are part of these syndromes, their motor patterns have not been defined in detail. Clinically, patients with an abnormal startle reflex as part of psychiatric symptoms show an inconsistent startle pattern with prolonged latencies. Anxiety disorders can also be accompanied by exaggerated startling possibly due to increased arousal.

Startle-induced disorders

In startle-induced disorders, the startle reflex triggers an abnormal movement, such as epilepsy, reflex myoclonus, paroxysmal kinesigenic dyskinesias, cataplexy, and occasionally a tic. Startle epilepsy concerns an epileptic seizure precipitated by a sudden stimulus. Clinically, usually an asymmetric tonic seizure is induced. Most startle epilepsy patients suffer from infantile cerebral hemiplegia.

Table 3 Neuropsychiatric startle syndromes

Culture-bounded	Jumping Frenchmen of Maine
	Latah
	Myriachit
	Leaping ague of Scotland
	Tigretetier of Abessynia,
	Imanenjana of Madagascar
Psychiatric	Startle neurosis
	Posttraumatic stress disorder
	Withdrawal periods anxiolytic drugs, opiates or alcohol
	Hysterical jumps

Progressive myoclonus epilepsy due to different causes is also a part of these epilepsy syndromes, each of which has a characteristic clinical picture. Reflex myoclonus, especially reticular and propriospinal myoclonus, can be discriminated from HPX by an EMG-reflex test. In paroxysmal kinesigenic dyskinesias, movements are luxated by an unexpected stimulus, but concern chorea or dystonia rather than a startle reflex. Patients with cataplexy have a loss of muscle tone due to unexpected stimuli rather than an increase in tone. Cataplexy is usually induced by laughter, but may occur after being startled. Incidentally, a normal startle reflex can induce a tic **Table 4**.

Transient Stiffness in Relation to Unexpected Stimuli

Transient stiffness in relation to unexpected stimuli can occur in the hereditary and sporadic major form of HPX. Strychnine poisoning mostly resembles HPX, but its incidence is very low. The startle-induced stiffness group mainly concerns stiff-person syndrome (SPS) characterized by progressive axial stiffness and intermittent spasms mainly evoked by stimuli. It usually starts in the fourth or fifth decade, and is frequently associated with diabetes mellitus. Antibodies against GABAergic neurones, especially antiglutamic acid decarboxylase (GAD), occur in many patients. The combination of stiffness and startle-induced falls closely resembles the major form of HPX; however, the stiffness in SPS is nearly continuous, contrasting sharply with the stiffness in adult HPX, which occurs only after a startle and lasts 1–2 s. The syndrome of 'continuous muscle fiber activity' of peripheral origin is Isaacs' syndrome, or neuromyotonia. Distal, proximal, and cranial muscles may be involved. The symptoms persist during sleep (**Table 5**).

Stiffness in the Neonatal Period

Continuous stiffness in the neonatal period can occur in the hereditary or sporadic major form HPX. Occasionally, stiff-man syndrome presents in the first months of life. Congenital generalized muscle hypertonia as a distinct autosomal recessive disorder was described in a Mexican family. The clinical description resembles HPX, but these children also suffered from cardiopulmonary distress. The most important differential diagnosis is formed by perinatal asphyxia. Pyramidal signs and irritability discriminate these newborns from HPX. Extrapyramidal signs, including stiffness, can occur in a child born to a mother using drugs such as phenothiazine and cocaine. Neonates with paroxysmal extreme pain disorder (familial rectal pain disorder) have tonic attacks associated with flushing and severe syncopes. These attacks are mainly triggered by perineal toilet, but also by bathing. The syndrome of continuous muscle activity of peripheral origin, Isaacs' syndrome, or neuromyotonia has already been discussed earlier. The Schwartz–Jampel syndrome, osteo-chondro-muscular dystrophy is a rare autosomal recessive syndrome. It consists of not only muscular stiffness but also abnormal facial appearance and skeletal abnormalities (**Table 6**).

Management

Clonazepam is the most effective drug for HPX for hereditary as well as for sporadic forms. Both the stiffness in the neonatal period and the stiffness related to the startle

Table 4 Stimulus-induced disorders

Epilepsy	Startle epilepsy

reduce with the treatment. Several other drugs have been tried with contrasting results mainly concerning case reports. Clonazepam potentiates the inhibitory neurotransmitter GABA. In various species, and presumably also in humans, GABA-A and glycine receptors show a widespread colocalization in the central nervous system.

Physical and cognitive therapy to reduce the fear of falling and, thereby, improving walking can be considered, but no randomized trial has been done.

Prognosis

In the major form hereditary HPX, the excessive startle reflexes to unexpected, especially auditory, stimuli are present from birth and throughout life. The frequency of startle responses varies between subjects, but also over the course of time. The generalized stiffness immediately after birth normalizes during the first years of life. The stiffness is still slightly visible while walking, manifesting as a mildly wide-based gait. The short period (seconds) of generalized stiffness after the startle response remains throughout life, but the frequency also varies largely between subjects. In patients with the minor form hereditary HPX, little is known on the prognosis.

Hypophonia

E Q Wang, Rush University, Chicago, IL, USA

Glossary

Fundamental frequency (F0) – Is the physical correlate of pitch. It is an acoustic measure that directly reflects the vibrating rate of the vocal folds and it also refers to the component in the vocal fold tone with the lowest frequency. The unit of measurement is Hertz (Hz).
Hypophonia – A breathy and hoarse vocal quality with reduced loudness that is mostly seen in the voice of patients with Parkinson's disease (PD). It is thought to be related to the rigidity in the laryngeal muscles.
Jitter and shimmer – Jitter or frequency perturbation refers to the cycle-to-cycle variability in the fundamental frequency of the vocal fold vibration while shimmer or amplitude perturbation refers to the cycle-to-cycle variability in the amplitude of the vocal fold vibration.
Lee Silverman Voice Treatment (LSVT/LOUD) – An evidence-based treatment method for hypophonia and hypokinetic dysarthria experienced by 89% of patients with IPD. It targets a single treatment target of loudness with high intensity in its delivery mode and sensory retraining.
Phonation – Is the physical-physiologic act of sound production: the oscillations of the vocal folds driven by the exhaled air stream.
Vocal intensity – The physical correlate of loudness. It varies as a function of both subglottal pressure (P_s) and vocal fold vibratory amplitude. It is measured in decibel (dB) and can be simply measured using a sound-level meter. Reduced intensity may be indicative of poor respiratory support, incomplete glottal closure, or reduced tissue pliability restricting the vocal fold vibratory amplitude.

Definition and History

Hypophonia refers to a vocal quality that is abnormally weak, soft, and breathy; it is mostly observed in patients with Parkinson's disease (PD). The word 'hypophonia' comes from the combination of the Ancient Greek prefix 'hypo,' meaning 'under,' and noun 'phōnia,' meaning 'voice.'

Pathophysiology

The pathophysiology underlying hypophonia in PD has been suggested to be the bowing of the vocal folds due to rigidity in the laryngeal musculature, while for atypical Parkinsonism, the pathophysiology may be bilateral vocal fold paresis or paralysis.

Epidemiology/Risk Factors

Epidemiology as Related to Different Etiologies

The underlying neurological disturbances most commonly associated with hypophonia are PD. However, acute onset of hypophonia has been reported to be associated with cerebrovascular diseases. Hypophonia may occur alone (45%) or as part of the symptoms of hypokinetic dysarthria (89%) in PD. Hypophonia is characterized by breathy and hoarse vocal quality with a significantly reduced vocal loudness. For patients with atypical Parkinsonism such as PSP or MSA, hypophonia may appear as one of the early symptoms of hypokinetic dysarthria. However, that may quickly change as the disease progresses. For example, the vocal quality of patients with PSP and Shy–Drager syndrome may change from initially extremely soft and breathy (sometimes even aphonic, i.e., no voice), a sign of hypophonia, to breathy strained and strangled. Articulation, resonance, and prosody may also be involved around the same time. These symptoms taken together indicate the presence of mixed spastic/hypokinetic dysarthria, which often develops within 1–5 years after the disease onset.

Risk Factors

In idiopathic PD, the most important risk factors for developing hypophonia are progression of the disease and disease severity level. In atypical Parkinsonism, however, when the symptoms of laryngeal dysfunction or hypophonia are present, they are usually much more severe and may be part of mixed dysarthrias rather than hypophonia alone. Risk factors in atypical Parkinsonism include fast disease progression and sleep-related disordered breathing with stridor.

Clinical Features/Diagnostic Criteria

Characterization

The main characteristic of hypophonia is that its symptoms are only in the laryngeal or phonatory subsystem.

Salient Voice Features

Perceptually, characteristics of hypophonia are limited to breathy and hoarse vocal quality, reduced loudness, and reduced pitch and loudness variability. There is no involvement of articulation or resonance. Even at early stages, the hypophonia due to IPD versus that resulting from atypical Parkinsonism may show qualitative difference: it is much more severe in atypical Parkinsonism. In addition, the selective abductor paralysis or paresis seen in atypical Parkinsonism could be life threatening due to glottic airway compromise.

Diagnosis of Hypophonia

Certified and licensed speech-language pathologists (SLP) are trained to diagnose *hypophonia*, using a combination of perceptual and instrumental tests. A typical evaluation has the following components: an in-depth medical history, including a voice history, voice handicap index (VHI), a complete oral motor examination, acoustic analyses of voice, and a videostroboscopy for direct examination of the laryngeal structure and vocal fold movement during phonation. Based on the findings, the SLP will be able to diagnose or rule out hypophonia.

Management

Medication

Hypophonia of PD usually appears early in the disease progression. The response to dopaminergic stimulation in hypophonia is very limited.

Deep Brain Stimulation

There is limited evidence indicating that unilateral deep brain stimulation (DBS) of the subthalamic nucleus (STN) in the nonlanguage dominating side (right side) in the right-handed speakers may increase the vocal intensity. However, bilateral STN DBS has been shown repeatedly to negatively impact on voice and speech and that is a common adverse effect of the procedure.

Speech Therapy

Speech therapy that has demonstrated clear efficacy is Lee Silverman Voice Treatment (LSVT/LOUD), an intensive treatment program for treating hypophonia and hypokinetic dysarthria in patients with IPD, targeting a single treatment target of loudness with high intensity in its delivery mode and sensory retraining. It works best when the main symptoms are soft, hoarse, and breathy voice. Symptoms such as inability to initiate speech, frequent hesitations, and palilalia seen in more advanced hypokinetic dysarthria are less responsive to LSVT/LOUD, but can be controlled by altered auditory feedback (AAF) provided by a wearable device.

Prognosis

Hypophonia in patients with IPD will worsen to become part of hypokinetic dysarthria when symptoms progress beyond phonation as the underlying disease progresses. Early onset of severe speech deficits such as palilalia in PD may indicate atypical Parkinsonism such as PSP or MSA especially when dysphagia, sleep-related breathing disorder, and stridor as well as gait disturbances are present.

Hypoprebetalipoproteinemia, Acanthocytosis, Retinitis Pigmentosa, and Pallidal Degeneration (HARP Syndrome)

R W Orrell, UCL Institute of Neurology, London, England

Glossary

Acanthocytosis – The microscopic appearance of spiculated erythrocytes. This should be a spikey appearance. Not to be confused with echinocytes that have more than 30 spurs.
Dystonia – A neurological movement disorder characterized by abnormal movements or postures.
Eye-of-the-tiger – The MRI finding (T2 weighted) of decreased signal intensity in the pallidal nuclei, with a centrally located area of increased intensity.
Globus pallidus – A major component of the basal ganglia. Pallidal degeneration is usually associated with abnormal movement.
Hallervorden–Spatz disease – A rare autosomal recessive disease characterized by an early onset of progressive dystonia and dementia, and pathologically by bilateral degeneration of the globus pallidus and substantia nigra reticulata associated with deposition of iron in the affected regions and more widely distributed neuronal axonal spheroids. Mutations in the *PANK2* gene are a common cause. This may then be referred to as PKAN.
HARP – The clinical syndrome of hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration. It is caused by homozygous mutations of the *PANK2* gene.
Hypoprebetalipoproteinemia – A reduction (or absence) in the intensity of the prebeta band on high-resolution lipopoprotein electrophoresis, reflecting a reduction in predominantly very low density lipoprotein (VLDL).
NBIA – Neurodegeneration with brain iron accumulation (NBIA) is a rare group of neurodegenerative conditions, which include PKAN (Hallervorden–Spatz disease). Other forms of NBIA include infantile and adult neuroaxonal dystrophy, acerulopasminemia, and neuroferritinopathy
PANK2 – The pantothenate kinase 2 gene (*PANK2*). Mutations in PANK2 cause PKAN (Hallervorden–Spatz disease and related syndromes, including HARP).
PKAN – Pantothenate kinase-associated neurodegeneration (PKAN) is the neurodegenerative condition, often with clinical features of Hallervorden–Spatz disease, and other features, caused by mutations in the *PANK2* gene.
Retinitis pigmentosa – A pigmentary disorder of the retina, leading to a progressive loss of vision.

Definition and History

Higgins et al. reported a patient with features of Hallavorden–Spatz disease, distinguished by the presence of a lipoprotein abnormality (hypoprebetalipoproteinemia), acanthocytosis, retinitis pigmentosa, and pallidal degeneration. Orrell et al. reported a further patient.

Both of these patients have now been found to have mutations of the *PANK2* gene, with autosomal recessive inheritance. The clinical syndrome of HARP is a variant of Hallervorden–Spatz disease, PKAN, or neurodegeneration with brain iron accumulation (NBIA).

Pathogenesis/Pathophysiology

HARP is an autosomal recessive disorder with mutations of the *PANK2* gene. The precise pathogenesis of neurodegeneration is unknown, but relates to that of PKAN. There is bilateral degeneration of the globus pallidus and substantia nigra pars reticulata, with deposition of iron in the affected regions (as demonstrated on MRI scan) and more widely distributed neuronal axonal spheroids (demonstrated in PKAN but there is no neuropathological report of HARP). The significance of the lipid changes and acanthocytosis is uncertain.

Epidemiology/Risk Factors

HARP is very rare, with only two reported patients. Other possible variants include two patients with acanthocytosis, retinitis pigmentosa and pallidal degeneration (ARP) with no lipid abnormality. HARP is an inherited condition, autosomal recessive, with no other specific risk factors known.

Clinical Features and Diagnostic Criteria

The clinical features are those of a variant of Hallervorden–Spatz disease, with an early onset (3 and 16 years) and prominent orofacial dyskinesia or dystonia. There may be pyramidal signs, including spasticity. Plantar responses may be flexor or extensor. There may be progressive dementia. Hypoprebetaliproteinemia on lipoprotein electrophoresis, acanthocytosis on a blood film, or preferably electron microscopy, and retinitis pigmentosa, which may include circumferential restriction of visual fields, are key features of the syndrome.

Differential Diagnosis

The differential diagnosis of the movement disorder includes other types of dystonia. The clinical features of Hallervorden–Spatz disease, or PKAN, are typical with predominant orofacial dystonia. Other forms of neuroacanthocytosis may be considered as well as other lipid-related movement disorders.

Diagnostic Workup/Test

Sequencing of the *PANK2* gene should demonstrate mutations in both alleles. MRI scan of the brain should show the 'eye-of-the-tiger' sign. Lipid abnormalities may be present on standard laboratory lipid analysis, but high-resolution lipoprotein electrophoresis is required for full definition. Electrooculography may identify features of tapetoretinal degeneration. The assessment of acanthocytosis is more complex than a standard examination of a blood film, and specialized assessment, including electron microscopy, is needed to fully define the nature of the spiculed cells to quantify and exclude artifact. Pedantically, many cells that have been termed acanthocytes may be echinocytes.

Management

The management is of the dystonic condition. Additional management may be needed for dementia and other related conditions. In the patient described by Orrell et al., we tried putative neuroprotective agents (selegiline and antioxidants) with no clear benefit. *PANK2* is one of the four human genes that encode pantothenate kinase. This enzyme is important in the synthesis of coenzyme A from pantothenate (vitamin B5). As coenzyme A is central to cell function, including phospholipid and membrane synthesis, we sought to overcome the PANK2 enzyme defect by giving a supplement of pantothenic acid 1 g twice daily. When reassessed, there was no clinical, laboratory, or radiologic improvement. There is no curative or preventive treatment available at present. Symptomatic treatment is given as appropriate.

Prognosis

Only two patients with the full presentation of HARP have been described. The patient of Higgins et al. had a disease onset age of 11 years and was severely disabled at age 11 years. The patient of Orrell et al. had a disease onset age of 16 years, and was significantly disabled at age 29 years, although with a relatively stable condition.

Idebenone and Friedreich Ataxia

A Filla and C Rinaldi, Università Federico II Napoli, Naples, Italy

Glossary

Aconitase – An enzyme in the tricarboxylic acid cycle (Krebs cycle) that catalyzes the isomerization of citrate to isocitrate via *cis*-aconitate. It is also an iron–sulphur protein involved in iron homeostasis.
Cardiomyopathy – A disease of the heart muscle which occurs frequently in Friedreich's ataxia (FRDA) patients. Presentations most frequently include concentric thickening of the left ventricle (LV) of the heart but also asymmetric LV thickening or dilated LV.
Ejection fraction (EF) – A measure of the pumping function of the heart, which can be assessed by echocardiography.
Electron transport chain (ETC) – The ETC couples a chemical reaction between an electron donor (such as NADH) and an electron acceptor (such as O_2) to the transfer of H^+ions across a membrane, through a set of mediating biochemical reactions, with the goal of these H^+ions to produce adenosine triphosphate (ATP), the main energy intermediate in living organisms.
Endomyocardial biopsy – A procedure by which a small piece of heart muscle tissue can be obtained for morphological or biochemical analysis.
8-Hydroxy-2′deoxyguanosine – An oxidative DNA damage product excreted in urine.
Iron–sulfur (Fe–S) clusters – These clusters are prosthetic groups commonly found in various proteins that participate in oxidation–reduction reactions. Iron–sulfur clusters are found in a variety of metalloproteins, such as NADH dehydrogenase, succinate dehydrogenase, cytochrome reductase. Best known for their role in the oxidation–reduction reactions of mitochondrial electron transport.
Krebs cycle – Also known as the tricarboxylic acid cycle. It is a series of enzyme-catalyzed chemical reactions that uses oxygen as a part of cellular respiration. The cycle is part of a metabolic pathway involved in the chemical conversion of carbohydrates, fats, and proteins into carbon dioxide and water to generate energy.
Lipoperoxidation – The oxidative degradation of lipids and process whereby free radicals 'steal' electrons from the lipids in cell membranes, resulting in cell damage.
Mitochondrial complexes – Five membrane-bound complexes identified in mitochondria that consist of an extremely complex transmembrane structure embedded in the inner membrane: Complex I (NADH dehydrogenase), Complex II (succinate dehydrogenase), Complex III (cytochrome reductase), Complex IV (cytochrome oxidase), and Complex V (ATP synthase). Complexes I–III contain Fe–S clusters.
Oxidative stress – An imbalance between the production of reactive oxygen and a biological system's ability to readily detoxify the reactive intermediates or easily repair the resulting damage.
Ubiquinone – A component of the electron transport chain and involved in aerobic cellular respiration, generating ATP. Also known as coenzyme Q_{10}, ubidecarenone, coenzyme Q, and abbreviated at times to CoQ_{10}, CoQ, Q10, or Q. A benzoquinone, where Q refers to the quinone chemical group and 10 refers to the isoprenyl chemical subunits.

Definition and History

Idebenone (6-[10-hydroxydecil]-2,3-dymethoxy-5-methyl-1,4-benzoquinone) is a quinone analogue, which is used in the treatment of several neurological disorders: Friedreich ataxia (FRDA), mitochondrial encephalomyopathies, senile dementia, and Huntington disease. Idebenone acts as an

antioxidant through the action of its quinone ring and diffuses more rapidly than ubiquinone across biological membranes due to the modification of the composition and length of its side chain. Besides being a potent antioxidant, idebenone also functions as an electron transport carrier and has been reported to have various other effects, including stimulation of nerve-growth factor production and blockade of voltage-sensitive calcium channels. Idebenone is rapidly absorbed and has a plasma half-life of 14.9 ± 0.7 h. It crosses the blood–brain barrier. Within 48 h, most of the compound is excreted as metabolites in urine and faeces.

In vitro Studies of Idebenone

FRDA is an autosomal recessive disorder characterized by progressive neurological impairment (ataxia, dysarthria, weakness, and sensory loss), cardiac dysfunction (left ventricular hypertrophy), diabetes mellitus, and skeletal abnormalities (scoliosis and pes cavus). The causative mutation is an expansion of a GAA repeat within the first intron of the *FXN* gene, leading to decreased levels of the corresponding transcript and of the mitochondrial protein frataxin. Frataxin has been demonstrated to be involved in the assembly of the iron–sulfur (Fe–S) clusters. Decreased levels of frataxin decrease the activity of the iron–sulfur enzymes, such as complexes I–III of the mitochondrial electron transport chain, and mitochondrial and cytosolic aconitase.

When frataxin deficiency was demonstrated to cause mitochondrial iron accumulation and oxidative stress in the yeast model of FRDA, idebenone was considered a potential therapeutic tool for FRDA. In 1997, Rustin et al. showed in heart homogenates that reduced iron (Fe^{2+}), but not oxidised iron (Fe^{3+}) decreased the activity of respiratory complex II and increased lipoperoxidation. Addition of ascorbate increased lipoperoxidation by reducing Fe^{3+} to Fe^{2+}. Desferoxamine protected complex II from iron injury, but the activity of the Krebs cycle enzyme aconitase was decreased. Only idebenone protected complex II and lipids from iron injury in heart homogenates without modification of aconitase activity. A normalization of mitochondrial complexes I, II, III, and aconitase has been reported in a repeated endomyocardial biopsy after 5 years of 5 mg kg^{-1} day^{-1} idebenone treatment.

Idebenone and Mouse Models

Animal models with frataxin deficits have been used to test the efficacy of idebenone. A conditional knock-out model, in which frataxin was specifically deleted in cardiac muscle, resulted in a rapidly progressive disease. The murine cardiomyopathy is characterized by an early onset of dilatation with development of left ventricle (LV) hypertrophy followed by reduced systolic function. In this animal model, high dose idebenone (90 mg Kg^{-1} day^{-1}) delayed disease onset, slowed progression, and prolonged survival by 10%, with an average survival rate of 79 ± 9 days versus 71 ± 9 days for placebo treated mutant animals. Of note, this dose was 18-fold greater than the dose usually given to FRDA patients.

Human Studies of Idebenone in FRDA

Low Dosage

The 'in vitro' findings described above prompted a trial on three patients with FRDA and LV hypertrophy. The treatment with idebenone 5 mg Kg^{-1} day^{-1} for 4–9 months was accompanied by substantial decreases in interventricular septum and LV posterior wall thickness and in left ventricle mass (LVM) index. Most open-label and one randomized placebo-controlled trial with idebenone 5 mg kg^{-1} day^{-1} confirmed the effect on LV hypertrophy. While most of these trials included neurological endpoints, only one small, open-label trial with 5 mg kg^{-1} day^{-1} found in pediatric patients a significant improvement, which was related to idebenone plasma concentration.

A large open-label prospective survey has been recently reported. The trial included a total of 104 FRDA patients, 88 of whom received idebenone 5 mg Kg^{-1} day^{-1} and 16 of whom preferred not to be treated. The patients were followed for a median time of 5 years. The neurological picture, as measured by international cooperative ataxia rating scale (ICARS), worsened in both groups but there was a trend towards clearer deterioration in those who were not treated (1.93 ± 0.25 vs. 4.43 ± 1.56 per year). The cardiac hypertrophy decreased in the treatment group (LVM index decreased by -4.1 ± 1.5 g m^{-2} per year), but the cardiac function did not improve as the ejection fraction decreased by -1.3 ± 0.3 per year (**Table 1**).

High Dosage

The safety of high dosages of idebenone has been shown in two phase I studies. In the first trial, 78 patients completed a dose escalation to a maximum of 75 mg kg^{-1} without evidence of dose limiting toxicity. The most common adverse effect was transient mild nausea. Plasma levels of total idebenone were found to increase proportional to the drug dose up to 55 mg kg^{-1}. The second trial included 15 patients who received 60 mg Kg^{-1} day^{-1} for a month. One child experienced nausea and diarrhea, and the drug was discontinued. Urine discoloration was frequently reported.

On the basis of these results, a randomized, placebo-controlled, double-blind, phase II study was designed to

Table 1 Idebenone trials in FRDA

	Design	*Number*	*Idebenone dose*	*Treatment period*	*Cardiac outcomes*	*Neurological outcomes*
Rustin et al.	OL	3	5 mg kg^{-1} day^{-1}	4–9 months	↓ IVS ↓ LVPW ↓ LVMi	Ataxia not quantified
Hausse et al.	OL	38	5 mg kg^{-1} day^{-1}	6 months	↓ LVMi	Ataxia not quantified
Artuch et al.	OL	9	5 mg kg^{-1} day^{-1}	12 months	No change LVPW No change IVS	50% ↓ ICARS in pediatric patients
Rustin et al.	OL	40	5 mg kg^{-1} day^{-1}	6 months	↓ IVS ↓ LVPW ↓ LVMi	No change of ataxia
Mariotti et al.	DBPC	29	5 mg kg^{-1} day^{-1}	12 months	↓ IVS ↓ LVM	No change
Buyse et al.	OL	8	5 mg kg^{-1} day^{-1}	12 months	↓ LVMi ↓ Cardiac strain ↓ Strain rate	↑ CAG
Ribai et al.	OL	88	5 mg kg^{-1} day^{-1}	60 months	↓ LVMi ↓ EF	↑ ICARS

OL, open-label; DBPC, double-blind placebo-controlled; IVS, interventricular septum; LVPW, left ventricule posterior wall; LVMi, left ventricule mass index; EF, ejection fraction; ICARS, international cooperative ataxia rating scale; CAG, Cooperative Ataxia Group; FARS, Friedreich ataxia rating scale; ADL, activities of daily living; ↑ of ataxia scores (ICARS, CAG) indicates worsening.

further assess tolerability and to obtain initial efficacy data. Forty-eight FRDA patients were enrolled in a 6-month, double-blind, placebo-controlled trial. The patients received either placebo or three doses of idebenone (ca 5, ca 15, ca 45 mg kg^{-1}). Urinary 8-hydroxy-2′deoxyguanosine, a peripheral marker of oxidative DNA damage, was chosen as the primary end point. It was not increased in patients and did not significantly change during treatment. The secondary endpoints included change in the ICARS, the Friedreich ataxia rating scale (FARS), and a survey of activities of daily living (ADL). After 6 months of treatment, there was no significant difference among the groups in the degree of change from baseline in the ICARS, FARS, or ADL, even though an indication of dose-dependent improvement was present in the ICARS. A second prespecified analysis excluding patients, who required wheelchair assistance, showed a significant improvement in ICARS and suggested a dose-related response in ICARS, FARS, and ADL scores (**Table 1**). Changes in eye movements and speech contributed the most to the overall change in score. The changes in ICARS and FARS scores at high doses were modest. With regard to safety, one patient receiving the high dose developed neutropenia that resolved shortly after discontinuation of the drug.

Several phase III studies examining high dose idebenone in FRDA are currently underway. A phase III multicenter randomized, placebo-controlled, double-blind study is currently in progress in adult FRDA patients in Europe. FRDA patients will be randomized to one of the same three idebenone doses described above and followed for 1 year. The study will investigate the efficacy of idebenone on hypertrophic cardiomyopathy, as measured by LVM index, and on neurological signs, as measured by ICARS. A shorter 6-month, phase III trial in pediatric patients is in progress in the US. This trial uses a midrange dosage (450–900 mg day^{-1}) and a high dosage (1350–2250 mg day^{-1}), according to body weight $\leq$45 kg or $>$45 kg. The primary endpoint of this trial is the ICARS score. New quinone analogues such as mito-Q are promising molecules but have not yet been tested in clinical trials.

Immunophilin Ligands

J P Steiner and N J Haughey, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

Glossary

Cyclophilin – Cyclic undecapeptide, a high-affinity receptor for the immunosuppressant cyclosporine A.
FK506 – Macrolide antibiotic with immunosuppressant activity, prototypic ligand for FKBP immunophilins.
FKBP – FK506 binding protein, a high-affinity receptor for the immunosuppressant FK506.
GPI 1046 – 3-(3-Pyridyl)-1-propyl (2S)-1-(3,3-dimethyl-1,2-dioxopentyl)-2-pyrrolidinedinecarboxylate, a nonimmunosuppressant immunophilin ligand.
Immunophilin – FKBP and cyclophilin, the high-affinity receptor proteins for immunosuppressants FK506 and cyclosporine respectively.

Definition and History

Immunophilins are ubiquitous cellular proteins that display a peptidylprolyl cis–trans isomerase (PPI'ase) enzymatic activity and are broadly classified into two major groups: the cyclophilins (cyclosporine A binding protein; CyP) and the FKBPs (for FK506 binding protein). These immunophilin proteins, named for their interactions with the immunosuppressant molecules cyclosporine A and FK506, respectively, catalyze the rotamerization of X-Proline bonds in proteins. The FKBPs are often listed as FKBP, followed by the apparent molecular weight of the protein, such as FKBP 12. Numerous FKBP proteins have been characterized in humans, including FKBP 12, 12.6, 13, 25, 36, 38, 51, 52, 63, 65, and FKBPL protein. These FKBPs have very different functions and act as calcineurin inhibitors, molecular chaperones, and endoplasmic reticulum, nuclear, and mitochondrially targeted proteins. The cyclophilins include cyclophilin A, B, C, D, E, F, H, 40, and NK, which are localized to cytoplasm, nuclear, and microsomal fractions, and also have diverse functions as listed earlier for the FKBP immunophilins.

The mechanism of immunophilin-mediated immunosuppression regulated by FK506 and cyclosporine A (CsA) is now well understood. Although FK506 and CsA are structurally very distinct, both interact with their respective immunophilin protein and then target and inhibit the protein phosphatase, calcineurin. Calcineurin inhibition regulates transcription of genes for interleukin-2 (IL-2) protein and blocks Ca^{2+}-dependent signaling pathways in T-cells. Initially, it was thought that the FK506-FKBP12 and CsA-CyPA binding, and the subsequent inhibition of the immunophilin's PPI'ase activity, was responsible for immunosuppression, but synthetic derivatives of FK506, while potent PPI'ase inhibitors, were not able to inhibit T cell proliferation. Thus, inhibition of the PPI'ase activity of the immunophilin was not required for immunosuppression.

Neuroprotective/Neuroregenerative Effects

Immunophilin proteins, such as FKBP12, are highly enriched in the nervous system and are distributed with their target proteins, suggesting that they may perform a significant function in the brain. In early studies in neuronal cultures, Dawson and colleagues demonstrated that the immunosuppressive drugs FK506 and CsA protected primary cortical neurons from glutamate toxicity with nanomolar potency. The proposed neuroprotective mechanism of action of FK506 in these cultures was to maintain neuronal NOS in a highly phosphorylated and therefore inactive state. These effects on NOS were mediated primarily via calcineurin inhibition, since the neuroprotective effects of FK506 were antagonized by rapamycin, an FK506 antagonist. Low nanomolar concentrations of FK506, CsA, and rapamycin promoted neurite outgrowth from PC12 cells, rat sensory ganglion cells, and hippocampal neurons, demonstrating a neurotrophic and neuroregenerative action of these compounds.

The neurotrophic and immunosuppressive effects of FK506 and CsA were separated when nonimmunosuppressive derivatives of each compound were similarly neuroprotective. The prototypic nonimmunosuppressive immunophilin ligand, GPI1046, elicited an increased neurite outgrowth from embryonic and adult sensory neuronal explant cultures. GPI-1046 also protected organotypic spinal cord cultures of motor neurons from excitotoxic lesions and promoted survival of mesencephalic dopamine neurons from cell death induced by MPP+ and 6-OHDA. In SY5Y neuroblastoma cells, Gold and colleagues found that FK506 and FK1706 promoted neurite outgrowth. The work of Costantini and Isacson demonstrated a significant effect of FK506 and V-10 367 on increased neurite length in mesenchephalic dopamine neurons and protection against MPTP and 6-hydroxydopamine (6-OHDA) in rodents. More recent studies including JNJ460 and FK1706 demonstrate the neuroprotective effects of these immunophilin ligands in vitro and in vivo.

Parkinson's Disease Models

Immunophilin ligands have demonstrated significant neuroprotective and neuroregenerative actions in animal models of Parkinson's disease. In mouse MPTP models, both FK506 and GPI 1046 afforded a significant protection of dopaminergic cells, which was accompanied by increased striatal dopamine levels. Remarkably, when GPI1046 treatment was initiated after 90% of nigrostriatal DA neuron degeneration had occurred, a significant increases in tyrosine hydroxylase (TH) immunostaining in the striatum of lesioned mice was measured. These effects were the result of regenerative actions of the GPI1046, since the nigral cell counts following drug treatment were unchanged. In the 6-OHDA model of Parkinson's disease, significant increases in striatal TH immunoreactivity were found in rats treated with GPI1046 up to 1 month after lesioning. The protective effects of GPI1046 on sparing dopamine neurons and striatal innervation by dopaminergic projections were also evident in MPTP-lesioned rhesus monkeys. In this study, the GPI1046, administered prior to and during MPTP infusion, resulted in the protection of dopaminergic cell bodies in SNc and in improved clinical rating scores when all of the treated animals were evaluated as one treatment group compared with MPTP/Vehicle control, even though individual dose groups were not significantly neuroprotective.

Effects on Peripheral Nerve Models

Immunophilin ligands (FK506, L-685818, GPI1046, V-13670, FK1706) also demonstrated significant effects when evaluated in rats with crushed sciatic nerves, where immunophilin ligand treatment resulted in an increased number of larger-sized axons, significantly increased myelination levels and a more rapid functional recovery of the injured hindlimb following immunophilin ligand treatment. In a rodent cavernous nerve crush model that mimicked the urogenital nerve damage that occurs as a result of radical prostatectomy surgery, these immunophilin compounds have also demonstrated a striking neuroprotective efficacy.

Potential Neurotrophic/Neuroprotective Mechanism(s) of Action

The neurotrophic/neuroprotective mechanism of action of immunophilin ligands remains unclear. Some of the effects of FK506 and CsA may be mediated by the inhibition of calcineurin. The nonimmunosuppressive compounds may have multiple modes of action and multiple FKBPs as targets. FKBP12 is not likely the primary target, since neurotrophic effects of FK506 and GPI1046 persist even in neuronal cultures devoid of FKBP12. Instead, the neurotrophic target of these compounds may be FKBP52 via steroid hormone signaling, since FKBP52 is an integral part of the unliganded steroid hormone receptor. Activation of these receptors by steroid ligand causes dissociation of FKBP52 from the receptor complex and may lead to activation of MAP and ERK kinases. Addition of FK506 and GPI 1046 to neuronal cells in culture leads to upregulation of heat shock proteins 70 and 27, which in turn may provide cytoprotective effects.

Tanaka's studies show that treatment of neurons and glial cells in culture and intact animals with these compounds has demonstrated heightened levels of the

antioxidant glutathione, thus reducing the level of reactive oxygen species. In addition, treatment of neurons in culture and MPTP-intoxicated mice with FK506 and GPI 1046 resulted in increased levels of neurotrophins, BDNF and GDNF in dopamine neurons, within the nigrostriatal pathway.

Recently, two immunophilin proteins, FKBP12 and 52, were found to interact with multiple distinct transient receptor potential (Trp) C channels and modulate calcium influx. Immunophilin ligands can dissociate interactions and restore calcium homoeostasis. These results suggested that immunophilins are TRPC channel accessory proteins that play an important role in the mechanism of channel activation following receptor stimulation.

Lastly, Fischer and colleagues have discovered that immunophilin ligands may target FKBP 38 and calmodulin to elicit their neuroprotective effects. They found that GPI 1046 treatment disrupted the interaction of FKBP-38/calmodulin with the antiapoptotic protein Bcl-2, at the mitochondrial outer membrane. By promoting the dissociation of the FKBP38-Bcl-2 complex, GPI 1046 treatment freed Bcl-2 to interact with and bind up all of the apoptotic BH3-containing proteins, such as Bad, Bax, and Bak. The projected beneficial role of immunophilin ligands in this model then was to facilitate Bcl-2 mediated antiapoptotic effects.

Indirect Pathway

J W Bogenpohl and Y Smith, Emory University, Atlanta, GA, USA

Glossary

Axon collateral – A side branch of a neuronal axon that can give rise to multiple terminals either in the main target structure of the axon, in a secondary structure, or in the structure from which the axon originates.

Basal ganglia – A group of interconnected subcortical nuclei, including the striatum, globus pallidus, subthalamic nucleus, and substantia nigra, that play a role in motor, limbic, and cognitive functions.

Dopamine – A monoamine neurotransmitter produced mainly in the substantia nigra and ventral tegmental area, known to be important for motor control, reward, and learning; it stimulates two families of receptors: the excitatory D1 family and the inhibitory D2 family.
Dyskinesia – Abnormal involuntary movements commonly associated with progressive motor side effects of chronic administration of dopaminergic drug treatments for Parkinson's disease.
GABA – γ-Aminobutyric acid, the main inhibitory neurotransmitter in the central nervous system.
Parkinson's disease – The second most common neurodegenerative disease, after Alzheimer's disease, characterized by severe, often idiopathic, degeneration of the nigrostriatal dopaminergic projection. Symptoms include bradykinesia, akinesia, muscle rigidity, resting tremor, cognitive impairment, and depression.

Definition

Indirect pathway is a major route of information flow through the basal ganglia circuitry. The classical view of the indirect pathway relies on the following connectivity network. Extrinsic information from the cerebral cortex and thalamus enters the basal ganglia circuits via the striatum (input nucleus), reaching D2 dopamine receptor-containing GABAergic medium spiny neurons (MSN), which send projections to the external globus pallidus (GPe). In turn, the GPe extends a massive GABAergic projection to the subthalamic nucleus (STN), which then provides glutamatergic innervation of the basal ganglia output nuclei, the internal globus pallidus (GPi), and the substantia nigra pars reticulata (SNr). Collateral projections of pallidosubthalamic axons that end in the GPi and SNr, without a relay in the STN, are also part of this system. The indirect pathway is parallel to the 'direct pathway' of the basal ganglia, in which D1 dopamine receptor-containing striatal neurons project directly to the GPi/SNr. The following discussion will pertain to different basal ganglia nuclei that are part of the primate indirect pathway; subtle differences exist in rodents.

Striatum

More than 90% of the total striatal neuronal population is made up of one main type of projection neuron, called MSN, because their distal dendrites are densely covered with spines. Striatal MSNs can be divided equally into two groups based on their distinct chemical phenotypes and main projection targets. Indirect pathway (GPe-projecting) MSNs preferentially express D2 dopamine receptors, adenosine A2A receptors, and the neuropeptide enkephalin, whereas direct pathway (GPi/SNr-projecting) MSNs preferentially express D1 dopamine receptors and the neuropeptides substance P and dynorphin. Other subtle, though functionally important, differences exist in the physiology and morphology of direct and indirect pathway MSNs. D1-containing MSNs are less excitable than D2-containing MSNs, which is likely due to the larger dendritic area of D1-containing MSNs.

The segregation between these two populations of striatal MSNs has been challenged based on evidence for significant coexpression of D1 and D2 dopamine receptors in subsets of striatofugal neurons and the existence of axonal projections from individual MSNs that innervate both the GPe and GPi/SNr. The exact degree of functional segregation and the significance of D1/D2 coexpression remains a controversial issue that generates continued interest in basal ganglia research. It is also important to note that direct and indirect pathway MSNs communicate with each other via local axon collaterals in the striatum.

In any case, indirect pathway striatal neurons project preferentially to the GPe in a topographic fashion, where they form dense bands of axon terminals that completely ensheath the dendritic tree of pallidal neurons with GABAergic symmetric synapses, thereby providing the most massive inhibitory input to the GPe.

External Globus Pallidus (GPe)

The next step in the indirect pathway is the projection from the GPe to the STN. However, this projection is not a simple linear connection, but rather made up of a highly collateralized set of axons that connects the GPe not only with the STN, but also with the GPi, SNr, or both. In nonhuman primates, four major types of GPe projection neurons have been characterized based on their projection targets. About half of all GPe neurons project to the STN and SNr, while the remaining half is split about evenly between neurons projecting to the STN and GPi; the STN, GPi, and SNr; or to the striatum. Most GPe projection neurons also give rise to local axon collaterals that terminate on the cell bodies of other GPe neurons.

Projection neurons of the first, most prevalent type send axons that form a highly focused, dense field of terminals that innervate the whole extent of the somatodendritic domain of individual STN neurons. Axon collaterals from this projection descend into the SNr, where they form dense pericellular baskets around the somata of SNr output neurons. The next two types of GPe projection neurons follow a similar path, creating highly focused pericellular projections to GPi output neurons. These GPe projections are distributed in a highly specific and topographic fashion with respect to functional regions in the target structures. A specific subset of GPe neurons

also sends reciprocal connections to the striatum that terminate in a widespread fashion throughout the structure, where they give rise to GABAergic terminals that preferentially target interneurons, at least in rodents.

Subthalamic Nucleus (STN)

The final step in the indirect pathway is the glutamatergic projection from the STN to the output nuclei. Like other projections in the indirect pathway, STN projection neurons have axons that collateralize and terminate in multiple structures. In addition to GPi and SNr, STN efferents contact the striatum, the substantia nigra pars compacta, the pedunculopontine nucleus, the spinal cord, and send reciprocal projections to the GPe. In nonhuman primates, the most common types of STN projection neurons are those collateralizing to both GPi and GPe (comprising about half), followed by neurons contacting GPe, GPi, and SNr (comprising about 20%), striatum only (~17%), and GPe only (~10%). The STN terminals have a similar morphology in all target nuclei and form asymmetric synapses with dendrites and perikarya. The STN projections to the output nuclei and GPe are highly topographic and functionally organized such that neurons related to the same functional modality remain connected through segregated loops. In addition to the striatum, the STN is another site of entry of extrinsic information into the basal ganglia circuitry, receiving direct inputs from the cerebral cortex (so-called the 'hyperdirect pathway'), thalamus, and brainstem.

Indirect Pathway Neurons and Basal Ganglia Disorders

Imbalanced activity between the indirect and direct striatofugal pathways is one of the key pathophysiological features of Parkinson's disease (PD). In patients with PD, degeneration of the nigrostriatal dopaminergic projection oppositely changes the level of activity in 'direct' versus 'indirect' striatal MSNs, due to their differential expression of dopamine receptors. D1-containing direct pathway neurons, which are normally excited by dopamine, decrease their activity, whereas D2-containing indirect pathway MSNs, normally inhibited by dopamine, display an increased activity in PD. The increased striatal GABAergic outflow to the GPe reduces inhibitory pallidal influences on the STN which, in turn, provides an increased glutamatergic drive to the output nuclei. Together with the decreased inhibition from the direct pathway, this increased glutamatergic drive from the STN leads to an overactive inhibitory basal ganglia outflow to thalamocortical neurons, thereby contributing to reduced motor cortex activity and inhibition of voluntary movements (**Figure 1**).

Current pharmacological treatments for PD largely focus on replacing the diminished striatal dopamine in order to balance the activity between the direct and indirect pathways. However, long-term dopamine therapy often results in the progressive development of dyskinesias and other nonmotor side effects. Consequently, intensive ongoing research aims at testing nondopaminergic drugs that could normalize the activity of the basal ganglia

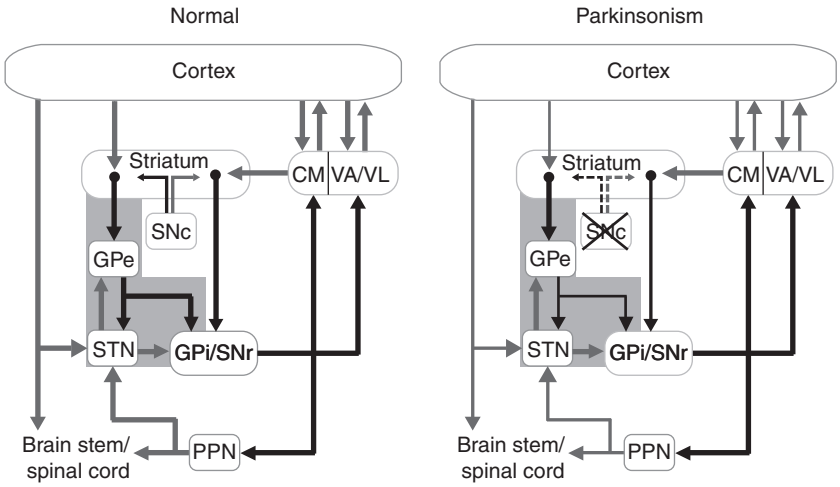

Figure 1 Schematic diagram of the basal ganglia under normal and parkinsonian conditions. Black arrows represent inhibitory projections, and gray arrows represent excitatory projections. In the parkinsonian condition, the weight of the arrows represents the level of neuronal activity relative to the normal state. The connections that makes up the indirect pathway are shaded in gray. CM, centromedian thalamic nucleus; GPe, external globus pallidus; GPi, internal globus pallidus; PPN, pedunculopontine nucleus; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus; VA/VL, ventral anterior/ventral lateral thalamic nuclei. output nuclei. Although an optimal compound remains to be developed, there is good preclinical and clinical evidence that the antagonism of adenosine A_{2A} receptors, which are selectively expressed on indirect pathway MSNs, is a good strategy to reduce Parkinsonian motor symptoms. In addition, knowledge gained from many years of electrophysiological and anatomical studies in animal models has lead to development of surgical interventions for PD aimed at lesioning or stimulating the STN or GPi.

Huntington's disease (HD) is a genetic disorder in which a mutation in the huntingtin protein leads to protein aggregation and death of striatal MSNs (as well as cortical neurons), resulting in chorea, psychiatric problems, cognitive decline, and eventually death. Postmortem studies from HD brains showed that indirect pathway neurons are more sensitive to degeneration than direct pathway neurons, which could explain the chorea and unwanted movements seen in HD; a situation, opposite to that in PD, where an underactive indirect pathway leads to reduced inhibitory basal ganglia outflow to thalamocortical neurons, thereby increasing cortical excitability and problems controlling movements.

Inflammation and Parkinson's Disease

M Vila, Vall d'Hebron Research Institute-CIBERNED and Catalan Institution for Research and Advanced Studies (ICREA), Barcelona, Spain

Glossary

BDNF – Brain-derived neurotrophic factor is a trophic factor that can be released by glial cells and that can support the survival of dopaminergic neurons.

GDNF – Glial cell line-derived neurotrophic factor is a potent neurotrophic factor that can be released by reactive astrocytes and activated microglia and protects catecholaminergic neurons from toxic damage and induces fiber outgrowth.

Glial cells – Glial cells are nonneuronal cells that represent at least half the volume of the human brain and outnumber neurons by about ten to one. Glia is mainly composed of macroglia, which includes astrocytes and oligodendrocytes, and microglia. Glial cells have traditionally been considered to provide structural support and nutrition to neurons. However, it is now known that glial cells are also critical for the development of the nervous system and have a wide range of functions, including the control of synapse formation and function, the regulation of brain vasculature and blood–brain barrier or the optimization of environmental conditions for neuronal function.

LPS – Lipopolysaccharide are large molecules constituted by a lipid and a polysaccharide joined by a covalent bond that are found in the outer membrane of gram-negative bacteria, act as endotoxins and elicit strong inflammatory responses in animals.

MPTP – 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine is a by-product of the chemical synthesis of a meperidine analog, with potent heroin-like effects, that can induce a parkinsonian syndrome in humans and nonhuman primates almost indistinguishable from PD on both clinical and neuropathological standpoints. Over the years, MPTP has been used in a host of different animal species, especially in mice, to recapitulate the hallmark of PD cellular pathology, namely the degeneration of the nigrostriatal dopaminergic pathway.

NOS – Nitric oxide synthase is the enzyme of synthesis of nitric oxide (NO), a short-lived, endogenously produced gas that acts as a signaling molecule in the body. So far, three distinct NO-synthesizing isoenzymes have been purified and molecularly cloned: neuronal NO synthase (nNOS), inducible NOS (iNOS), and endothelial NOS. nNOS is the main NOS isoform in the brain, as its catalytic activity and protein are identifiable throughout the central nervous system. In contrast, iNOS normally is not or is minimally expressed in the brain. However, in pathological conditions, iNOS expression can increase in brain glial cells and invading macrophages in response to a variety of injuries. Endothelial NOS is mainly localized in the endothelium of blood vessels and to a minimal extent in different discrete regions of the brain.

ROS – Reactive oxygen species such as superoxide and hydroxyl radicals are constantly produced during normal cellular metabolism, primarily as by-products of the mitochondrial respiratory chain. At high levels, however, these species may damage cellular components, including lipids, proteins and DNA, leading to cellular dysfunction and cell death.

Definition and History

The loss of nigral dopaminergic neurons in PD has long been associated with a marked inflammatory response, mainly composed of activated microglial cells and reactive astrocytes. Astrocytes are crucial to the homeostatic control of the neuronal extracellular environment, while microglia are the most efficient and aggressive phagocytes of the central nervous system. In contrast, oligodendrocytes, which are involved in the process of myelination, have not been so far implicated in PD. In addition to the glial response, T-lymphocyte infiltration has also been identified in PD, indicating an involvement of the adaptive immune system in the inflammatory process seen in the disease.

The glial response in PD was initially regarded as irrelevant to the pathogenic process of the disease. More recently, however, human epidemiological studies have suggested that inflammation may increase the risk of developing PD. In addition, studies in experimental PD models have shown that the inflammatory response can modulate nigrostriatal dopaminergic neuronal death. In particular, it is believed that inflammatory events secondary to the initial neuronal damage could influence the fate of compromised neighboring neurons, thus contributing to the amplification and progression of the neurodegenerative process.

Inflammatory Reaction in PD

In normal brains, resting astrocytes and microglial cells are not evenly distributed. The density of microglial cells is remarkably higher in the substantia nigra compared to any other brain region. In contrast, the density of astrocytes is moderate in the substantia nigra and higher in areas least affected by PD, such as the gray substance.

In PD, glial reaction occurs in both substantia nigra pars compacta (SNpc) and striatum. However, while the damage to dopaminergic elements is consistently more severe in the striatum than in the SNpc, the response of glial cells is consistently more robust in the SNpc than in the striatum. This discrepancy probably reflects the fact that dopaminergic structures are in dominance in the SNpc, whereas in the striatum dopamine synapses represent only a small percentage (about 10–15%) of the entire pool of synapses.

Regarding the magnitude of the astrocytic and microglial responses occurring in PD, SNpc postmortem PD samples only exhibit a mild increase in the number of astrocytes, most of which appear with a resting-like morphology with thin and elongated processes, with only a few having a true reactive aspect with hypertrophic cell body and short processes. In contrast, the activation of microglial cells in PD is consistently more dramatic. Using positron emission tomography imaging techniques, widespread microglial activation can be detected in living PD patients. Microscopical examination of postmortem PD samples indicates that the microglial response in the SNpc mostly occurs in the subregions most affected by the neurodegenerative process. Moreover, activated microglial cells are predominantly found in close proximity to free neuromelanin in the neuropil and to remaining neurons, onto which they sometimes agglomerate to produce an image of neuronophagia.

In addition to the glial reaction, a marked accumulation of CD8+ and CD4+ T lymphocytes has been observed in the SNpc of PD patients, either in close contact with blood vessels or having migrated deep into the brain parenchyma close to neuromelanin-containing dopaminergic neurons.

Similar to sporadic PD, postmortem examination of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-intoxicated individuals also reveals a marked glial reaction

in the SNpc, the magnitude of which seems to parallel that of dopaminergic neuronal loss. In these autopsy cases, the SNpc exhibits both reactive astrocytes and activated microglial cells, as well as images of neuronophagia, indicative of an active, ongoing process of cell death, even if the acute intoxication with MPTP occurred several years before. These results indicate that a single acute insult in the SNpc could set in motion a self-sustaining cascade of molecular events with long-lasting deleterious effects on dopaminergic neurons.

While human postmortem studies do not provide information about the temporal relationship between inflammatory reaction and dopaminergic neuron cell death, experiments in MPTP-intoxicated mice indicate that reactive astrocyte formation parallels dopaminergic degeneration in both the striatum and the SNpc and that it remains increased even after the main wave of neuronal death has occurred. In contrast, activation of microglial cells in MPTP-intoxicated mice occurs much earlier than that of astrocytes and reaches a maximum before the peak of dopaminergic neurodegeneration. These results indicate that the response of both astrocytes and microglial cells in the SNpc occurs within a timeframe compatible with these glial cells to influence the fate of dopaminergic neurons following MPTP intoxication, and possibly in PD. When compared with the time course of glial cell activation, the T cell brain infiltration following MPTP intoxication to mice was found to arise after the increase of microglial cells and concomitantly with astrogliosis. Such dynamics are compatible with a possible role of activated microglial cells in the brain region-specific recruitment of T cells.

Role of Inflammation in PD

Studies in experimental models of PD have demonstrated that inflammation may have either neuroprotective or neurotoxic effects on dopaminergic neurons.

Neuroprotective Effects of Inflammation in PD

Various types of glia and T cells can provide trophic factors that are essential for the survival of dopaminergic neurons. Among those, glial-derived neurotrophic factor (GDNF), which can be released by reactive astrocytes and activated microglia, seems to be the most potent factor in supporting SNpc dopaminergic neurons during their period of natural developmental death in postnatal ventral midbrain cultures. Moreover, ablation of GDNF in adult mice results in pronounced catecholaminergic cell death, mostly affecting the locus coeruleus and the substantia nigra, thus indicating that GDNF is indispensable for adult catecholaminergic neuron survival. Intracerebral administration of GDNF induces dopaminergic nerve fiber sprouting in the injured rodent striatum and has been shown to attenuate dopaminergic neuronal death and to boost dopaminergic function within injured neurons in both MPTP-treated monkeys and mice. In PD patients, however, repetitive intraventricular injections of recombinant GDNF has been poorly tolerated and failed to halt the progression of the disease. Brain-derived neurotrophic factor (BDNF) and mesencephalic astrocyte-derived neurotrophic factor (MANF) are other trophic factors that can also be released by glial cells and that can support the survival of dopaminergic neurons.

Glial cells could also exert a neuroprotective effect in PD by scavenging toxic compounds released by dysfunctional and dying neurons. Dopamine can produce reactive oxygen species (ROS) through different routes, and glial cells may protect remaining neurons against the resulting oxidative stress by metabolizing dopamine via monoamine oxidase-B and catechol-*O*-methyltransferase present in astrocytes, as well as by detoxifying ROS through the enzyme glutathione peroxidase, which is detected almost exclusively in astrocytes.

Finally, glia can take up extracellular glutamate, which could mitigate the presumed excitotoxic effects resulting from the hyperactivity of the subthalamic input into the substantia nigra that occurs in PD.

Deleterious Effects of Inflammation in PD

Many compelling findings indicate that glial cells, in particular activated microglia, could be harmful for dopaminergic neurons in PD. Stereotaxic injection of bacterial endotoxin lipopolysaccharide (LPS) into the SNpc causes a strong activation of microglia throughout the substantia nigra, followed by a marked degeneration of dopaminergic neurons. Conversely, pharmacological inhibition of microglial activation prevents LPS-induced SNpc neuronal death.

Activated microglial cells can produce a variety of noxious compounds, including ROS, reactive nitrogen species, proinflammatory prostaglandins, and cytokines. Significant attention has been given to reactive nitrogen species, due to the prevalent idea that nitric oxide (NO)-mediated nitrating stress could be pivotal in the pathogenesis of PD. So far, however, none of the characterized isoforms of nitric oxide synthase (NOS) has been identified in SNpc dopaminergic neurons. In contrast, numerous glial cells in the SNpc of both PD patients and MPTP-treated mice express high levels of inducible NOS (iNOS). This NOS isoform, upon its induction, produces high amounts of NO for a prolonged period of time, as well as superoxide radicals, two reactive species which can either directly or indirectly promote neuronal death by inflicting oxidative damage. Supporting an instrumental role for glial-derived NO in PD, ablation of iNOS in mutant mice has been shown to attenuate MPTP-induced neurodegeneration.

Another major source of glial-derived ROS emanates from the microglial enzymatic complex NADPH-oxidase, which upon its induction and activation can produce large amounts of superoxide radicals. NADPH-oxidase is activated in the SNpc of both PD patients and MPTP-intoxicated mice and its genetic inactivation has been shown to attenuate MPTP-induced neurodegeneration in mice.

Prostaglandins and their synthesizing enzymes, such as cyclooxygenase type 2 (Cox-2), constitute a second group of potential deleterious effectors of inflammation. In both PD and MPTP-intoxicated mice, the expression of Cox-2 and its products, such as prostaglandin E2, is significantly increased. In MPTP-injected mice, Cox-2 is induced via a c-Jun N-terminal kinase-dependent pathway, the blockade of which, like that of Cox-2 itself, has been shown to attenuate neurodegeneration.

A third group of glial-derived compounds that can inflict damage in PD is constituted by proinflammatory cytokines, several of which, such as tumor necrosis factor-α and IL-1b, are increased in both SNpc tissues and cerebrospinal fluid of PD patients. These cytokines may act in PD by stimulating the activation of other astrocytes and microglia, thus amplifying the inflammatory response, or by directly binding to specific cell surface cytokine receptors in dopaminergic cells, leading to the activation of apoptotic molecular pathways in these neurons.

A deleterious role of the adaptive immune response has also been reported in experimental PD models. For instance, MPTP-induced dopaminergic cell death is markedly attenuated in the absence of mature T lymphocytes in immunodeficient mouse strains. This protection is specifically associated with a lack of CD4+, but not CD8+, T cells. In addition, PD-associated oxidative protein modifications, such as nitration of α-synuclein, can create novel antigenic epitopes capable of a peripheral adaptive T cell response that exacerbates MPTP-induced nigrostriatal degeneration in mice.

In order to reconcile the inherent protective role of glial cells with a potential detrimental action, it has been proposed that, during normal aging or in pathological situations, glial cells may become progressively disabled and lose their functional capacity to support neurons, which would consequently result in neuron cell death. Whether such a scenario is relevant to PD, however, remains to be determined.

Therapeutic Implications

Potential therapeutic strategies for PD based on targeting inflammation should aim at balancing the protective versus the deleterious roles of glial cells.

If the effects of inflammation in PD are mainly considered as deleterious, then attempts to prevent the glial reaction, and more specifically microglial activation, may be envisaged. Along this line, several preclinical studies in MPTP and 6-OHDA models of PD have succeeded in attenuating dopaminergic neurodegeneration by preventing microglial activation with a variety of agents, including the antibiotic minocycline, the peroxisome proliferator-activated receptor-γ agonist pioglitazone, the vasoactive intestinal peptide, and some opiate receptor antagonists. Alternatively, potential therapeutic strategies could be aimed at blocking the effects of specific proinflammatory mediators, such as iNOS-derived NO or NADPH-oxidase-derived ROS.

Other strategies aiming at targeting the adaptive arm of the immune system in PD may involve the development of vaccines for antigens that promote cell-mediated antiinflammatory responses or the blockade of the migration of immune cells across the blood–brain barrier. For instance, in the MPTP mouse model of PD, immunization strategies with CNS antigens expressed at the lesion site have been shown to reduce dopaminergic neurodegeneration by inducing T cells to enter inflamed CNS tissue, attenuate innate glial immunity, and increase local neurotrophic factor production. These data suggest that vaccination strategies with antigens derived from proteins at the site of neurodegeneration may be potentially used as a therapeutic approach for PD. However, a note of caution is necessary, as the use of proteins that are prone to nitrate modifications can result in a deleterious, rather than protective, peripheral adaptive T cell responses in experimental models of PD.

Conversely, because of the inherent supportive role of glial cells, strategies to boost or preserve glial functions may also be proposed to protect neurons from degenerating. Along this line, it has been reported that the beneficial effect on MPTP-induced behavioral alterations in monkeys obtained by implanting undifferentiated human neural stem cells (hNSCs) in the nigrostriatal pathway may result from the differentiation of hNSCs into GDNF-producing astrocytes rather than its differentiation into dopaminergic neurons. However, whether such a strategy may be applicable to PD remains to be demonstrated.

International Cooperative Ataxia Rating Scale (ICARS)

T Schmitz-Hübsch, Unversitätsklinikum Bonn, Bonn, Germany

Glossary

Ataxia – Literally (Greek) absence of order. Clinically referred to as a specific motor syndrome with difficulty to stabilize the trunk against gravity, difficulty to stabilize gaze, and difficulty in goal-directed limb movements and dysarthria.
Cerebellar sign – Neurological sign attributed to lesions of the cerebellum.
Clinical rating scale – Assessment tool used to document and compare disease status, for example, in clinical trials that are based on a standardized clinical examination of selected disease features. Standardization refers to instructions of test performance and rating.
Outcome parameter – Type of assessment that is chosen to document and compare the effects of an intervention in clinical trials. This can be a clinical scale or any instrumental or laboratory test known to change with disease severity.
Reliability – Accuracy of an assessment tool, that is, how consistent or repeatable the measurements are. For clinical rating scales, reliability is usually documented by good internal consistency and minimal variance between different raters (interrater) or between test and retest.
Sensitivity – Ability of an assessment tool to pick up differences between different disease states. Sufficient sensitivity (or responsiveness) to change over time is a prerequisite for use of a clinical rating scale as an outcome parameter in clinical trials.
Validity – Appropriateness of content of an assessment tool, that is, does it measure what it is intended to measure what it is intended to measure. It is usually documented by good correlations with other assessments of the same construct: for example, a clinical scale supposed to measure disease severity could be compared to other measures known to change with disease severity.

Definition and History

The conduct of multicenter therapeutic trials depends on reliable and sensitive assessment tools. Consequently, clinical rating scales have been established for different diseases for the testing of potential therapeutic agents. Ataxia disorders are diseases characterized by prominent ataxia due to lesions of the cerebellum or its afferent or efferent connnections. In these disorders, ataxia is often

accompanied by other neurological symptoms. Ataxia research has recently focused on the hereditary neurodegenerative ataxias, rare disorders that are clinically and genetically heterogeneous, and are often slowly progressive. For clinical research in ataxia disorders, three clinical rating scales have been published to date: the International Cooperative Ataxia Rating Scale (ICARS), the Friedreich Ataxia Rating Scale (FARS), and the Scale for the Assessment and Rating of Ataxia (SARA). Of these, ICARS, published in 1997, was the first standardized clinical rating scale for ataxia (**Figure 1**).

Development of the Scale

The World Federation of Neurology formed an ad hoc Committee, in 1993, to develop a practical standard tool for the evaluation of cerebellar ataxia suitable for clinical trials. The group aimed to propose a scale that would describe and quantify cerebellar ataxia symptoms, and could be administered in a relatively short time. The authors of the scale acknowledged that the presence of noncerebellar symptoms in ataxia patients (they use the term ataxia as equivalent to cerebellar syndrome) may

International Cooperative Ataxia Rating Scale

I. Posture and gait disturbances

1. Walking capacities
(Observed during a 10 m test including a half-turn, near a wall, at about 1,5 m)

0 normal
1 almost normal naturally, but unable to walk with feet in tandem position
2 walking without support, but clearly abnormal and irregular
3 walking without support but with considerable staggering; difficulties in half-turn
4 walking with autonomous support no longer possible, the patient uses the episodic support of the wall for a 10 m-test
5 walking only possible with one stick
6 walking only possible with two special sticks or a stroller
7 walking only with accompanying person (wheelchair)

2. Gait speed
(Observed in patients with preceding scores 1-3; preceding score 4 and up gives automatically score 4 in this test)

0 normal
1 slightly reduced
2 markedly reduced
3 extremely slow
4 walking with autonomous support no longer possible

3. Stance
(The patient is asked first to try and stay on one foot, if impossible, to stand with feet in tandem position; if impossible, to stand with feet together; for the natural position, the patient is asked to find a comfortable standing position)

0 normal; able to stand on one foot more than 10s
1 able to stand with feet together, but no longer able to stand with feet in tandem position
2 no longer able to stand with feet together, but able to stand in natural position without support, with no or moderate sway
3 Standing in natural position without support, with considerable sway and corrections
4 Unable to stand in natural position without strong support of one arm
5 Unable to stand at all, even with strong support of two arms

4. Spread of feet in natural position without support, eyes open
(The patient is asked to find a comfortable position; then the distance between medial malleoli is measured)

0 normal (<10 cm)
1 slightly enlarged (<10 cm)
2 clearly enlarged (25 cm<spread<35 cm)
3 severly enlarged (>35 cm)
4 standing in natural position impossible

Figure 1 (Continued)

hamper the assessment of ataxia severity. ICARS claims to assess only ataxia, even in the context of a more complex neurological syndrome. Items included in the ICARS were selected according to the assumed specificity for ataxia with reference to the early clinical reports.

Scale Structure

The ICARS is a 100-point, semiquantitative, examination-based clinical assessment of 19 items that are grouped into four subscales: (1) posture/gait disturbance (seven items, maximum 34 points), (2) kinetic functions (seven items, maximum 52 points), (3) speech disorder (two items, maximum eight points), and (4) oculomotor disorder (three items, maximum six points). Kinetic functions are assessed separately for both right and left sides the ratings of which are then added for the proposed subscale score. The subscales are assumed to correspond to anatomically defined regions of the cerebellum concerning the vermis and hemispheres. The authors propose adding the ratings of each subscale to form the subscore for each of the four sections and subsequently,

5. Body sway with feet together, eyes open

0 normal
1 slight oscillations
2 moderate oscillations (<10 cm at the level of the head)
3 severe oscillations (>10 cm at the level of the head), threatening the upright position
4 immediate falling

6. Body sway with feet together, eyes closed

5 normal
6 slight oscillations
7 moderate oscillations (<10 cm at the level of the head)
8 severe oscillations (>10 cm at the level of the head), threatening the upright position
9 immediate falling

7. Quality of sitting position
(Thighs together, on a hard surface, arms folded)

0 normal
1 with slight oscillations of the trunc
2 with moderate oscillations of the trunc and legs
3 with severe dysequilibrium
4 impossible

II. Kinetic functions

8. Knee-tibia test (decomposition of movement and intention tremor)
(The test is performed in the supine position, but teh head is tilted, so that visual control is possible. The patient is requested to raise one leg and place the heel on the knee, then slide the heel down the anterior tibial surface of the resting leg towoards the ankle. On reaching the ankle joint, the leg is again raised in the air to a height of approx. 40 cm and the action is repeated. At least three movements of each limb must be performed for proper assessment)

0 normal
1 Lowering of heel in continuous axis, but the movement is decomposed in several phases, without real jerks, or abnormally slow
2 Lowering jerkily in the axis
3 Lowering jerkily with lateral movements
4 Lowering jerkily with extremely strong lateral movements or test impossible

9. Action tremor in the heel-to knee test
(Same test as preceding one: the action tremor of the heel on the knee is specifically observed when the patient holds the heel on the knee for few seconds before sliding down the anterior tibial surface; visual control is required)

0 no trouble
1 tremor stopping immediately when the heel reaches the knee
2 tremor stopping in less than 10s after reaching the knee
3 tremor continuing for more than 10s after reaching the knee
4 uninterrupted tremor or test impossible

Figure 1 (Continued)

summing all subscores to compute a total score of the ICARS, which reflects a global measure for the severity of ataxia, ranging from zero (= no ataxia) to 100 (= most severe ataxia).

Metric Properties and Validation Studies

The ICARS was originally published without validity assessment. Since then, however, several groups have contributed to validate the ICARS construct and define its metric properties and reliability. These studies are highlighted in this section.

Internal consistency was found to be excellent in a sample of 50 patients with multiple system atrophy, and factorial analysis supported the four subscores of the scale. However, the items nystagmus and Archimedes' spiral had a low factor loading for their subscales and ICARS total. Parkinsonian features such as gait impairment and limb

10. Finger-to-nose test: decomposition and dysmetria
(The subject sits on a chair; the hand is resting on the knee before the beginning of the movement; visual control is required. Three movements of each limb must be performed for proper assessment)

0 no trouble
1 oscillating movement without decomposition of the movement
2 segmented movement in 2 phases and/or moderate dysmetria in reaching the nose
3 segmented m vement in more than 2 phases and/or considerable dysmetria in reaching the nose
4 dysmetria preventing the patient from reaching the nose

11. Finger-to-nose test: intention tremor of the finger
(The studied tremor is that appearing during the proximal ballistic phase of the movement; the patient is sitting comfortably, with his/her hand resting on his/her thigh; visual control is required; three movements of each limb must be performed for proper assessment)

0 no trouble
1 simple swerve of movement
2 moderate tremor with estimated amplitude <10 cm
3 tremor with estimated amplitude between 10 and 40 cm
4 severe tremor with estimated amplitude >40 cm

12. Finger-finger test (action tremor and/or instability)
(The sitting patient is asked to maintain medially his/her index fingers pointing at each other for about 10s, at distance of about 1 cm, at the level of the thorax, under visual control)

0 normal
1 mild instability
2 moderate oscillations of finger with estimated amplitude <10 cm
3 considerable oscillations of finger with estimated amplitude between 10 and 40 cm
4 jerky movements >40 cm of amplitude

13. Pronation-supination alternating movements
(The subject, comfortably sitting on a chair, is asked to rais his/her forearm vertically and to make alternative movements of the hand. Each hand is moved and assessed separately)

0 normal
1 slightly irregular and slowed
2 clearly irregular and slowed, but without sway of the elbow
3 extremely irregular and slowed movement, with sway of the elbow
4 movement completely disorganised or impossible

14. Drawing of Archimedes' spiral on a predrawn pattern
(The subject is comfortably settled in front of a table, the sheet of paper being fixed to avoid artefacts. The subject is asked to perform the task without timing requirements. The same conditions of examination must be used for follow-up: same table, same pen. The dominant hand is examined. For rating see examples in original publication.)

0 normal
1 impairment and decomposition, the line quitting the pattern slightly, but without hypermetric swerve

Figure 1 (Continued)

bradykinesia seemed to contaminate the ataxia assessment with ICARS in this patient group. In a study of 22 patients with different hereditary ataxias rated using video assessments, interrater and test–retest reliability were high, notably without rater training other than written test instructions. The interrater reliability for ICARS total was higher than that of the subscores, and lowest in the speech subscale. The authors of that study found scoring instructions of the kinetic items potentially confusing. In a sample of 77 Friedreich ataxia patients, only the ICARS total and posture/gait subscore satisfied established psychometric test criteria. Specifically, the criterion of internal consistency was not met by the two items, finger–finger-test and fluency of speech; and the speech and oculomotor subscales had low test–retest reliability. Further evaluations questioned the proposed grouping of the ICARS items into subscales. Thus, the authors of that study questioned the proposed grouping of the ICARS items into subscales and did not recommend the use of ICARS in Friedreich ataxia. Factorial analysis in a different sample of 96 FRDA patients resulted in four factors, but only of them loaded for a single ICARS subscale (oculomotor function).

2 line completely out of the pattern with recrossings and/or hypermetric swerves
3 major disturbance due to hypermetria and decomposition
4 drawing completely disorganised or impossible

III. Speech disorders

15. Dysarthria: fluency of speech
(The patient is asked to repeat several times a standard test sentence, always the same,...)

0 normal
1 mild modification of fluency
2 moderate modification of fluency
3 considerably slow and dysarthric speech
4 no speech

2 clearly saccadic

19. Dysmetria of saccades
(The two index fingers of the examiner re placed in each temporal visual field of the patient, whose eyes are in the primary position; the patient is asked to look laterally at the finger, on the right and on the left; the average overshoot or undershoot of the two sides is then estimated)

0 absent
1 bilateral clear overshoot or undershoot of the saccade

Figure 1 International Cooperative Ataxia Rating Scale.

In the same sample ICARS was correlated with disease duration, and with both SARA and FARS (part III) sum scores. The ICARS was also validated in a sample of 156 spinocerebellar ataxia patients and 8 controls. The mean time to complete the scale was 21 min. Interrater and test–retest reliability were high, and internal consistency was excellent although it increased when the oculomotor items were deleted. Correlations with different functional ratings supported validity. However, factorial analysis again did not support the use of subscores as proposed in the original publication. The authors noted difficulties with overlapping and interdependent ratings in the posture/gait subscale. In conclusion, they questioned the usefulness of the scale for this ataxia patient group, but noted that ratings in a small number of controls differed from the patient group. In an evaluation of scale responsiveness in Friedreich ataxia patients, the effect sizes of the ICARS total were moderate, while the FARS performed superiorly in this respect. One publication supported face validity by association of ICARS total with the expected clinical course after surgery of the cerebellum. Factorial analysis in this sample of 136 patients with focal cerebellar lesions revealed five factors that coincided with the proposed four subscales of ICARS, while the fifth factor accounted for the laterality of the kinetic items. The authors concluded that ICARS subscales may be used in patients with focal cerebellar lesions, whereas in degenerative ataxias, only the ICARS sum score should be reported.

Clinical Trials

The ICARS has been used as a secondary outcome measure in a NIH trial of high-dose idebenone in Friedreich ataxia. In a sample of 47 patients with mean baseline scores of 40.4, mean changes in the treatment and placebo arm over a 6-month interval were reported between 0 and −4.5 (estimates from figures in the original publication). As no treatment effect was detected, these data can be seen as an estimate of the 'natural' progression in Friedreich ataxia. In a prospective 5-year follow-up of 104 Friedreich ataxia patients, yearly ICARS changes were significant with an increase of 4.4 ± 1.6 in 16 untreated subjects and 1.9 ± 0.3 in 88 idebenone-treated subjects. Changes were also significant for all subscores except for the oculomotor subscore in this patient group. Estimates of progression rates were higher in the subgroup with earlier onset, thereby suggesting of higher discriminant ability of the scale in less severely affected patients. Of note, the authors noted a plateau in ICARS ratings despite further clinical deterioration in late-stage (wheelchair-bound) Friedreich ataxia patients. In an observational study in 34 patients with Machado–Joseph disease, a mean yearly increase of +5.1 was found, and progression rates were not dependent on disease duration, age at onset or number of CAG repeat in this sample. The ICARS has been used as a secondary outcome measure in a NIH trail of high-dose idebenone in Friedreich ataxia. As no treatment effect was detected, the mean changes in the treatment and placebo arm over a 6 month interval of 0 and −4.5 (estimates from figures in the original publication) give a different estimate of the "natural" progression in Friedreich ataxia. The ICARS has also been used as a primary outcome measure in several pilot studies of, for example, branched-chain amino acid therapy ($n = 16$), L-carnitine ($n = 16$), and ondansetron ($n = 46$), gabapentin in SCA6 (n = 11), Coenzyme Q10 and vitamine E (n = 50) or idebenone (n = 24) in FRDA. It was chosen as secondary outcome measure for the ongoing pilot study of Lithium in spinocerebellar ataxia type 1 and a phase II trial of high-dose idebenone in FRDA.

Criticism

Although the scale was developed as a general measure for cerebellar ataxia, subsequent validation trials revealed limitations in samples with substantial noncerebellar involvement like multiple system atrophy or some spinocerebellar ataxias. Although the time to administer the scale is acceptable for clinical trials, some difficulties were noted in the test and rating descriptions even by trained raters. Importantly, the proposed subscale structure was not supported by different trials in Friedreich ataxia and spinocerebellar ataxias. Thus, the reporting of subscores does not seem justified in these particular patient groups. In addition, in Friedreich ataxia patients, the scale did not seem to discriminate well in more severely affected patients. Like many other clinical scales, the ICARS is not well characterized in terms of sensitivity to change or clinical relevance of score differences.

Conclusion

ICARS was the first standardized clinical rating scale for ataxia published in 1997 by an international consortium, and is now widely used. Its metric properties were only determined in later studies, and revealed several shortcomings for its use in clinical trials. Some scoring instructions were found potentially confusing, and they underline the need for rater training. The reporting of subscores, though supported in patients with focal cerebellar lesions, may not be well suited for Friedreich ataxia and spinocerebellar ataxia patients. Furthermore, the presence of parkinsonian features may affect the use of ICARS in multiple system atrophy. Therefore, new ataxia scales have recently been developed for ataxia in general (the SARA) or for specific diseases (the Unified Multiple System Atrophy Rating Scale, UMSARS, or the Friedreich Ataxia Rating Scale, FARS) with the aim to address such concerns.

Interspike Interval

E A Christou, Texas A&M University, Kingsville, TX, USA

Glossary

Action potential train – A single action potential is a very large and rapid rise in the cell membrane potential that lasts ~1 ms before the membrane potential returns again close to its resting potential. A train of action potentials refers to consecutive action potentials, which are sometimes referred to as 'spikes.'

EPSP – Excitatory postsynaptic potentials result from excitatory inputs from another neuron or neurons that depolarize the cell membrane (resting potential becomes less negative).

Histogram – It is a graphical display that indicates the proportion of cases that fall into each of several categories (time or frequency bins).

Interspike interval – The time between successive action potentials discharged by a neuron.

Motor unit – The spinal motor neuron and all of the muscle fibers that it innervates.

Motor unit synchronization – When interspike intervals from two motor units are compared, synchronization indexes can be obtained, which reflect the common input from higher centers. These common inputs can be quantified in the time (short-term synchronization) or frequency (coherence) domain.

Definition and History

Interspike interval (ISI) refers to the time between successive action potentials discharged by a neuron. Dr. Edgar D. Adrian (1928) was most likely the first physiologist, who demonstrated that the ISI is a communication tool for the nervous system.

A single action potential is a very large and rapid rise in the cell membrane potential that lasts ~1 ms before the

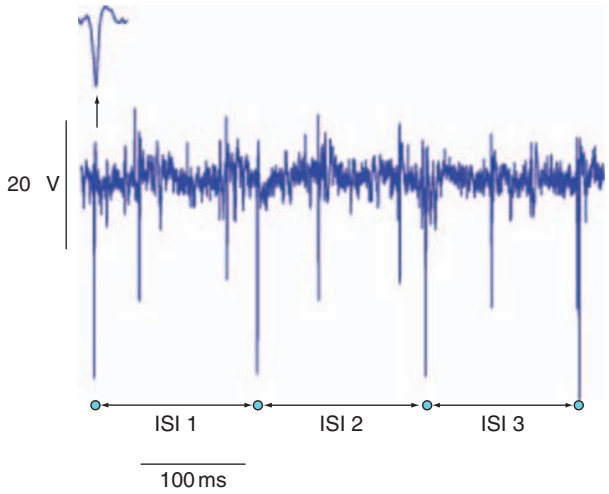

Figure 1 Recording of action potentials from a human motor unit. This recording shows two different motor units recorded at the same time from fine wires inserted into the first dorsal interosseous muscle. The ISI of the motor unit with the largest action potential is identified by quantifying the time between two successive spikes (action potentials).

membrane potential returns again close to its resting potential (∼−70 mV; potential difference between the inside of the cell and the external environment). It typically results from excitatory inputs (EPSP; excitatory postsynaptic potentials) from another neuron or neurons, which depolarize the cell membrane (resting potential becomes less negative). The action potentials (often called 'spikes') propagate along the neuronal axon to reach the nerve terminal to release chemical signals (neurotransmitters) and consequently excite or inhibit other neurons. The train of action potentials is a very important way by which neurons carry information. Therefore, neurophysiologists are interested in the pattern of the action potential discharge. The amplitude of the action potential is not so important, because the cell membrane will either depolarize or not (all-or-none phenomenon).

The simplest way to examine the pattern of the action potential discharge is to record from a single neuron and construct a histogram of the time intervals. In humans, this is typically achieved by recording the extracellular action potentials from a single motor unit using fine wire electrodes placed in the muscle of a subject. Since a motor unit is defined as the spinal motor neuron and all of the muscle fibers that it innervates, the recording of fiber action potential provides a window into the behavior of the spinal motor neuron in vivo. The action potentials that come from the same motor neuron are often discriminated by amplitude and shape algorithms. The time between two consecutive action potentials is calculated (e.g., ISI 1, ISI 2, ISI 3; **Figure 1**) and then a histogram (**Figure 2**(**a**)) is constructed of all the time intervals recorded. For the construction of a good histogram, ∼1000 such time intervals are needed, which would require the recording of

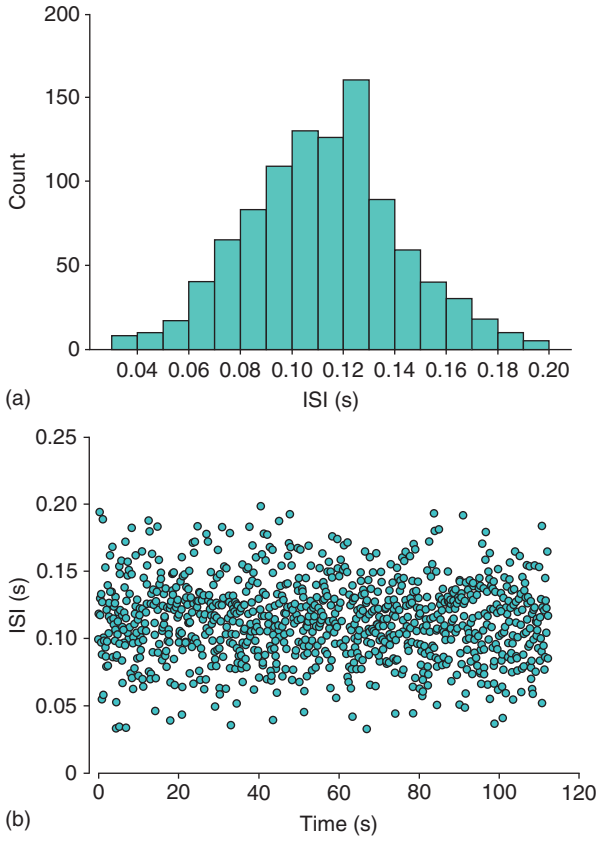

Figure 2 Graphing of ISI, (a) demonstrates a histogram from the recording of a train of action potentials (112 s), whereas (b) shows the ISI as a function of time.

action potentials from 2 to 3 min (assuming an average discharge rate of 6–8 actions potentials per second). Another way to visualize the ISI is to graph it against time (**Figure 2**(**b**)). Basic statistics such as the mean, standard deviation, and coefficient of variation are calculated from the recorded train of action potentials to identify the mean discharge rate and the variability of discharge rate. Furthermore, when ISI from two motor units are compared, synchronization indexes can be obtained. Such synchronization of motor unit discharge times have been attributed to common input that has been delivered to spinal motor neurons either by branched axons from last order neurons or by presynaptic synchronization of efferent fibers from the motor cortex.

Intra-Individual Variability in Movement

K M Newell and S M Slobounov, The Pennsylvania State University, University Park, PA, USA

Glossary

Interindividual variability – The variation from moment to moment or trial to trial that arises from the same individual attempting to perform the same movement or postural outcome.
Noise – The random processes that create the unexplained observed variability in movement and posture. Most behavioral accounts of noise are based on an analysis of the system output that is measured in distributional and frequency properties. There are many different kinds of noise but most analyses of movement variability use white noise when they estimate the levels of system noise.
Tremor – It is an unintentional, somewhat rhythmic, muscle movement involving to-and-fro movements (oscillations) of one or more body parts.

Definition and History

Variability within and between species has been a construct of longstanding theoretical significance in many fields of biology. Nevertheless, in the human movement domain, variability has traditionally been interpreted, largely without experimental examination, as merely noise leaving the theoretical focus to the invariance rather than the variance of movement control. It is only in recent years that the variability of movement in disordered systems has received direct theoretical, experimental, and clinical attention.

There are many measures and interpretations of intraindividual variability in human movement that can also vary with the time scale (within-trial, across trials, and/or movement sessions) over which the intraindividual movement variation is determined. The standard approaches to the analysis of variation used linear measures but more recent analysis of variability, including those in movement disorders, are motivated by the constructs, and hence the measures of nonlinear dynamics and chaos theory.

Measures of Movement Variability

In behavioral motor control, the measures of movement variability tend to focus on three aspects: (1) the outcome of the action in relation to the task goal (the most prevalent); (2) properties of the movement trajectories of the limbs and torso; and (3) coordination measures of the movement relations between body segments. In each category, the intraindividual variability of a movement property can be determined often with multiple indices. Nevertheless, the traditional emphasis to variability has been on the dispersion of the respective movement variable as reflected in distributional descriptive statistics such as standard deviation (SD) and coefficient of variation (SD/M).

A general finding across a range of motor tasks and population groups has been the SD scales with the parameter value of each variable. Thus, the SD of movement outcome and trajectory properties whether measured in space, time, or force tends to be higher as the scaling demands on those respective dimensions are increased. This is the essence of the movement speed-accuracy trade-off, which is a classic example of the scaling of movement variability.

In general, the SD of a movement property, such as peak velocity or movement extent, is s-shaped over the full range of scaling though approximations to linearity in the change of SD tend to be obtained in the middle range of movement scaling. The coefficient of variation (relative variability) of movement properties is, thus, not constant over the full range of movement conditions. This scaling property of the amount of variation over movement conditions leads to the position that the amount of system noise and the structure of movement variability is task dependent.

The time- and frequency-dependent properties of the within-subject variability also provide a way to characterize movement variation as a function of conditions and population group. These measures of the structure of variability provide insight into the nature of the movement variability that can be independent of the dispersion

estimates of the amount of variation. For example, spectral analysis and its variants can provide clues as to the nature of system control through signal decomposition of the frequency regimen. Time-dependent analysis of the sequential structure of variability (autocorrelation, ApEn, SampEn, recurrence) can reveal aspects of the attractor dynamics of the movement or posture time series.

Analysis of the structure of movement variability in either the outcome or the movement trajectory rarely approximates white Gaussian noise (Gaussian amplitude, equal contribution of frequencies, and independence of sequential points). Instead, there is systematic time- and frequency-dependent structure to the movement variability of a time series. Enhanced variation in the time- and frequency-dependent structure is adaptive in some tasks, whereas the opposite is the case in other tasks. Thus, the structure and amount of movement variability, together with their relation, is dependent on the confluence of the performer, environmental, and task constraints.

There is also variation in the coupling between body and limb segments in movement as a function of the different time scales of measurement and movement conditions. Enhanced variation in coupling measures, such as relative phase, has been used as an index of the stability of the motor system and the onset of coordination mode changes. On the other hand, in some tasks, enhanced variability but with covariation between effectors can lead to a reduced amount of variation in the movement outcome. Thus, the direction and nature of change in the variability of coordination measures is also specific to the constraints on action and the movement property investigated.

The variability of movement output has also been related to the variability in the output at other system levels, including muscle (EMG), heart (EKG), and brain (EEG). Indeed, many of the measures and outcomes outlined above for the behavioral aspects of movement can also be applied to these other levels of analysis. A central question has been the degree of coherence in the variability across systems in the execution of posture and movement. Experimental findings show the adaptive- and task-dependent nature to this variability relation within a bounded range and that variability can be adaptive as opposed to necessarily a negative process.

Variation and Theories of Motor Control

It is generally presumed that there is noise at all levels of the sensorimotor system, though measures of variability have been limited to only certain levels of analysis during movement and action. Early physiological and psychological accounts of movement variation, such as in tremor, were signal plus noise models in which the noise was additive to the system output. These models tend to accommodate well the findings on the scaling of amount of movement outcome and trajectory variability but not the systematic changes in the time- and frequency-dependent structure of variability. This is because the variability of motor output is clearly not white noise though a very small contribution of white noise is present in the motor output, including that from the experimenter's measuring instrument(s).

A number of recent studies have shown the structure of the different timescales of movement and posture variability to reflect 1/f-like properties. 1/f noise (pink noise) is a signal or process with a frequency spectrum such that the power spectral density is proportional to the reciprocal of the frequency. White noise with equal frequency contributions is $1/f^0$, brown noise is $1/f^2$, and black noise is $1/f^3$. The exponent can take non integer values leading to what is called fractal noise. 1/f-like noises are prevalent in a range of physical systems and they have been increasingly shown in a range of human performance tasks and movement disorders. These estimates of the noise are on the motor output and it is likely that noise in the system is filtered prior to influencing the movement outcome.

The range of 1/f-like scaling processes in movement and posture variability holds a number of theoretical implications for motor control. It provides evidence against the simple signal plus noise additive models of variation, such as those traditionally postulated for tremor. It reveals interesting mixes of deterministic and stochastic processes that need to be examined more directly in movement and posture variability. It is consistent with the idea that noise is multiplicative rather than additive in system control.

A final point to note is that the measures of the time- and frequency-dependent variability in movement and posture have been shown to be more sensitive to change in clinical movement disorder conditions than standard measures of the amount of variability. The faster time scale of moment-to-moment variation in movement execution reflects a different time scale of influence to the variability of performance than the between-trial variation. In summary, the study of intraindividual variation in movement and posture is revealing new insights into motor control and movement disorders.

J

Jumping Frenchmen of Maine

M J Bakker and M A J Tijssen, University of Amsterdam, Amsterdam, Netherlands

Glossary

Coprolalia – Pathological use of foul language.
Culture-specific syndrome – Forms of abnormal behavior restricted in distribution to defined racial or social groups, discrete areas of the world, or particular historical periods.
Echolalia – Pathological repetition of words just spoken.
Echopraxia – Pathological repetition of the acts of other people.

Definition and History

The Jumping Frenchmen of Maine was first mentioned in an article in the *Journal of Nervous and Mental Disease* from 1880, written by the American physician George Beard. Dr. Beard described 50 cases of French Canadians from the Beauce region, living in the Moosehead Lake region in Maine. According to Beard, the individuals were not able to prevent themselves from starting, striking, dropping, jumping, and repeating words or sounds once another person startled them with sudden exclamations or commands. Some, when addressed quickly in a language foreign to them, would echo the phrase, even to the point of quoting from the Odyssey or Iliad. If one person was suddenly asked to strike another, he would do so without hesitation, even when it was his mother and he had an axe in his hand. Beard felt that the disorder was a 'fixed psychological state,' 'a survival of habits,' and 'a remarkable demonstration of involuntary life.'

The symptoms and classifications of presently living subjects are very similar to Beard's description. The Jumping Frenchmen of Maine is a syndrome consisting mainly of nonhabituating excessive startle responses combined with various behavioral responses like *echolalia*, *echopraxia*, suggestibility, and 'forced obedience' (involuntary, immediate obedience to commands). As the features of the matching behavior and forced obedience are prominent, the Jumping Frenchmen of Maine is also referred to as startle-matching syndromes. There are several other similar syndromes, for example, Latah in Indonesia/Malaysia and Myriachit in Siberia. The clinical details of the three syndromes are given in **Table 1**. For each society affected, the presentation of characteristics varies only slightly. In addition to these three syndromes, there are other rare entities like 'Yaun of Burma,' 'Bah-Tsche of Thailand,' 'Mali-Mali in the Philippines,' 'Lapp panic,' 'The raging Cajuns of Louisiana' (related to the Jumpers of Maine'), 'Ainu in Japan,' 'Leaping ague of Scotland,' 'Tigretetier of Abessynia,' 'Imanenjana of Madagascar,' etc. However, as the literature contains no recent references to them, these syndromes are mainly of historical interest. The Jumping Frenchmen of Maine and other culture-specific startle syndromes are most often classified as a neuropsychiatric startle syndrome, although some authors claim that they are merely cultural phenomena.

Epidemiology

There is no information available other than that the condition is very rare; less than 70 cases have been described. A decreased prevalence of the present-day Jumping Frenchmen of Maine compared with that of the earlier times has been attributed to the reduced boredom and isolation experienced by the lumberjacks.

Pathophysiology

Jumping Frenchmen of Maine, Latah, and Myriachit present with an excessive startle or startle-like response,

Table 1 Culture-specific startle disorders

	Jumping Frenchmen of Maine	*Latah*	*Myriachit*
Gender	M > F	F > M	F > M
Onset	Childhood	Adult	Adult
Familial	Yes	Yes	No
Local terms	Yes	Yes	Yes
Excessive startle-like response	+	+	+
Coprolalia	?	+	?
Echolalia	+	+	+
Echopraxia	+	+	+
Forced obedience	+	+	+

M = male, F = female.

echolalia, *echopraxia*, and forced obedience (involuntary, immediate obedience to commands). Only descriptive, but neither functional nor electrophysiological, studies have been performed in these patients. The neurophysiological background of the excessive startle responses remains, therefore, largely unknown.

The onset, occurrence, and nature of the symptoms in the culture-specific syndromes seem to be influenced by both psychological and cultural factors. There is an ongoing debate on whether culture-specific startle syndromes should be seen as behavioral phenomena belonging in the cultural or anthropological realm or whether they represent a somatic neuropsychiatric disorder in which only the actual expression is open to local cultural influences. There is a striking cross-cultural similarity of behaviors of startle syndromes. The Latah paradox is a term first used by Geertz and refers to the contrast of the connection between Latah behavior and the norms of Malayo–Indonesian culture on the one side and the occurrence of similar syndromes in completely different cultures on the other side. Therefore, in general, an underlying universal neuropsychiatric basis is likely. Gilles de la Tourette saw resemblance between the Jumping Frenchmen of Maine and the syndrome to date known as Gilles de la Tourette. He suggested that the syndromes shared a similar etiology. Nowadays we know that tics are suppressible, in contrast to the initial startle response in culture-specific startle syndromes. However, although a nonhabituating startle response is described to be part of the jumping syndrome this has not yet been confirmed with electromyographical studies. Therefore, similarities in etiology of Gilles de la Tourette and culture-specific startle syndromes should not be ruled out. Yap compared culture-specific startle syndromes with reflex-like fright reactions in German soldiers in the First World War. Heightened arousal or anxiety elicits exaggerated startle responses, and therefore, may indeed explain the symptoms. Accordingly, anxiety or mood disorder symptoms and negative or intense life events are associated with the onset of culture-specific startle syndromes. However, the behavioral features related to the startle response of patients with culture-specific startle syndromes are clearly more complex than in patients with anxiety disorders. The initial brainstem-mediated motor startle response phase, which is roughly uniform from time to time and from individual to individual, is followed by a secondary phase occurring at a longer latency, which shows more variation. This secondary phase contains variable, more complex behaviors, possibly under the influence of psychological factors. It consists of orienting toward the stimulus source by postural adjustments and autonomic changes and may include emotional and voluntary components. A prolonged series of 'orienting' and even vocalizations following a startle response is common and considered normal. Culture-specific startle syndromes may be an abnormal exaggeration of the late, secondary phase of the startle response. Accordingly, a recent observational study described that the startle-associated behavior such as echolalia and forced obedience can be suppressed. (like tics in Gilles de la Tourette). There is evidence suggesting that an exaggerated startle response can be part of a learned response. The 'minor' form of hyperekplexia occurs in families of individuals affected with the 'major' form of hyperekplexia, an organic condition. However, clinically, electromyographically and genetically the 'minor' form differs from the 'major' form. Finally, the behavioral symptoms of the culture-specific startle syndromes may be seen as an exaggerated dependency on the environment for behavioral cues. Such behavior, in the form of utilization and imitation behavior, is also observed in frontal lobe syndromes. Frontal dysfunction has the potential for releasing brain-stem centers normally under inhibitory control, for example, circuits within the brainstem.

Specifically for the French Jumpers of Maine, the occurrence of Jumping Frenchmen is related to specific conditions in lumber camps in the nineteenth and the beginning of the twentieth century. That is, as the isolated life of the French–Canadian lumberjacks was quite boring, jumping seemed to have a clear entertaining function. Beard described that after a long day's work, the loggers engaged in mutual tickling, punching, and startling of the fearful, and he thought that this repeated horseplay eventually resulted in the condition.

Clinical Features and Diagnostic Criteria

There are no clear diagnostic criteria other than the clinically stimulus-induced responses. The individuals

startle excessively to unexpected stimuli, and when startled, may jump, scream or swear, throw objects, strike out at objects or others, assume defensive postures, and obey commands (such as 'dance,' 'jump,' or 'run'). *Echolalia* is also common and *echopraxia* has been described. There is some disagreement whether *coprolalia* is part of the syndrome. Therefore, the swearing following a startle in the jumpers may somewhat different from the blurting of obscene language reported to occur in Latah. Some of the behaviors, such as throwing knifes, striking hot stoves, or jumping into fire, were potentially dangerous or injurious. Jumping is elicited by loud noises, sudden gestures or commands, and unexpected physical sensations such as the sudden arrival of someone from behind. The subjects are typically adult male lumberjacks from the Beauce region of Quebec or from Maine. In contrast to Latah in Indonesia/Malaysia, the Jumping Frenchmen of Maine usually starts in childhood. In six of the eight cases described by Saint-Hilaire, the onset coincided with the start of work as a lumberjack. Similar to Latah in Indonesia/Malaysia, anxiety and depressive symptoms are mentioned as comorbidity simultaneously with the onset of the disorder. The startle responses become more exaggerated with increased frequency of startling.

Prognosis

The condition is usually chronic. Beard described the Jumping Frenchmen of Maine as lasting throughout life.

Differential Diagnosis and Diagnostic Work-up Tests

Detailed history taking will exclude hyperekplexia (major form) and other neurological causes of exaggerated startle reflexes. Further, this may reveal the behavioral features typical of culture-specific startle syndromes. EMG studies for the pattern of the startle reflexes in the Jumping Frenchman of Maine have never been performed, and therefore, have no diagnostic value.

A prominent difference with Gilles de la Tourette is that the Jumping phenomenon is externally driven or stimulus-induced. In contrast, the tics in Gilles de la Tourette syndrome are considered to be due to an internal urge. Further, the onset of Gilles de la Tourette is during childhood. Hysterical jumps, pyschogenic startle, and the minor form of hyperekplexia clinically resemble the culture-specific startle syndromes, but are not culture-specific.

Management

In the past, both serotinergic and dopaminergic agents have been suggested with little effect. As culture-specific startle syndromes are considered neuropsychiatric startle syndromes, psychiatric treatment is indicated. There are a few brief reports describing the effect of psychiatric treatment on neuropsychiatric startle syndromes. The excessive startle reflexes of one patient described as 'latah' (although he did not belong to a certain cultural group) were successfully treated by psychiatric therapy including both suggestion (known to be effective in conversion disorders) and exposure elements (known to be effective in anxiety disorders). Similar treatments are described for (other) psychogenic startle syndromes.

Jumpy Stumps and Phantom Dyskinesias

C Zadikoff, Northwestern University, Chicago, IL, USA

Glossary

Jumpy stump – Sudden, jerking movements of the amputation stumps, often but not always, associated with stump pain.
Phantom dyskinesias – Involuntary movements that the patient perceives to be occurring in the phantom limb itself.
Segmental myoclonus – Brief, involuntary, twitching, or 'shock-like' contractions of a muscle or muscle group innervated by the affected spinal cord segments or peripheral lower motor neurons.

Definition

Jumpy stumps are 'spasms' or sudden jerking movements of the amputation stump.

Phantom dyskinesias refer specifically to involuntary movements (often choreic) that the patient perceives to be occurring in the phantom limb itself, and not just in the amputation stump.

History

Neurological sequelae after amputation have been well described. Commonly, amputees experience stump pain and phantom limb sensation. Much less frequent are persistent, abnormal movements that occur in the amputation stump. These movements have been referred to as 'spasms,' 'jumping,' or 'convulsive movements' of amputation stumps, or '*trepidation du moignon*.' In 1875, Weir Mitchell compiled a group of patients with abnormal amputation stump movements among amputees from the American civil war. Since that time, there have been a few case reports of these types of movements in the literature. When these cases are published, standardized reporting and follow up are often lacking, leaving many questions regarding these movements unanswered.

Pathophysiology

The pathophysiology underlying jumpy stumps remains poorly understood. Some have suggested that these movements are a form of segmental myoclonus. The mechanisms postulated include injury-related structural reorganization of local neuronal circuitry by axonal sprouting, resulting in disinhibited intraspinal reflex pathways or hyperexcitable motor neurons. Others have suggested that the disorder is due to alterations of either cortical or subcortical central nervous system function. Proponents of the concept that peripheral trauma can induce a centrally organized movement disorder often use the example of the postamputation stump movements to support this concept, postulating that peripheral injury alters the processing of afferent sensory input to central cortical and subcortical structures and leads to central reorganization.

Studies have demonstrated changes in both the somatosensory system and in the motor cortex after amputation. There are several experiments involving both primates and humans that have shown that digit amputation causes the cortical representations of adjacent digits to expand topographically and to occupy most of the cortical territories formerly representing the amputated digit. However, firm evidence defining the mechanism underlying peripherally induced movement disorders is still lacking. While the 'jumpy stump' has always been taken at face value to represent an organic entity, at least one case report in the literature suggests that jumpy stumps may also, at times, be psychogenic.

Risk Factors

Because the literature is so sparse, the prevalence of 'jumpy stumps' is unknown and no risk factors other than amputation have been identified. In the cases reported, common (but not uniform) themes include traumatic amputation, infection of the limb and/or amputation stump, central nervous system trauma, and severe pain preceding development of abnormal movements.

Clinical Features

Typically, postamputation stump movements consist of sudden jerking of the stump associated with severe stump pain although abnormal movements in the absence of pain have been reported as well. 'Jumpy stumps' have been reported in lower and upper extremity amputees and are often characterized by alternating flexion and extension or abduction and adduction of the stump. In three

cases, choreic movements have been described. However, two of these cases had movements, aptly termed 'phantom dyskinesias' and the stump movements occurred in the context of tardive dyskinesias in the setting of D2 blocking agents. These cases not only developed choreic movements of the amputation stump, but they also perceived constant choreic movements of the phantom limb itself.

Postamputation stump movements begin at variable time periods following amputation. Sometimes, they occur in the immediate postoperative period, but they may also develop gradually following a variable latent period, with the longest latency from amputation to development of movements reported as 10 years. Most reports do not comment on whether these movements typically persist during sleep, but in at least some cases, movements occur in both wakefulness and sleep. While jerking can occur spontaneously when the stump is at rest, it is usually precipitated by voluntary movement of the stump, and can be triggered by cutaneous stimuli. In one case, talking provoked the movements. Often there are no alleviating factors but some patients report temporary relief by putting pressure on the stump, such as a 'strong vibration on the thigh.' Other modifying maneuvers include applying counter stimulation on the side opposite, a noxious stimulation, and 'vigorously squeezing' the stump. Intense concentration was temporarily helpful in one report, and in one case, clearly thought to be psychogenic in origin, distraction also resulted in the cessation of abnormal stump movements.

Differential Diagnosis

The differential diagnosis of abnormal movements in the stump is limited. Based on appropriate history, seizures may feature in the differential diagnosis.

Diagnostic Work up

No standardized work up has been defined for jumpy stump. A history and detailed examination should include assessment of distractibility, entrainability, and variability in the amplitude and frequency of the movement. Ancillary studies can include electrophysiology, including electromyography (EMG) and multichannel EMG with back averaging, electroencephalography, and spinal and brain MRI.

Management and Prognosis

In most cases, treatment of the jumpy stump is unsatisfactory. The movements can diminish without intervention over time, but in many, the movements persist unabated. Many previously published cases either do not mention treatment trials or report efficacious treatments. In two case reports by the same author, local and epidural anesthesia were temporarily effective, but multiple other interventions including diphenylhydantoin, diazepam, carbamazepine, lumbar sympathetic blockage, intrathecal saline, and direct injection of saline into the sciatic nerve failed to alleviate either the pain or the movements. More recent single case reports have suggested some level of success with baclofen, clonazepam, doxepin, gabapentin, and topiramate. There is a single report of a patient with stump pain and dyskinesias who benefited from centromedian–parafascicular complex thalamic deep brain stimulation. Spontaneous and complete resolution has been reported in only one patient who developed a jumpy stump 3 days postamputation. The movements began to improve 2 weeks later and by 1 year, they had disappeared entirely.

Junctophilin

H Takeshima, Kyoto University Graduate School of Pharmaceutical Sciences, Kyoto, Japan

Glossary

Afterhyperpolarization (AHP) – Hyperpolarizing potential observed in many neurons following a train of action potentials.
Ca^{2+}-activated K^+ channels – K^+-conducting channels activated by increased cytoplasmic Ca^{2+}; classified as small-conductance (SK), intermediate-conductance (IK), and big-conductance (BK) channels.
Ca^{2+}-induced Ca^{2+} release (CICR) – Ryanodine receptor-mediated Ca^{2+} release from intracellular stores, which is usually activated by Ca^{2+} influx.
Junctional membrane complex (JMC) – An ultrastructure showing close association between the endoplasmic reticulum and the plasma membrane, that is a proposed platform for functional communication among intracellular and cell-surface channels and transporters in excitable cells.
Ryanodine receptor (RyR) – Ryanodine-sensitive Ca^{2+} release channel on the endoplasmic reticulum that is usually activated by increased cytoplasmic Ca^{2+}.
Ryanodine – A plant alkaloid that binds to open ryanodine receptor channels.

Definition and History

Junctional Membrane Complex and Junctophilin

The junctional membrane complex (JMC) is characterized by a close association between the plasma membrane (PM) and the endoplasmic/sarcoplasmic reticulum (ER/SR) in excitable cells, and it is a predicted structural platform for functional crosstalk between ionic channels on both membrane systems. In striated muscle, the SR and the transverse tubule of the invaginated PM form JMCs, called the 'triad' in skeletal muscle and the 'diad' in cardiac muscle. Electron-microscopic analysis has also detected JMCs in other excitable cell types, such as the 'subsurface cistern' in neurons and the 'peripheral coupling' in immature striated muscle and smooth muscle. Of several proteins identified from skeletal muscle triads in our screening, junctophilin (JP) contributes to JMC formation. JP is composed of two major parts: a carboxyl-terminal hydrophobic segment that spans the ER/SR membrane, and a remaining cytoplasmic domain that interacts with the PM (**Figure 1(a)**). MORN motifs of 14 amino acid residues appear eight times in the cytoplasmic region and probably bind to phospholipids as membrane components. Indeed, JP effectively constructs JMC similar to the subsurface cistern and peripheral coupling in an amphibian embryonic cDNA expression system (**Figure 1(b)**). To date, four JP subtypes (JP1–JP4) have been identified in mammalian excitable tissues.

During the contraction of striated muscle, JP subtypes are essential for JMC formation to establish the functional coupling between L-type voltage-gated Ca^{2+} channel subtypes (Cav1.1 and Cav1.2) on the PM and ryanodine receptor subtypes (RyR1 and RyR2) on the SR. JP1 is predominantly expressed in skeletal muscle, and JP1-knockout mice show sucking failure and die immediately after birth. In mutant muscle lacking JP1 showing a deficiency in triad formation, low efficiency in excitation–contraction coupling is observed, that is presumably due to impaired communication between Cav1.1 and RyR1. In cardiomyocytes expressing JP2, functional coupling between Cav1.2 and RyR2 in diads converts the depolarization signal into the cellular Ca^{2+} signal through the Ca^{2+}-induced Ca^{2+} release (CICR) mechanism. JP2-knockout mice exhibit embryonic lethality because of cardiac failure, and the mutant cardiomyocytes exhibit poor formation of the peripheral coupling and random SR Ca^{2+} release likely due to disconnected crosstalk between Cav1.2 and RyR2.

JPs in Hippocampal Pyramidal Neurons

In the central nervous system, both JP3 and JP4 are expressed in all neuronal sites and probably contribute to the formation of the subsurface cistern. Knockout mice lacking either JP3 or JP4 do not show severe abnormalities, suggesting functional redundancy between the subtypes. Although double-knockout mice lacking both JP3 and JP4 (JP-DKO mice) retain normal brain histology, they show severe growth retardation and lethality 3–4 weeks after birth under normal housing conditions. This lethality is likely caused by a feeding defect due to the dysfunction of salivary secretion, because JP-DKO mice can be rescued when their diet is switched from normal pellets to hydrated paste. Mature JP-DKO mice exhibit an aberrant behavior known as the 'foot-clasping reflex,' that has been reported in several mutant animals with neurological defects, including Huntington's disease

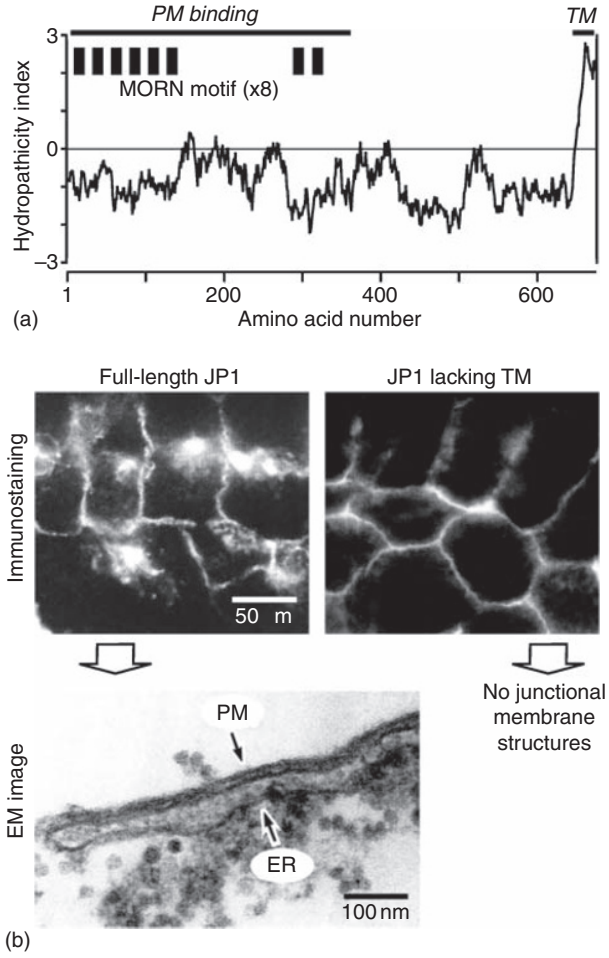

Figure 1 Structure and basic function of JP. (a) Hydropathicity profile of rabbit JP1: the Kyte–Doolittle algorithm with a window size of 19 residues is used for the analysis. MORN motifs for interacting with the PM and the C-terminal transmembrane segment spanning the ER/SR membrane (TM) are indicated. (b) JP-mediated JMC formation: in amphibian embryos injected with the full-length rabbit JP1 cRNA, expressed JP1 was detected at the cell periphery by immunofluorescent staining (upper panels), and JMCs were frequently constructed as shown in the electron-microscopic image (lower panel). When mutant protein lacking the C-terminal transmembrane segment was expressed, this truncated JP1 was detected on the PM but could not construct JMCs.

(HD) model mice. When normal mice are suspended by the tail, their lower limbs remain opened. In contrast, JP-DKO mice always cross their legs when hung upside-down (**Figure 2**). Therefore, JP-DKO mice seem to bear abnormal neural circuits for controlling the salivary and hindlimb reflexes.

JP-DKO mice show impaired performance in learning and memory tasks. Despite a lack of abnormal histological features, hippocampal neurons display corresponding abnormal excitability and synaptic plasticity in JP-DKO mice. CA1 neurons generate the afterhyperpolarization (AHP) phase following action potentials. This phase is

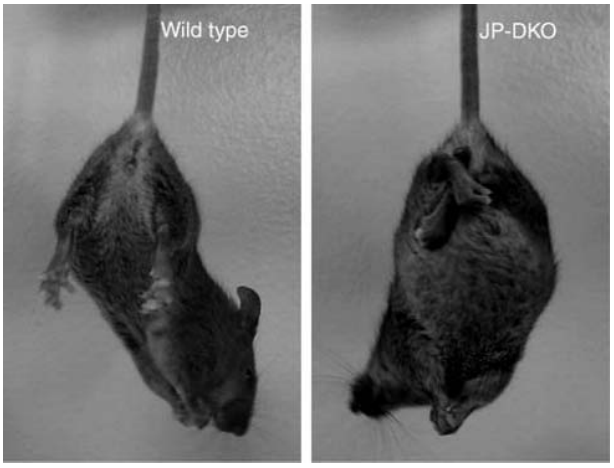

Figure 2 Foot-clasping reflex in JP-DKO mice. When hung upside-down, control mice open their hindlimbs but JP-DKO mice cross their legs.

sensitive to apamin, an inhibitor of small-conductance Ca^{2+}-dependent K^+ channels (SK channels). However, JP-DKO CA1 neurons completely lack apamin-sensitive AHP. Pharmacological examinations indicate that SK channel opening in CA1 neurons requires Ca^{2+} influx through *N*-methyl D-aspartate receptors (NMDARs) and subsequent RyR-mediated Ca^{2+} release. Therefore, NMDAR-mediated Ca^{2+} influx seems to activate RyR-mediated Ca^{2+} release by the CICR mechanism, and then Ca^{2+} released from intracellular stores likely opens SK channels to generate AHP (**Figure 3**). In JP-DKO CA1 neurons, the functional crosstalk between NMDARs, RyRs, and SK channels is probably abolished in under JMC-deficient conditions. On the other hand, long-term potentiation (LTP) in CA1 is closely linked with learning and memory. With an accompanying hyper activation of Ca^{2+}/calmodulin-dependent protein kinase II, a key enzyme for LTP induction, JP-DKO CA1 neurons demonstrate impaired LTP.

JPs in Cerebellar Purkinje Cells

Cerebellum-dependent tasks detect impaired motor coordination and learning in JP-DKO mice. Cerebellar Purkinje cells (PCs) receive distinct types of excitatory inputs from parallel fibers (PFs) and climbing fibers (CFs). Individual PF synapses are weak, but one PC establishes roughly $\sim 10^6$ PF synapses. In contrast, PCs are innervated by single CFs, but CFs form strong excitatory synapses on proximal PC dendrites. The JP-DKO cerebellum retains the normal properties of PF-PC and CF-PC synapses, but it exhibits severe electrophysiological abnormalities in PCs.

CF stimulation elicits a complex spike in PCs, consisting of a fast initial spike, several subsequent slow spikelets, followed by slow afterhyperpolarization (sAHP). However,

JP-DKO PCs lack this sAHP generated by apamin-sensitive SK channels. In addition to SK channels, PCs contain another type of Ca^{2+}-activated K^+ channels known as big-conductance Ca^{2+}-activated K^+ channels (BK channels). Ca^{2+} influx through P/Q-type voltage-gated Ca^{2+} channels activates both SK and BK channels in control PCs, and normal levels of BK channel activity are detected in JP-DKO PCs. Therefore, both Ca^{2+} influx through P/Q-type channels and subsequent Ca^{2+} release through RyRs are essential for the activation of SK channels, whereas Ca^{2+} influx directly activates BK channels (**Figure 3**). It may be that SK and BK channels are localized in distinct cell-surface microdomains, and that neural JPs functionally connect RyRs to SK channels by constructing specific JMC in PCs.

Long-term depression (LTD) at PF-PC synapses is presumably the cellular basis of cerebellar motor learning. After our LTD-inducing conjunctive stimulation (CJS) of CF and PF, the amplitude of PF inputs is consistently decreased by ~25% from the baseline level in control PCs. In contrast, an opposite change in the PF-induced current, recognized as LTP, is induced by the same stimulation in JP-DKO PCs. This reversed synaptic plasticity in the JP-DKO cerebellum is mainly due to sAHP deficiency, because a weak reversion of plasticity can be induced by apamin application to control cerebellar slices.

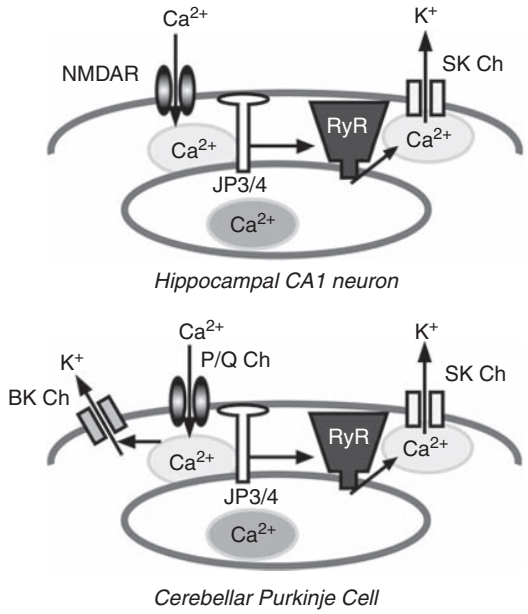

Figure 3 JP-mediated channel communication in neurons. In hippocampal CA1 neurons, JPs support Ca^{2+}-mediated channel crosstalk between NMDARs, RyRs, and SK channels to generate AHP following action potentials. In cerebellar PCs, JPs establish crosstalk between P/Q-type voltage-gated Ca^{2+} channels, RyRs, and SK channels to produce the slow AHP following CF-mediated complex spikelets. In both neurons, the JP deficiency, ryanodine application, or apamin treatment abolishes AHP generation.

In addition to impaired sAHP, the hyper activation of protein kinase Cγ and the altered expression of transcription regulators are predicted in JP-DKO PCs and may further aggravate the reversed plasticity.

HDL-2 and JP3 Gene

Similar to authentic Huntington's disease (HD), Huntington's disease-like 2 (HDL2) is an adult onset, progressive, neurodegenerative, autosomal dominant disorder clinically characterized by abnormal movements, dementia, and psychiatric syndromes. HDL2 is generally rare, accounting for only a few percent of total HD/HDL patients. HDL2 is caused by a CTG/CAG expansion mutation on the JP3 gene, but is not a typical polyglutamine disease. On the basis of the available evidence, HDL2 mutations accompanying triplet repeat expansion might disrupt the functional JP3 gene or reduce gene expression. Our studies demonstrated that JPs are essential for modulating neural excitability and plasticity by providing a structural platform for channel crosstalk. Indeed, JP-DKO mice show abnormal reflexes, motor discoordination, impaired memory, and diminished motor learning. In HDL2 patients, reduced JP3 expression together with age-related neural changes may lead to functional abnormalities, such as unstable membrane potentials or hyperactivation of Ca^{2+}-dependent enzymes. These abnormalities might further induce cell death in a certain set of damaged neurons.

Juvenile Myoclonic Epilepsy

P Motika and D C Bergen, Rush University Medical Center, Chicago IL, USA

Glossary

Electroencephalogram (EEG) – A recording of electrical activity produced spontaneously by neurons in the brain, commonly used in the diagnosis and management of seizure disorders.
Myoclonic – Large, brief contractions of a muscle or group of muscles such as the arms, legs, or proximal muscles. Myoclonus may be a normal occurrence or, as in the case of juvenile myoclonic epilepsy, a seizure-related finding.
Seizure – Paroxysmal abnormal electrical activity produced by nerve cells in the central nervous system. These discharges may result in overt clinical symptoms or signs which may be experienced by the patient or observed by others.
Tonic–clonic – A type of seizure (also known as 'grand mal') consisting of a phase of tonic stiffening of muscles typically preceding or coinciding with repetitive jerking movements (clonic phase).

Definition and History

Juvenile myoclonic epilepsy (JME) is one of the most common of the idiopathic generalized epilepsy syndromes. It is characterized by myoclonic seizures (which define the disorder), generalized tonic–clonic seizures, and frequently absence seizures. As the name implies, onset is typically in the adolescent years. A clear genetic abnormality associated with JME has been known for some time.

A clinical description of JME was first recorded by Herpin in 1867, describing a 13 year old patient with myoclonic jerks who subsequently developed tonic–clonic seizures. Though similar patients were described by other physicians in the intervening years, it was not until 1955 and 1957 that Janz and colleagues in Germany carefully described a number of cases of JME, labeling the syndrome 'impulsive petit mal' epilepsy. This was subsequently known as JME (of Janz). The international league against epilepsy in 1989 settled on the current term 'juvenile myoclonic epilepsy' which had been proposed by Lund and colleagues several years earlier.

Pathogenesis/Pathophysiology

A genetic basis for JME has long been suspected based on the typically strong family history, with some reports describing up to half of all JME patients having family members with epilepsy. Several genes have been reported in association with JME, though none have been identified in all cases. Several researchers have reported a strong link to abnormalities on the short arm of chromosome 6, and mutations on chromosome 5, 10, and 15 have also been identified. Isolated abnormalities associated with JME have also been described in several cellular ion channels including γ-aminobutyric acid (GABA) receptors and chloride channels. It appears that JME may have a complex and polygenic etiology.

Epidemiology/Risk Factors

JME is the most common of the idiopathic generalized epilepsy syndromes. It is estimated that JME represents

between 4% and 10% of all cases of epilepsy. The prevalence in the general population is estimated at up to 0.1%. However, as it is frequently pointed out, this number may be underestimating the true prevalence as the diagnosis is frequently delayed or missed. Prevalence across all population groups appears similar. There is approximately equal division between males and females, with females having slightly increased risk in some studies. There is a hereditary preponderance in family members of patients with JME being at slightly higher risk of having JME compared with the normal population. The occurrence of other genetic epilepsies in patients' families is common.

Clinical Features and Diagnostic Criteria

The diagnosis of JME is made clinically. Supportive data from testing may be useful but is not always required. As suggested by its name, JME has onset during adolescence, typically between ages 12 and 18 but with a range of 8–30. Myoclonic seizures are the predominant and defining feature, and thus are present in all cases. These consist of sudden, large amplitude jerks, most commonly seen in the arms and upper body. Rarely there may be loss of consciousness with these jerks. They typically occur within 1–2 h of awakening in the morning. Frequently, patients will not think about mentioning these jerks unless specifically asked, leading to delayed or missed diagnoses. In a minority of patients with JME (~2–10%), this may be the only seizure type. However, generalized tonic–clonic seizures occur in the majority (90%) of patients with JME, often months to years after onset of the myoclonic seizures. Usually these seizures prompt a medical evaluation. The tonic–clonic seizures also have a propensity to occur after awakening and sometimes to occur at the end of a cluster of myoclonic seizures. Absence seizures also occur in about a third of patients with JME and have even been reported as occurring prior to the onset of myoclonus in some cases. The absence seizures tend to be relatively mild compared with the typical seizures seen in absence epilepsy of childhood. As with many other seizure disorders, seizures in JME are often precipitated by lack of fatigue and sleep deprivation, stress, alcohol intake, and missed medications.

Patients with JME have normal intelligence, development, and neurological examinations. No decline in neurological status occurs.

Differential Diagnosis

The symptoms of JME can overlap with a number of other epileptic disorders as well as nonepileptic syndromes. Included in the differential diagnosis are the other forms of idiopathic generalized epilepsies (childhood absence epilepsy, juvenile absence epilepsy), epilepsy with generalized tonic–clonic seizures on awakening, absence syndromes, progressive myoclonic epilepsies, epilepsy with myoclonic–astatic seizures, Unverricht–Lundborg disease, frontal lobe epileptic syndromes, and symptomatic localization-related epilepsies.

Diagnostic Work up/Tests

The most helpful diagnostic tool is a thorough and detailed history. Neuroimaging with MRI is typically normal and is often not required, though some studies have shown suggestions of minor cortical developmental abnormalities. The electroencephalogram (EEG) is the diagnostic tool of choice, as there are characteristic findings on the EEG recordings of patients with JME. Bursts of generalized, bisynchronous polyspike, and polyspike-wave discharges are superimposed on a normal or nearly normal electrographic background. The frequency of spike/polyspike-wave discharges is 3.5–6 Hz, which is faster than those seen in childhood absence epilepsy, though they may occasionally occur at slower frequencies. A high proportion of patients (20–40%) with JME demonstrate photosensitivity. Hyperventilation may also trigger epileptiform activity. Both of these findings are diagnostically helpful. During stage II sleep, there is often suppression of discharges, in contrast to many other forms of epilepsy. Myoclonic seizures are invariably associated with bursts of polyspike and polyspike-wave discharges.

Management

Treatment with antiepileptic medication is necessary in JME, and due to the low remission rate, it may need to be continued for many years and possibly for life. Valproic acid, lamotrigine, zonisamide, topiramate, and more recently levetiracetam have been used with success. Lamotrigine in some cases may worsen myoclonus. For many patients, excellent seizure control may be achieved with relatively low doses of antiepileptic medications.

Prognosis

Currently there is no cure for JME. Although antiepileptic drug treatment usually controls the seizures, long term, possibly lifetime therapy appears to be necessary. Unlike the case with some other epilepsies, there is a high risk of recurrence (~80%) with medication withdrawal even after several years of seizure freedom. Avoidance of

excessive alcohol and sleep deprivation is crucial for successful control of seizures.

Juvenile Parkinsonism

T R Thomsen and R L Rodnitzky, University of Iowa, Iowa City, IA, USA

Glossary

Bradykinesia – Slowing of voluntary movements.
Dystonia – Involuntary muscle contractions causing abnormal movements.
Juvenile parkinsonism – Defined as onset of parkinsonian symptoms prior to age 21.
Parkinsonism – A syndrome involving symptoms of rest tremor, rigidity, motor impairment and postural instability.
Parkinson disease – A degenerative disorder of the central nervous system that often impairs the sufferer's motor skills and speech.
Postural instability – Impaired ability to maintain an upright posture.
Tremor – Involuntary oscillatory movements.

Definition and History

Juvenile parkinsonism (JP), first described nearly a century ago, is defined as onset of parkinsonian symptoms prior to age 21. In contrast, young-onset Parkinson disease (YOPD) encompasses those patients with onset of typical parkinsonian symptoms between 21 and 39 years of age. Some sources use the term early-onset parkinsonism to describe onset before age 40. JP is relatively rare and is typically due to secondary or hereditary causes. YOPD is more common and tends to more closely resemble idiopathic Parkinson disease (PD), except for slower progression, longer disease duration and earlier onset of motor fluctuations and dyskinesias.

Pathogenesis/Pathophysiology

JP is a syndrome that encompasses many underlying etiologies; thus, the pathogenesis and pathophysiology will depend upon the specific diagnosis and cannot be succinctly summarized. Rather, the individual diagnoses will be discussed further below in the sections on Differential Diagnosis and Diagnostic Work-up/Tests. Typical Lewy body pathology is rarely observed in JP cases that come to autopsy, suggesting that idiopathic PD is not a common cause of JD.

Epidemiology/Risk Factors

JP comprised 0.6% of 918 parkinsonian patients seen over a 6 year period at a movement disorders center. The mean age of onset was 12.5 with a range from 7 to 19. Incidence of JP has been reported at 0.8 per 100 000 per year for ages 0–29. In another group of 149 patients presenting with apparent idiopathic PD onset prior to age 40, 10 of these patients had onset prior to age 21. The risk of mortality was noted to be threefold that of the general population. A positive family history of parkinsonism was reported in 50% of cases of JP in this group. There was a 4:1 male predominance. The mean age of onset was 17, with a

range of 5–19. JP is reported to occur more frequently in Japan, this is presumed to be due to the high historical rate of consanguinity because of the increased incidence of recessive early-onset parkinsonism.

Clinical Features and Diagnostic Criteria

Cardinal features of JP include bradykinesia, rigidity, and postural instability. Dystonia is a common presenting symptom of JP and tremor is also commonly observed. Non-parkinsonian symptoms such as supranuclear opthalmoparesis, dementia, seizures, myoclonus, diminished reflexes, and pyramidal signs suggest structural causes or one of the childhood encephalopathies. In pure parkinsonian syndromes, dopaminergic medications typically produce improvement of motor symptoms; however, dyskinesias and motor fluctuations tend to occur earlier (after an average of 6 months) and with greater severity than in similarly treated late-onset PD patients. JP patients tend to have relatively preserved cognitive function and postural stability compared to late-onset PD patients with similar disease duration. Dystonia is a presenting symptom in as many as 60% of JP patients, a finding that is probably more common in this group than in YOPD. The onset is with tremor in ~50% of JP patients and with an akinetic-rigid syndrome in 20%. Both JP and YOPD typically have an excellent response to levodopa (L-dopa).

Differential Diagnosis

The differential diagnosis of JP is broad and includes genetic, toxic, metabolic, infectious/inflammatory, and structural causes; these are further discussed below.

Diagnostic Work-Up/Tests

Potentially treatable causes of JP should be ruled out. Screening tests for Wilson disease includes urine and serum copper, serum ceruloplasmin and slit lamp examination for Kayser–Fleischer rings. Dopa-responsive dystonia–parkinsonism can be evaluated by looking for an immediate and impressive resolution of the associated dystonia with L-dopa therapy. Drug-induced parkinsonism may be caused by dopamine-receptor blocking medications such as neuroleptics, antiemetics, certain calcium-channel blockers and others. Structural lesions, such as stroke, tumor, extrapontine myelinolysis and hydrocephalus are rare causes of JP and can be evaluated by brain MRI or CT.

JP without associated atypical non-parkinsonian features is likely to be genetic in nature. The most common genetic cause of JP is a mutation in the *Parkin* gene (PARK 2), with 77% of JP cases found to have a *Parkin* mutation in one study. Other mutations known to cause JP, albeit less commonly, are *PINK1* (PARK6) and *DJ1* (PARK7), both of which are autosomal recessive. Commercial testing is available for *Parkin* and *PINK1*.

Other genetic causes of JP, particularly when there are associated atypical features, include Huntington disease (Westphal variant), spinocerebellar ataxia (SCA 2 and 3), neuroacanthocytosis, rapid onset dystonia-parkinsonism, X-linked dystonia-parkinsonism (Lubag), mitochondrial disorders, Niemann Pick type C, juvenile neuronal ceroid lipofuscinosis, Gaucher's disease, neurodegeneration with brain iron accumulation, neuroferritinopathy, cerebrotendious xanthanomatosis, and Fahr's syndrome.

Management

In those with secondary causes, treatment should first be tailored to the underlying cause. Symptomatic treatment of the component of parkinsonian symptoms is also indicated in those cases. Medications used in the treatment of idiopathic PD may be employed, with adjustment to pediatric dosing as required. Anticholinergics (trihexyphenidyl, benztropine) may be particularly helpful in cases with prominent dystonia. L-dopa in combination with a dopa decarboxylase blocker (carbidopa or benserazide) is the gold standard dopaminergic medication; however, it is associated with a higher incidence of dyskinesias and motor fluctuations than dopamine agonists, such as pramipexole and ropinirole. Dopamine agonist use has been associated with excessive daytime somnolence and neuropsychiatric complications, such as psychosis and impulse control disorders, although L-dopa can also cause these side effects. A trial of amantadine, selegiline or rasagiline (the latter two being monoamine oxidase B inhibitors) can be considered for early, mild symptoms or later as an adjunct to L-dopa or a dopamine agonist. Entacapone and tolcapone (catechol-*O*-methly transferase inhibitors) prolong the duration of L-dopa response, but tolcapone requires liver function monitoring.

Anti-parkinsonian medications can cause multiple side effects, including orthostasis, nausea, sedation, confusion/mental status changes, dyskinesias, motor fluctuations, and psychosis. Orthostatic hypotension may respond to dietary salt supplementation, fludrocortisone, or midodrine. Nausea can be treated with additional carbidopa or domperidone. Modafinil is useful to combat sedation. Psychosis and hallucinations may respond to atypical antipsychotics, such as quetiapine or clozaril; however, clozaril requires frequent monitoring due to the risk of agranulocytosis. Clozaril and amantadine may help control dyskinesias. Motor fluctuations and dyskinesias may improve with smaller, more frequent L-dopa doses. A reduction in total dosage of anti-parkinsonian medications may ultimately be necessitated by intractable side effects.

Surgical treatment of JP has not been systematically studied. Deep brain stimulation surgery has been shown to be effective in the treatment of adults with both Parkin-related and idiopathic PD and is also used in the treatment of dystonia.

Prognosis

As discussed above, mortality is significantly increased compared to the general population. Initial response to dopaminergic medications is good; however, efficacy is often limited by early and severe dyskinesias and motor fluctuations. As in all forms of parkinsonism, disability supervenes over time. After a mean disease duration of 6.5 years, 83% of JP patients were recently found to require assistance with activities of daily living. Data on JP is somewhat limited due to its relative rarity. Patients with early-onset parkinsonism have a shorter life expectancy than those with late-onset PD. Elucidation of the specific etiology underlying a particular case of JP allows a more definitive statement regarding expected morbidity and mortality.

K

Kainic Acid Model of Dystonia

R S Raike, H A Jinnah, and E J Hess, Emory University School of Medicine, Atlanta, GA, USA

Motor Phenotype

Low-dose microinjections of kainic acid into the cerebellum induce a motor disorder in both rats and mice that closely resembles generalized dystonia in humans. Approximately 10–20 min after injection, mice exhibit transient hindlimb adductions that are generally preceded by volitional movements. Shortly thereafter, the dystonic movements become sustained and spread to involve the entire body to include the trunk, forelimbs, head, neck and even tail. Truncal flexion often causes the perineum to be pressed downward while the hindlimbs frequently exhibit paddling motions. Furthermore, although kainate is commonly used to induce seizures in rodents, no abnormalities are detected with EEG following intracerebellar microinjections of kainate, which is inconsistent with epileptic seizures.

Neuroanatomy

The dystonia observed in rodents following cerebellar microinjections of kainate arises from the local effects of the drug, since injections into other brain regions do not induce the dystonia. Moreover, microinjections of kainate into the cerebellar vermis result in bilateral dystonia, but injections into the cerebellar hemispheres generate ipsilateral symptoms, consistent with the ipsilateral wiring of the cerebellum. Furthermore, kainic acid does not induce dystonia in mice lacking Purkinje cells, demonstrating that output from the cerebellar cortex is necessary for expression of the dystonia.

Kainate-induced dystonia likely results from a gross distortion of cerebellar output. Assessments of c-*fos* mRNA expression demonstrate that the dystonia is associated with abnormal increases in neuronal activation almost exclusively within the cerebellum and the red nucleus, which is a prominent efferent target of the deep cerebellar nuclei. In contrast, the striatum exhibits significant decreases in both neuronal activation and extracellular dopamine levels. Partial lesions to the striatum exacerbate the dystonia in this model, arguing that the basal ganglia may actually exert a protective influence in cases of dystonia originating from cerebellar dysfunction.

Neurochemical Mechanisms

Kainate-induced dystonia is dose and time dependent. The dystonia produced by 25 $\mu g\ ml^{-1}$ is mild to moderate, whereas the dystonic postures produced by 100 $\mu g\ ml^{-1}$ are much more severe and prolonged. The dystonia probably does not arise from a mechanism involving excitotoxic cell death, as injections over consecutive days reliably induce the disorder (**Figure 1**). Furthermore, the doses of kainic acid that kill neurons are 10-fold higher than those used to elicit dystonia.

Kainic acid, which is a potent agonist at AMPA and kainate-sensitive glutamate receptors, likely elicits dystonia through excessive excitation of glutamatergic signaling within the cerebellum. Indeed, intracerebellar administration of domoic acid, another glutamatergic agonist, also induces generalized dystonia. The dystonia does not arise from simply perturbing glutamatergic signaling within the cerebellum, as microinjections of NBQX, a kainate and AMPA receptor antagonist, do not elicit the disorder. However, coadministration of the glutamatergic antagonist with kainate prevents the induction of dystonia, indicating that excessive activation of glutamate signaling within the cerebellum is necessary to produce the dystonia.

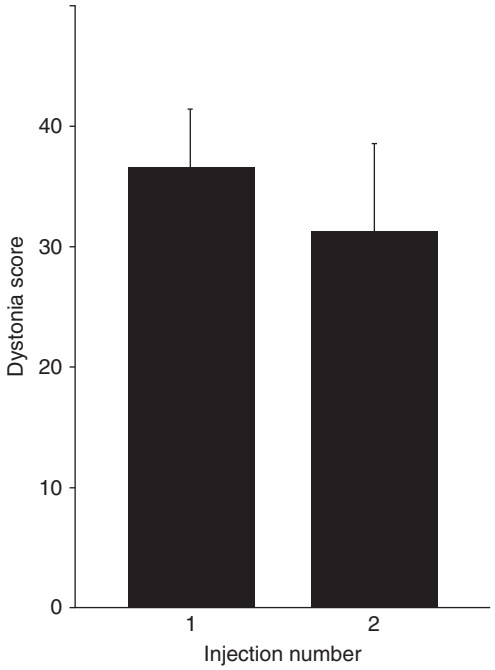

Figure 1 Repeated intracerebellar microinjections of kainate reliably induce dystonia in mice. Mice (n = 3) with implanted cannula were administered 0.5 μl of 100 μg ml^{-1} kainic acid on two consecutive days. Mice were scored for the severity of dystonia once every 10 min over a 2 h time period following injection whereby 0 = normal motor behavior; 1 = slightly slowed or abnormal movements; 2 = mild impairment, limited ambulation unless disturbed or transient abnormal postures; 3 = moderate impairment, limited ambulation unless disturbed and frequent abnormal postures; 4 = severe impairment, almost no ambulation and sustained abnormal postures. The mean dystonia severity scores were not statistically different (Student's t-test; $p > 0.5$).

Kayser–Fleischer

T Mizen and B Larsen, Rush University Medical Centre, Chicago, IL, USA

Introduction

The Kayser–Fleischer ring is an ocular finding defined by a pigmented ring of copper deposition in the peripheral corneal secondary to a dysfunction in copper metabolism. The most common systemic condition associated with a Kayser–Fleischer ring is Wilson's disease; however, this finding has been reported in other hepatic disorders and with intraocular copper foreign bodies.

Background

A brownish pigment in the corneal periphery was first described by Bernhard Kayser in 1902 in a patient with

multiple sclerosis. In 1912, Bruno Fleischer linked the peripheral coloration to Wilson's disease. The composition of the corneal deposits was first thought to be related to a breakdown in hemoglobin. Heavy metal deposition then became the leading theory as silver and copper were found in large amount in the viscera of patients with Wilson's disease. In 1936, Policard, Bonnet, and Bonnamour demonstrated the absence of silver and the sole presence of copper in the area of peripheral corneal pigmentation in patients with Wilson's disease. This work was supported by others including Harry and Tripathi in 1970 using electron microscopy to demonstrate copper deposition in the corneal periphery of a patient with Wilson's disease.

Ocular Anatomy

The cornea is an optically clear lens located in the anterior globe which bends and directs light to the posterior retina. Histologically, it is composed of five layers: epithelium, Bowman's layer, stroma, Descemen's membrane, and endothelium. The epithelium functions as a barrier and provides a smooth refractive surface to refract light. Bowman's membrane is made up of type I collagen and is found between the epithelium and stroma. The stroma is the thickest layer and is composed of collagen, keratin sulfate, glycosaminoglycans, and numerous cells including keratocytes, melanocytes, and Langerhans' cells. Below the stroma, Descemen's membrane is a basement membrane composed of type IV collagen secreted by the endothelium. The endothelium is a monolayer of cells that actively pumps water out of the stroma and keeps the cornea clear. It is in the posterior lamella of Descemen's membrane that copper is deposited to form the Kayser–Fleischer ring.

Copper Physiology

Copper is absorbed by cells in the small intestine. Approximately 25–60% of ingested copper is absorbed by the gastrointestinal system and transported to the liver by the portal vein. Copper is taken up by hepatocytes in the liver and is acted upon by the transmembrane protein ATPase ATP7B encoded by the gene *ATP7B*. ATP7B has at least two functions related to copper metabolism. One is to transport intracellular copper into the Golgi apparatus where it is incorporated into plasma protein to form ceruloplasmin. Copper, as part of ceruloplasmin, accounts for 90–95% of plasma copper. ATP7B also acts intracellularly to transport copper to the bile canaliculus for excretion into bile. Thus, the ATP7B transporter has dual synthetic and excretory roles in copper metabolism. In the eye, copper is found in the aqueous humor, which fills the anterior chamber, at a concentration equal to that of plasma ($\sim$1 mg ml^{-1}).

Pathophysiology

As stated above, the most common condition associated with a Kayser–Fleischer ring is Wilson's disease. Wilson's disease is an autosomal recessive disorder of copper metabolism characterized by hepatic and neurologic disease. It is caused by a defect in the *ATP7B* gene which as described above codes for the ATP7B protein that is essential for the incorporation of copper into ceruloplasmin and excretion of copper into bile. Without proper functioning of this protein, copper begins to accumulate in the liver in toxic levels. Toxic injury occurs by formation of free radicals, binding of sulfhydryl groups to cellular proteins, and displacing other metals in hepatic metalloenzymes. This can lead to fatty changes, acute hepatitis, chronic hepatitis, cirrhosis, and liver necrosis. Once the liver is saturated, nonceruloplasmin bound copper begins to spill into the systemic circulation and accumulates in other tissues such as the brain, eye, and kidneys. It is believed that the source of copper found in the Kayser–Fleischer ring comes from the aqueous humor in the anterior chamber of the eye and is either passively or actively introduced by the endothelial cells into Descemen's membrane.

Other hepatic disorders that cause a rise in unbound copper and intraocular containing copper foreign bodies are presumed to have a similar mechanism of creating a pigmented peripheral corneal ring.

Clinical Findings

Wilson's disease may present with symptoms related to hepatic dysfunction, neurologic dysfunction, or a combination of both. Hepatic disease may manifest with signs of coagulopathy or encephalopathy. Ascites, portal hypertension, and splenomegaly may be presenting signs of cirrhosis. Neurological dysfunction may present with behavioral changes, psychosis, or mild dementia and seizures. Often a Parkinson's like picture is evident or other movement disorder; these are generally the first signs and symptoms that present as copper deposits in the liver and brain. Ocular findings may not be present at this time.

The timing of ophthalmic findings in Wilson's disease is variable. Often changes in the cornea can only be seen by slit lamp examination or using a specially designed goniolens to examine the very corneal periphery. Liver stores must be saturated before copper begins to deposit in other tissues: this fact may be the reason that not all patients with hepatic dysfunction and a diagnosis of Wilson's disease have a Kayser–Fleischer ring on exam.

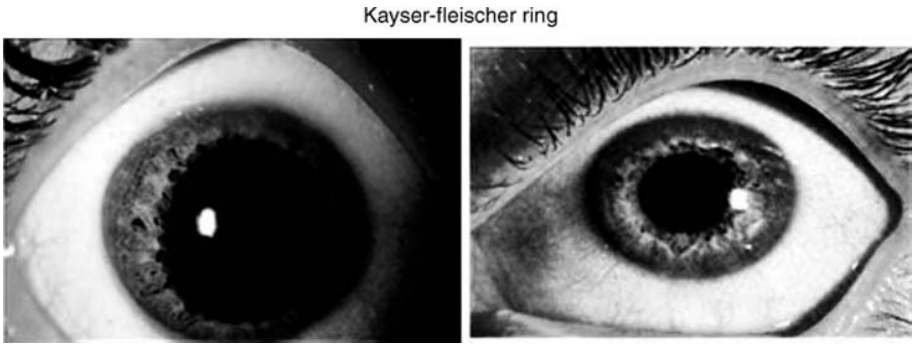

Figure 1 Peripheral corneal deposition as seen in Kayser-Fleischer ring.

Figure 2 Classic Kayser-Fleischer ring.

However, by the time most patients develop neurological dysfunction, a Kayser–Fleischer ring can be observed. The ring can appear to be different colors but generally it is described as golden brown, dark red, or green in pigmentation. The deposits often begin in the superior cornea first, then the inferior cornea, and extend until the full circumference of the peripheral cornea is affected. The deposition begins in the far periphery and extends centrally. As the disease is treated and the copper levels decrease, the ring can fade and even disappear.

Other conditions that should be considered include primary biliary cirrhosis, hepatitis, cryptogenic cirrhosis, multiple myeloma, alcoholic liver disease, and intraocular copper foreign body. A pigmented peripheral corneal ring has been reported in each of these diseases. However, only Wilson's disease has decreased levels of ceruloplasmin and the unique neurologic symptoms described above.

Treatment

The copper deposition in the cornea does not interfere with the function of the eye and as such, treatment is not aimed at eliminating the Kayser–Fleischer ring. The ring is a sign of elevated copper levels due to a disruption in copper metabolism and therapy is directed at correction of the underlying disorder and at reducing systemic copper levels.

Kernicterus

D Osredkar, University Children's Hospital, Ljubljana, Slovenia; University of California San Francisco, San Francisco, CA, USA
D M Ferriero, University of California San Francisco, San Francisco, CA, USA

Glossary

Exchange transfusion – Simultaneous withdrawal of the recipient's blood and transfusion with the donor's blood in the treatment of extreme hyperbilirubinemia.
Hyperbilirubinemia – The presence of an excess of bilirubin in the blood.
Jaundice – Yellowish pigmentation of the skin, tissues, and body fluids caused by the deposition of bile pigments.
Kernicterus – A rare neurological disorder that occurs in some newborns with severe hyperbilirubinemia, marked by the deposition of bile pigments in the nuclei of the brain and spinal cord and by degeneration of the nerve cells.
Phototherapy – The application of light for therapeutic purposes.

Definition and History

The term kernicterus was initially applied to the yellow staining of the basal ganglia found at the autopsy of severely jaundiced infants who died with severe erythroblastosis fetalis. Currently, the term kernicterus has come to be used interchangeably with both the acute and chronic findings of bilirubin encephalopathy. To avoid confusion, the American Academy of Pediatrics (AAP) recommends that in infants the term 'acute bilirubin encephalopathy' be used to describe the acute manifestations of bilirubin toxicity seen in the first weeks after birth, and that the term 'kernicterus' be reserved for the chronic and permanent clinical sequelae of bilirubin-induced neurologic dysfunction (BIND).

Pathogenesis/Pathophysiology

Benign jaundice is observed during the first week of life in ~60% of term infants and 80% of preterm infants. Some infants, however, may experience extreme hyperbilirubinemia, which can result in kernicterus, if not recognized and treated vigorously. Kernicterus is a disease of the infants because of their immature blood–brain barrier, which normally protects older children and adults from the devastating effects of extreme hyperbilirubinemia. The efficacy of the blood–brain barrier may be further diminished by disease, asphyxia, and other factors.

The pathogenesis of kernicterus is multifactorial and involves an interaction between unconjugated bilirubin levels, albumin binding, passage across the blood–brain barrier, pH, and neuronal susceptibility to injury. Laboratory investigations have demonstrated that bilirubin is neurotoxic at a cellular level. The potential mechanisms for bilirubin neurotoxicity are impairment of glucose utilization, oxidative stress, impairment of DNA and protein synthesis, and others. Bilirubin staining can be noted on autopsy in basal ganglia, particularly globus pallidus and subthalamic nucleus, hippocampus, substantia nigra, dentate nuclei, cerebellar vermis, and cranial nerve nuclei (such as the oculomotor, vestibular, and cochlear). Neuronal injury corresponds closely to the distribution of bilirubin staining, but nonpigmented areas may also be damaged, characterized by neuronal loss, reactive gliosis, and atrophy of involved fiber systems. Conversely, bilirubin staining may be present but unrelated to bilirubin toxicity.

Epidemiology/Risk Factors

The exact incidence of kernicterus is not known. A few European population-based studies reported the incidence to be in the range between 1/100 000 and 1.4/100 000.

The exact blood level above which free (not bound to albumin) unconjugated (indirect) bilirubin will be toxic for an individual infant is not known. Approximately 1 in 650–1000 infants, >35 weeks of gestation, develop serum bilirubin values of $\geq$427 μmol l^{-1} ($\geq$25 mg dl^{-1}), and ~1 in 10 000 have levels of $\geq$510 μmol ($\geq$30 mg dl^{-1}). In otherwise healthy infants, extremely high total serum bilirubin levels of more than 30 mg dl^{-1} are known to cause kernicterus, but the risks associated with less extreme elevations of total serum bilirubin levels seem to be minimal.

Race (more in Caucasian) and sex (more in male infants) influence risk of bilirubin encephalopathy. The more immature the infant is, the greater is the susceptibility to bilirubin encephalopathy. The duration of exposure needed to produce toxic effects is unknown.

Table 1 Clinical signs of acute and chronic bilirubin encephalopathy

Presentation	*Timeframe*	*Signs*
Acute	Phase 1 (first 1–2 days)	Hypotonia, poor sucking, stupor, seizures
	Phase 2 (middle of first week)	Hypertonia of extensor muscles, opisthotonos, retrocollis, fever
	Phase 3 (after first week)	Hypertonia, high-pitched cry
Chronic	First year	Hypotonia, active deep tendon reflexes, obligatory tonic neck reflexes, delayed motor skills
	After first year	Movement disorders (athetosis, chorea, ballismus, dystonic posturing, tremor), gaze disturbances, sensorineural hearing loss

Source: Dennery PA, Seidman DS, and Stevenson DK (2001) Neonatal hyperbilirubinemia. *New England Journal of Medicine* 344: 581–590.

Among infants reported in the US kernicterus registry, glucose-6-phosphate dehydrogenase deficiency was diagnosed in 26 of 116 infants (22%); severe hemolytic processes were identified in 22 infants (19%), birth trauma in 17 infants (15%), and other causes such as galactosemia, Crigler–Najjar syndrome, and sepsis were diagnosed in eight infants (7%). In 43 infants (37%), no etiology for the severe hyperbilirubinemia was discovered.

Clinical Features and Diagnostic Criteria

The early signs may be subtle and indistinguishable from those of sepsis, asphyxia, hypoglycemia, intracranial hemorrhage, and other acute systemic illnesses in a neonate. Although the majority of the affected infants exhibit neurological signs, 15% of infants with proven kernicterus will not demonstrate neurological abnormalities in the neonatal period.

The clinical signs (**Table 1**) of acute bilirubin encephalopathy usually occur within the first week of life. Infants present with lethargy, hypotonia, paucity of movement, and poor suck. Subsequently, the infant may appear severely ill and irritable, with increased muscle tone, which can evolve to opisthotonos. The cry is usually high-pitched. In advanced cases, stupor or coma and persistent increased muscle tone occur. The infant with acute bilirubin encephalopathy may also present with seizures. In the first year of life, the survivors of the acute phase of bilirubin encephalopathy exhibit hypotonia (evolving from neonatal hypertonia), pronounced deep tendon reflexes, persistent and obligatory tonic neck reflex, and delayed motor development. The clinical picture of chronic bilirubin encephalopathy may take several years before it becomes fully developed. The major features include extrapyramidal movement abnormalities (athetosis, chorea, ballismus, dystonic posturing, tremor), gaze disturbances (especially of upward gaze), bilateral high-frequency sensorineural hearing loss, and intellectual deficits. Chorea develops earlier in kernicterus than after hypoxic-ischemic encephalopathy.

Table 2 Differential diagnosis of kernicterus

Bacterial meningitis
Cerebral palsy
Fetal alcohol syndrome
Head trauma
Hearing impairment
Herpes simplex virus infection
Hyperammonemia
Hypoglycemia
Hypothyroidism
Hypoxic-ischemic brain injury in the newborn
Intracranial hemorrhage
Periventricular leukomalacia
Sepsis

Differential Diagnosis and Diagnostic Work-up/Tests

Evaluation of the hematologic parameters is the cornerstone of evaluation of an infant with hyperbilirubinemia and identification of infants who are at risk for brain injury due to bilirubin toxicity. Total and direct bilirubin, blood type, complete blood cell count, reticulocyte count, direct Coombs test, and serum electrolytes are recommended. Sepsis can be excluded by evaluating inflammatory parameters such as C-reactive protein or procalcitonin and lumbar puncture. **Table 2** lists differential diagnoses of kernicterus.

The value of ultrasound and computed tomography is limited in evaluation of newborns with bilirubin encephalopathy, but brain MRI is of major value in evaluation of acute and chronic period of bilirubin encephalopathy. The posteromedial aspect of the globus pallidus is bilaterally affected in more than 90% of cases (**Figure 1**), a finding present in both acute and chronic phases. Subthalamic nuclei and hippocampi may be affected as well. MR spectroscopy provides additional data in the acute period.

Brainstem auditory evoked response is of great value for the early detection of hearing loss.

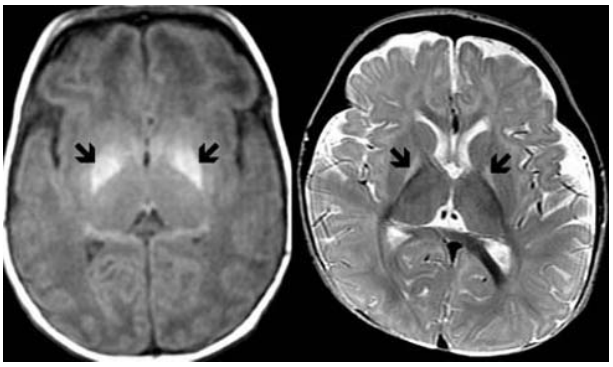

Figure 1 MRI images of a 9-day old infant with acute (left; T1) and an 8-month old infant with chronic (right; T2) bilirubin encephalopathy. The typical findings of bilateral signal change in posteromedial aspect of the globus pallidus (arrows) are present in more than 90% of infants with bilirubin encephalopathy. Courtesy of Dr. A James Barkovich.

Management

The essential aspect of kernicterus management is the prevention and early detection of the infant at risk for brain injury caused by bilirubin. Phototherapy and, if unsuccessful, exchange transfusion remain the primary treatment modalities used to keep the maximal total serum bilirubin below the pathologic levels. The risk of injury to the central nervous system (CNS) from bilirubin must be balanced against the potential risk of treatment. The AAP has published guidelines on the bilirubin level at which phototherapy or exchange transfusion in infants of $\geq$35 weeks of gestation has to be initiated (see Further Reading).

Exchange transfusion is not effective in improving neurological outcome when bilirubin levels are in the region of 35–40 mg dl^{-1}. In fact, neurological signs may become more prominent in these individuals if treated with exchange transfusion. Enhanced deposition of unconjugated bilirubin in the CNS is thought to result from decreases in blood albumin concentration during the exchange transfusion.

Treatment with intravenous immunoglobulin (IVIG) reduces jaundice in many cases of neonatal isoimmunization. The recommended dose of IVIG is 500 mg kg^{-1} infused over a 2-h period.

A potentially important alternative pharmacological therapy is the use of metalloporphyrins (e.g., tin-mesoporphyrin (SnMP)) for hyperbilirubinemia. The use of bilirubin oxidase, an enzyme that degrades bilirubin to biliverdin, dipyroles, and other products is still experimental, but has shown some promise.

The AAP has identified potentially preventable causes of kernicterus: (1) early discharge (<48 h) with no early follow-up (within 48 h of discharge), (2) failure to check the bilirubin level in an infant noted to be jaundiced in the first 24 h, (3) failure to recognize the presence of risk factors for hyperbilirubinemia, (4) underestimation of the severity of jaundice by clinical (visual) assessment, (5) lack of concern regarding the presence of jaundice, (6) delay in measuring the serum bilirubin level despite marked jaundice, or delay in initiating phototherapy in the presence of elevated bilirubin levels, and (7) failure to respond to parental concern regarding jaundice, poor feeding, or lethargy.

Prognosis

In the kernicterus registry mentioned above, 5 of 115 (4.3%) patients died. The number of patients who died from kernicterus without being reported to the registry is unknown, as is the experience in countries other than the United States. Of patients reported to the kernicterus registry, 92 of 110 survivors (84%) had severe sequelae due to BIND; 9 of 110 babies (8%) had no discernible sequelae after the age of 1 year.

Kinesia Paradoxica

L C Shih and D Tarsy, Beth Israel Deaconess Medical Center, Boston, MA, USA

Glossary

Akinesia – Akinesia ('without movement') is the inability to initiate movement often associated with parkinsonism.
Akinesia paradoxica – A temporary increase in akinesia with levodopa therapy.
Kinesia paradoxica – A sudden and temporary disappearance of akinesia in the face of an immediate threat of catastrophe; also may be an improvement in motor performance with increasing motivation.

Definition and History

Kinesia paradoxica is a motor phenomenon, occasionally observed in Parkinson's disease (PD) patients, that is characterized by a sudden and temporary disappearance of akinesia during a threat of catastrophe or sudden shock. It may also be defined as an improvement in motor performance with increasing motivation. It is distinguished from akinesia paradoxica, the latter referring to a temporary increase in akinesia with levodopa therapy.

The phrase was first coined by Bing in 1923 and expanded upon by Kinnier Wilson in 1925. Several vivid examples, such as one patient described by Schwab, demonstrate the sudden ability of a parkinsonian subject to move when faced with a natural disaster:

> A 61-year-old woman with advanced bilateral, totally disabling Parkinson's disease had become restricted to a wheel chair existence, requiring full time attendance of her daughter and nurse in the home where a 1-year-old grand-daughter resided. The patient lived on the second floor of the house. One night while the infant's parents were away briefly, the house caught fire, burning briskly with great columns of smoke. The patient jumped out of her wheel chair, grabbed the baby in her arms and ran down the stairs to the arriving firemen, and then collapsed back to her state of total invalidism.

Pathogenesis

The pathogenesis of kinesia paradoxica is not known. Observations by Kinnier Wilson in PD patients demonstrated a relative preservation of what he called 'movements of reaction and defense.' As such, when severely affected parkinsonian patients were tilted abruptly while seated, they automatically developed extension and abduction of the arms and legs. Other similar observations included the retained ability to blink to loud auditory stimuli in spite of severe facial masking or withdrawal of a body part from an applied noxious stimulus even when the patient could not volitionally move. He recognized that a 'conscious element' played a role in more complex movements such as the removal of a hand from a hot surface or the ability to walk after complex external stimuli were applied, and that these types of responses were retained and highly intact even in the face of severe parkinsonism. He conjectured that apathy and indifference played a role in parkinsonian akinesia, and reasoned that the cortex had to be involved with mediating paradoxical kinesia in patients with striatal disease.

Because dopamine is known to play a critical role in reward pathways, there has been some research into which neurochemical pathways might mediate kinesia paradoxica. Stricker recognized that activating situations could restore motor activity to rodents that were made parkinsonian with intraventricular 6-hydroxydopamine. Subsequent work in this animal model provided evidence that dopamine release is not the mechanism by which activating circumstances resulted in the loss of akinesia. Keefe et al. demonstrated that rats that were given intraventricular 6-hydroxydopamine were able to escape from an ice bath with relatively preserved speed compared to control rats. Haloperidol, a dopamine antagonist, did not block this effect. This observation led them to postulate three possibilities: (1) dopamine is potentially only a modulator of striatal response to sudden, threatening sensory stimuli; (2) norepinephrine or serotonin are critical for motor behavior during times of stress; and (3) spinal cord, brain stem and cerebellar pathways, and limbic/motor integration networks can mediate motor behavior in systems with striatal damage.

The precise manner by which sudden increased motor performance can be elicited under sudden, stressful conditions has been a subject of debate. In humans, response times to externally cued stimuli have been compared in healthy controls and subjects with PD, showing that externally cued stimuli are more effective in generating a faster response compared to a self-initiated cue. Muscles of facial expression and verbal fluency have also been thought to be susceptible to this phenomenon. The types of stimuli that best elicit kinesia paradoxica may be sensory modality-specific, and may serve as clues to defining the anatomic pathways involved in this phenomenon. In studies of a related observation, namely the ability of parkinsonian patients to

overcome gait freezing with visual cues, Glickstein and Stein suggested that having conscious goals or subgoals may enable patients to move in a way that is not normally feasible. They felt that visual stimuli could represent such goals, referring to well-known anecdotes of patients being able to ambulate after placing transversely oriented stripes along the floor. They hypothesized that visual information could be routed to the cerebellum for motor guidance, bypassing the dysfunctional striatum in PD. They cited a body of work indicating that visual information is relayed to cerebellar cortex by way of pontine nuclei. However, impending threat is not always represented in a singularly visual or auditory manner, and it seems likely that multiple modalities and their corresponding pathways may mediate similar sudden changes during an unexpected threat or stressful event.

Epidemiology

Epidemiological studies of the incidence of kinesia paradoxica are lacking. The phenomenon may be observed uncommonly since near-catastrophic or life-threatening events occur very infrequently in disabled patients. One notable study by Schlesinger et al. interviewed 50 PD patients in northern Israel who came under heavy rocket fire during July 2006. Only two patients experienced kinesia paradoxica, one in response to evacuation alarms from an impending rocket attack and the other in response to a cup of hot coffee almost spilling into the patient's lap. The overall phenomenon was thought to be uncommon. The authors concluded that this observation supports the idea that visual stimuli rather than extensive auditory cueing is critical for instigating externally cued rapid motor responses.

Practical Issues

The phenomenon of paroxysmal kinesia can be explained to families and patients who will find comfort in understanding that in dire emergencies, even very impaired PD patients may successfully mobilize themselves to safety.

Kuru

K Kompoliti, Rush University Medical Center, Chicago, IL, USA

Introduction

Kuru is believed to have developed in the early part of this century in a small isolated Eastern Highlands population of Papua New Guinea, where the people regarded it as a form of sorcery. It was the first noninflammatory degenerative disease of man proved to be caused by a filterable agent, by transmission to chimpanzees and monkeys. Because of its histopathological similarities to kuru, Creutzfeldt–Jakob disease (CJD) was soon demonstrated to be similarly transmissible. Both kuru and CJD are now believed to be caused by strange atypical infectious agents who lack any DNA or RNA and are infectious nucleants made from a normal host precursor protein by a conformational change to its cross β-pleated conformation. In this new conformation the molecules self-assemble and autocatalytically induce a similar change in normal precursor protein molecules, producing further infectious protein nucleants (or prions). These discoveries rapidly led to a demonstration of transmissibility and similar etiology for familial genetically dominant forms of CJD and to the further delineation of its clinical and

pathological variant, Gerstman–Sträussler–Scheinker syndrome. Scrapie in sheep and goats, transmissible mink encephalopathy, chronic wasting disease in Rocky Mountain mule deer and elk, and bovine spongiform encephalopathy (mad cow disease), were all shown to have the same cause. All these diseases share the characteristic vacuolating lesions inside the neurons, as observed by electron microscopy and the resulting status spongiosus of the gray matter, seen by light microscopy.

The word 'kuru,' in the language of the Fore people of the Eastern Highlands of New Guinea means shivering or shaking and refers to one of the several movement disorders seen in this disease. The story, which resulted in the discovery and disappearance of a disease, as well as the Nobel Prize for Dr. Gajdusek in 1976, started in a rather unorthodox and exotic way in 1957. D.C. Gajdusek was a visiting investigator at the Walter and Eliza Hall Institute of Medical Research with Frank McFarlane Burnet in Melbourne, Australia from 1955 to 1957, when a territorial health officer from New Guinea, Dr. V. Zigas, reported to the government Public Health Service a strange fatal neurologic disorder, that was decimating the primitive Fore people in the Eastern Highlands of New Guinea.

The disease was confined to an area east of Mt. Michael (elevation 12 000 ft) inhabited by 35 000 people in 169 villages and hamlets, consisting of 9 linguistic groups afflicted by kuru, living in stone age culture. It was specifically limited to the Fore people and their immediate neighbors, who intermarried with the Fore. The total population affected was 17 000 (Fore plus the neighboring tribes), of which 11 000 were the Fore.

Kuru is believed to have resulted from the contamination of women and their infants and toddlers with highly infectious brain tissue during ritual cannibalism as a rite of mourning and respect for the dead close kinsmen. Women and children crowding about or in the arms of women were more exposed to the kuru infected human tissue than were the men, who left this ritual largely to women. Brain tissue infected with kuru has a high infectivity and is transmissible, using bacteria free infiltrates of brain, even at dilutions as high as 1:1 000 000 and therefore self inoculation through the mouth, eyes, nose, or skin was a certainty whenever a victim was eaten. It has been postulated that the disease had its origin in a case of sporadic CJD, was perpetuated through endocannibalism, and dissipated with cessation of endocannibalism, after this initially Stone Age culture acculturated to Western civilization.

Epidemiology

In 1957, when Gajdusek and Zigas went to the Eastern Highlands of New Guinea, kuru had a yearly incidence and prevalence rate of about 1%. Over 1% of the entire population died annually of kuru. In most affected villages, active cases comprised 5–10% of the inhabitants. In the first decade after the discovery of the disease by western scientists, kuru claimed about one quarter of all deaths, and in the villages with the highest incidence it accounted for over 90% of all deaths. In childhood and adolescence the male female ratio was close to 1:1, but among adults, in whom 60% of the cases occurred, the female–male ratio was over 14:1. Incubation period ranged from 4 to more than 40 years.

The incidence of kuru has declined sharply, falling from 220 registered cases in 1959 to 86 in 1970 and disappearance in people under the age of 35 by 1985 and under 45 by 1995. The incidence has declined more markedly among women than men. It has disappeared from children, adolescents, and young adults. The gradual disappearance of kuru, regularly by age group, resulted from the cessation of the practice of ritual cannibalism among the Fore people after 1957.

Clinical Presentation

Kuru is characterized by predominantly cerebellar symptomatology, which follows a progressive and remarkably uniform course to total incapacitation and death, usually within 3–9 months. Different MDs occur preferentially in different stages of the disease. It starts insidiously without acute antecedent illness, and is divided into three stages: the first or ambulant stage, the second or sedentary, and the third or terminal stage. Some patients report prodromal symptoms of headache and limb pains.

The first stage or ambulant is usually self diagnosed, with ataxic gait and postural instability, truncal tremor and titubation being the first signs. Dysarthria develops early and speech progressively deteriorates as the disease advances. A convergent strabismus often appears early in the disease and persists. For most of the first stage of the disease the patient usually continues to work in the garden and attempts to pursue his normal activities and take full part in village social life, in the latter part of this first stage, he starts utilizing a stick for support.

The second or sedentary stage is reached when the patient can no longer walk without complete support. Tremor becomes progressively more severe and other movement disorders appear. Mental slowing is apparent, but severe dementia is conspicuously absent. Emotional liability, leading to outbursts of pathological laughter, is frequent. Laughter and smile can be persistent with slow relaxation, reminiscent of facial dystonia. This feature has given rise to the unfortunate journalistic synonym of 'laughing death.' Most patients show a resignation to, and a light-hearted attitude toward their disease bordering on true euphoria.

The third or terminal stage is reached when the patient is unable to sit up without support, and ataxia, tremor and dysarthria become progressively more severe and

incapacitating. Some patients show characteristic extrapyramidal defects of posture and movement. A grasp reflex may appear and tendon reflexes become exaggerated. Urinary and fecal incontinence develop, and dysphagia leads to thirst and starvation. Of interest is that even in the advanced stage of incapacitation, the mute patient who occasionally groans may still respond intelligently to requests, with a feeble motor response after much verbal urging.

L

Lafora Disease

A C Jansen, UZ Brussel, Brussels, Belgium

Glossary

Autosomal recessive inheritance – Autosomal recessive inheritance means that the gene carrying the mutation is located on one of the autosomes, and that both copies of the gene must have a mutation in order for a person to have the trait. One copy of the mutation is inherited from the mother, and one from the father. A person who has only one recessive gene mutation is said to be a 'carrier' for the trait or disease, but he/she does not have any health problems from carrying this one mutation. Once parents have had a child with a recessive disease, there is a 25% chance, with each subsequent pregnancy, for another child to be born with the same disorder.

Dual-specificity phosphatase – Subclass of the protein tyrosine phosphatase (PTP) gene superfamily, which appears to be selective for dephosphorylating the critical phosphothreonine and phosphotyrosine residues within MAP kinases.

E3 ubiquitin ligase – A ubiquitin ligase is a protein that covalently attaches ubiquitin to a lysine on a target protein via an isopeptide bond. In general, the ubiquitin ligase is involved in polyubiquitination: a second ubiquitin is attached to the first, a third is attached to the second, and so forth. Polyubiquitination marks proteins for degradation by the proteasome.

Lafora bodies – Lafora bodies are composed of starch-like polyglucosans, which are insufficiently branched and hence insoluble glycogen molecules, which accumulate in neurons, skin, muscle, liver, and other tissues.

MAP kinases – Mitogen-activated protein (MAP) kinases are important players in signal transduction pathways activated by a range of stimuli, and mediate a number of physiological and pathological changes in cell function.

Photosensitive epilepsy – Patients are called photosensitive when seizures are triggered by certain frequencies of flashing lights or contrasting light and dark patterns such as stripes or checks.

Definition and History

Lafora's disease is named after Gonzalo Rodriguez Lafora (1887–1971), a Spanish neuropathologist who reported the presence of spherical inclusions in brains of patients with myoclonus epilepsy, which were called Lafora bodies. Lafora bodies would later prove to be the key feature to distinguish Lafora's disease from other epileptic conditions.

The diagnosis of Lafora's disease is suspected in a previously healthy older child or adolescent with fragmentary, symmetric, or generalized myoclonus, and/or generalized tonic–clonic seizures, visual hallucinations (occipital seizures), and progressive neurological deterioration, including cognitive and/or behavioral deterioration, dysarthria, ataxia, and at later stages, spasticity and dementia.

Diagnosis is confirmed by the identification of two mutations in one of the two genes known to be associated with Lafora's disease, *EPM2A* or *NHLRC1*.

Pathogenesis/Pathophysiology

EPM2A is located on chromosome 6q24, and encodes the dual-specificity phosphatase laforin. By differential splicing of its transcripts, *EPM2A* encodes two laforin isoforms having distinct carboxyl termini. *NHLRC1* is located on chromosome 6p22.3, and encodes an E3 ubiquitin ligase called malin.

The mechanisms by which mutations in either *EPM2A* or *NHLRC1* result in Lafora's disease, and the exact role of the Lafora bodies has not been entirely clarified. Laforin

and malin participate in different mechanisms involved in the regulation of glycogen metabolism, including the proteasome-dependent degradation of protein targeting to glycogen (PTG) and muscle glycogen synthase (MSG), suppression of excessive glycogen phosphorylation, and degradation of misfolded proteins.

Epidemiology/Risk Factors

Exact prevalence figures for Lafora's disease are not available. It occurs worldwide, but because of its autosomal recessive inheritance, it is relatively more frequent in ethnic isolates, and other parts of the world with a high rate of consanguinity.

Apart from two mutational hotspots in *NHLRC1* (p.Pro69Ala and p.Gly158fs), mutations are distributed evenly across the *EPM2A* and *NHLRC1* genes. Some mutations occur more frequently in specific populations. Examples include the relatively frequent presence of the p.Arg241X mutation in *EPM2A* in the Spanish population, and the p.Cys26Ser mutation in *NHLRC1* in French Canadian families.

Clinical Features and Diagnostic Criteria

Lafora's disease typically starts between ages 12 and 17 years, after a period of apparently normal development. Many affected individuals experience isolated febrile or nonfebrile convulsions in infancy or earlier in childhood. Intractable seizures rarely begin as early as the age of 6. In families with more than one affected child, clinical signs such as subtle myoclonus, visual hallucinations, or headaches are noted earlier in subsequent affected children than in the proband. Intra- and interfamilial variability in the age of onset is considerable.

The main seizure types in Lafora's disease include myoclonic seizures and occipital seizures, although generalized tonic–clonic seizures, atypical absence seizures, and atonic and complex partial seizures may occur.

Myoclonus can be fragmentary, symmetric, or massive (generalized). It occurs at rest and is exaggerated by action, photic stimulation, or excitement. Both negative (loss of tone) and positive (jerking) myoclonus can occur. Myoclonus usually disappears with sleep. Trains of massive myoclonus with relative preservation of consciousness have been reported. Myoclonus is the primary reason for early wheelchair dependency. In the advanced stages of the disease, affected individuals often have continuous generalized myoclonus.

Occipital seizures present as transient blindness, simple or complex visual hallucinations, photomyoclonic or photoconvulsive seizures, or migraine with scintillating scotomata.

The course of the disease is characterized by increasing frequency and intractability of seizures. Status epilepticus with any of the previously mentioned seizure types is common. Cognitive decline becomes apparent at or soon after the onset of seizures. Dysarthria and ataxia appear early, while spasticity late. Emotional disturbance and confusion are common in the early stages of the disease, and are followed by dementia.

By their mid-twenties, most affected individuals are in a vegetative state with continuous myoclonus. Some maintain minimal interactions, such as a reflex-like smiling, with the family. Affected individuals who are not tube-fed aspirate frequently as a result of seizures; death from aspiration pneumonia is common.

Results of additional investigations and their evolution over time are summarized in **Table 1**.

Differential Diagnosis

Although the occurrence of myoclonus and generalized tonic–clonic seizures in adolescence may raise the possibility of juvenile myoclonic epilepsy, the persistence of EEG background slowing and cognitive deterioration should raise the suspicion of a more severe epilepsy syndrome, such as progressive myoclonus epilepsy.

Later age of onset, more rapid rate of disease progression, and presence of Lafora bodies on skin biopsy differentiates Lafora's disease from Unverricht–Lundborg disease.

Careful ophthalmologic examination, including electroretinography, is useful in addressing the possibilities of neuronal ceroid-lipofuscinoses and sialidosis.

Other conditions to consider are myoclonic epilepsy with ragged red fibers, subacute sclerosing panencephalitis, or schizophrenia.

Diagnostic Work-up/Tests

Molecular Genetic Testing

Diagnosis is confirmed by detection of two mutations in *EPM2A* or *NHLRC1*.

Although some evidence suggests that persons with *NHLRC1*-associated Lafora's disease tend to live longer than those with *EPM2A*-associated Lafora's disease, the clinical manifestations caused by mutations in either gene are so similar that it is not possible to predict which gene will be mutated in any given individual.

Studies of the combined mutation detection frequency by sequence analysis of *EPM2A* and *NHLRC1* reveal that between 88% and 97% of mutations in these two genes can be detected using sequence analysis alone. The proportion of mutations in *EPM2A* and *NHLRC1* not detected

Table 1 Clinical evaluation of Lafora's disease

Evaluation	*At onset*	*Later in disease course*
General physical examination	Normal	Normal
Neurological examination, including fundi and reflexes	Normal	Dysarthria, ataxia, spasticity; fundi remain normal
Mental state examination	Visual hallucinations (epileptic), depressed mood, cognitive deficits	Increased hallucinations, agitation, dementia
EEG	Normal or slow background, loss of α-rhythm and sleep features, photosensitivity is common	Slow background, paroxysms of generalized irregular spike-wave discharges with occipital predominance, and focal, especially occipital, abnormalities
Visual-, somatosensory-, and auditory brainstem-evoked potentials	High-voltage visual and somatosensory evoked potentials	Amplitudes may return to normal size; prolongation of brainstem and central latencies
Nerve conduction studies	Normal	Normal
MRI of the brain	Normal	Normal or atrophy[a]
Proton MR spectroscopy of the brain	Reduced NAA/creatine ratio in frontal and occipital cortex, basal ganglia, and cerebellum[b]	Reduced NAA/creatine ratio in frontal and occipital cortex, basal ganglia, and cerebellum[a]

[a]No significant correlation observed with disease evolution.
[b]At least 2 years after onset of symptoms.

by sequence analysis that are attributable to deletions is unknown. Deletions should be suspected in affected individuals who have a single heterozygous mutation in one of the genes, and in patients who have an apparently homozygous mutation in one of the genes but the mutation is carried by only one parent.

Finally, two independent studies have provided evidence for the existence of a third locus for Lafora disease.

Skin Biopsy

Before the advent of molecular genetic testing, diagnosis was confirmed by the presence of Lafora bodies on skin biopsy. Lafora bodies are present in either eccrine duct cells or in apocrine myoepithelial cells. The interpretation of findings on skin biopsy includes a risk of false negative results, especially in newly symptomatic individuals, and a risk of false positive results because of the difficulty in distinguishing Lafora bodies from normal Periodic Acid-Schiff positive polysaccharides in apocrine glands. It is therefore favored to biopsy the skin outside the axilla and genital regions, as eccrine duct cell Lafora bodies are unmistakable.

Management

To establish the extent of disease in an individual diagnosed with Lafora's disease, a clinical evaluation with special attention to speech, walking, coordination, handwriting, school performance, and emotional status is recommended. Follow-up consists of clinical and psychosocial evaluations at 3–6-month intervals throughout the teenage years.

Antiepileptic drugs have a major effect against generalized seizures, sometimes controlling seizures for many months. Valproic acid is the traditional antiepileptic treatment for Lafora's disease because it is a broad-spectrum drug that controls both the generalized tonic–clonic seizures and myoclonic jerks. Clonazepam can be used as an adjunctive medication for the control of myoclonus. Other possible treatments include zonisamide, piracetam, and levetiracetam.

The use of phenytoin should be avoided. Anecdotal reports describe possible exacerbation of myoclonus with carbamazepine, oxcarbazepine, and lamotrigine.

Myoclonus is often drug-resistant in Lafora's disease, and care should be taken not to overmedicate patients for this reason.

Placement by percutaneous endoscopy of a gastrostomy tube for feeding can be helpful in decreasing the risk of aspiration pneumonia in individuals with advanced disease.

Prognosis

Since there is no curative treatment, and therapy is mainly supportive and symptomatic, most affected individuals die within 10 years of onset, usually from status epilepticus or from complications related to nervous system degeneration.

Lance–Adams Syndrome

H Shibasaki, Takeda General Hospital, Kyoto, Japan

Glossary

Action myoclonus – Myoclonus induced by execution of willed movement.
Cortical myoclonus – Myoclonus originating from hyperexcitable motor cortex.
Cortical reflex myoclonus – Myoclonus induced by a transcortical reflex mechanism via the sensorimotor cortex.
Hypoxia – Decreased arterial oxygen causing insufficient oxygen supply to brain.
Intention myoclonus – Myoclonus induced by initiation of willed movement.
Myoclonus – Shock-like involuntary movements.
Negative myoclonus – Myoclonus caused by sudden lapses (silent period) of ongoing muscle contraction.
Positive myoclonus – Myoclonus caused by abrupt muscle contraction.
Postural myoclonus – Myoclonus induced during maintenance of posture (isometric muscle contraction).
Reticular reflex myoclonus – Myoclonus induced by a reflex mechanism via the brainstem reticular nucleus.

Definition and History

Lance–Adams syndrome is characterized by persistent postural or action/intention myoclonus occurring after acute hypoxic insult to brain, and is also called posthypoxic myoclonus.

In 1963, James W. Lance and Raymond D. Adams wrote a famous paper entitled 'The syndrome of intention or action myoclonus as a sequel to hypoxic encephalopathy' in *Brain*. In that paper, they described thoroughly the clinical and electrophysiological features of four cases of this condition. The cause of anoxia was cardiac arrest in two cases and airway obstruction in the other two. They were initially comatose for 2–4 days, and they were followed up by the authors for 1–8 years. Three cases had generalized convulsions while they were unconscious. Soon after recovery from coma, they exhibited multiple, intensive jerks. The jerks were more generalized in the early stage soon after the episode of hypoxia, but after a few days, the jerks became more restricted in site and more irregular. The arms were chiefly affected in two cases and legs in the other two. The jerks were elicited or enhanced by willed movement requiring precision and by emotional arousal. In addition, the jerks were very sensitive to external stimuli such as touch, pin prick, passive movement, and in two cases, to sound as well. They were especially sensitive to unexpected presentation of stimuli, showing a feature of startle myoclonus.

Electrophysiologically, electroencephalogram (EEG) in three cases showed positive–negative biphasic spike discharges at the central electrodes. Electromyogram (EMG), recorded with electrodes placed on the skin over the contracting muscles, showed abrupt muscle discharges in association with myoclonic jerks, which were often associated with the EEG spike activities. The spikes were localized to the midline vertex when the myoclonus involved legs, and to the lateral convexity when the myoclonus involved hands. The initial positive peak of the cortical spike led the myoclonic jerk by 7 ms for occipital muscles, 12 ms for biceps, 16 ms for wrist extensors, and 32 ms for quadriceps, which was compatible with the conduction time of impulses from the motor cortex descending to each muscle via the corticospinal tract and peripheral motor nerves.

Lance and Adams paid special attention to silent periods or lapses of muscle contraction, lasting up to 340 ms, either following myoclonic jerks or in isolation, which explained frequent falling attacks of those cases. The EEG spikes were often followed by slow wave lasting 80–250 ms. Thus, the time course was similar in the two electrophysiological parameters; spike followed by slow wave on EEG and abrupt muscle discharge followed by silent period on EMG. They also found that the EEG response similar to the spike-and-wave complex was elicited by pin prick of hand and it was accompanied by myoclonic EMG burst followed by silent period. The authors postulated a role of the thalamocortical volley relayed down the corticospinal tract as a possible mechanism underlying generation of those jerks.

Halliday in 1967 classified myoclonus into pyramidal, extrapyramidal, and segmental type, and the electrophysiological features of the above posthypoxic myoclonus matched with those of pyramidal myoclonus. Later Young and Shahani coined the term 'negative myoclonus' for the lapses of EMG discharges causing falling of limbs or drop attack.

Pathophysiology

The main feature of myoclonus described by Lance and Adams corresponds to what is now known as cortical myoclonus or cortical reflex myoclonus. In this condition, both the primary somatosensory cortex and the primary motor cortex are pathologically hyperexcitable, which can be demonstrated by electrophysiological studies. Spontaneous myoclonus is preceded by spike discharges arising from the corresponding area of the primary motor cortex which is located in the precentral gyrus. Electrical stimulation of peripheral nerves evokes extremely enhanced cortical responses in the corresponding area of the primary somatosensory cortex which is located in the postcentral gyrus, and this enhanced cortical response is followed by motor evoked potential at the stimulated site via a transcortical reflex mechanism. This long-loop reflex is also present in normal subjects while the corresponding muscle is kept in gentle contraction, but it is extremely enhanced in the patients with cortical reflex myoclonus and called C (named after 'cortical') reflex. The same phenomena can be demonstrated for the negative myoclonus. Namely, the EMG silent period is preceded by spontaneous cortical spikes arising from the corresponding part of the motor cortex, and somatosensory stimuli elicit silent periods via the transcortical reflex mechanism, thus called cortical reflex negative myoclonus. Since the patients with cortical or cortical reflex myoclonus often develop generalized convulsions, this type of myoclonus is also called epileptic myoclonus.

In case 3 and case 4 of the Lance and Adams' series, myoclonic jerks were induced by external stimuli including auditory stimulus especially when the stimuli were presented unexpectedly. As the startle myoclonus is an exaggerated form of physiological startle response and is mediated by brainstem reticular nucleus, it is most likely that those two cases had an additional feature of myoclonus called reticular reflex myoclonus. In this condition, the initial reflex jerk to the stimulus occurs in the muscles innervated by medulla oblongata, such as sternocleidomastoid and trapezius muscles, and then the jerks spread rostrally to involve facial muscles as well as caudally to limb muscles.

Autopsy cases of anoxic encephalopathy show extensive neuronal damage in multiple areas of brain, but neuropathological correlates of posthypoxic myoclonus have not been clearly elucidated. However, based on the common observation of cerebellar ataxia and cerebellar pathology in

these patients, impairment of cerebellar input to the motor cortex is postulated to be an important physiological mechanism underlying the pathogenesis.

Attempts to produce experimental models of posthypoxic myoclonus have been made to induce myoclonus in animals by experimental cardiac arrest or mechanical obstruction of major cardiac vessels. The rats subjected to these experiments, after recovering from acute anoxic state, manifested generalized reflex jerks in response to auditory stimulus. Thus, the clinical pattern in these experimental rats seems to resemble, at least in part, the reticular reflex myoclonus occasionally seen in patients with posthypoxic myoclonus. Pharmacological studies suggested dysfunction of neuronal circuits mediated by serotonin receptors, and valproate, clonazepam, and 5-hydroxytryptophan were found to suppress the jerks in the animals. However, typical positive and negative myoclonus of cortical origin commonly seen in patients with Lance–Adams syndrome have not been successfully produced in animals.

Epidemiology

The incidence and prevalence of posthypoxic myoclonus vary among geographical regions and among clinical institutions. It is the most common cause of postural and action myoclonus in cardiovascular disease centers, but in general neurology centers it is perhaps second to a group of diseases causing progressive myoclonus epilepsy, as listed in the Differential Diagnosis section.

Clinical Features and Diagnostic Criteria

Since postural or action/intention myoclonus is seen in a variety of diseases, the clinical manifestation itself does not make a final diagnosis of this condition. Therefore, the final diagnosis has to be confirmed by the preceding history of coma, often accompanied by generalized convulsions, due to cardiac arrest or airway obstruction. However, certain features are more commonly seen in the posthypoxic myoclonus than in other similar conditions. Abrupt falling of limbs and drop attacks due to negative myoclonus seem to be more commonly seen in patients with posthypoxic myoclonus as compared with other conditions presenting with similar clinical pictures. Further, the negative myoclonus tends to be more severe and even the dominating feature in posthypoxic cases. By contrast, generalized convulsive seizures seem to be less commonly encountered in posthypoxic cases, except for the acute phase of the illness, as compared with various conditions causing progressive myoclonus epilepsy.

In addition to myoclonus, the patients with posthypoxic myoclonus show cognitive and motor disturbances of various kinds and variable degrees depending on the severity of hypoxic insult to the brain.

Differential Diagnosis

A variety of diseases cause cortical or cortical reflex myoclonus. Among them, hypoxic encephalopathy and progressive myoclonus epilepsy are the two most common causes. The latter category is composed of a variety of conditions including Unverricht–Lundborg disease, Lafora disease, lipidosis, dentatorubral–pallidoluysian atrophy (DRPLA), ceroid lipofuscinosis, myoclonic epilepsy associated with ragged red fibers (MERRF) which is a form of mitochondrial disease, and benign adult familial myoclonic epilepsy. These are all hereditary neurodegenerative diseases. In addition, similar kinds of myoclonus are seen in patients with renal failure or uremic encephalopathy, and 'transient myoclonic state with asterixis in the elderly.'

The diagnosis of posthypoxic myoclonus is made without difficulty if the preceding history of hypoxic episode is known. However, when the precise history is not available, the clinical manifestation itself does not help distinguishing from other similar conditions. If there is similar condition in the patient's family, it suggests other conditions such as a group of neurodegenerative diseases comprising progressive myoclonus epilepsy. Metabolic encephalopathy, especially uremic encephalopathy, can cause positive and negative myoclonus of cortical origin, and its diagnosis depends on the results of laboratory test suggestive of renal failure. 'Transient myoclonic state with asterixis in elderly patients' was reported by Hashimoto et al. in 1992 and is characterized by negative myoclonus involving upper limbs seen only in the elderly people and lasting for 1–2 weeks. It is benign although the episode may recur.

Clinical symptoms and signs other than myoclonus are not helpful in the differential diagnosis, because other conditions, especially a variety of diseases causing progressive myoclonus epilepsy, show other associated clinical features such as motor and cognitive disturbances. In posthypoxic myoclonus, however, these symptoms and signs are usually not progressive whereas, in progressive myoclonus epilepsy, other symptoms and signs are slowly progressive.

Psychogenic myoclonus is commonly seen, and its diagnosis is sometimes established with difficulty. In psychogenic disorders, the jerks are often incongruous or difficult to be explained on the basis of recognized organic diseases. The jerks change from time to time in terms of their pattern, distribution, and frequency and tend to be suppressed by drawing the patient's attention to other

subjects; the effect of distraction. Furthermore, the patients often show other behavioral abnormalities or have psychogenic factors in the background.

Diagnostic Tests

Polygraphic recording of EMG and EEG is useful for confirming the nature of the jerks and for elucidating the underlying pathophysiology. In cortical myoclonus, EMG shows abrupt discharges of short duration (usually less than 50 ms) involving agonist and antagonist muscles synchronously. Silent periods are often recognized in the records, and they also involve agonist and antagonist muscles simultaneously. Simultaneous recording of EMG from multiple muscles is especially useful to see the distribution and spread of myoclonic jerks. The EMG polygraph also helps to detect the reticular reflex myoclonus which starts from the muscles innervated by medulla oblongata and spreading rostrally as well as caudally.

EEG shows spike-and-wave or multiple spikes-and-wave discharges at the central region. However, absence of spikes on EEG does not exclude the diagnosis of Lance–Adams syndrome. If the EEG discharges are associated with the EMG discharges, it strongly suggests the cortical origin of the myoclonus. Application of jerk-locked back averaging technique may disclose EEG spikes which are not otherwise detected on the conventional EEG records and will help investigating the precise time and spatial relationship between the cortical activities and myoclonus. Somatosensory evoked potentials might be pathologically enlarged. However, absence of giant somatosensory evoked potentials does not exclude the diagnosis of cortical myoclonus. Imaging study of brain may show some cortical and cerebellar atrophy, but no specific abnormality for this condition is known.

Management

Antimyoclonus agents such as clonazepam and sodium valproate are used, but myoclonus in this condition often tends to be resistant to the conventional anticonvulsants. Recently, levetiracetam was reported to be effective in some cases of posthypoxic myoclonus. Furthermore, in some patients whose myoclonus responds to ethanol like essential tremor, γ-hydroxybutyric acid, which is prescribed as sodium oxybate for treating cataplexy accompanying narcolepsy in the United States, was shown to be effective. A serotonin precursor, L,5-hydroxytryptophan, has been reported to be effective in some cases of posthypoxic myoclonus.

Prognosis

Posthypoxic myoclonus is usually persistent, causing severe disability for daily life, and resistant to various anticonvulsant treatment. Development of more effective antimyoclonus agents is expected to improve the prognosis.

Latah

M J Bakker and M A J Tijssen, University of Amsterdam, Amsterdam, The Netherlands

Glossary

Coprolalia – Pathological use of foul language.
Culture-specific syndrome – Forms of abnormal behavior restricted in distribution to defined racial or social groups, discrete areas of the world, or particular historical periods.
Echolalia – Pathological repetition of words just spoken.
Echopraxia – Pathological repetition of the acts of other people.

Definition and History

Latah is originally a Malay term for a broad category of strange behavior. Literally it means 'Tiklish,' 'Jumpy' or 'Love-madness.' It was suggested by Yap that references to Latah in Malay literature date to the fourteenth century. In 1849, Logan was the first to write in English about Latah behavior and to describe it as an uncontrollable startle reaction. There are only a few recent descriptions. Remarkably, the characteristics of Latah described over 100 years ago and those who were described recently are quite similar. However, the equal sex distribution described by O'Brien in 1884 has changed; Latah is nowadays a predominantly female disorder. The nature of the European presence in the Malayan World during colonial times has probably influenced the occurrence and/or the older reports on the Latah phenomenon.

Clinically, Latah is a *culture-specific syndrome* consisting of complex of behaviors occurring in Malayan or Indonesian patients. It includes nonhabituating hyperstartling and various other stereotypic behavioral responses like *coprolalia, echolalia, echopraxia*, 'forced obedience' (involuntary, immediate obedience to commands), and hyper suggestibility. It was described to occur in Indonesia and Malaysia but was also reported in certain regions of Africa and Arabia (this separate form differs slightly from the Malay/Indonesian form; e.g., it does not include *coprolalia*). As the features of the matching behavior are prominent and highly exploited by others, culture-specific startle syndromes like Latah are also referred to as startle-matching syndromes. There are several other similar syndromes (Jumping Frenchmen of Maine and Myriachit in Siberia), but the most extensive descriptions concern Latah. Latah is most often classified as a neuropsychiatric startle syndrome but to some extent may be seen as behavior and part of the Malay/Indonesian culture.

In 1968, Geertz described some Latah women at a party:

> "The first latah exclaimed in a loud voice to the second latah, 'Dag!', the Dutch greeting, 'Good-day!'. The latah, immediately responded, 'Dag!' several times, raising her hand automatically each time. When she paused, the first latah woman started her up again. Then, tired of this game, the first latah cried out, 'Merdeka!', the Indonesian slogan 'Freedom!' and the second latah imitated her, and again repeated it over and over. The first latah then left us to take care of her guests, and the second Latah quieted down. She was a very tense-looking woman, with large nervous eyes, of about sixty. She said nothing unless spoken to. It is the custom in Java at one of these feasts, for all of the guests to urge each other politely to eat, saying over and over again, 'Mangga!', 'Please eat!' The second latah had been sitting at the side for some time when she suddenly burst out – this time without being teased – with 'Manga, manga, manga!', compulsively repeating the polite word and its accompanying gesture, over and over. People then began to tease her and she grew more rattled, and in this upset condition began mixing obscene words in her speech. At one point she offered a cup of tea to someone, with the words 'please have some vagina'. The word for tea has something of the same sound as the word for vagina."

Pathophysiology

See Jumping Frenchmen of Maine. Malay/Indonesian cultural beliefs and habits play a role specifically in the etiology of Latah. Geertz mentioned the importance of elegant and polite speech, the concern over status, sexual prudery, and the dread of being startled as four cultural themes which are possibly related to Latah. It has been suggested by several authors that social repression of the women with often a low social status is an important etiological factor. The Indonesian neurologist Syahrir states that Latah patients demonstrate regression both as a form of protest and to evoke sympathy, acceptance, and pity for the person. He argues that rebellion (do prohibited things), dread or fear (for an authorial figure), and conditioning by the environment (attention) may play a part in the development of the symptoms.

Epidemiology

According to a study of Chiu published in 1972, the prevalence of Latah is well under the 1% (of 13.219 Malays, 69 Latah patients were identified). However, the same author estimated that Latah occurred in 15% of Malay females. In an earlier report of 1924, a number of 300 patients in total were described as seen by Dutch physicians working in Indonesia; about 80% of all the Dutch physicians who were interviewed indicated to have come across a Latah patient.

Clinical Features and Diagnostic Criteria

As the responses of the patients were never recorded, there are no clear diagnostic criteria other than that the responses are stimulus induced. Clinical features are *coprolalia* (more specifically, involuntary blurting of sexually charged words like genitalia), saying idiosyncratically stereotyped things or calling out the name of the thing that excited them (e.g.,'tiger!') *echolalia*, *echopraxia*, and compulsive unquestioning obedience when ordered to perform actions which may be ridiculous, improper, or even dangerous ('forced obedience'). Usually, the patients are prone to constant teasing by others. Latah is typically evoked by being poked forcefully in the side, loud noises, unexpected, or phobic objects (snakes, spiders, etc.) and possibly merely the presence of Westerners. The individuals are conscious while being Latah and able to recollect their behavior afterwards, but claim to not be able to constrain their actions. Latahs are typically middle-aged women of low social–economical status. However, Latah is also prevalent among homosexual transvestite males. In contrast to the Jumping Frenchmen of Maine, there is an absence of Latah among preadolescent children. Geertz described that the persons severely afflicted with Latah give an appearance of being under extreme tension. Those only mildly afflicted seem no different from the other people around them. The patients described in early recordings are typically servants of European employers, but this may be caused by an author's bias. Onset, often sudden and specific, tends to occur during periods of anxiety, depression, or worry, or in a situation in which the person finds himself (herself) wary. Intense life events (e.g., the death of a loved one), being intensely startled by others and a 'preonset' dream (of a sexual or a frightful nature) have been described as occurring shortly before onset of the symptoms. There may be different types of Latah, including at least a mild form, in which the response is associated with hyperstartling itself, and a more extreme form. One classification consists of the immediate-response Latah (episodes of hyperstartling with or without throwing, dropping, striking out, or cursing), attention-capture Latah (episodes in which matching or obedience may occur) and enacted Latah (a long sequence of absurd-appearing behavior, even in the absence of adequately startling stimuli). Concerning the latter, several authors wrote that Latah patients have to be separated into genuine cases and those which are basically histrionic and exhibitionistic in nature. Latah has a social function in the Malay/Indonesian society. Virtually everyone in the Malay community participates in the complex of behaviors concerning Latah, either as a Latah, or as an elicitor of Latah episodes, or as a spectator. Simons concluded: "to a great extent, it is the behavior of others towards potential Latah that results in developing Latah, and it is the behavior of others towards Latah that largely determines the behaviors that Latah perform." The other way round, Latah patients have a license to mock those about them regardless of relative social status and show conduct considered improper for Malay women. Lower-status persons are more likely to receive startle teasing than those of higher status. Although they are often embarrassed, Latahs are not considered either morally or legally responsible for what they do after being startled.

Prognosis

The condition is usually described as chronic. In Chiu's study of 37 Latah patients, 23 claimed that their symptoms were static, 8 improved, and 6 worsened.

Leaner Mouse

L C Abbott, Texas A&M University, TX, USA

Glossary

Ataxia – An inability to coordinate voluntary muscular movements, which is symptomatic of some nervous disorders.
Channel open probability – This is the probability that at any given point in time, a specific ion channel is likely to be open and to allow ions to pass through the channel instead of being closed and impermeable to ions.
Cortical spreading depression – Cortical spreading depression is a short-lasting depolarization wave that moves across the cortex at a rate of 3–5 mm min^{-1} and is associated with sensory disturbances during migraine auras.
Gangliosides – Gangliosides are unique acidic glycolipids that are selectively concentrated in the plasma membrane of cells. Gangliosides are found in highest concentration in cells of the nervous system, where they can constitute as much as 5% of the lipid.
n-NOS – Nitric oxide synthase (NOS) catalyzes the conversion of L-arginine to NO and L-citrulline. NOS exists in three major isoforms: (1) neuronal NOS (n-NOS); (2) endothelial NOS (e-NOS); and (3) inducible NOS (i-NOS). n-NOS is constitutively expressed and dependent on calcium ions and calmodulin to function.
Paroxysmal dyskinesia – These disorders are neurologic conditions that exhibit sudden episodes of abnormal involuntary movements. These may include combinations of involuntary, rapid, irregular movements (chorea), and slow, writhing motions (athetosis) as well as other types of involuntary movements. The term paroxysmal indicates that the abnormal movements are episodic and the individual will eventually return to normal motor function and/or behavior.
Phospholipids – These can be any of a variety of phosphorus-containing lipids that are composed mainly of fatty acids, a phosphate group, and a simple organic molecule such as glycerol. Phospholipids are the main lipids found in cell membranes.
SGGLs (sulfoglucuronyl glycolipids) – SGGLs are a type of ganglioside. Gangliosides are a type of glycosphingolipid. Gangliosides are expressed in the surface membranes of vertebrate nerve cells. SGGLs are temporally and spatially regulated during the development of the nervous system.
Spike-and-wave discharges – These are abnormal discharges that are observed in an electroencephalogram (EEG) and typically observed during epileptic seizures. The absence seizure (also called 'petit mal' epilepsy) displays a very distinctive oscillation consisting of generalized and bilaterally synchronous spike-and-wave EEG patterns recurring at a frequency of about 3 Hz in humans.

History

In 1960, an AKR/J mouse displayed a prominent movement disorder phenotype, which was due to a spontaneous, autosomal recessive mutation, but this mutation had not received the name, 'leaner,' until 1963. In 1971, this mutation was identified as an allele at the tottering locus and also discovered to be closely linked to serum esterase, *Es-1* and oligosyndactyly, *Os*. Crossing over events are exceedingly rare between the tottering locus and *Os*, making *Os* an extremely useful marker to visually distinguish between heterozygous and homozygous leaner (and tottering) mice. Currently, the leaner mutation resides on the C57BL/6 background. It is important to note that when the leaner mutation was transferred to an inbred Swiss White Webster background, no significant alteration in phenotypic expression was observed.

Description of the Mutation

The leaner mutation maps to the *Cacna1a* gene, which codes for the α_{1A} calcium channel pore-forming subunit of Cav2.1 (P/Q-type) voltage-gated calcium ion (Ca^{2+}) channels. Several different mutant mouse alleles also exist at this same locus, including tottering, rolling Nagoya, and rocker. The leaner mutation is designated as *Cacana1a*$^{tg\text{-}la}$. The resulting defect is a splice donor mutation that causes truncation of the open reading frame and deletion of the C-terminus of the α_{1A} protein. There appear to be few differences in *Cacna1a* mRNA or protein expression levels in the leaner cerebellum compared with age-matched wild-type mouse cerebella. Three human neurological diseases are attributed to CACNA1A mutations: episodic ataxia type 2 (EA-2), familial hemiplegic migraine (FMA), and spinocerebellar ataxia type 6 (SCA6).

Clinical and Morphological Features

Clinical and morphological features of leaner mice were first described in the Catalog of the Neurological Mutants of the Mouse and are summarized in **Table 1**. Homozygous leaner male and female mouse pups exhibit major locomotor abnormalities as early as postnatal days 8–10, and include ataxia, stiffness, and reduced motor activity. Motor impairments increase during the second and third postnatal weeks with juvenile homozygous leaner mice demonstrating increased periods of brief immobility as well as periodic rigid hypertonia of trunk and limb muscles, but curiously, leaner mice do not exhibit tremor, which is typically associated with cerebellar defects. Leaner mice are among the most severely affected cerebellar mutant mice with respect to ataxia and typically exhibit a wide-based hind limb stance when standing or attempting to walk. Leaner mice typically repeatedly fall to their side after only one or two steps and they cannot swim.

Leaner mice also exhibit nonconvulsive, generalized spike-and-wave discharges (SWDs) that are quite similar to human absence epilepsy. SWDs display an average of 6–7 spikes per second with typical durations of one to several seconds. Numerous SWDs can occur when mice are awake and SWDs are accompanied by absence seizures, which are characterized as a behavioral arrest with a fixed staring posture, twitching of vibrissae, and sometimes

Table 1 Summary of leaner mouse characteristics

Neurological disorders	*Morphological characteristics*	*Biochemical characteristics*	*Electrophysiological characteristics*
Severe cerebellar ataxia without tremor	Purkinje cell, granule cell, golgi cell loss postnatally	Reduced calretinin mRNA and protein expression in cerebellar granule cells	60% reduction in P-type Ca^{2+} current
		Reduced calbindin and parvalbumin mRNA expression in Purkinje cells	
6–7 Hz spike and wave epileptiform discharges that are accompanied by absence seizures	Reduced cerebellar volume and weight	Decreased nNOS mRNA in cerebellar granule cells at postnatal day 20; n-NOS mRNA and NADPH-d staining decreased in adult cerebella	Threefold reduction in the open-probability of Cav2.1 channels and no difference in single-channel conductance
	Atrophic dendritic branches and reduced Purkinje cell area	Aberrant TH and zebrin II (aldolase C) protein expression in surviving Purkinje cells	Decreased α_{1G} (T channel) mRNA expression in cerebellar granule cells and increased α_{1G} expression in Purkinje cells
	Ectopic spines on Purkinje cell dendrites	Significantly reduced serum and cerebellar IGF-I protein concentrations at postnatal day 30	
Paroxysmal dyskinesia expressed in juvenile and young adult leaner mice and decreasing after postnatal days 50–60	Minor atrophy in leaner inferior olive	Elevated phospholipids and decreased gangliosides in leaner cerebellum at postnatal day 21	10x resistance to cortical spreading depression and slower transcortical propagation speeds
	Moderate proliferation of glia in sites of Purkinje cell loss	Sulfoglucuronyl glycolipids (SGGLs) decreased in surviving Purkinje cells	Purkinje cells exhibit lower current threshold for Na^{+} spike firing, larger subthreshold membrane depolarizations and do not generate Ca^{2+}–Na^{+} spike bursts
	Moderate loss of myelinated fibers in cerebellar white matter	Calcium buffering values (ratio of bound/free calcium ions) significantly reduced	

myoclonic jerks of the head or jaw. A third neurologic disorder, previously described in various ways but currently thought to be paroxysmal dyskinesia, has been reported to be present in homozygous leaner mice. Paroxysmal dyskinesia episodes decrease significantly after postnatal days 40–50 in leaner mice, which is the age of peak Purkinje cell loss in the leaner cerebellum (see the following paragraph), suggesting that dysfunctional Purkinje cells in the anterior cerebellum are important for the expression of paroxysmal dyskinesia and loss of Purkinje cells decreases the expression of this phenomenon in adult leaner mice. This observation is supported by lesioning the anterior cerebellum in homozygous tottering mice, which also reduces the incidence of paroxysmal dyskinesia, indicating that the anterior cerebellum is important for maintaining the expression of this specific neurological disorder.

Adult leaner mice exhibit severe cerebellar atrophy (see **Figure 1**; arrows indicate cerebellum), resulting from a gradual degeneration of cerebellar granule, Purkinje, and Golgi cells. Peak cerebellar granule cell death occurs at P20, while Purkinje cell death peaks at P40–50. Cerebellar Purkinje cell loss is restricted to alternating sagittal compartments of the leaner cerebellar cortex. There is significantly more Purkinje cell loss in the anterior cerebellar lobe than in the posterior lobe, which is accompanied by aberrant expression of tyrosine hydroxylase (TH) expression in surviving adult Purkinje cells. The expression of TH is normal in the major catecholaminergic nuclei in homozygous leaner mice, but the normally transient developmental expression of TH in a parasagittal 'striped' pattern remains in surviving cerebellar Purkinje cells in adult leaner mice and not in wild-type mice. Purkinje cells primarily use GABA as a neurotransmitter and TH expression in noncatecholaminergic neurons may have an important but transient role in neuronal development that is not suppressed in leaner mice. The leaner Purkinje cells expressing TH also express zebrin II. The major clinical features correlate well with localization of major Purkinje cell loss in the anterior cerebellar lobe. Additional changes in cellular physiology and protein expression in leaner mice are summarized in **Table 1**. Leaner cerebella exhibit enlarged parallel fiber varicosities synapsing on two or more Purkinje cell dendritic spines along with the typical one-to-one spine to varicosity contacts. Leaner Purkinje cells commonly present atrophic dendritic branches with ectopic spines, and Purkinje cell axons display numerous swellings called 'torpedos.' Minor atrophy also has been observed in leaner inferior olive nuclei. Changes in IGF-1 and n-NOS expression has been observed in specific cerebellar neurons and at specific ages in leaner mice (see **Table 1**).

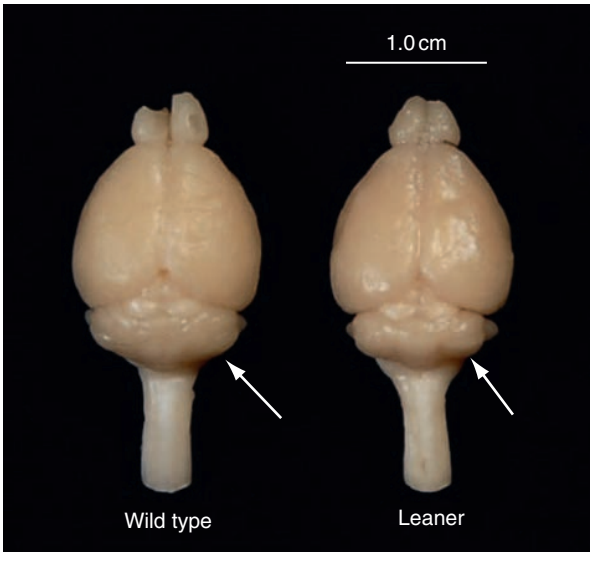

Figure 1 Photomicrograph comparing the dorsal view of an adult wild-type mouse brain to an age-matched homozygous leaner mouse brain. The arrows point to the cerebellum. Note the much smaller leaner cerebellum compared to the wild-type cerebellum.

Homozygous leaner mice are reported to exhibit reduced viability and often die in the third or fourth postnatal week. However, leaner mice die due to hypothermia, dehydration, and/or starvation brought on by their locomotor deficits. If homozygous leaner pups are fostered to lactating foster dams and their diet is supplemented with moistened rodent chow that is easily accessible, both male and female leaner mice actually have a longer life span than wild-type C57BL/6 mice. The critical time period for survival of homozygous leaner mice appears to be postnatal weeks 3–8, which is the time frame during which the majority of cerebellar neuronal cell death takes place.

Channel Characteristics

Leaner Purkinje cells show a 60% decrease in Ca^{2+} current density with little to no alteration in the voltage dependence of channel gating. Leaner Purkinje cells also show a threefold reduction in the open-probability of channels relative to wild-type Purkinje cells, which may account for the observed reduced whole-cell current. Calcium buffering values (ratio of bound/free ions) were significantly reduced in leaner Purkinje cells relative to wild-type cells and calbindin D28k and parvalbumin mRNA levels also were reduced in leaner Purkinje cells, while calretinin expression was decreased in cerebellar granule cells. Altered T channel expression, cortical spreading depression, and transcortical propagation speeds have been noted for the leaner mouse (see **Table 1**).

Characteristics of Heterozygous Leaner Mice

Early reports suggested that heterozygous leaner mice were behaviorally and morphologically indistinguishable from wild-type mice, but we now know that this is not the case. Functional studies showed a reduction of ~30% in Ca^{2+} conductance in heterozygous leaner Purkinje cells. Heterozygous leaner mice show age-dependent impairment on the rotarod and hanging wire test and spatial learning and memory impairments in the Morris water maze. Progressive dysfunction in escape reflexes also are observed in heterozygous leaner mice and they exhibit impaired motor learning in the vestibulo-ocular reflex, suggesting that subtle disruption of Cav2.1 Ca^{2+} currents is sufficient to disrupt motor function.

Leigh Syndrome

M Hirano, University Medical Center, New York, NY, USA

Glossary

ATP synthase – Complex V of the mitochondrial pathway that generates ATP by oxidative phosphorylation.
Cytochrome *c* oxidase (COX) – Complex IV of the mitochondrial respiratory chain.
Heteroplasmy – A mixture of different forms of multicopy DNA molecules (e.g., mtDNA).
Homoplasmy – A uniform population of multicopy DNA molecules.
Maternal inheritance – Vertical transmission of DNA from mother to progeny.
Mitochondrial DNA – A small (16 569 base-pair) circular DNA molecule within mitochondria and encoding 37 genes. Abbreviated to mtDNA.
Oxidative phosphorylation – The mitochondrial metabolic pathway that utilizes energy released by the oxidation of nutrients (mainly carbohydrates and fatty acids) to generate adenosine triphosphate.
Ragged-red fibers – Abnormal muscle fibers with subsarcolemmal reddish appearance by modified Gomori trichrome stain.
Respiratory chain – A set of four multisubunit enzymes (complexes I–IV) embedded in the mitochondrial inner membrane that transfer reducing

equivalents (electrons) to generate a transmembrane proton gradient.
Succinate dehydrogenase – Complex II of the mitochondrial respiratory chain, abbreviated to SDH, and a component of the tricarboxylic acid cycle.
Transfer RNA – A small RNA molecule that transfers an amino acid to a growing polypeptide.

Definition and History

Leigh syndrome (LS or subacute necrotizing encephalomyelopathy) was originally described in 1951 by Dr. Denis Leigh, a British neurologist, who reported a 6.5-month-old infant boy presenting with developmental regression that progressed quickly and led to death 6 weeks later. At autopsy, Dr. Leigh observed multiple symmetric foci of spongy degeneration with microvascular proliferation in the brainstem tegmentum, thalami, cerebellum, posterior columns of the spinal cord, and optic nerves. He astutely noted that the neuropathological alterations resembled those of Wernicke syndrome but spared the mamillary bodies: a consistent feature that distinguishes the two disorders. Subsequently, hundreds of patients with 'Leigh disease' were reported and the condition was renamed LS in recognition of the diverse biochemical and genetic etiologies. The term Leigh-like syndrome has been used to describe patients with clinical and other manifestations of LS, but have uncharacteristic features such as atypical neuropathology or unusual or normal brain MRI scans.

Pathogenesis and Pathophysiology

Deficiency of pyruvate carboxylase was the first biochemical defect linked pathogenically to LS. We now know that the biochemical causes of LS are heterogeneous and include defects of pyruvate dehydrogenase complex (PDHC) and mitochondrial respiratory chain complexes I, II, IV, and V. The inheritance pattern depends on the specific defective gene, but may be autosomal recessive, X-linked recessive, or maternal. Although the specific causes of LS are biochemically and genetically diverse, the unifying metabolic defect in all patients is impaired adenosine triphosphate (ATP) synthesis.

Among the mitochondrial DNA (mtDNA) defects that cause LS, the m.8993T→G and m.8993T→C point mutations in the ATP synthase gene are particularly common (**Table 1**). Both mutations were originally described in patients with neuropathy, ataxia, and retinitis pigmentosa

Table 1 Molecular genetic causes of Leigh or Leigh-like syndrome

Biochemical or genetic defect	*Transmission*	*Approximate frequency*
Pyruvate dehydrogenase complex (PDHC) deficiency		
PDHC E1-alpha subunit	XR	20%
Complex I defects		
NDUFS1, NDUFS2, *NDUSF4*, *NDUFS6, NDUFS7*, *NDUFS8*, *NDUFV1,* and *NDUFV2*	AR	20%
NADH dehydrogenase (ND) subunits	Maternal	<10%
ND6: m.14487T→C, m.14459G→A, m.14484T→C		
ND5: m.13513G→A, m.13514A→G, m.12706T→C		
ND4: m.11777C→A m.10197G→A		
ND3: m.10158T→C, m.10191T→C		
Complex II defects	AR	Rare
SDHA		
Complex IV	AR	25%
SURF1, COX10, COX15, SCO2, LRPPRC		
COXIII	Maternal	
Complex V defects		
ATP synthase subunit 6	Maternal	15–20%
m.8993T→G, m.8993T→C, m.9176T→C, m.9176T→G, m.9191T→C, m.8851T→C, m.9185T→C		
Multiple respiratory chain complex defects		< 5%
mtDNA tRNA genes		
m.3243A→G, m.1624C→T m.1644G→t, m.8363G→A, m.5537insT	Maternal	
mtDNA single deletion	Sporadic	
mtDNA depletion	AR	
SUCLA2		
mitochondrial protein synthesis defects	AR	
EFG1		
Biotinidase deficiency	AR	Rare
Pyruvate carboxylate deficiency	AR	Rare

(NARP), but later found to also cause maternally inherited LS (MILS). In addition, mtDNA mutations in complex I (NADH dehydrogenase (ND)) subunit genes are common causes of LS; the ND5 and ND3 genes are hotspots for LS mutations. The disorder is often caused by autosomal recessive mutations affecting structural subunits or ancillary factors required for the synthesis of mitochondrial respiratory chain complexes I, II, IV, or V. Nuclear genes for complex I structural subunits and complex IV ancillary factors (e.g., *SURF1*) are especially common causes of autosomal recessive LS. Primary CoQ_{10} deficiency can also cause LS.

Epidemiology/Risk Factors

In southeastern Australia, the prevalence of LS or Leigh-like syndrome was estimated to be 1:40 000 live births and in western Sweden, the prevalence of LS in preschool children was 1:34 000 live births. The major risk factor is the presence of a LS-associated mtDNA mutation in the maternal lineage or LS-associated nuclear mutations in relatives.

Clinical Features and Diagnostic Criteria

The diagnosis of LS is based upon the clinical features of motor and intellectual regression with dysfunction of the basal ganglia, brainstem, or both along with either neuroradiological or neuropathological evidence of symmetric lesions in the basal ganglia, thalamus, and brainstem.

The clinical presentations of LS are heterogeneous, due to variations in age-of-onset, rates of progression, frequency of epilepsy, and presence or absence of pigmentary retinopathy. The onset is often acute and may coincide with a febrile illness or may follow a seizure. Most LS patients present in infancy with psychomotor regression, while some present in childhood or adolescence. Adult-onset LS is uncommon. In infants with LS, besides developmental regression, generalized hypotonia, feeding problems, progressive vision loss due to optic neuropathy or pigmentary retinopathy, progressive external ophthalmoplegia, hearing loss, nystagmus, ataxia, and seizures are typical manifestations. In addition, failure to thrive, dysarthria, vomiting, and diarrhea are common manifestations. Respiratory dysfunction is often prominent and often causes death. In older infants or young children, LS may begin with ataxia, dystonia, or intellectual decline. Typically, patients show episodic deterioration with periods of clinical stability.

Genotype–phenotype correlations in patients with LS show that patients with T8993G NARP mutation often (40%) have retinitis pigmentosa, which is a clue to the molecular diagnosis, because retinitis pigmentosa is rarely – if ever – seen in other forms of LS. In addition, seizures are more common in patients with the NARP mutation or PDHC deficiency compared with children with LS due to COX deficiency.

Differential Diagnosis

Psychomotor regression, the major clinical manifestation of LS, is also a common presentation in other inborn errors of metabolism, including white matter diseases (e.g., vanishing whiter matter disease), congenital disorders of glycosylation, defects of amino acid metabolism, and disorders of carbohydrate metabolism.

Diagnostic Workup/Tests

The clinical diagnosis of LS is usually confirmed by brain magnetic resonance imaging (MRI) scans, which reveal increased signals in the basal ganglia and brainstem on T2-weighted or FLAIR images. The lesions are typically symmetric and commonly affect the putamen, globus pallidus, caudate, thalami, substantia nigra, inferior olivary nuclei, periaqueductal gray matter, and brainstem tegmentum. Magnetic resonance spectroscopy (MRS) scans reveal decreased *N*-acetylaspartate and increased lactate in the affected brain regions.

Urine organic acid and amino acid analyses are useful to exclude other inborn errors of metabolism and may reveal elevated urine lactate in patients with LS due to a respiratory chain defect. An increased urine excretion of methylmalonic acid has been reported in patients with LS due to mutations in *SUCLA2*.

To identify the molecular genetic cause of LS in patients, blood lactate and pyruvate may provide helpful preliminary clues. Defects of the mitochondrial respiratory chain and oxidative phosphorylation typically elevate lactate out of proportion to pyruvate (lactate:pyruvate ratio > 20:1). By contrast, a defect of PDHC may be suspected when pyruvate and lactate are similarly increased. PDHC deficiency can be determined in cultured fibroblasts. Defects of the mitochondrial respiratory chain are better identified by biochemical analyses of skeletal muscle biopsies, but can also be detected in cultured fibroblasts. In patients suspected of having MILS, based on family history, blood DNA can be screened for point mutations in the *ATPase 6* gene.

In patients with mitochondrial respiratory chain defects, screening for cardiac, hepatic, and renal involvement is important.

Management

Treatment of LS is mainly symptomatic, but important and includes the management of seizures with anticonvulsants (avoiding valproic acid and barbiturates if

possible), the treatment of dystonia (e.g., benzhexol, baclofen, tetrabenazine, and gabapentin), and standard therapies for cardiomyopathy and renal disease if present. CoQ_{10} supplementation is often given to LS patients with respiratory chain defects, but is particularly crucial for patients with CoQ_{10} deficiencies at high doses (up to 30 mg kg^{-1} day^{-1}). Thiamin (vitamin B1) is a cofactor for PDHC and can be beneficial in PDHC defiency. Riboflavin (vitamin B2) may have modest therapeutic value in deficiencies of complex I or II. Antioxidants (e.g., vitamin C, alpha lipoic acid, and idebenone) are often administered, but have not been proved to be efficacious through placebo-controlled clinical trials. Dichloroacetate (DCA) reduces lactic acid by activating PDHC and has been used to acutely lower lactate in LS, but long-term DCA use in patients with MELAS caused peripheral neuropathy, indicating that chronic use may be more harmful than beneficial.

In families with an identified molecular genetic defect, prenatal diagnosis is often feasible, particularly with autosomal recessive mutations or with mtDNA mutations in the *ATP6* gene (see NARP section).

Prognosis

The clinical course of LS is variable and characterized by episodic deterioration with periods of clinical stability. Most infantile-onset LS patients die before the age of 2 years of respiratory or cardiac failure.

Lesch–Nyhan Disease

H A Jinnah, Emory University School of Medicine, Atlanta, GA, USA

Glossary

Dystonia – Involuntary movements characterized by twisting and unnatural posturing.
Gout – A form of arthritis caused by precipitation of uric acid in the joints.
Hyperuricemia – Elevated serum uric acid.
Nephrolithiasis – Kidney stones.
Purines – A class of small organic molecules required by all living cells for many basic biochemical processes, examples include ATP, adenosine, and uric acid.
Tophi – Plural form of tophus, which is a solid subcutaneous deposit of uric acid.
Uric acid – A naturally occurring end-product of purine metabolism that may serve as an antioxidant.

Definition and History

Lesch–Nyhan disease (LND) is an inherited metabolic disorder that was described by William Nyhan and his

student Michael Lesch in 1964. The clinical features of the classical phenotype include a characteristic neurobehavioral developmental syndrome along with signs of overproduction of uric acid.

Clinical Features

The neurobehavioral syndrome includes severe generalized dystonia, sometimes with spasticity and chorea. The majority of patients also have mild or moderate cognitive disability, with the most prominent difficulties with attention and executive functions. They also exhibit stereotypical self-injurious behavior, a telltale feature characteristic of the classical phenotype (**Figure 1**). Signs indicative of overproduction of uric acid include hyperuricemia, gouty arthropathy, uric acid kidney stones, or subcutaneous tophi (**Figure 1**).

In addition to the classical phenotype, there has been increasing recognition of variant forms of the disease where some clinical features are attenuated or absent. The LND variants all suffer overproduction of uric acid, but they lack the telltale feature of self-injurious behavior. Some have normal cognition, and motor disability varies greatly. Some have severe generalized dystonia with spasticity and chorea similar to the classic phenotype. Others have milder generalized dystonia, focal patterns of dystonia, or minor clumsiness. The most mildly affected cases overproduce uric acid but have no apparent neurobehavioral abnormalities.

Epidemiology

LND and its variants are considered 'ultra-rare' diseases, occurring worldwide with no significant regional variations. Incidence estimates range from 1 per 235 000–380 000 births and prevalence estimates range from 1 per 2.3–3.5 million persons. Since LND is inherited as an X-linked recessive disorder, virtually all cases are male.

Pathogenesis

LND and its variants are caused by mutations in the gene that encode an enzyme, hypoxanthine–guanine phosphoribosyltransferase (HPRT). The mutations are heterogeneous, with more than 300 distinct gene defects reported.

Figure 1

Mutations that result in dysfunctional proteins with less than 1.5% of normal HPRT enzyme activity cause the classical phenotype of LND. Mutations that result in enzymes with more than 2% of residual function result in the milder phenotypes. There is a good correlation between residual enzyme function and clinical severity.

The HPRT enzyme plays a central role in the recycling pathway for purines, small organic molecules that play an essential role in many cellular processes (**Figure 2**). Without HPRT, the bases hypoxanthine and guanine cannot be recycled. Instead, they are excreted or degraded to uric acid. Since uric acid is close to its limit of solubility in the body, increased levels cause it to precipitate in certain areas of the body. Precipitation in the joints causes gouty arthritis, and precipitation in the subcutaneous tissues results in solid masses known as tophi. Uric acid is excreted by the kidneys, where high levels result in kidney stones. Thus, many of the clinical manifestations of the disorder result from the poor solubility of uric acid.

The pathogenesis of the neurobehavioral disturbances is less well understood. Neuroimaging with CT or MRI does not reveal any dramatic structural anomalies. Neurochemical studies of brain tissue reveal 60–90% reductions of dopamine in the basal ganglia. These results led to speculation that nigrostriatal dopamine axonal projections fail to develop properly, or that they undergo early degenerative changes. However, studies in animals and tissue culture models suggest that the loss of dopamine is due to metabolic processes instead. In keeping with this concept, human autopsy studies fail to reveal any consistent histopathology among dopamine neurons.

It is likely that early developmental failure of the dopamine pathways contributes to the neurobehavioral phenotype. Early loss of dopamine is known to cause dystonia in other metabolic disorders, such as dopa-responsive dystonia. The pattern of cognitive dysfunction is also consistent with a loss of dopamine. Finally, animal studies show that early brain dopamine loss sensitizes to the development of self-injurious behavior. Thus, dysfunction of basal ganglia dopamine pathways during early development may be a central process underlying much of the neurobehavioral phenotype in LND.

Diagnosis

Preliminary suspicion for LND arises when all of the clinical features are apparent. The diagnosis is more challenging during early development, when all of the features are not yet apparent. The diagnosis is particularly challenging in the LND variants, because they do not exhibit certain telltale features of the disease.

Laboratory confirmation is essential, because of the implications for treatment and genetic counseling. Serum uric acid can be obtained by most clinical laboratories, and hyperuricemia provides a useful early clue to the diagnosis. Hyperuricemia is found in most cases, but its magnitude may be minor and easily overlooked, and some patients have normal serum levels (**Figure 3**). Serum uric acid is sometimes elevated in disorders other than LND. Thus, hyperuricemia is neither sufficiently sensitive nor specific to serve as a definitive test.

Genetic testing can identify mutation in the HPRT gene. Since mutations are heterogeneous, the entire coding region is usually sequenced. Genetic testing provides the most convenient means for screening potential female carriers. Its main limitation is that it does not always

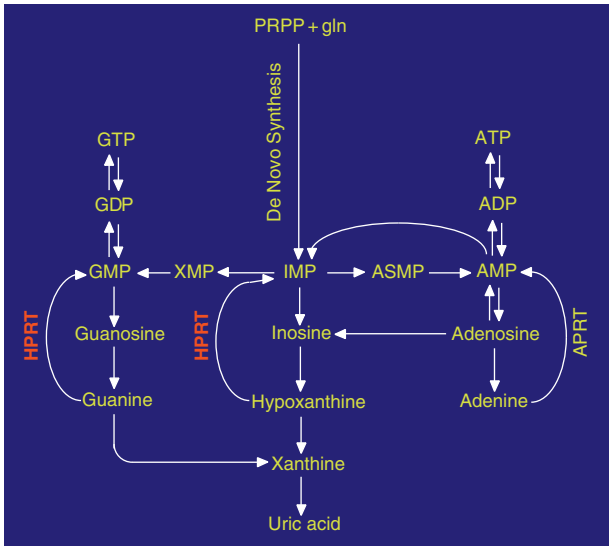

Figure 2

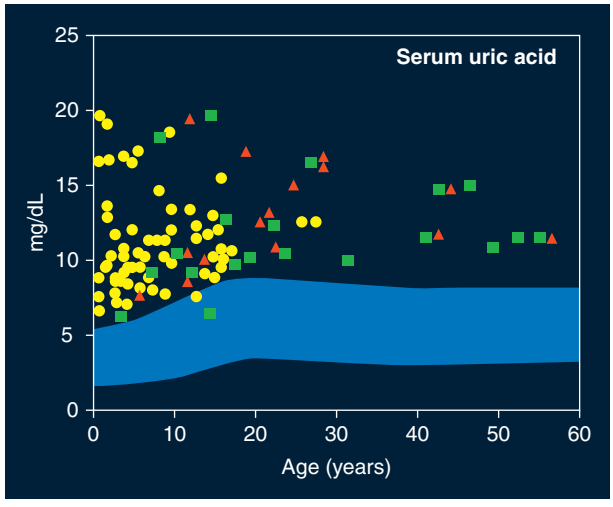

Figure 3

provide prognostic value for distinguishing classic LND from the less severely affected variants.

Biochemical testing of HPRT enzyme activity is not standardized, and many different assays are in use. Assays based on live cells (e.g., whole erythrocytes in suspension or cultured fibroblasts) are considered superior to extract-based assays for predicting disease severity. Its main limitation is that it is technically more demanding and less suitable for carrier detection. A combination of biochemical and genetic tests is performed for most cases.

Management

Uric Acid Overproduction

Controlling overproduction of uric acid is essential for preventing kidney stones and gout. Proper treatment requires two interventions. One is allopurinol, which inhibits the production of uric acid by the enzyme xanthine oxidase. The other is generous hydration to maintain high urine volumes. Despite best medical therapy, regular renal ultrasounds are sometimes needed, because some patients will continue to develop kidney stones. Lithotripsy or surgical extraction is sometimes needed in refractory cases.

Motor Disorder

Like most other generalized dystonias, medical treatments are limited. Anticholinergics and levodopa do not appear to have a major impact, but may be useful in some patients. Muscle relaxants such as baclofen or benzodiazepines can help reduce muscle tone. Severely affected patients remain wheelchair-bound and need assistance for basic activities such as feeding and hygiene. A custom wheelchair, with all dangerous parts covered with padding to prevent self-injury, is an important part of good supportive care.

Aberrant Behaviors

Self-injurious behaviors are the most challenging to control. These behaviors are exacerbated by physical or psychological stressors. The most effective approach involves a combination of behavioral therapy to extinguish problem behaviors, protective devices to prevent self-injury, and ancillary medications when required. Protective devices include arm splints or straps to prevent the hand from reaching dangerous places. Many patients require tooth extraction for definitive control of self-biting. Useful medications include benzodiazepines, gabapentin, and neuroleptics. Enthusiasm for chronic use of neuroleptics is limited by known side effects, but occasional use can be helpful during difficult periods.

Prognosis

Although many texts and reviews list LND among the hereditary degenerative syndromes, there is no evidence for a degenerative process. The clinical features evolve in a manner suggestive of a developmental disorder analogous to cerebral palsy, with evolution during the first few years of life, followed by a static level of disability.

With good supportive care, patients with LND live to their fourth or fifth decades. Typical causes of death include aspiration pneumonia or renal failure from recurrent nephrolithiasis. Some suffer sudden and unexpected death of unknown cause.

Levodopa

J Aldred and J Nutt, Oregon Health & Science University, Portland, OR, USA

Glossary

Decarboxylation – The metabolism of L-DOPA into the neurotransmitter dopamine.
Large neutral amino acid transporter – Transporter found in bowel and blood–brain barrier that is specific to large and branched chain amino acids.
Long-duration response – Clinical effect of levodopa seen early with treatment with levodopa that builds up after several days of drug administration and declines several days or longer after drug withdrawal.
Short-duration response – Clinical effect of levodopa seen when motor fluctuations occur. This may reflect plasma levodopa concentration.

Biochemistry of Levodopa

Levodopa or dihydroxyphenylalanine (DOPA) is a large neutral amino acid (LNAA) that is the precursor for catecholamines: dopamine, norepinephrine, and epinephrine. Levodopa is not normally found in the diet of humans and must be synthesized from the dietary LNAAs, phenylalanine, and tyrosine. Tyrosine is taken into neurons and hydroxylated to DOPA by the enzyme tyrosine hydroxylase, which is the rate-limiting step in catecholamine synthesis. The concentration of tyrosine in the brain depends on plasma levels of tyrosine and other LNAAs competing for transport into the brain by the LNAA transporter.

The discovery by Hornykiewcz that dopamine concentrations were extremely low in the striatia of humans with PD suggested that replacement of dopamine in the striata would reduce the signs of the disease. Dopamine, however, would not cross the blood–brain barrier and therefore would not raise striatal levels of dopamine. However, the work of Carlsson had shown that DOPA could be administered to rats that had the brain catecholamines depleted by reserpine and reverse the catatonia induced by reserpine. The DOPA required only decarboxylation by the enzyme aromatic amino acid decarboxylase (AAAD) to be converted into dopamine. Hornykiewcz and Birkmayer were stimulated by Carlsson's observations to try administering DOPA intravenously to patients with PD. They reported brief resolution of parkinsonism. Their observations were difficult to reproduce and intravenous administration of DOPA was clearly impractical. In 1967, Cotzias reported that L-DOPA administered in large oral doses would markedly improve parkinsonism and thereby changed the treatment of PD. Soon thereafter, the biologically active form of DOPA, the levo isomer, L-DOPA or levodopa, which is the mainstay of PD treatment today, became available.

Absorption and Distribution of Levodopa

Unlike most centrally active drugs that diffuse across membranes, levodopa is actively transported by the LNAA transporter that carries all the dietary LNAAs across cellular membranes. This transporter may be saturated by high concentrations of dietary LNAAs and limit the amount of levodopa absorbed. After oral administration, levodopa is absorbed in the small bowel where LNAA transporters are located. The stomach and large bowel do not have the LNAA transporters and therefore are not absorptive sites for levodopa. Thus, the absorption of levodopa is limited to the time for which levodopa is in the small bowel, a fairly constant, 2–3 h in most people. This point is particularly important to understanding the variable relationship between oral levodopa administration and the plasma levodopa concentrations. Thus, factors that alter delivery of levodopa to small bowel or passage through the small bowel will affect when and to what extent levodopa will appear in plasma.

Gastric emptying greatly influences the timing of levodopa absorption. The administration of levodopa in the morning before breakfast generally results in a rapid absorption, plasma levodopa peaking within 1 h. Delayed gastric emptying caused by meals with high fat and protein content or by medications that slow gastric motility may result in a delayed passage of levodopa to the small bowel and thus entry into blood. As gastric acidity increases, the time to peak plasma concentration of levodopa increases, presumably due to delayed gastric emptying. A small study has implicated *Heliobacter pylori*-induced alteration in gastrointestinal function, which may impair levodopa handling and result in poor response to oral therapy.

The absorption of levodopa in the small bowel is influenced by two factors. First, competition for transport between levodopa and other LNAAs may occur during absorption in the gut. However, the LNAA system has a large capacity in the gut so that the competitive inhibition of levodopa at this location is probably not an important issue.

The second is an enzymatic barrier to entry. The bowel has high concentrations of AAAD and decarboxylation of levodopa will make it unavailable as a precursor to dopamine synthesis in the brain. Inhibitors of AAAD, such as carbidopa or benserazide, reduce this first pass metabolism of levodopa by the gut and the liver.

After oral dosing levodopa appears rapidly in the plasma and is rapidly distributed from plasma into tissue. The distribution half-life is about 15 min. This means that after stopping an intravenous infusion of levodopa, the plasma concentration is halved in 15–30 min and represents the passage of levodopa from plasma into other body tissues. This rapid distribution and rapid metabolism result in a plasma half-life of <2 h.

Levodopa, as a member of the essential LNAA class of amino acids, enters all tissues and there are large amounts in liver and muscle. Distribution of levodopa to brain is the essential step for the therapeutic efficacy of levodopa. The transport of levodopa through the blood–brain barrier is proportional to the ratio of plasma concentration of levodopa and the concentrations of other LNAAs competing for the limited capacity LNAA transporter. This LNAA transporter is saturated at normal plasma concentrations of LNAAs so that changes in the ratio may make big changes in the entry of levodopa into the brain. A large meal may double or triple the dietary LNAAs in plasma and thus reduce levodopa transport by one half or more. Experiments in parkinsonian patients have demonstrated that aromatic or branched chain amino acid administration will reduce the clinical effectiveness of levodopa. Phenylalanine or leucine orally administered at 100 mg kg^{-1} during levodopa infusion reversed the antiparkinsonian actions of the intravenous levodopa without reducing plasma levodopa concentration. A 100 mg kg^{-1} dose of an amino acid from another class of amino acids had no effect on the infused levodopa effects. This suggests that competition between levodopa and other dietary LNAAs at the blood–brain barrier is a critical step for the therapeutic effect of levodopa. Conversely, a carbohydrate meal may enhance the effectiveness of levodopa. A glucose load has been shown to lower the concentration of branched chain amino acids, one component of the LNAAs. By decreasing the branched chain amino acids, aromatic amino acid transport, including levodopa, may be enhanced. Occasionally, PD patients report this effect but it is not as prominent as the problems encountered after high-protein meals. To enhance the effects of levodopa, some patients severely limit protein intake until the end of the day.

Experiments in dogs suggest that there is a gradient to the absorption of levodopa in the small bowel with more absorbed proximally in the duodenum and less in the ileum. Direct administration of levodopa into the duodenum results in rapid appearance of levodopa in the plasma. This notion is behind the intestinal infusion methods to be discussed shortly.

Metabolic Pathways of Levodopa and Dopamine

Metabolism of levodopa and dopamine may proceed by four pathways: decarboxylation, *O*-methylation, transamination, and oxidation.

Levodopa is decarboxylated to dopamine by the enzyme AAAD. This enzyme is ubiquitously distributed in the gut, liver, and kidney. The gastric and intestinal wall contains AAAD that significantly metabolizes levodopa. At least half of an oral levodopa dose is decarboxylated during absorption and first pass hepatic metabolism. Further decarboxylation may occur by AAADC during successive circulation through these tissues. Approximately 70% of the levodopa metabolites appear as dopamine and its degradation products, indicating that decarboxylation is the major route of metabolism. The portion of the orally administered levodopa that is decarboxylated to dopamine in peripheral tissues will not enter the brain, and therefore is lost for the intended therapeutic purpose, elevation of dopamine in the brain.

Decarboxylation of levodopa in the brain is essential to its antiparkinsonian actions. AAAD is present in dopamine nerve terminals in the striatum but is also in serotonergic nerve terminals, and perhaps other cellular elements of brain, as well as in the endothelial cells of the brain capillaries. AAAD is reduced in the brain of PD patients as well as in laboratory animals with toxin-induced parkinsonism. However, the AAAD appears to be in adequate concentration to convert levodopa into dopamine and produce a pharmacological effect. Drugs that block the AAAD in the brain will also block the central pharmacologic actions on the motor system in laboratory animals.

Since extensive decarboxylation of levodopa may occur in peripheral tissues, the inhibition of AAAD was an important development in the therapy of PD. Carbidopa and benserazide are inhibitors of the AAAD enzyme. One or the other of these drugs is typically given in combination with levodopa to inhibit AAAD in peripheral tissues and to augment the effect of levodopa while reducing the peripheral adverse effects of dopamine, namely anorexia, nausea, and vomiting. The addition of an inhibitor of AAAD to levodopa reduced the dose of levodopa required by $\sim$75%. Carbidopa and benserazide given in low doses do not penetrate the blood–brain barrier. Thus, levodopa transported into the brain is assumed to be largely converted into dopamine by central AAAD unaffected by carbidopa or benserazide and utilized in dopaminergic neurotransmission.

Conversion of levodopa to 3-*O*-methyldopa and dopamine to 3-*O*-methyldopamine by catechol-*O*-methyltransferase (COMT) is an important metabolic pathway, especially when decarboxylation is inhibited. *O*-Methylation of levodopa produces a metabolite that cannot be converted into dopamine in the brain. *O*-Methylation of

dopamine is one manner in which to deactivate the neurotransmitter. COMT is present in many peripheral tissues as well as in brain. This pathway is probably responsible for metabolizing about 10% of levodopa when levodopa is administered without an inhibitor of AAAD, and may be more significant when coadministered with AAAD inhibitors that increase levodopa concentration. Tolcapone and entacapone are two competitive COMT inhibitors used in the treatment of parkinsonism. Entacapone acts peripherally to inhibit COMT and thereby to increase the portion of a levodopa dose that enters the brain as levodopa. Tolcapone inhibits the enzyme both centrally and peripherally; whether the central inhibition of COMT is clinically important is not known. A Cochrane review of these drugs found both reduced 'off' time and increased 'on' time. Diarrhea and discoloration of the urine are the most common specific side effects reported with the use of these drugs. Additional side effects associated with increased concentration of levodopa may occur, and usually responds to the decreasing of either the dose or frequency of levodopa administration. Three cases of fatal liver toxicity have occurred in association with use of tolcapone. Although this occurred out of 40 000 patient years of use, strict monitoring of liver function is required during the first 6 months of tolcapone therapy.

Monoamine oxidase (MAO) metabolizes dopamine and 3-*O*-methyldopamine. It exists in two isoforms: MAO-A and MAO-B. MAO-B is the predominant form found in the human brain. MAO-A is primarily found in the gut and is responsible for deactivating catecholamines and vasoactive substances in the periphery. The role of MAO-A in central nervous system metabolism is believed to be minor. The historical role of nonselective MAO inhibition has been in the treatment of psychiatric disorders. Nonselective inhibition of MAO may result in the 'cheese effect' with tachycardia and hypertension. Patients ingesting cheese containing high amounts of tyramine have made this a well-known syndrome. Selective inhibition of MAO-B has a role in the treatment of parkinsonism, presumably because it slows the metabolism of dopamine in the brain and thereby prolongs its actions. Since the MAO-A is not inhibited, the inhibition of MAO-B does not produce the adverse effects of nonselective MAO inhibition. Selegiline was the first MAO-B to have widespread use in the treatment of PD. Given in oral tablet form, it undergoes extensive first pass metabolism and has a relatively low bioavailability. At low doses, selegiline selectively inhibits MAO-B, but at higher doses it loses its selectivity and has been associated with a 'cheese effect.' Selegiline has an amphetamine metabolite although it is the less active isomer and of uncertain significance. An orally disintegrating form may largely avoid the first pass metabolism of standard formulations. Rasagaline is a newly introduced MAO-B inhibitor that does not result in amphetamine metabolites. Overall, the bioavailability of rasagiline may be slightly higher than that of selegiline, and animal studies suggest that it may be a better inhibitor of brain MAO-B. Like selegiline, rasagiline may be more specific to MAO-B at lower doses and lose this specificity at higher doses. Both selegiline and rasagiline have shown mild but significant symptomatic benefits in reducing off time in PD. The excitement about selective MAO-B inhibitors is their putative neuroprotective effects, which remain to be proved.

Clinical Effects of Levodopa

The short-duration response is an antiparkinsonian response to a dose of levodopa that parallels the plasma concentrations of the drug. As the plasma concentrations rise the clinical effects appear and as the plasma levels drop the clinical response wanes. There is a lag between the clinical response and the plasma levodopa levels so that the clinical state at any point in time is not directly related to the concurrent plasma levels. It is the short-duration response that is responsible for motor fluctuations. The key point for clinicians to know is that the short-duration response is not very dose responsive; once a dose exceeds a threshold level, the full response is achieved and higher levels do not influence the maximum response. However, the duration of the response is dose responsive; larger doses produce longer effects.

The long-duration response is a response that builds up over days and also declines over days. Thus, when patients have been on levodopa for weeks or more, stopping the drug will produce an immediate loss of motor function as the short-duration response disappears, but then there is a slow, gradual decline in motor function over days to weeks and the long-duration response decays. Thus, the 'practical off' after overnight without antiparkinsonian medications is not a reflection of a person's untreated disease severity.

Dyskinesia is an unwanted response to levodopa that emerges during chronic therapy in most patients that receive benefit from levodopa. Dyskinesia is linked to the short-duration response with very similar time course and threshold. Although other antiparkinsonian medications occasionally cause dyskinesia, levodopa is the drug that is primarily responsible for dyskinesia.

Formulations of Levodopa

The most common medication used to treat PD is the combination drug carbidopa/levodopa. Different strengths and ratios (1:10 and 1:4) of carbidopa and levodopa are commercially available. Carbidopa is also available in stand-alone form. Extra carbidopa is sometimes used to reduce gastrointestinal side effects that are present despite

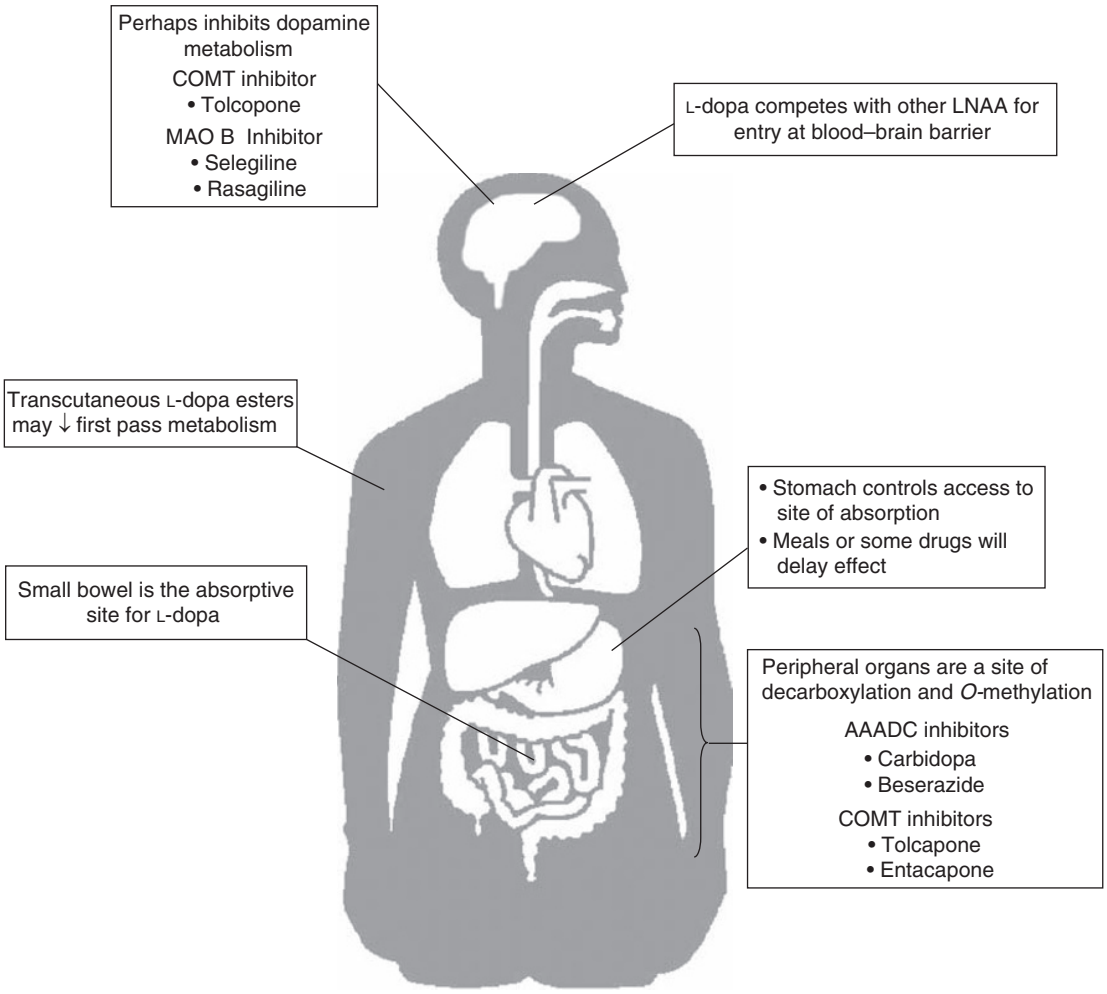

Figure 1 Possible sites for levodopa modulation.

using the usual carbidopa/levodopa combination. It is generally believed that at least 75 mg of carbidopa should be administered to fully inhibit peripheral AAAD. Thus, when initiating levodopa, it is preferable to give it as a 25/100 carbidopa/levodopa combination to get full inhibition of AAAD with the usual daily dose of one tablet 3 times per day. On the other hand, when patients get on very large doses of levodopa, it may be better to use the carbidopa/levodopa preparations with a 1:10 ratio to limit the total amount of carbidopa administered, although no clinical effects of very high doses of carbidopa are recognized. Levodopa without carbidopa is sometimes used in patients who are very sensitive to the medication. Levodopa is available commercially but must be prepared by a compounding pharmacy for oral use. An alternative is to dissolve a 25/100 carbidopa/levodopa tablet in water and take aliquots of the well mixed solution to get small doses.

Levodopa has a very short plasma half-life and is metabolized quickly in both peripheral compartments, necessitating multiple doss throughout the day. Further dose escalation is very typical as parkinsonism progresses and may require dosing every few hours to maintain the optimum clinical effect. The rapid metabolism of levodopa means that there are peaks and troughs of plasma levodopa throughout the day. A common misperception is that this variability in plasma levodopa concentrations can be reduced by giving smaller doses more frequently. The consequence is that the response often becomes more variable, because the peak concentrations are closer to the threshold concentrations and variability in absorption will result in doses that do not exceed threshold so that no clinical effect is obtained. Further, the duration of response to a dose is related to the size of the dose. Small doses will give briefer clinical responses.

Controlled release carbidopa/levodopa was developed in the hope that gradual and sustained release of levodopa in the gut would result in more stable plasma concentrations of levodopa. The problem, however, is that absorption takes place in only the small bowel, a section of the gut where gut contents move along quickly with an average transit time of 2–3 h. The bioavailability of controlled release preparations are reduced by 25% and the peak

concentrations are at hour 2 rather than at hour 1. Clinically, controlled release preparations tend to be absorbed more erratically. Early in PD, the controlled release preparation is effective in reducing symptoms, but as the disease progresses, the therapeutic response becomes less predictable with each dose of sustained release carbidopa/levodopa. If unpredictability of response to each dose of carbidopa/levodopa is an issue, at this point predictability may be improved by switching back to regular or immediate release carbidopa/levodopa. The slower rise of plasma levodopa after controlled release carbidopa/levodopa causes a longer latency to the onset of antiparkinsonian actions. This delay in clinical effects may be counteracted by giving a small dose of immediate release carbidopa/levodopa with the controlled release preparation. Efforts to produce preparations with a more rapid onset of action combined with a more sustained delivery over many hours are underway.

Orally disintegrating cardidopa/levodopa is an immediate release preparation available in a 1:4 or 1:10 ration of carbidopa to levodopa. Limited clinical data on this drug is available. Since it may be given without water, it may be useful in patients experiencing delayed on from gastric emptying problems or in those undergoing surgery who cannot take other oral forms of carbidopa/levodopa.

The three-drug combination of carbidopa/levodopa/entacapone has come into clinical use in recent years and takes advantage of peripheral decarboxylase and COMT inhibitors to improve the clinical effect of levodopa. Although this combination appears similar in benefits and side effects to carbidopa/levodopa given separately with entacapone, ease of dosing and patient preference make this drug a useful alternative. Plasma levodopa levels with this three-dose preparation are more similar to controlled release preparations than to immediate release carbidopa/levodopa preparations.

Due to the inherent problems with the oral administration of levodopa, other means of drug delivery have been investigated. The intravenous infusion of levodopa along with orally administered decarboxylase inhibitor has resulted in a therapeutic benefit for parkinsonian patients. This type of infusion reduces motor fluctuations seen in parkinsonian patients. The requirement of a pump, poor solubility of levodopa necessitating large volumes of levodopa solution, and complexity of drug administration by an intravenous route have made this approach suitable for short times in experimental settings. Also, in the United States of America this can only be done under an investigational drug license.

Enteral infusions of levodopa began in the 1980s. Initial results were promising and the clinical benefit appeared similar to studies of intravenous levodopa infusion. Problems with this method of delivery included relatively large volumes of infusate because of levodopa's low solubility and problems with keeping the tube tip positioned in the duodenum. A more stable suspension of levodopa and carbidopa in a methycellulose gel has led to lower volumes of infusate that can be delivered by an ambulatory pump into tubes placed into the stomach or directly into the duodenum. The improvement in pump technology and drug formulation has led to chronic use of this type of therapy in a small subset of patients with motor fluctuations.

Transcutaneous delivery of levodopa is under investigation. In animals, the transcutaneous administration of an esterified form of levodopa can produce plasma levels that begin to approximate those that would be necessary in humans. Bypassing intestinal and first pass metabolism has been shown to result in stable levels of levodopa in plasma even in animals not given carbidopa. A very recent small study on humans suggests that the transcutaneous administration of levodopa results in stable plasma levels of levodopa and its metabolites.

The bean *Mucuna pruriens* is the only recognized food source of levodopa. Mucuna has been used for over two thousand years as part of Ayurvedic medicine and is being used in the United States as a 'natural levodopa.' To be successful, it generally requires the coadministration of carbidopa. The benefits of mucuna relative to commercially manufactured levodopa are unknown.

Side Effects of Levodopa

The most prominent peripheral adverse effects of levodopa are gastrointestinal anorexia, nausea, and vomiting. Tolerance to these effects generally develops over days to weeks. These effects are thought to arise from peripheral dopamine affecting the area postrema, which lies outside the blood–brain barrier. Increasing the carbidopa dose will reduce this effect, or the use of a dopamine D_2 receptor antagonist that does not enter the brain, such as domperidone, will counteract these adverse events.

Visual hallucinations become more common in PD as the condition progresses and cognitive impairment emerges. Earlier in PD, patients may experience hallucinations related to the use of levodopa. It is not unusual for these patients to describe nonthreatening visual hallucinations of animals or people. Typically, the hallucinations remit when the dose of levodopa and other antiparkinsonian medications are adjusted. More complex hallucinations may occur in advanced stages and are likely related to several factors, including polypharmacy with centrally acting medications used to treat PD as well as to underlying dementia. These types of hallucinations may not remit with the lowering of the dose of levodopa and require other interventions such as cholinesterase inhibitors or antipsychotics such as quetiapine or clozapine.

An increased prevalence of melanoma has been described in parkinsonian patients. Levodopa may be

metabolized into melanin in dopaminergic neurons, and this has raised the notion that levodopa use predisposes to the development of melanoma. Based on several studies, levodopa has not been demonstrated to have a causal association with melanoma, but further investigation may reveal the dynamics of this association.

Glossary

Central pattern generators – A group of interconnected neurons that provide for the timing and organization of rhythmic behavior patterns. A key feature of CPG's is that the behavior pattern does not rely on sensory feedback to trigger or elicit the next step in the response sequence.
Dopamine – A monoamine neurotransmitter involved in Parkinson's disease, schizophrenia, reward-related behavior, and drug abuse.
Dysarthria – Disturbance in the musculature used for speech.
Dysphagia – Difficulty in swallowing.
Fourier analysis – A set of operations for mathematically decomposing a time series of complex waveforms into combinations of separate, simple periodic components. In doing so, Fourier analysis extracts frequency (rhythmic) information from the data.
Hypoglossal nucleus – A group of motor neurons and interneurons in the brain stem that gives rise to the twelfth cranial nerve, which innervates the tongue muscles enabling the tongue to be quickly protruded and retracted.
Inferior olive – A dense collection of neuronal cell bodies that give rise to axons (the climbing fibers) that contact Purkinje cells in the cerebellum; involved in motor control and some types of learning.

Introduction

Rodents, like most mammals, have muscular tongues that bring food or water into the oral cavity for ingestion. Rhythmic repetitions of such tongue movements are usually referred to as licking. Although rodent licking is often

measured with the purpose of making inferences about motivation or hedonic qualities of ingestants, our development of the lick-force-rhythm methods arose from the interest in pharmacological and nervous systems variables that affect motor behavior.

It has been long noted that rodent ingestive licking has a 'stereotyped' quality in that the alternating protrusions and retractions of the tongue are quite regular. The well-regulated rhythmicity is thought to be due to central pattern generators (CPGs) in the brainstem that control the tongue's motor neurons located in the hypoglossal nucleus. Accumulating evidence shows that licking is not only controlled by brainstem structures, but is also modulated by cortical, subcortical, and cerebellar influences. Tongue sensory fibers, moreover, relay data on the properties of foods or liquids to both cortical and subcortical loci in the brain, thereby providing information that can influence the force, shape, orientation, and rhythm of the tongue as it extends from and returns to the oral cavity. It is also important to recognize that tongue control must be effectively coordinated with mastication, swallowing, and respiration. Rodent licking is the product of coordinated, parallel operations of many different brain structures. Thus, the measurement of rodent ingestive licking can be used to address a wide variety of biobehavioral questions.

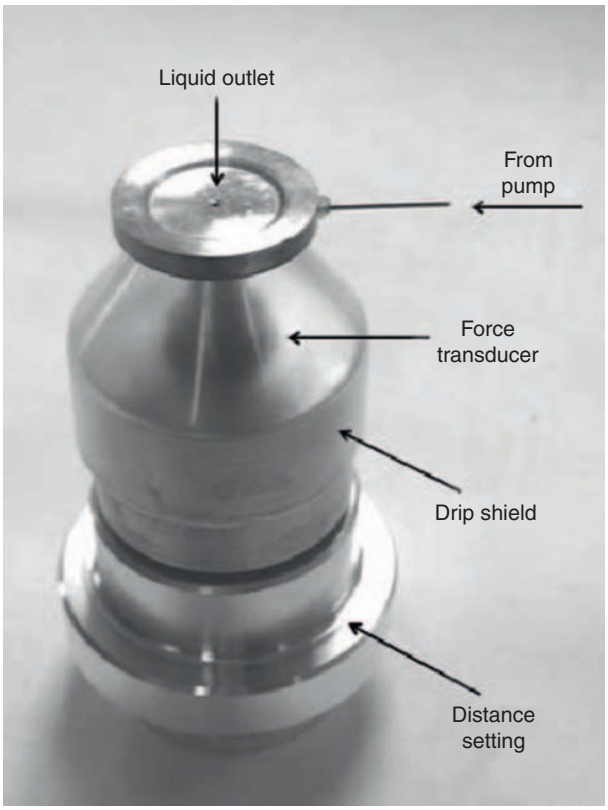

Figure 1 Photograph of a hardware ensemble for measuring tongue force during licking of liquids by rats or mice. Liquids to be ingested are carried to the lick disk by a computer-controlled peristaltic pump. The lick disk through which the liquid emerges for consumption is 18 mm in diameter. Rats or mice access the disk by protruding their tongues through a 12-mm-diameter hole.

Lick-Force-Rhythm Method

The lick-force-rhythm task for rodents was developed as an improved alternative to the more commonly used contact circuit method for quantifying licking. With the contact circuit, a very low voltage is arranged between a drinking spout and the floor of the chamber. When the rodent licks the spout, its body completes the circuit and an imperceptible, nondamaging electric current flows through the animal. The occurrence and duration of the contact can then be recorded. With the force method, an appropriately sensitive force transducer (see **Figure 1**) is used to measure the force of tongue contacts during licking. The force method eliminates the flow of current through the rats tongue and body and provides information about the tongue force which is not available with the contact circuit method. In addition, the force method requires interfacing and appropriate software for sampling and recording the force signal and parsing the analog signal into tongue-strike events and the time between these events (see **Figure 2**). Data analysis software provides measures of lick number, peak force, duration, interlick interval, and lick rhythm.

A lick begins when force rises above a force threshold (see **Figure 2**) and ends when the force drops below threshold. We usually select a threshold of 2 g-force for rats and 1 g-force for mice. The threshold is selected so that

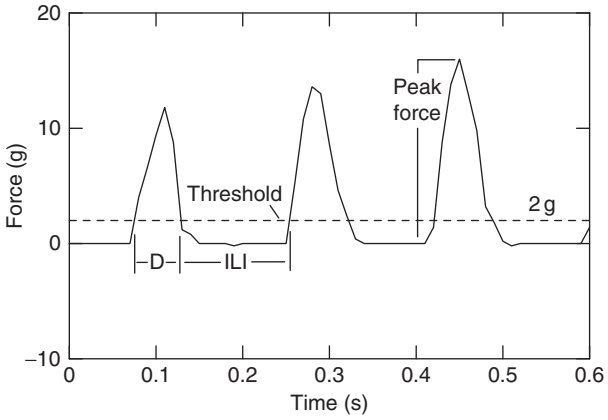

Figure 2 Illustration of dependent measures derived from the force–time output of the force-transducer detector shown in **Figure 1**. The force (expressed in gram-equivalent forces) of a rat's licking is plotted on the *y*-axis as a function of time on the *x*-axis. Three consecutive licks are shown. D = Duration of the lick; ILI = Interlick interval.

neither extraneous environmental vibrations nor vibrissae contacts will be mistakenly recorded as licks. Thus, the force-based method effectively eliminates artifacts that

often arise with contact circuit methods where, for example, water bridging via wet snout hair or wet vibrissae can cause the recording of impossibly short-duration events or mask lick detection. As shown in **Figure 3**, peak force, rhythm and number of licks recorded are all significantly affected by the distance between the rodent's muzzle and the location of the liquid to be ingested. For this reason, specifying and calibrating this distance is critical to obtaining reliable measurements of tongue motility during licking.

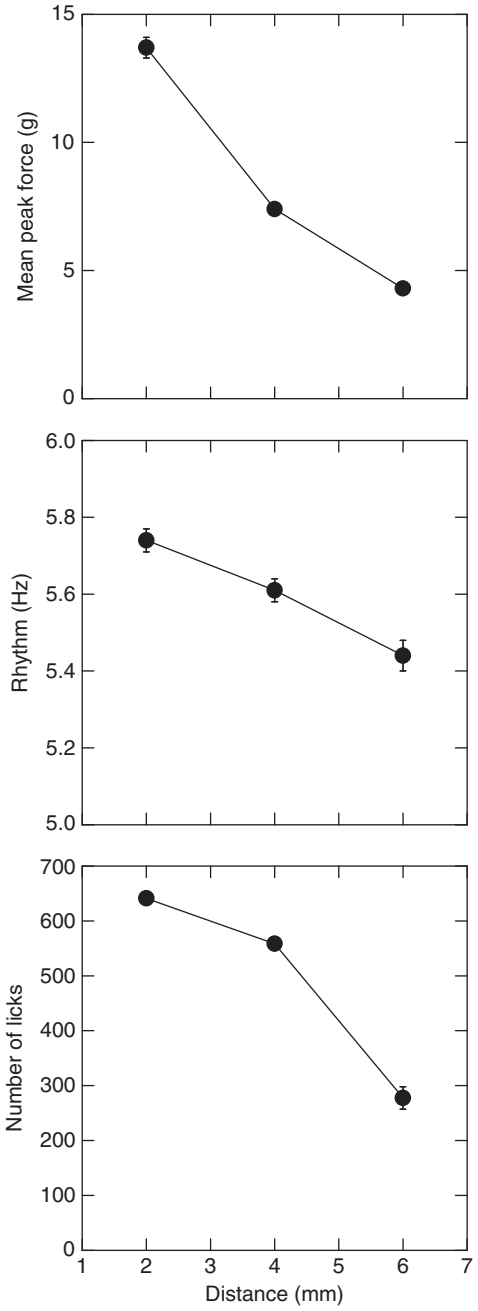

Figure 3 Effects on lick measures as a function of distance between the muzzle and the liquid orifice. Mean peak force (expressed in gram-equivalent forces), lick rhythm (Hz), and number of licks each significantly decreased as a function distance. Data were taken from Table 2 in Fowler SC, McKerchar TL, Zarcone TJ (2005) Response dynamics: Measurement of the force and rhythm of motor responses in laboratory animals. In LeDoux, M (ed.) *Animal Models of Movement Disorders*, pp. 73–100. San Diego, CA: Academic Press.

Experimental control of the 'lick-distance' is facilitated by mounting the transducer on a positioning device such as a micrometer. Our experience suggests that distance specification is facilitated by locating the liquid source below the horizontal floor that supports the rodent as it licks. The arrangement is more 'natural' than the sipper tube located above the animal, because licking of liquid ingestants, such as water, from horizontal surfaces (i.e., water puddles) evolved long before sipper tubes were invented. By careful specification of the distances and force variables, one can probe for deficits in orolingual motor behavior by posing distance or force challenges. In regard to quantifying the lick rhythm (i.e., frequency of nearly periodic repetitions of licks expressed in cycles per second or Hz), we prefer the Fourier analysis approach because it is the method of choice for detecting periodic repetitions in time series of analog data.

Research Applications

The lick-force-rhythm method has been used in research involving the motor effects of drugs, neurotoxic brain lesions, genetic variables, aging, and neurodegenerative diseases. We will now provide a brief synopsis of findings across several studies these domains.

Drug Effects

In the case of drug effects, the atypical antipsychotic drug, clozapine was shown to reduce lick rhythm and peak force in male Sprague–Dawley rats (see **Figure 4**). In addition, clozapine caused irregularly shaped force-time waveforms compared with saline control conditions (note ellipse marking a 'notched' waveform in **Figure 4**). The notched waveforms likely reflect poor tongue control arising from the strong sedative effect of this drug upon acute administration.

Neurotoxic Lesions

Other research has assessed linguomotor function in a rat model of Parkinson's disease caused by unilateral dopamine depletion of the striatum produced by 6-hydroxydopamine (6-OHDA). Dopamine depletion significantly reduced all of the dependent measures discussed: peak force, number of licks, and lick rhythm. Such results suggest that the lick-force-rhythm method may be a useful procedure for evaluating experimental therapies in Parkinson's disease models. In a different study examining the role of the

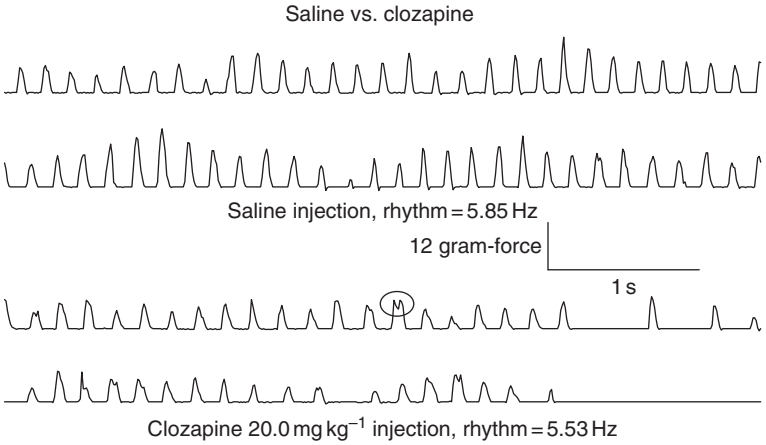

Figure 4 Effects of saline (top two rows) and the atypical antipsychotic drug, clozapine (bottom two rows), on lick-force-time waveforms generated by a rat licking water from the disk shown in **Figure 1**. Note the diminution in peak force in the lower set of graphs, as well as the appearance of long inter-lick intervals. An illustrative example of a 'notched' lick waveform induced by 20 mg kg^{-1} clozapine is indicated by the ellipse.

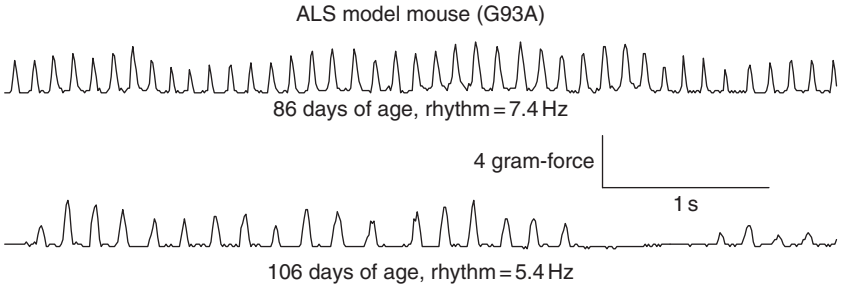

Figure 5 Change in licking rhythm as a function of disease progression in an ALS model mouse (G93A).

olivocerebellar system in licking patterns, rats were exposed to 3-acetylpyridine (a neurotoxin that preferentially kills inferior olive neurons) prior to testing on the lick-force task. Compared with baseline measures, near-total destruction of the inferior olive neurons reduced lick peak force and number of licks. Interestingly, lick rhythm was preserved, showing the independent nature of the lick measures we have described. Additionally, the lack of effect on lick rhythm suggests that the inferior olive is not a major CPG for ingestive licking.

Inbred Mice

In the context of genetic influences on lick rhythm, recent results suggest that differences in lick rhythm among inbred strains are potentially traceable to genomic differences. For example, the inbred strains of mice 129Sv/J, C3H/J, DBA/2J, and BALB/cJ exhibit similar lick rhythms around 8.2 Hz, whereas C57BL/6J mice consistently have rhythms near 7 Hz. Mice that peripherally (i.e., outside the brain and spinal cord) overexpress neurotrophic peptide 3 exhibit a significantly decreased lick peak force, but do not have altered lick rhythm or number of licks.

Rodent Aging Models

In human aging, diminished tongue motility and oromotor force generation can contribute to dysarthria and dysphagia. The F344 and F344/BN rat models of aging exhibit significant decreases in licking rhythm beginning in middle age (18 months for these rats). The decline in tongue motility may be related to changes that have been reported not only in neuromuscular function, but also in brain regions associated with the coordination of licking, swallowing, and respiration (e.g., the basal ganglia, cerebellum and medial bulbar reticular formation). Although these rats did not exhibit age-related tongue force deficits, they have not been challenged with increased tongue force requirements in a manner analogous to human clinical tests.

Neurodegenerative Models

Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis (ALS) are neurodegenerative diseases with prominent oromotor impairments. As rodent models continue to develop, the lick-force-rhythm task should be a valuable tool in charting the course of motor

function loss as well as providing a set of measures for evaluating experimental therapies. An illustrative example of the rapid decline in orolingual motor function in the SOD1-G93A mouse model of ALS is shown in **Figure 5**. The prominent decline in lick rhythm suggests the existence of neuromuscular deficits associated with hypoglossal motor neuronal degeneration in this model of ALS.

Summary

Although licking may seem like a simple response, appreciation of the various brain regions involved in licking control and its synchronization with other biological functions, such as swallowing and respiration, reveals a highly modulated, adaptable behavior. Such appreciation has led us to suggest that licking may be used to investigate a wide range of questions. Our methods of addressing those questions rely on force-based measurement of licking. Not only does the method provide for a more naturalistic posture while licking, but also the additional force and rhythm-related information may be recorded. We have reviewed several domains of investigation spanning pharmacological work, murine genetics, and neurodegenerative disease where our methods have been applied. We hope that our descriptions demonstrate the utility of force-based methods for a wide variety of research questions.

Locus Coeruleus and Norepinephrine

A-Ch Granholm, J Lockrow, H Boger, and M Buhusi, Medical University of South Carolina, Charleston, SC, USA

Glossary

Alzheimer's disease (AD) – The most common form of dementia, afflicting up to 40% of individuals over 80 years of age. AD is a multisystem neurological disease with alterations in the hippocampus, cortex, and basal forebrain cholinergic neurons. Some of the most common pathological signs of AD are intracellular neurofibrillary tangles and extracellular amyloid plaques.

Dyskinesia – Abnormal involuntary movements occurring as a complication during the course of DA-replacement therapy in PD patients.

Locus coeruleus (LC) – A nucleus in the pontine region of the brain chiefly consisting of noradrenergic (NE) neurons, which regulate sleep/wakefulness, memory, and attention among other things. NE neurons send their axons to the spinal cord and most regions of the brain, most likely playing a regulatory role in many brain regions.

Microglial cells – These cells play a major role in the innate immune system of the central nervous system. Microglial cells can exist in a resting state, and when triggered by an external or internal trigger, they will become activated and release proinflammatory cytokines, such as IL-1 and TNF-α.

Norepinephrine – One of the monoamine neurotransmitters, which is found in both central neurons of the locus coeruleus and peripheral neurons (sympathetic ganglion cells).

Oxidative stress – This cellular condition is common and thought to play a major role in cell damage occurring in many types of disorders, such as neurodegenerative diseases, cardiovascular disease, and stroke, as well as in the normal aging process. It is caused by an imbalance between production and scavenging of free radicals, which are normally broken down by endogenous enzymes in the cell, including glutathione and super oxide dismutase.

Parkinson's disease (PD) – A motor disorder characterized by muscle rigidity, tremor, bradykinesia (slowness of movement), akinesia (lack of movement), and in some cases, cognitive impairment. PD is a neurodegenerative disorder affecting dopaminergic neurons of the substantia nigra, noradrenergic neurons (NE) of the locus coeruleus, olfactory system, motor neurons, and other nerve cells in the brain; it is thought to be caused by an interplay of genetic and environmental factors.

Introduction

Due to the 'baby boomer' generation, the rate of senior citizens in the western world will increase dramatically in the next 2–3 decades. For example, the number of individuals over the age of 65 is expected to double by the year 2030 in the United States. With this increase in aged individuals, we will see a specialized set of health issues that may become a major public health problem. In particular, movement dysfunction and cognitive decline become progressively worse as the individual ages, so that up to 50% of individuals over the age of 85 have one or both of these conditions. This article provides an interesting correlation between two degenerative disorders that are known to increase with age: Parkinson's disease (PD) and Alzheimer's disease (AD). Interestingly, a significant portion of individuals who have been diagnosed with idiopathic PD develop cognitive impairment with time, and conversely, individuals with AD are known to exhibit a progressive decline on Parkinson's rating scales. Noradrenergic neurons (norepinephrine, NE) of the pontine nucleus locus coeruleus (LC) have been noted to deteriorate in both number and function in AD and PD patients. Recent data even suggest that LC-NE neuronal loss occurs relatively early in the disease process for both conditions, before a significant loss of nigra dopamine neurons (PD) or basal forebrain cholinergic neurons (AD) has occurred. In addition, animal studies using neurotoxins targeting LC-NE neurons demonstrate that both cholinergic and dopaminergic central neurons are negatively affected by noradrenergic degeneration. The data therefore suggest a causative role for LC-NE neurons in the progressive degeneration of both cholinergic and dopaminergic central neurons, and also that the loss of function of this particular cell group in the brainstem is a common denominator for these two diseases.

Functional Roles of the Central NE Transmitter System

There is clear evidence for a strong influence of the LC-NE system on learning and memory. NE, released at nerve terminals in target areas of the limbic system, facilitates shifts in attention, information processing, and memory through its well-documented gating and tuning effects, and its permissive role in hippocampal long-term potentiation (LTP). Specifically, it has been shown in both humans and animal models that LC-NE neurons play a crucial role in

- Inhibitory avoidance
- Delayed matching-to-sample tasks
- Spatial reference and spatial working memory
- Novelty seeking behavior
- Visual discrimination
- Motor coordination
- Motor-related memory
- Rapid eye movement (REM) sleep
- Attention and anxiety

Compton and collaborators found that unilateral or bilateral destruction of the LC-NE nucleus in rodents leads to moderate versus severe deficiencies in spatial memory tests such as the Morris water maze and the Greek cross task. Collier and collaborators have shown that transplantation of fetal LC-NE neurons to the brain of aged rats can restore spatial memory function similar to that found in young rats. Activation of the LC-NE neurons by electrical stimulation results in an increased NE release in areas of the limbic system such as the amygdala and the hippocampus, and enhances both spatial and emotional memory task performance. Thus, encoding and storage of memory for both emotional and spatial events seem to be dependent upon LC-NE stimulation, at least in animal models. In humans, it has been shown that genetic variants of NE receptors correlate with performance in both memory and irritability tasks, further substantiating the importance of the NE neurons in memory-related processing. There are several other higher brain functions influenced by LC-NE neurons, such as REM sleep, attention, depression, and motor coordination; therefore, it may not be a coincidence that one of the earliest signs of PD is related to disruption of attention, endogenous depression, and development of sleep problems (see below).

Altered Noradrenergic Neurotransmission During 'Normal' Aging

It has been documented that aging may alter endogenous neurotransmitters, especially acetylcholine, NE, and dopamine. Numerous studies of brains from aged humans and other mammals have demonstrated a significant loss of NE phenotype in the LC nucleus during aging, although others have found less marked effects of aging on LC-NE cell number. A summary of previous findings in humans, in terms of 'normal' aging, age-related disease, and LC-NE cell loss, is shown in **Table 1**. In experimental animal models, significant reductions in NE activity have been reported throughout the aged brain, as well as a loss of NE synapses in the frontal cortex. Furthermore, a number of other indices of NE function have been found to be altered in the aged rat, such as loss of postsynaptic-α and β-adrenergic receptor sensitivity, increased sensitivity to the noradrenergic toxin *N*-(2-chloroethyl)-*N*-ethy-2-bromobenzylamine (DSP-4), and decreased behavioral response to NE agonists in the aged rat. A positive correlation has been shown between the loss of LC-NE neurons and the level of cognitive impairment in aged mice. In addition, as mentioned earlier, transplantation studies have demonstrated that cell replacement with fetal LC-including transplants to the hippocampal formation can alleviate age-related memory loss in the rodent. These studies suggest that there are functional alterations in the NE transmitter system that have consequences for behavioral components regulated by this pathway.

Table 1 LC-NE loss in aging and age-related neurodegenerative disease

Condition	*Direction of LC-NE alteration*	*References*
Normal human aging	Loss of NE phenotype in LC	Vijayashankar and Brody and Chan-Palay and Asan
Aged mouse brain	↓ NE activity in aged mouse brain	Qi and Nomura
	↓ NE synapses in cortex	Ishida et al.
Aged rat	Increased sensitivity to NE neurotoxins	Riekkinen et al.
PD	Early loss of LC-NE neurons	Braak and Del Tredici
AD	Early loss of LC-NE neurons	Weinshenker
AD	Density of LC-NE neurons ↓50%	Strong et al.
AD	↓ NE concentrations in limbic structures	Matthews et al.
PD animal model	Loss of NE lead to increased severity and earlier onset of L-DOPA-related dyskinesias	Fulceri et al.
PD mouse model	Previous LC lesion increased SN DA sensitivity to MPTP lesions	Fornai et al.

Loss of LC-NE Neurons is an Early Event in PD

Recent data by Braak and other investigators have clearly demonstrated that LC-NE cell loss or phenotypic loss occurs early in PD. It is important to note that actual cell death versus phenotypic loss of this neuronal population can only be assessed by using a specific marker for LC-NE neurons (most commonly used marker for this population is dopamine-β-hydroxylase (DBH), antibodies) in combination with a more common neuronal marker such as neurofilament or cresyl violet. These authors found that in a number of patients, the disease process starts in lower brainstem regions, including motor neurons and LC-NE neurons, and only later extends progressively to include substantia nigra dopamine (SN DA) neurons. Thus, the recently described Braak neuropathological staging of PD includes loss of brainstem motor neurons, olfactory neurons, and LC-NE neurons, in addition to the classical progressive SN DA cell loss. This progression had already been mimicked in animal models, since several investigators demonstrated prolonged and increased effects of DA neurotoxins, such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and 6-hydroxydopamine (6-OHDA), after lesioning the LC, using a selective NE neurotoxin, DSP-4. These studies further pointed to a causative effect of LC-NE degeneration upon SN DA neurons, and further basic science work was initiated as described in the following section regarding the biological mechanisms involved. There is also behavioral evidence that alterations to the LC-NE system underly the earlier events in PD patients, such as sleeping disturbances and depression, which are noted years before the onset of the classical signs of the disease (tremor, bradykinesia, and rigidity). It is also possible that LC-NE degeneration directly contributes to the motor impairment that develops over time in PD patients, since studies performed by Paula Bickford and her collaborators, as well as others, have shown that noradrenergic innervation of the cerebellum is deficient in aging and results in hampered motor coordination and motor-related memory performance.

A commonality between NE and DA neurons in the brain is the dependency on similar growth factors. In recent work, we performed studies of mice, genetically engineered to be deficient in the glial cell line-derived neurotrophic factor ($GDNF^{+/-}$ mice), a DA-trophic factor. As shown in our previous work by Boger et al., 2006 and in **Figure 1(a)** and **1(b)**, $GDNF^{+/-}$ mice exhibited loss of both SN DA and LC-NE neurons. However, the LC-NE loss was evident already at birth, while SN DA loss occurred later in life. These studies suggest that even though SN and LC-NE neurons are both dependent on GDNF for their maintenance, the NE population appears more vulnerable,

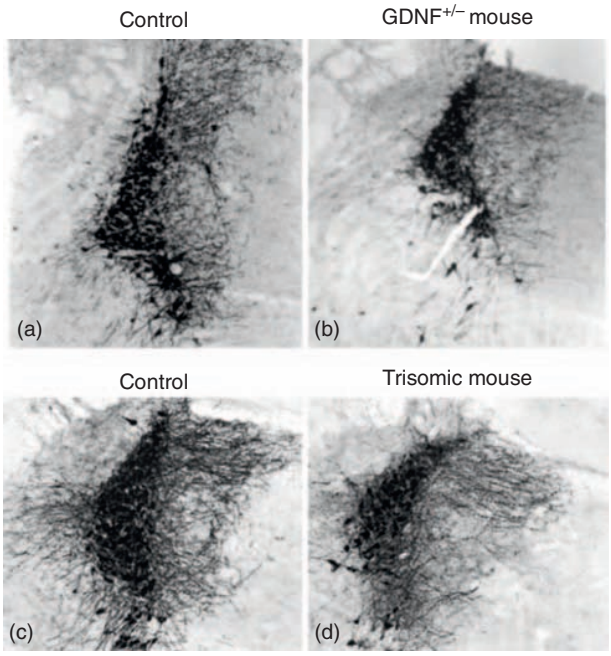

Figure 1 Loss of LC-NE neurons in mice with a partial genetic loss of GDNF (GDNF ± mice) and in a mouse model for DS and AD, the Ts65Dn mice. These data show that the LC-NE neurons are sensitive to different types of genetic alterations such as lack of growth factors (B), or chronic increase in oxidative stress which occurs in Ts65Dn mice (D), suggesting a selective vulnerability of these particular neurons.

at least to the loss of GDNF, and deteriorates at an earlier age in $GDNF^{+/-}$ mice. Interestingly, GDNF is reduced in the SN of PD patients; therefore, clinical trials are being conducted using GDNF supplementation, either by viral delivery techniques or by the direct infusion of GDNF into the brain.

The influence of NE neurons upon progression of PD is not limited to loss of the SN DA neurons; studies both in humans and in animal models have recently suggested that the integrity of the LC-NE neurons is related to the onset of L-DOPA-induced dyskinesia. Animal studies by Angela Cenci and others, using selective NE neurotoxins, demonstrated that the loss of NE innervation accelerates the onset and increases the severity of L-DOPA-induced dyskinesias.

Loss of LC-NE Neurons in AD

AD is characterized neuropathologically by β-amyloid-containing plaques, tau-containing neurofibrillary tangles, and progressive loss of basal forebrain (BF) cholinergic neurons. In addition to the hallmark cognitive impairment, the disease is associated with other neuropsychiatric abnormalities, including sleep problems, aggression, and depression. Some, if not all, of these additional neuropsychiatric symptoms can be attributed, at least in part, to an early loss of NE innervation of cortical areas. Indeed, it has been shown that patients with AD have a significant reduction in NE concentration in limbic structures, and this NE reduction correlates with the level of dementia. Interestingly, it appears that LC-NE neurons may degenerate before the significant loss of cholinergic neurons has occurred.

In our laboratory, we are studying a trisomic mouse model for Down syndrome (DS), the Ts65Dn mouse. More than 90% of individuals with DS develop pathological hallmarks of AD, and more than half also develop cognitive impairment consistent with the findings in AD patients. Ts65Dn mice exhibit progressive deficiencies in working memory, cholinergic cell loss, and altered nerve growth factor (NGF) transport to the BF, all similar to the findings in AD patients. Our recent data show that Ts65Dn mice exhibit an early loss of LC-NE neurons (see **Figure 1(c)** and **1(d)**) and that LC-NE alterations occur prior to cholinergic cell loss, making this animal model an interesting target for mechanistic studies of the relationship between LC-NE denervation and cholinergic neuron vulnerability. In addition, Ts65Dn mice show early signs of mitochondrial dysfunction, with increased oxidative stress occurring in hippocampal, cortical, and subcortical regions, thus recapitulating cellular alterations observed in individuals with AD and DS. We found that the LC-NE degeneration in Ts65Dn mice correlates with elevated oxidative stress markers, and that vitamin E treatment reduced oxidative stress markers as well as reduced degeneration of LC-NE neurons in Ts65Dn mice, suggesting that oxidative stress aggravates loss of LC-NE neurons in our animal model. These data suggest a possible preventive antioxidant treatment in DS individuals, to prevent LC-NE cell loss, that may directly or indirectly protect against the cholinergic loss occurring later in the disease process.

Why Do LC-NE Neurons Die with Aging and in Neurodegenerative Diseases?

Central monoamine neurons such as LC-NE and SN DA neurons are especially sensitive to neurotoxin exposure. It has been shown that LC-NE neurons are selectively sensitive to the toxin DSP-4. Grzanna and investigators found that NE axons originating in non-LC-NE neurons were largely resistant to the neurotoxic action of DSP-4. This neurotoxin reduces the NE levels in cerebral cortex, cerebellum, and hippocampal formation, but has no effect on hypothalamic NE levels, further supporting its LC-NE specificity. The biological mechanism for DSP-4 actions on LC-NE neurons is largely unknown, although previous studies suggested a role for monoamine oxidase-B (MAO-B) in DSP-4 activity. The damage induced by DSP-4 has been related to the formation of a cyclic compound (azyridinium ion) that in turn would be metabolized by MAO-B and taken up by LC-NE terminals. The selective and irreversible MAO-B inhibitor L-deprenyl

prevents chronic loss of LC-NE neurons induced by DSP-4. However, another selective MAO-B inhibitor (MDL72974) failed to protect these neurons against DSP-4. In addition, recent studies with MAO-B knockout mice indicated that this enzyme is not essential for DSP-4 activity. While these knockout mice were protected from the dopamine and serotonin neurotoxin 3,4-methylenedioxymethamphetamine (MDMA, 'ecstasy'), they were as sensitive to DSP-4 as the wild-type littermates. Recently, it has been shown that L-deprenyl and its metabolites were also able to block DSP-4 uptake, suggesting that L-deprenyl's neuroprotective efficacy may instead rely on preventing DSP-4 uptake via the NE transporter (NET), although this mechanism of action still requires study. DSP-4 effects are more severe in aged than in young rats, suggesting perhaps altered responsiveness to this neurotoxin in aged rats and providing a potential explanation for the vulnerability of LC neurons to toxic events with aging.

Another explanation as to why LC-NE neurons often succumb to endogenous and exogenous irritants is related to their spontaneous activity, and hence, to high energy demand and high production of reactive oxygen species. Recent work has shown that aberrant oxidation of NE via *o*-quinone may be involved in the pathogenetic mechanisms underlying the degeneration of LC-NE cell bodies in PD, AD and loss of these neurons during the normal aging process, providing further evidence for NE neurons' vulnerability during these conditions.

A Reciprocal Dependency of Cholinergic, Noradrenergic, and Dopaminergic Transmitter Systems in the Brain

An interesting correlation between LC-NE loss and ChAT activity in the LC region was presented by Strong and collaborators, who found that both the density of LC-NE neurons and presynaptic ChAT activity in the same region were reduced by an average of 50% in patients diagnosed with AD compared with age-matched control subjects. It is possible that a 'downwards' spiraling effect may occur in this disease, since ChAT activity has been shown to affect the physiology of LC-NE neurons, which in turn affects many parameters of hippocampal and forebrain activity, such as expression of neurotrophic factors and immediate early genes (cAMP response element binding (CREB) and c-fos). As demonstrated in **Figure 2**, LC-NE neurons innervate and influence both BF and substantia nigra, providing a powerful 'triangle' of action between the limbic system, midbrain, and pontine systems influencing movement and cognition. It is easy to imagine that an imbalance in this system can have significant results on higher brain functions such as movement and cognitive performance, especially when considering the powerful behavioral effects that are achieved by pharmacological agents targeting cholinergic, dopaminergic, or noradrenergic neurotransmission.

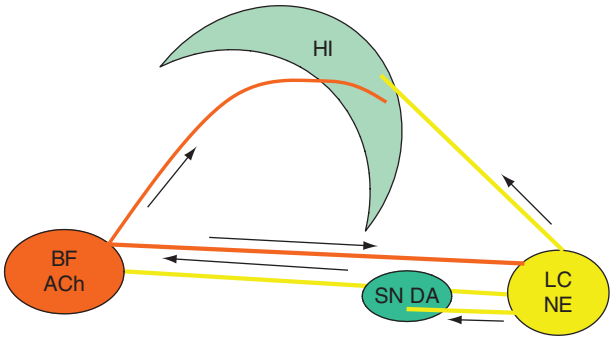

Figure 2 The cholinergic basal forebrain neurons (BF) innervate the hippocampus (HI), substantia nigra (SN), and locus coeruleus (LC), and the LC-NE neurites innervate all the other brain regions involved. The innervation patterns indicate a reciprocal dependency of intact transmission for the three transmitter systems, and it is likely that LC-NE neurons are the first to upset this balance between the BF, hippocampus, and midbrain/pontine regions during either AD or PD, since they appear to be more sensitive to endogenous and exogenous irritants than other neuronal populations.

Neuroprotective Role for LC-NE Neurons

Although it has not been completely determined yet, studies suggest that noradrenergic innervation of target areas, including the SN, BF, and hippocampus, has multiple neuroprotective functions. Studies have shown that LC-NE neurons are dependent on two growth factors: GDNF (glial cell line-derived neurotrophic factor) and BDNF (brain-derived neurotrophic factor). BDNF is also a strong neuroprotective agent for BF cholinergic neurons, and both BDNF and GDNF are neuroprotective for SN DA neurons. In addition, it was shown that LC-NE activity regulates BDNF expression in the hippocampus; lower spontaneous firing rates of LC-NE neurons occurring during, for example, sleep give rise to a significant reduction in BDNF mRNA expression in target areas. This member of the neurotrophin family has been implicated in both AD and PD, with lower levels of BDNF found in the hippocampus and the SN, respectively. It is likely that the loss of LC-NE neurons early in the disease process, coinciding with a degeneration of noradrenergic innervation in these target regions, would result in a loss of target growth factor support that would in turn jeopardize BF cholinergic, hippocampal, and SN DA neuron function and survival.

A second prominent theory for the LC-NE dependency of BF cholinergic and SN DA neurons is the rich microglial environment, which is found intermingled with both of these neuronal populations. Microglia contain functional NE receptors, and culture studies indicate that NE attenuates the inflammatory response of these cells. A DSP-4 lesion of NE innervation in rodent models results in the activation of microglial cells in the BF and SN, suggesting a potential role for NE in suppressing

inflammation in these regions. Neuroinflammation and secretion of proinflammatory cytokines from microglial cells have been demonstrated in both AD and PD; BF cholinergic and SN DA neurons are extremely sensitive to microglial activation, and in vitro studies demonstrate a direct connection between proinflammatory cytokines and disease progression in both AD and PD patients and animal models for these two neurodegenerative diseases. Third, it is also possible that these neuronal populations innervated by LC-NE neurons may be damaged by increased reactive oxygen species production during altered LC-NE neurotransmission, especially if free radical scavenging enzymes are deficient with aging. NE neurons are known to respond to damaged processes by producing more NE in remaining neurons, leading to increased toxicity by increased NE metabolism. Therefore, increased cellular energy metabolism and oxidative stress should be considered in LC-NE influence on both DA and cholinergic neurons.

Conclusions

The data discussed here collectively demonstrate a prominent and often neglected role for LC-NE neurons in protecting both SN DA and BF cholinergic neurons from degeneration with normal aging and age-related neurodegenerative disease. These data provide evidence that PD and AD share common elements, including profound LC cell loss, and may in fact be different manifestations of a common pathophysiological process. Specifically, it is thought that LC-NE neurons regulate expression of growth factors (GDNF and BDNF) and reduce microglial activation, thereby eliminating dangerous proinflammatory cytokines in these brain areas. Therefore, targeting LC-NE neuroprotection may function indirectly to alleviate problems associated with both cognitive impairment and movement disorders of aging.

Lupus Chorea

K M Shannon, Rush University Medical Center, Suite, Chicago, IL, USA

Glossary

Antiphospholipid antibodies – A class of autoantibodies that includes anticardiolipin antibodies and the lupus anticoagulant. Antiphospholipid antibodies have been associated with clotting disorders and fetal loss. Circulating antiphospholipid may be seen in the normal population. Illnesses associated with antiphospholipid antibodies include primary antiphospholipid antibody syndrome and antiphospholipid antibody associated with another autoimmune disorder, such as systemic lupus erythematosus (secondary antiphospholipid antibody syndrome).
Autoimmunity – The failure of the immune system to adequately differentiate the organism's own tissue (self) from foreign tissues, resulting in the activation of immune mechanisms against self antigens.
Chorea – Involuntary movements that are rapid, purposeless, and flowing.
Choreoathetosis – Involuntary movements that combine the rapid, purposeless, and flowing movements of chorea with the slower more sinuous movements of athetosis.
Systemic lupus erythematosus – A systemic autoimmune disease characterized by variable involvement of the skin, muscles, joints, heart, liver, kidney, lungs, and central nervous system and the presence of certain antibodies against self antigens, including anti-DNA antibodies.

Definition and History

The involvement of the central nervous system (CNS) in systemic lupus erythematosus (SLE) was first noted by Hebra and Kaposi in 1875. Chorea is a known manifestation of SLE and is one of the 19 neuropsychiatric syndromes identified in an American College of Rheumatology consensus document. While neuropsychiatric involvement in SLE is common, occurring in up to 90% of cases, chorea is a rare manifestation. Studies suggest movement disorders, especially chorea, occur in 1–4% of SLE cases.

Pathogenesis/Pathophysiology

Autopsy studies have not established a clear localization or specific pathology for lupus chorea. Most studies have shown multiple small infarctions in gray and white matter with cerebral atrophy and granular cortical atrophy. Although some cases have shown damage (neuronal loss and gliosis) to striatal structures, there are clear cases in which striatal damage did not cause chorea. Lupus chorea has an immune-mediated substrate. Three possible mechanisms have been proposed: (1) inflammatory vasculopathy with ischemic basal ganglia injury, (2) immune complex-mediated neuronal dysfunction, and (3) immune and nonimmune effects of infection or toxins. The relationship with antiphospholipid antibodies and lupus anticoagulant suggests that antibody-mediated CNS dysfunction is important in the production of the disorder.

Epidemiology/Risk Factors

SLE has a prevalence of 6–50 per 100 000. Women are more susceptible to SLE as are persons of African Caribbean and Asian racial origin. Neuropsychiatric involvement in SLE is common, affecting up to 90% of patients. Chorea is a well-recognized, although a rare manifestation of neuropsychiatric SLE, affecting 1–4% of patients. Parkinsonism and myoclonus are also seen. In series of SLE cases with neuropsychiatric involvement, the prevalence of antiphospholipid (anticardiolipin) antibodies and lupus anticoagulant was higher than in cases without neuropsychiatric involvement.

Clinical Features and Diagnostic Criteria

A review of 51 cases of SLE chorea found that the gender ratio of 9:1 favors women, similar to the ratio in SLE itself. The mean age at the onset of chorea in SLE is 19 years, and children seem more likely to have choreic manifestations. Since the age range is similar, lupus chorea is often confused with Sydenham's chorea. In about 25% of lupus chorea cases, chorea is the presenting symptom of the lupus. In some cases, the chorea is precipitated by pregnancy or oral contraceptive use. The duration of chorea ranges from days to a few years, and some patients have recurrent bouts of chorea. Chorea is most often generalized, but may have a hemibody distribution. Common comorbid symptoms

include dysarthria, hypotonia, confusion, psychosis, seizures, hemiplegia, and mental deterioration.

An ad hoc committee of the American College of Rheumatology lists two diagnostic criteria: (1) observed abnormal movements and (2) random, unpredictable sequence of movements. The criteria exclude Wilson's and Huntington's disease, and licit and illicit medication-induced movements and list associations with stroke/vascular malformation/hypoxia, tumor, chorea gravidarum, Sydenham's chorea, and antiphospholipid antibody.

Differential Diagnosis

Choreic movements must be differentiated from dystonia, myoclonus, and tics. The differential diagnosis of choreic movements includes degenerative diseases (Huntington's disease, dentatorubropallidoluysiian atrophy), Sydenham's chorea, chorea gravidarum, chorea associated with drugs or metabolic derangements, chorea-acanthocytosis, and benign hereditary chorea.

Diagnostic Workup/Tests

Using clinical criteria, the diagnosis of SLE can be made with 75% sensitivity and 95% specificity. The diagnosis requires the presence of four or more of the following criteria: malar rash, discoid rash, photosensitivity, oral ulcers, arthritis, serositis, renal disorder, neurologic disorder (seizures or psychosis), hematologic disorder, immunologic disorder (anti-double-stranded DNA, anti-Smith or antiphospholipid antibodies), or antinuclear antibodies. There is a relationship between the presence of antiphospholipid antibodies and chorea. Chorea is one manifestation of primary antiphospholipid antibody syndrome and there is a correlation between the presence of chorea and the presence of antiphospholipid antibodies in primary antiphospholipid antibody syndrome.

In children and adolescents, it is most important to exclude Sydenham's chorea in the context of acute rheumatic fever (ARF). The diagnosis of ARF is made by Jones criteria. ARF is characterized by the presence of two major or one major and two minor Jones criteria with evidence of recent group A β-hemolytic strep infection. Major criteria include migratory polyarthritis, carditis, erythema marginatum, subcutaneous nodules, and chorea. Minor criteria include fever, arthralgia, elevated sedimentation rate, elevated C-reactive protein, and P–R interval prolongation on electrocardiogram. Streptococcal infection can be documented by elevated antistreptolysin O titers or throat culture. The presence of carditis should be assessed using echocardiogram. Isolated cases have shown increased T1 signal intensity in the basal ganglia in patients with lupus chorea.

Management

Appropriate treatment for active SLE is the most important approach to lupus chorea. A treatment guideline published in 2007 suggested that treatment of SLE should be individualized and the most important drugs were nonsteroidal antiinflammatory agents, hydroxychloroquine, corticosteroids, and immunosuppressive drugs (azathioprine, cyclosphosphamide, methotrexate, and mycophenolate). Antiinflammatory agents and hydroxychloroquine are useful for milder symptoms, but more aggressive management is generally required for C lupus. In these cases, corticosteroids and immunosuppressive drugs are recommended. Chorea generally improves with adequate treatment of the disease. In a single case, chorea responded dramatically to intravenous immune globulin when corticosteroid treatment was not tolerated.

Should chorea remain a problem in appropriately treated patients, additional symptomatic therapy for the movements themselves should be considered. There is limited evidence on which to base recommendations, but positive responses to valproic acid and to dopamine receptor blocking drugs such as haloperidol have been reported. Agents that effectively treat chorea in other disorders, such as tetrabenazine and amantadine, can also be considered. It is important to initiate symptomatic treatments at a low dose and to titrate the drugs as tolerated. Since lupus chorea tends to be self-limited, frequent reassessments for the need for continued treatment are essential.

Prognosis

With appropriate treatment of the SLE, chorea is generally self-limited. However, chorea in SLE may be recurrent. The overall prognosis for SLE depends on the aggressive nature of the disease itself and on the progressive accumulation of end-organ damage produced by the underlying disease process.

Magnetoencephalography (MEG)

Alfons Schnitzler, University of Duesseldorf, Duesseldorf, Germany; Universitaetsklinikum Duesseldorf, Duesseldorf, Germany
Joachim Gross, University of Glasgow, UK

Glossary

Dewar – Special container used in MEG systems to hold liquid helium and protect the subjects from the cold liquid.
Event-related fields – Neuromagnetic time series that were averaged time-locked to a stimulus. Event-related fields represent the time-locked responses of brain areas to a sensory, motor, or cognitive event.
Local field potential (LFP) – LFPs represent extracellularly recorded voltage fluctuations of a local neuronal population.
Postsynaptic potential – Membrane depolarization (hyperpolarization) of the postsynaptic neuron following excitatory (inhibitory) input.
Superconducting quantum interference devices (SQUIDS) – Highly sensitive sensors used in MEG systems for the measurement of tiny magnetic fields originating in the brain. SQUIDS operate at a very low temperature (−269 C) and require liquid helium for cooling.
Superconductivity – The absence of electrical resistance in certain materials at very low temperatures.
Tesla – Physical unit of magnetic flux named after Nikola Tesla.

Magnetoencephalography (MEG) is a noninvasive brain imaging technique that records the small magnetic fields associated with the electrical activity in the brain. The same electrical brain activity leads to fluctuations of electrical potentials that can be recorded at the scalp with the related measurement technique Electroencephalography (EEG).

MEG provides noninvasive recordings of brain activity with good spatial resolution and a very high temporal resolution (about 1 ms). Measurements are challenged by the small amplitude of the neuromagnetic field, which is typically below 10^{-12} Tesla. The earth's magnetic field for comparison is several orders of magnitude larger (about 10^{-4} Tesla). Consequently, MEG recordings require highly sensitive detectors and efficient attenuation of environmental magnetic background activity. State-of-the-art MEG systems are equipped with about 300 highly sensitive superconducting quantum interference devices (SQUIDS). These sensors have to be cooled with liquid helium and operate at a very low temperature of about −269 °C in the state of superconductivity. The sensors are arranged in a helmet-shaped dewar and cover most of the head at a typical scalp distance of about 2 cm. The many sensors allow precise measurements of brain activity in all cortical areas.

The environmental noise is suppressed in three ways. First, a MEG system is typically installed in a magnetically shielded room that consists of several layers of metal. These layers achieve a strong attenuation of magnetic disturbances that may be caused by cars, undergrounds, elevators, etc. Second, most MEG systems allow the measurement of the spatial gradient of the magnetic field. Magnetic fields originating in the brain are close to the MEG sensors and show a strong spatial gradient, whereas distant magnetic (noise) sources show a small spatial gradient. Subtracting signals from additional reference sensors (that are further away from the brain) from the MEG sensors effectively reduces background environmental magnetic noise. Third, noise reduction can be performed offline by removing components that most likely were caused by strong magnetic sources outside the brain.

In a typical experiment, 3–5 small coils are attached to the participants head. The location of these coils with respect to anatomical landmarks is recorded. Then the participant is seated in the MEG system below the helmet-shaped dewar. The small coils are activated with

small electric currents. The corresponding magnetic fields are recorded by the MEG system and the generators (the coils and thereby the participants head) can be accurately localized with respect to the MEG sensors.

During a typical experiment, sensory stimuli may be presented and the participant is asked to perform a specific task. Stimuli and participant's response are repeated many times (about 100 repetitions are common). Information processing in the brain is associated with the activation of neurons that is characterized by changes in their membrane potentials. The MEG signal is caused by magnetic fields that are associated with postsynaptic potentials and thus reflects fluctuations in local field potentials. Prerequisites for a measurable MEG signal are the simultaneous activation of several thousand neurons and a preferred spatial orientation of these neurons (such that the summation of the tiny individual magnetic fields increases the total magnetic field measured outside the head).

The traditional analysis of MEG recordings is based on averaging the measured signals time-locked to the presentation of the stimuli. This reduces components in the data that are not precisely time-locked to the stimulus (such as artifacts, environmental noise, etc.). The resulting event-related fields (ERFs) usually show a number of maxima and minima that can be further analyzed. In the simplest case, the latency and amplitude of these maxima and minima are noted and their modulation by the different experimental conditions can be investigated. For a given time after the stimulus onset, the different measurement values for each sensor can be spatially interpolated, taking into account the location of each sensor. The spatial configuration of magnetic field amplitudes (topography) may show a pattern that is characteristic of a small activated brain region (dipolar field pattern). These topographies contain information about the location of the activated brain areas.

Since magnetic fields (in contrast to electric potentials measured with EEG) are not much distorted by the different conductivities of the brain, cerebrospinal fluid, skull, and scalp, MEG researchers have worked extensively on the problem of estimating the activated brain areas from the neuromagnetic recordings – the so-called inverse problem. Unfortunately, it was already shown in 1853 by Helmholtz that this problem has no unique solution. Further constraints have to be formulated to yield a unique solution. A number of techniques that are based on different models of the underlying activated brain areas have been suggested and are available in commercial or public domain software. Although these algorithms cannot circumvent the nonuniqueness of the inverse problem, they can still provide useful information about the location of activated brain areas and the time course of their activation.

Recently, two new analysis methods have been introduced to the field of MEG research: time–frequency analysis and connectivity analysis. Time–frequency analysis accounts for the fact that oscillatory fluctuations are a prominent feature of brain activity. The result of this type of analysis is an image that displays the temporal changes of brain activity at different frequencies that are induced by a stimulus.

Connectivity analysis allows the identification of networks of interacting brain areas. This type of analysis is motivated by the observation that even simple tasks require a well-coordinated interplay between many specialized brain areas. New developments aim at a characterization of causality and the direction of information transfer between brain areas.

The applications of MEG are manifold.

MEG has been used in cognitive neuroscience to study language, neural plasticity, attention, memory, consciousness, motor control, etc. In addition, detailed studies of sensory processing in primary sensory areas have been conducted using the excellent temporal resolution of MEG.

A large number of studies have used MEG to investigate pathological mechanisms in many diseases.

Several clinical sites use MEG to measure and localize epileptic activity as a diagnostic tool for surgery or they use MEG for the presurgical mapping of eloquent brain areas (such as motor cortex and speech related brain areas). In recent years, MEG has been used to identify and analyze pathological oscillatory processes in the brain of patients suffering from movement disorders such as essential tremor, Parkinson's disease, dystonia, and Wilson's disease, as well as neuropsychiatric diseases such as hepatic encephalopathy and psychiatric disorders such as schizophrenia, obsessive compulsive disorder, and depression. Here, MEG has made important contributions toward a better understanding of the mechanisms leading to the various disorders.

In general, MEG is ideal for applications that require a high temporal and good spatial resolution. Although the spatial accuracy is better for functional magnetic resonance imaging (fMRI), no other noninvasive imaging technique offers a better temporal resolution with coverage of the entire brain combined with a good spatial resolution. These properties are particularly relevant to studying brain dynamics and oscillatory connectivity in healthy subjects and in patients with neurological and psychiatric diseases.

Malingering

K Gorfinkle and D T Williams, Columbia University, New York, USA

Glossary

Abasia – Inability to walk.
Atasia – Inability to stand.
Factitious – Fabricated.
Hemiparesis – Weakness on one side of the body.
Hemiplegia – Paralysis on one side of the body.
Malingering – Intentional falsification for specific gain.
Monoplegia – Paralysis of a single limb.
Obsessional – Involving intrusive, unwanted thoughts.
Quadraplegia – Paralysis affecting all four limbs.

Definition

Malingering in a medical setting involves the intentional falsification of a medical or psychiatric condition for a recognizable motive that generates tangible benefits to the presenting patient. Typically, motives are to evade social or personal obligations such as avoiding or shortening a jail sentence, avoiding work, avoiding military service, or avoiding financial obligations such as alimony or child support. Tangible benefits may include obtaining disability or workman's compensation or other financial benefits, or obtaining controlled substances for control of reported symptoms. These motives are distinguished from maladaptive and often self-harming psychological motives, of which an individual may or may not be consciously aware, that underlie factitious disorders and somatoform disorders. Malingering is not considered to be a psychiatric disorder, but rather involves the 'intentional production of false or grossly exaggerated physical or psychological symptoms' for pragmatic gain.

The investigation of the presence and causes of malingering can be influenced by the emphasis of the evaluator on either the legal or psychological aspects of the presenting clinical issue. In general, a balanced perspective is helpful. From the medico/legal standpoint, maintaining awareness of possible malingering in differential diagnosis is of value to prevent individuals from cheating society out of goods, services, or obligations. From a psychiatric standpoint, the psychosocial profile of the malingerer can help to identify the motivations of the malingerer and the reasons for success or failure in achieving his or her aims.

The mental health professions have historically evolved to evaluate, support, and provide care for patients. This predisposes to a clinical bias toward assuming truthfulness of the patient and minimizing ulterior motives for reported symptoms. A better understanding of malingering is, therefore, a helpful antidote to the clinician's becoming inadvertently complicit in authenticating a fabricated illness with potential untoward social consequences for all concerned.

Epidemiology

The incidence of malingering has been estimated to be twice as high in forensic (15.7%) as in psychiatric settings (7.4%). A large survey was conducted by the American Board of Clinical Neuropsychology (more than 33 000 subjects) in settings where some tangible benefit could potentially ensue to individuals from medical, personal injury, disability, or criminal referrals. Assessments of probable malingering were reported in 39% of those with mild head injury, 35% of those with fibromyalgia/chronic fatigue, 31% of those with chronic pain, 21% of those

with 'neurotoxic symptoms,' and 22% of those with electrical injury claims. Clearly, the clinician's level of sensitivity to the possibility of malingering needs to be influenced by the setting and context of the clinical assessment.

Clinical Features

The malingering patient fabricates a medical condition, claiming to have symptoms that are not supported by clinical examination and associated studies, or for which the patient has reportedly sought or received treatment with no reported clinical benefit. The severity of symptoms is often exaggerated in an effort to achieve the desired tangible benefit. The patient may either report a nonexistent accident or may stage a pseudoaccident and then refuse diagnostic evaluation or treatment. Malingerers often resist physicians' efforts to fully evaluate and treat the reported symptoms.

In the domain of movement disorders, common presenting symptoms may include tremors, spasms, weakness, and disturbances of ability to stand (astasia) or to walk (abasia).

Variations on the theme of weakness may include hemiparesis, hemiplegia, monoplegia, paraplegia, or quadraplegia. Other manifestations of somatic malingering may include occulomotor signs, dysfunctions of voice, swallowing and breathing, disorders of vision, disorders of sensation, vomiting, seizures, pain and falsified fever, or other falsified symptoms (e.g., hematuria). In addition, malingering can occur in domains affecting cognitive function and the genesis of pseudopsychiatric symptoms (e.g., posttraumatic stress disorder).

Differential Diagnosis

Malingering needs to be distinguished from factitious disorders and somatoform disorders, as well as from undiagnosed medical illness and psychological factors affecting a physical condition. Factitious symptoms are intentionally reported because of a psychological need to assume the sick-role, for example, to engender sympathy and to receive attention from care givers, as the primary definable goal. When a care giver fabricates or causes symptoms in (usually) a child in order to fulfill his or her own psychological needs, Munchausen by Proxy is diagnosed as a factitious illness variant. Somatoform disorders similarly involve the presentation of physical symptoms which, after adequate medical investigation, cannot be explained to have arisen from an organic cause. Yet, the genesis of these symptoms in somatoform disorders has a psychological basis derived from emotional causes, of which the patient is unaware. A variation on this theme is hypochondriasis, which involves an intrusive obsessional concern regarding postulated illness, with accompanying excessive attention to physical complaints. In both somatoform and factitious disorders, there may be some secondary pragmatic benefits to the patient ('secondary gain'), which should not be construed as an absolute indication that the entire clinical syndrome is simply malingering.

The most crucial category to consider in differential diagnosis is the possibility of an undiagnosed physical disorder. A premature rush to append a psychiatric etiology or to impute malingering because of presenting psychopathology or other atypical features on initial physical assessment runs the risk of destroying the therapeutic rapport that is essential for effective diagnosis and treatment.

Standardized psychological evaluation instruments such as those derived from Minnesota Multiphasic Personality Inventory (MMPI) subscales were designed to identify patient tendencies to falsify answers to diagnostic questions. These instruments have been employed to help to identify individuals attempting to receive fraudulent health benefits from government agencies. It should be noted, however, that such findings are relative, rather than absolute, diagnostic indicators. Furthermore, malingering can coexist with somatoform or factitious disorders, as well as with primary medical or psychiatric illness.

According to Rogers, malingering can be best understood as

1. a symptom of underlying mental illness (e.g., anxiety or depression, which the patient feels unable to express directly),
2. clinical evidence for an antisocial personality disorder, or
3. an adaptive (albeit devious) response to a threat or challenge in one's environment that the subject feels unable to confront directly.

The presence of an underlying medical illness neither excludes nor supports a diagnosis of malingering, which can coexist with documented medical illness. Similarly, the attribution of malingering to antisocial behavior merely describes, but fails to explain the use of falsification or deception to achieve instrumental gain. The adaptational model of Rogers provides a common sense explanation that encompasses most clinical presentations, and avoids the pitfall of pushing the clinician to unnecessarily confront the patient with moral disparagement. The model predicts that a patient may exaggerate and/or deceive more in settings where monetary and physical safety and security are at stake. This would include evaluations for fitness for military duty or forensic examinations for criminal or civil legal cases.

Management

To maintain the integrity of the doctor–patient relationship, it is inadvisable to directly confront the patient prematurely with suspicions of malingering, as this will harm any clinical alliance that has been formed. In a

hospital setting, observations of nursing and other support staff are valuable in delineating features of inconsistency of symptom state and aspects of the patient's interpersonal style that are relevant. It is reasonable to supportively apprise the patient of inconsistencies found between physical complaints and clinical findings, which point to the possibility that psychological factors play a role in symptom formation, although physical components may also pertain. Although a thorough medical evaluation of presenting symptoms is, of course, requisite, excessive ordering of nonrelevant tests is to be avoided. Proposing a psychiatric or psychological consultation with supportive clarification of the role played by stress in many illnesses can be a way of introducing this concept without rupturing the therapeutic alliance. The patient's response to this suggestion may be informative. A patient with somatoform disorder may be appreciative, whereas a malingering patient may become hostile and defensive. At the conclusion of one's evaluation, a supportive explanation to the patient that delineates the relative roles of physical versus psychological factors in symptom formation may be judicious, but use of the term malingering is best avoided, as it can often be difficult to establish with certainty and is likely to be inflammatory. Reports to the referring institution or clinical entity that are specifically authorized by the patient may reasonably allude to evidence of malingering as part of the differential diagnosis, but one wants to be cautious in delineating the conclusion of malingering in the absence of certainty because of the potential adverse effects for the patient, and, by extension, for a misdiagnosing clinician.

Prognosis

By definition, the prognosis for the persistence of a malingering symptom will be directly related to the duration of time that the tangible benefits associated with it persist. The termination of benefits or prospect thereof, such as the conclusion of a civil court case or criminal prosecution may, in that sense, be quite 'therapeutic.' It should be recalled, however, that malingering may coexist with both medical illness and psychiatric illness that may continue to be legitimate domains for clinical attention.

Glossary

Acquired hepatocerebral degeneration – A neurologic disorder secondary to chronic hepatobiliary diseases or portosystemic shunt, with presentations including parkinsonism, various hyperkinetic movements, ataxia, neuropsychiatric abnormalities, and altered mentation.

Chelator – A molecule that forms a complex structure with a metal ion. Chelation renders the bound metal no longer toxic, and facilitates its elimination.

Manganese – A heavy metal, the twelfth most abundant element in the earth's crust, and an essential trace mineral in organisms.
Manganism – The clinical manifestation of chronic manganese intoxication; it is called neuromanganism when referring specifically to the neurologic manifestation.

Introduction

Used for millennia, manganese (Mn) enters the scene of toxicology far behind lead and mercury, two metals known to be poisonous since antiquity. Not until 1837 was a syndrome including tremor, weakness, and a whispering voice first reported in workers at a Mn ore-crushing site. Since then, knowledge of manganism has advanced through studies of human cases and in animal models. It is now realized that excess Mn targets specific cerebral structures and produces distinctive symptoms. As a result, the epidemiology of manganism has extended beyond the realm of occupational medicine. What remains inconclusive is the role of Mn exposure as a risk factor for certain disorders generally considered to be due to other causes than metal intoxication.

Types of Manganism

Abundant in the environment, Mn enters the human body from air, water, and mostly from food, at a rate of 2–8 mg day^{-1}. Once absorbed, Mn is under homeostatic regulation, and is cleared by the liver into bile and then feces. A small fraction of Mn is also renally excreted. Physiologically, Mn is a trace element essential for multiple metabolic and cellular functions. However, when the amount of Mn exposure exceeds the capacity of clearance, Mn starts to accumulate and intoxication ensues. Mn can exist in an elementary form and in organic and inorganic compounds. Different forms of Mn vary with the mode of exposure, metabolism, and toxic effects.

Occupational exposure is the leading cause of manganism. With over eight million tons extracted annually, Mn finds plentiful uses in industries like iron- and steel-making, battery manufacture, and in products like gasoline, welding rods, and pesticides. Workers in these occupations are, therefore, at the risk of manganism when hazard-preventing measures in the work place are inadequate. From inhalation of Mn dust or fume, Mn miners and millers, smelters, welders, and workers in battery factories constitute the majority of cases of occupational manganism. Methylcyclopentadieny manganese tricarbonyl (MMT) is an Mn-containing additive in gasoline. Workers in gasoline industries and related occupations are susceptible to manganism when exposed to high ambient levels of Mn released from MMT. In farmers, gardeners, and other agricultural workers, manganism has been reported to occur from inhalation and dermal exposure to maneb and mancozeb, two Mn-containing pesticides.

Nonoccupational environmental exposure is a less frequent and less certain cause of manganism, but poses public health concerns. Of primary significance is the risk of manganism from drinking water with excess Mn. Few outbreaks of manganism have been attributed to drinking groundwater that is contaminated by Mn-containing waste, but in areas where drinking water has a high Mn level, surveys of local populations often disclose higher Mn burden in the body, and an association with neuropsychologic abnormalities. Inhalation of excess Mn emitted from MMT-supplemented gasoline has increasingly been scrutinized as a source of manganism in nonoccupational settings. Equally concerning is whether an Mn-rich diet increases the risk of manganism. While there have been no verified human cases of manganism from dietary sources, in animal models, ingestion of excess Mn can lead to intoxication.

An unusual category of manganism derives from nonenvironmental exposure, exemplified by manganism in patients who receive total parental nutrition with high levels of Mn. This iatrogenic type of manganism sometimes becomes reversible after reducing the concentration of infused Mn. Manganism has been observed in a child with pica who ingested Mn-laden soil. Furthermore, Mn plays a possible pathogenic role in a parkinsonian syndrome among users of an illicit substance methcathinone, which is often contaminated with potassium permanganate during its synthesis.

Manganism can conceivably result from inadequate hepatobiliary clearance of Mn. A candidate for this possibility is acquired hepatocerebral degeneration, a neurological syndrome seen in patients with hepatobiliary dysfunction. It shares clinical features with manganism, and Mn accumulation in the basal ganglia has been documented in acquired hepatocerebral degeneration. Acquired hepatocerebral degeneration has increasingly been considered a forme fruste of manganism.

Toxicopathology

Chronic Mn exposure exerts toxicity overwhelmingly to the brain. Other organ systems are less affected in chronic Mn poisoning; for instance, chronic Mn exposure sometimes leads to impotence, dermatitis, and pneumonitis. Acute Mn poisoning is rare, and has a more systemic involvement.

Mn reaches the brain across the blood–brain barrier via a number of mechanisms, including facilitated diffusion, transferrin-dependent transport, and divalent metal transport 1-mediated transport. At elevated Mn concentrations, the choroid plexus becomes the major route of Mn transport into the brain. Mn has high binding affinity for transferrin, and this binding may underlie the predilection of excess Mn to accumulate in the pallidum and

striatum, both with high expression of transferrin. At the cellular level, oxidative stress, mitochondrial dysfunction, excitotoxicity, and interaction with other metals have all been implicated as the mechanisms of Mn toxicity.

Neuropathology of manganism stems from a few autopsies of human cases, and mostly from studies in animal models. Pathologic findings of manganism center on the globus pallidus, especially the pars interna, which exhibits extensive neuronal loss and gliosis. The pars externa of the globus pallidus, striatum, subthalamus, and substantia nigra pars reticularis show less severe changes, sometimes observed in animal models only. The rest of the brain, specifically the substantia nigra pars compacta, which is the primary site of degeneration in Parkinson's disease (PD), is unaffected, and neither the Lewy body nor abnormal α-synuclein staining that typifies PD is present in manganism. These neuropathologic features underscore that manganism is distinct from PD.

Clinical Features and Diagnosis

Parkinsonism is the hallmark of manganism and can have a symmetric or asymmetric distribution. Every cardinal feature of parkinsonism – tremor, rigidity, bradykinesia, abnormal posture, and gait – has been observed in manganism. The tremor in manganism tends to occur in the upper extremity, lower face, and tongue, and often a postural tremor predominates rather than a rest tremor that typifies classic PD. Rigidity in manganism can be detected in the limb and trunk, and sometimes has a cogwheel property. Bradykinesia in manganism commonly manifests as masked faces, monotonous speech, impaired dexterity and slowness of limb motions, and paucity of overall movements. Postural and gait abnormalities in manganism include anteropulsion, retropulsion, and a peculiar gait aptly named 'cock-walk.' The cock-walk gait is a dystonic toe-gait with the trunk extended and arms flexed. Dystonia may occur at other sites, and is another prominant feature of manganism. None of these motor phenomena is specific to manganism, as they also occur to other parkinsonian disorders including PD. Nevertheless, compared with PD, in manganism, dystonia, antero- and retropulsion, and the cock-walk gait are more common, whereas tremor is less common, and if present, it is typically postural, of higher frequency, and in smaller amplitude.

Neuropsychiatric disturbances frequently accompany parkinsonism in manganism. There is a spectrum of affective and behavioral symptoms associated with manganism, from apathy, anxiety, compulsions to depression, and hallucinations. A psychotic state with aggression and emotional lability was formerly known as 'manganese madness' (locura manganica). Cognitive impairment is also common in manganism. Subtle changes in neuropsychological functions may be the earliest manifestation of manganism and can be the only manifestation in mild cases of manganism.

In addition to a history of exposure and neurologic findings, the definite diagnosis of manganism hinges on laboratory evidence of chronic Mn exposure, which can be provided by measurements of Mn and by magnetic resonance imaging (MRI). The likelihood of obtaining such evidence is determined in part by the factor of time. Due to continuous clearance of Mn, its accumulation starts to dissipate once the exposure has ceased, or in acquired hepatocerebral degeneration, once biliary excretion of Mn returns. After a period as short as several months, previously accumulated Mn may leave no trace on measurements of Mn or MRI. Under these circumstances, the diagnosis of manganism is primarily based on clinical grounds.

Mn levels can be measured in various body fluids and tissues such as blood, urine, feces, and hair. Certain measurements of Mn are reliable biomarkers of chronic Mn exposure only on a group basis, but not on an individual basis. Blood Mn reflects mixed cumulative and current exposure, and the levels often fluctuate. Therefore, levels of blood Mn and amounts of accumulated Mn do not always correlate. Nevertheless, hypermanganesemia that is repeatedly measured above a locally calibrated range is suggestive of chronic Mn exposure. Mn excretion in either urine or feces is not an accurate marker of Mn exposure. Hair Mn has been shown to be an accurate marker of Mn exposure, but this finding needs further validation. Currently, all measurements of Mn are considered approximate but not accurate biomarkers of Mn accumulation in the body.

A paramagnetic metal, accumulation of Mn generates signals of a characteristic pattern on MRI, which are hyperintense on T1-weighted images, but are normointense on T2-weighted and other images, a pattern seldom encountered in other pathological processes. On brain MRI of patients with manganism, T1 hyperintensity is often present in the pallidum, striatum, and midbrain tegmentum in a bilateral, symmetric distribution (**Figure 1**). Bilateral pallidal T1 hyperintensity has been documented in most types of manganism and is considered diagnostic of manganism.

Functional imaging modalities, including positron emission tomography (PET) and single photon emission computed tomography (SPECT) are instrumental in investigating the pathophysiology of manganism. The nigrastriatal pathway has been the focus of investigation in the light of presence of parkinsonism, and is assessed with tracers for the presynaptic and postsynaptic functions of dopaminergic transmission such as fluorodopa, 2β-carbomethoxy-3β-4-iodophenyltropane (β-CIT) for the former, and raclopride for the latter. These studies consistently demonstrate normal nigral functions but abnormal striatal functions in manganism. While they are useful research tools, functional imaging studies do not give a specific diagnosis of manganism. Functional imaging studies on other pathways or neurotransmissions have not been systemically performed.

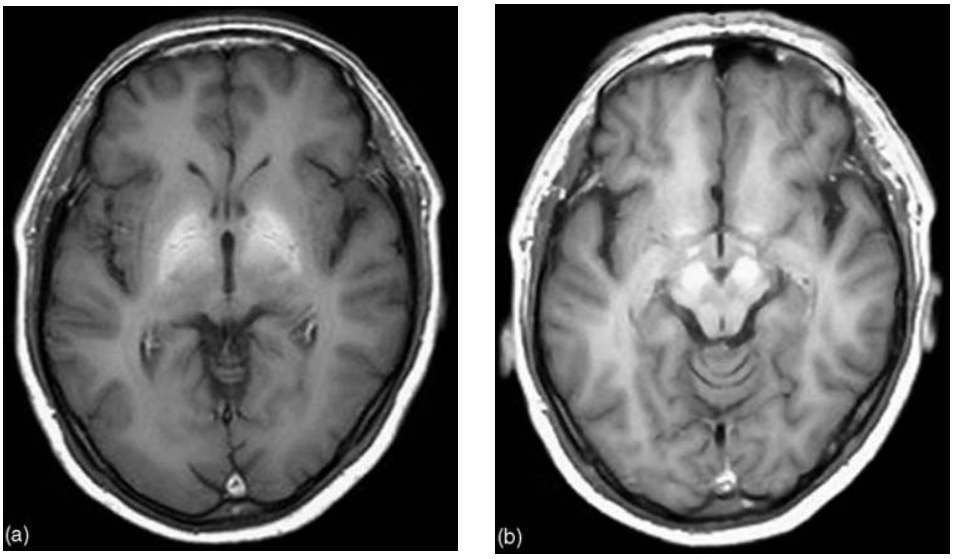

Figure 1 MRI findings in manganism. The brain MRI from a patient with welding-related manganism demonstrates bilateral, symmetric hyperintensity in the globus pallidus on the T-1 weighted images (a). Similar signal abnormalities are also present in the midbrain (b). Pictures provided here courtesy of Dr. Chin-Chang Huang of Chang Gung Memorial Hospital, Taipei, Taiwan.

The onset of manganism is insidious, and progression is gradual. Three clinical stages have been delineated in the progression of manganism, from behavioral symptoms to parkinsonism, and then to superimposed dystonia. Deterioration is typically more precipitous in the first several years after onset of the symptoms than later in the course. With continuing Mn exposure, manganism progresses relentlessly over a decade, but may eventually reach a plateau afterwards, likely representing a burnt-out state. If Mn exposure is finally removed after the diagnosis, manganism may improve but is not expected to resolve completely. Signs may persist at the same severity, or may even continue to progress for a period up to 10 years. The limited recovery or no recovery in absence of ongoing Mn exposure indicates that the damage in manganism is largely functionally irreversible.

Treatment

Treatment of manganism includes symptomatic and chelation therapy. In symptomatic treatment of manganism, symptoms of parkinsonism have been the focus, and levodopa is the most frequently used medication. As expected for secondary parkinsonism, in manganism the results of treatment with levodopa have been unsatisfactory; it is either ineffective, or only has partial, temporary benefit. In a 5-year follow-up study of patients with manganism, the response to levodopa declines quickly after 2–3 years. Other medications are less explored as symptomatic treatment for manganism.

Chelation therapy aims at reducing the toxicity and accumulation of Mn. Ethylenediaminetetraacetic acid (EDTA) is a chelator of lead and zinc, and its effectiveness in treating manganism has been evaluated in several case series. In EDTA-treated patients, their blood Mn levels decreased, and Mn excretion in urine increased, indicating EDTA has chelated and removed Mn, but their neurologic symptoms failed to improve accordingly. The discordance between efficacy of chelation and neurological outcome may be due to poor penetration of EDTA across the blood–brain barrier, or due to irreversible nature of Mn-induced cerebral damage.

Chelators with structures related to EDTA, such as cyclohexylene–aminotetraacetic acid (CDTA) and dimercaptol-1-propanesulphonic acid (DTPA), reduce Mn burden in animal models, but have not been tested for human manganism. Triethylenetetraamine (trientene), a copper chelator, has been used successfully to treat manganism in a case of acquired hepatocerebral degeneration. *para*-Aminosalicylic acid (PAS), first developed as an antituberculosis drug, has cast promise in treatment of manganism. In the experience garnered mainly in China, PAS not only eliminated Mn but also significantly alleviated neurological symptoms. PAS has been postulated as a Mn chelator or as an antiinflammatory neuroprotective agent, but its exact mechanism in treating manganism is still uncertain. The therapeutic potential of these chelators for manganism warrants further investigation.

Summary and Future Perspectives

Manganism is a disease with well-defined etiology, pathology, clinical manifestations, and paraclinical findings. Due to phenomenological similarity between manganism and PD, Mn toxicity has been speculated to be the mechanism of neurodegeneration in PD. Differences between manganism and PD in many aspects argue against a causative role of excess Mn in PD (**Table 1**).

Table 1 Comparison between manganism and Parkinson's disease in clinical, paraclinical, and pathological features

	Manganism	*Parkinson's disease*
Clinical manifestation	Tremor is postural and less common; dystonia, anteropulsion, and retropulsion are more frequent; Cock-walk gait is characteristic	Tremor is usually resting and more common; anteropulsion is rare and retropulsion occurs in advanced stage; festinating gait is typical
Response to levodopa	No response, or partial, temporary response	Significant, long-lasting response
Brain MRI	T1 hyperintensity in pallidum, striatum, and midbrain	Unremarkable
Functional imaging studies	Postsynaptic dopaminergic dysfunction	Presynaptic dopaminergic dysfunction
Pathology	Degeneration of pallidum and striatum, without Lewy body or synucleinopathy	Degeneration of substantia nigra, with Lewy body and synucleinopathy

However, a few epidemiologic studies, especially those in welders, have noted an increased incidence of PD in people exposed to excess Mn. A hypothesis has been raised that Mn exposure is, instead of a cause, a risk factor of PD which precipitates or accelerates its pathogenesis. This hypothesis awaits further testing.

For an illness that is mostly irreversible, has limited treatment options, but is preventable, prevention is critical. Regulatory agencies – for example, the Environmental Protection Agency (EPA), Food and Drug Administration (FDA) and Occupational Safety and Health Administration (OSHA) in the United States, and the World Health Organization (WHO) have set limits on Mn levels in air, drinking water, and diet. In an ever-industrialized world, new Mn-containing chemicals will continue to be synthesized, and their new applications to be found. Manganism in multiple environmental settings will therefore likely continue to emerge, necessitating vigilance for early recognition and prevention.

Marinesco-Sjogren's Syndrome

A-K Anttonen, University of Helsinki, Helsinki, Finland

Glossary

ATPase – Adenosine triphosphatase, an enzyme that hydrolyzes ATP into ADP and phosphate.
Chaperone – A protein required for the proper folding and/or assembly of another protein or protein complex.
Frameshift mutation – A mutation that alters the reading frame of a coding sequence.
Heat-shock protein 70 family – A class of molecular chaperones found in several compartments of cells. These proteins can interact with polypeptides during a variety of assembly

processes in such a way as to prevent the formation of nonfunctional structures.
MIM – Mendelian Inheritance in Man, its online version OMIM contains referenced overviews on all known Mendelian disorders and over 12 000 genes.
Missense mutation – A mutation that replaces one amino acid with another in the gene product.
Nonsense mutation – A mutation that converts a codon for an amino acid into a stop codon.
Rimmed vacuole – Autophagic, multilaminated membranous structure surrounded by filamentous material and found in muscle fibers.
Splice site mutation – A mutation that creates or destroys signals for exon–intron splicing.

Definition and History

Marinesco–Sjögren syndrome (MSS, MIM 248800) is an autosomal recessive disorder with marked phenotypic variability. The two acknowledged original reports include a report of Marinesco and colleagues in 1931, where they described a Romanian family with four affected children. Later, Sjögren saw four similar cases and identified 10 more in three Swedish families in 1950. The syndrome is a panethnic disease with 200 published cases, but exact prevalence figures are not available. The patients described in the literature form a clinically heterogeneous entity, and can be divided into classical MSS and MSS-like groups. Typically, classical MSS is characterized by cerebellar atrophy with ataxia, early-onset cataracts, mild to severe mental retardation, and myopathy. Additional features include hypergonadotropic hypogonadism, short stature, various skeletal abnormalities, and strabismus. In the MSS-like group some, but not all, of the main features are present together with several atypical symptoms.

Pathogenesis

So far, *SIL1* is the only gene known to be defective in MSS. The main transcript of the *SIL1* gene has 10 exons and encodes a 461-amino acid protein. A total of 17 MSS-associated mutations have been described in *SIL1*. Most mutations are nonsense, frameshift, or splice site mutations predicted to result in loss of SIL1 protein function due to premature termination of translation or abnormal splicing of the transcript. A single missense mutation has so far been described. Not all patients with a clinical MSS diagnosis have detectable mutations in the *SIL1* gene implying genetic heterogeneity.

Several pieces of information suggest that MSS pathogenesis is linked to abnormal protein quality control in the ER. As cochaperone, SIL1 regulates the ATPase cycle of the 78 kDa glucose-regulated protein (GRP78). GRP78 belongs to the heat-shock protein 70 chaperone family and has multiple roles in processing proteins targeted to the secretory pathway. Most of the *SIL1* mutations described so far are predicted to lead to nonfunctional or absent SIL1 and are thus likely to result in decreased rates of GRP78 hydrolysis and abnormal protein translocation and folding. The accumulation of unfolded proteins in the ER causes ER stress, and if stressful conditions are not alleviated, this may lead to cell death. MSS may, thus, be added to the growing number of protein misfolding and accumulation disorders due to defective molecular chaperone function.

In MSS, the severe cerebellar atrophy is due to loss of Purkinje and granule cells in all cerebellar lobules except the vestibulocerebellum. The remaining Purkinje cells are mostly vacuolated or binucleated. The brain lesions are almost exclusively limited to the cerebellum. The hypothesis of defective protein folding in MSS is supported by data from the *wz* mouse, a naturally occurring mouse model for MSS. In the Purkinje cells of the *wz* mouse, loss-of-function of SIL1 causes induction of the unfolded protein response and abnormal accumulation of proteins, with subsequent neurodegeneration in cerebellar Purkinje cells and ataxia.

Clinical Features and Diagnostic Criteria

The cerebellar signs dominate the central nervous system symptoms in MSS. Delayed motor milestones are among the first clinical signs. Gait or truncal ataxia is one of the most frequent symptoms. Dysarthria, nystagmus, and intention tremor have been noted in many cases. MSS patients have variable degrees of developmental delay. In classical MSS neuroimaging studies such as magnetic resonance imaging (MRI) and computed tomography (CT) show cerebellar atrophy, which is usually more pronounced in the vermis than in the hemispheres. The cerebellar fissures are widened and the fourth ventricle is enlarged. The neuromuscular manifestations described so far show considerable variation. Hypotonia, slowly progressive muscle weakness, and atrophy suggesting chronic myopathy have been the most frequent findings. Electromyography (EMG) typically shows only myopathic features. Demyelinating polyneuropathy, axonal polyneuropathy, or both have also been described.

The bilateral cataracts have been stated as congenital, but there are several reports on rapid postnatal development of lens opacities. The eyes are typically operated on in the first decade of life. Strabismus is a frequent finding. The most distinguishable skeletal features are shortening

Table 1 Diagnostic criteria for MSS and comparison between the clinical features of *SIL1* mutation-positive and -negative patients

Diagnostic criteria	*Patients with SIL1 mutations (number of cases)*	*Patients without SIL1 mutations (number of cases)*
Major criteria		
Cerebellar ataxia	100% (29/29)	85% (11/13)
Cerebellar atrophy	100% (26/26)	79% (11/14)
Cataracts	100% (30/30)	67% (10/15)
Myopathic changes	92% (23/25)	44% (4/9)
Muscle weakness	100% (9/9)	
Truncal/limb hypotonia	100% (29/29)	82% (9/11)
Mental retardation (mild to profound)	100% (30/30)	93% (14/15)
Minor criteria		
Hypergonadotropic hypogonadism	90% (19/21)	20% (2/10)
Short stature	60% (18/30)	50% (5/10)
Orthopedic manifestations	62% (16/26)	42% (5/12)
Dysarthria	100% (6/6)	
Nystagmus	69% (20/29)	55% (6/11)
Strabismus	89% (24/27)	44% (4/9)

of metacarpals and metatarsals, shortening of phalanges, and deformation of the sternum. In addition, small posterior cranial fossa, scoliosis, and kyphoscoliosis, scalloped vertebral bodies, gracile bones, pes planovalgus, and valgus deformities of elbows and hips are present.

Although atypical findings like optic atrophy, seizures, hearing loss, and peripheral neuropathy have been reported, it is not known if these are rare manifestations of MSS or features of a distinct disorder. The common clinical features and diagnostic criteria of MSS are summarized in **Table 1**. The diagnosis of classical MSS requires the presence of the major criteria including cerebellar atrophy and ataxia, cataracts, myopathy, and psychomotor delay.

Differential Diagnosis

Other syndromes presenting with cerebellar atrophy and ataxia should be considered in the differential diagnosis. The evaluation of an affected child without family history is challenging, since all MSS features, for example, cataracts and hypergonadotropic hypogonadism, may not yet be present.

The congenital cataracts, facial dysmorphism, and neuropathy syndrome (CCFDN, MIM 604168) share with MSS the key features of ataxia, cataracts, psychomotor delay, and hypogonadism. The presence of more severe mental retardation, marked cerebellar atrophy leading to severe ataxia, myopathy with specific features on muscle biopsy, and absence of peripheral neuropathy and microcornea distinguishes MSS from CCFDN.

Some recent reports have described disorders clinically similar to, but genetically different from, MSS. An X-linked CASM syndrome (cataracts, ataxia, short stature, and mental retardation, MIM 300619), affects males while female carriers present only cataracts. A Marinesco–Sjögren-like syndrome was reported in two siblings sharing most of the clinical features found in MSS but without marked cerebellar atrophy. As additional symptoms the patients presented external ophthalmoplegia and dysphagia.

There are some other rare, mainly autosomal recessive disorders that partly resemble MSS. The clinical entities include the Cataract–ataxia–deafness–retardation syndrome (MIM 212710), familial Danish dementia (FDD, MIM 117300), VLDLR-associated cerebellar hypoplasia (Dysequilibrium syndrome; MIM 224050), aniridia, cerebellar ataxia, and mental deficiency (Gillespie syndrome; MIM 206700), and Ataxia–microcephaly–cataract syndrome (MIM 208870). In addition, several other syndromes share some of the main clinical features with MSS, but they are distinguishable due to additional features.

Diagnostic Work-up

The diagnosis of MSS is based on clinical evaluation and neuroimaging studies (MRI or CT). Molecular genetic testing for *SIL1* mutations may help confirm the diagnosis. Muscle biopsy specimen show variation in muscle fiber size, atrophic fibers, fat accumulation, and rimmed vacuole formation under light microscopy. Rimmed vacuoles are most evident in samples taken at older ages. In electron-microscopy, autophagic vacuoles with myeloid bodies beneath the sarcolemma or near the nucleus, and a perinuclear dense double-membrane structure suggested to be specific to MSS, are seen. Radiography of the bones may help determine the extent of skeletal involvement. EMG can be helpful in assessing the myopathy. Serum creatine kinase concentrations are normal or moderately increased, usually two- to four-fold the upper normal limits.

Management

After diagnosis, surveillance at regular intervals is recommended. Patients usually undergo cataract surgery during the first decade of life. Only symptomatic treatment is currently available to muscle manifestations. If hypergonadotropic hypogonadism is present, hormone replacement therapy should be considered to prevent secondary problems including osteoporosis. Genetic counseling is recommended to the families to determine the genetic risk and to discuss the reproductive options.

Prognosis

MSS patients are usually born after uncomplicated pregnancies. Muscular hypotonia is typically present in early infancy. Muscular weakness becomes evident during the first decade of life in the distal muscles of the extremities, and some patients are never able to walk without assistance. Later, patients show truncal ataxia, dysdiadochokinesia, and dysarthria. Their mental performance varies usually from mild to moderate mental retardation. The motor functions of the patients worsen progressively, but the duration of the disease does not alone explain the variation in the severity of the muscle involvement. The development of a child sometimes deteriorates after febrile illness. Although many of the patients are severely handicapped in their adulthood, the life span of patients with MSS is near to normal.

McLeod Syndrome

R H Walker, James J. Peters VA Medical Center, Bronx, NY, USA; Mount Sinai School of Medicine, New York, NY, USA

Glossary

Acanthocytes – Contracted erythrocytes with thorny protrusions.

McLeod phenotype – An erythrocyte antigen pattern in which the Kx antigen is absent and the Kell antigen expression is markedly reduced.

McLeod syndrome – An X-linked recessive neurodegenerative disease due to mutation of the gene for the XK protein, characterized by involuntary movements (chorea) and acanthocytosis, in which there is reduced expression Kx and Kell antigens on erythrocytes.

Neuroacanthocytosis – A term for the group of neurological conditions in which there are abnormalities of red blood cell membranes resulting in thorny protrusions.

Definition and History

McLeod syndrome is one of the core neuroacanthocytosis syndromes (along with autosomal recessive chorea-acanthocytosis). It is transmitted in an X-linked recessive manner. McLeod syndrome is defined as a characteristic pattern of erythrocyte antigens, with decreased expression of the 23 Kell antigens, and absent expression of the Kx antigen, known as the McLeod phenotype, in combination with specific neurological signs. The abnormal red blood cell (RBC) phenotype is due to mutations of the *XK* gene resulting in absent or abnormal XK protein. The XK protein is linked by two disulphide bonds in the RBC membrane to the Kell protein, and thus, absent or abnormal XK causes decreased expression of the 23 antigens expressed on the Kell protein.

The RBC phenotype is often picked up many years before the appearance of any neurological abnormalities when carriers donate blood or have it cross-matched. This phenotype was discovered in the 1950s in a Harvard dental student, Hugh McLeod, when all the students were being screened for new blood antigen phenotypes. At that time, it was assumed to be benign, and it had not been until a number of years later that the connection was made with the neurological symptoms that developed in carrier individuals.

Some individuals have been incidentally identified by abnormalities of blood chemistry such as elevated creatine kinase (CK) or liver enzymes. Acanthocytosis, the appearance of contracted RBCs with thorny protrusions, is typically, but not invariably, present, and is not required to make the diagnosis. It is presumed that the membrane structural abnormalities are due to abnormal XK and reduced Kell expression, but this is neither confirmed nor well understood.

The neurologic features develop in middle age, often with a variable spectrum of cognitive and psychiatric problems, in additional to involvement of internal organs.

Pathogenesis

The relationship of abnormal XK to neurodegeneration of the central and peripheral nervous systems is not known. XK is widely expressed throughout the brain and various internal organs. In brain, it is not associated with Kell.

Neurodegeneration in the brain affects predominantly the caudate nucleus, putamen, and globus pallidus. Neuropathological findings consist of severe gliosis of this region, with mild gliosis of the cerebral cortex, but no inclusion bodies of any nature have been detected.

Epidemiology

McLeod syndrome is very rare. However, there are likely to be a number of undiagnosed cases. Cases have been reported from a variety of ethnic populations. In 2007, a summary was published of approximately 60 cases from 30 families in whom the mutations have been reported to date.

Typically males are affected, but occasionally, carrier females develop a milder phenotype thought to be due to X-chromosome inactivation.

Clinical Features and Diagnostic Criteria

The neurological features of McLeod syndrome typically develop in the 40s–50s and progress slowly over the next two decades. Often the initial presentation may be subtle cognitive or psychiatric symptoms. The use of neuroleptics may confound the recognition of the movement disorder. However, the appearance of seizures and the development of peripheral sensorimotor neuropathy and areflexia may suggest the diagnosis. The neuropathy, which along with the myopathy, causes hypotonia and peripheral weakness, is often a debilitating feature. Myopathy was initially thought to be a relatively benign feature, but has recently been recognized as being a significant cause of functional impairment. It may lead to a predisposition to neuroleptic malignant syndrome.

Nerve conduction studies show axonal loss, although occasionally demyelination can be seen. Electromyographic findings of myopathy may be seen at later stages.

A variety of movement disorders may be present and includes tics, parkinsonism, dystonia, and chorea. Additional somatic features consist of cardiomyopathy, skeletal myopathy, and hepatosplenomegaly. No specific features have been found in pathological examinations of cardiac or skeletal muscle.

Neuroimaging demonstrates bilateral atrophy of the caudate nuclei and may be reported as being similar to that seen in Huntington's disease.

Minimal symptoms can occasionally be seen if the mutation of *XK* interferes to a lesser extent than normal with XK protein function.

Differential Diagnosis

The differential diagnosis of McLeod syndrome depends upon the presentation. The full syndrome of a movement disorder, peripheral neuropathy, seizures, and cognitive changes is similar only to autosomal recessive chorea-acanthocytosis (ChAc), but can be distinguished by the absence of the self-mutilating lip and tongue

biting, which is characteristic of autosomal recessive chorea-acanthocytosis.

The initial workup may be that of a peripheral neuropathy or myopathy, especially if CK is elevated. Recognition of the syndrome may avoid the need for invasive and nondiagnostic tests such as muscle or bone marrow biopsy. Similarly, abnormalities of liver enzymes may prompt the performance of liver biopsy.

If there is a family history, this may indicate an X-linked disorder by the involvement only of males, and no male-male transmission. Maternal grandfathers or uncles may be affected.

Huntington's disease should be excluded, particularly if there is a possibility of non-paternity, or if the medical history of the father's family is not known.

Diagnostic Workup

The diagnosis is made by examination of the complete set of Kell antigens and Kx, which can be done at a regional blood center. The request should be made to 'exclude McLeod syndrome,' as just requesting the Kell status is not helpful. The diagnosis can be confirmed by sequencing *XK*.

McLeod syndrome may be suggested if acanthocytosis is found on peripheral blood smear. Sensitivity can be increased by incubating the RBCs with an equal volume of normal saline containing $10\,\mu l\,ml^{-1}$ heparin for 30–120 min on a shaker. Electron microscopy of glutaraldehyde-fixed RBCs is also confirmatory. However, the presence of acanthocytes in the neuroacanthocytosis syndromes is not constant, for reasons that are not well understood, and their absence does not preclude the diagnosis.

Elevated creatine kinase, often into the 1000s, is very suggestive of either McLeod syndrome or ChAc. Abnormal liver enzymes are also seen in both and require the exclusion of Wilson's disease as the only treatable neurodegenerative condition.

Echocardiography should be performed to evaluate for cardiomyopathy.

Electroencephalography may be helpful if seizures are a feature. Electromyography and nerve conduction velocity studies may document peripheral neuropathy or myopathy.

Management

Management is at present purely symptomatic. The involuntary movements do not typically impair function as much as the peripheral neuromuscular abnormalities. Psychiatric and cognitive symptoms should be treated appropriately.

Results of deep brain stimulation, predominantly targeted at reducing chorea and dystonia, have been variable. The optimal site and stimulation parameters remain to be determined.

Patients should be evaluated approximately annually by echocardiogram to monitor for the development of cardiomyopathy, arrhythmias, or congestive heart failure, which should be treated as appropriate.

Seizures usually respond to standard anticonvulsants, although carbamazepine and lamotrigine can worsen involuntary movements.

Evaluation by a speech therapist is essential to minimize problems due to dysphagia and weight loss. Physical and occupational therapists can assist with the difficulties with gait, balance, and activities of daily living.

As transfusion with heterologous (i.e. Kell+) blood may result in the generation of anti-Kell antibodies and a second transfusion may result in massive hemolysis (analogous to the reaction to Rhesus + blood in Rh− neonates), patients should be encouraged to bank their own blood, in case there is need for a blood transfusion.

Prognosis

McLeod syndrome is slowly progressive. Death is usually attributable to cardiac arrhythmias or seizure, but may be due to gradual, generalized debility, as seen in Huntington's or Parkinson's disease, with patients succumbing to pneumonia or other systemic infection.

Meige's Syndrome

L Abaroa and N S Garretto, Ramos Mejia Hospital, Buenos Aires, Argentina

Glossary

Akathisia – Inner restlessness and irresistible urge to move, resulting in the inability to sit quietly (káthisis = sitting).
Dystonia – Sustained muscle contractions, frequently causing twisting and repetitive movements or abnormal postures.
Stereotypy – Involuntary, patterned, repetitive, coordinated, purposeless, or ritualistic movement, posture, or utterance.
Tardive dyskinesia (TD) – A variety of hyperkinetic involuntary movement disorders, associated with the use of dopamine receptor blocking drugs.

Definition and History

Meige syndrome is considered to be a type of segmental dystonia, because it involves contiguous body regions. It is characterized by blepharospasm (BSP), and oromandibular dystonia (OMD), but frequently dystonia may also be present in cervical and laryngeal muscles (**Figure 1**). More rarely, muscle groups beyond those of the cranial cervical structures can be affected. BSP refers to involuntary spasms of the orbicularis oculi (OO) muscle, resulting in forceful eyelid closure. OMD consists of contractions of the perioral or masticatory muscles, or both, resulting in jaw movements, lip or tongue protrusion, and lower facial twitching.

Meige syndrome can be primary (idiopathic), or secondary (symptomatic). The primary forms are the most prevalent. The disorder was named after Henry Meige, the French neurologist who first described its symptoms in detail in 1910. The term *craniocervical dystonia* (CCD) is preferred, because 'Meige syndrome' was originally used to refer only to the primary forms. *Cranial dystonia* is also appropriate, because cervical regions are not always necessarily involved. *Brueghel syndrome* has been used as an eponym, but it is preferably reserved for those cases where spasmodic jaw opening is the most prominent feature.

Epidemiology and Risk Factors

Idiopathic craniocervical dystonia (ICCD) is more common in women, with a 3:1 predominance, and usually

Figure 1 Patient with idiopathic CCD showing BSP, OMD, and anterocollis.

occurs in individuals older than age 50. A meta-analysis of major series of patients published in the English literature in the last 25 years showed that the mean age of onset is 38 years for hand dystonia, 41 years for cervical dystonia, 43 years for laryngeal dystonia and 56 years for BSP together with cranial dystonia. Evidence from epidemiological studies suggests that with increasing age, the site of onset of focal dystonias, shifts caudorostrally. Focal dystonias are more prevalent than generalized dystonias. Studies from various geographic areas indicate that BSP and cervical dystonia are the most frequent subtypes. Patients with BSP are more likely to experience spreading of symptoms to other body parts than patients with other focal primary dystonias. The greater risk of spread is within the first 5 years. Peripheral trauma is increasingly recognized as a trigger of dystonia. There are reports of OMD following jaw injury or surgery and of ocular trauma prior to the onset of BSP. Two case control studies found a significant association between BSP and diseases of the anterior segment of the eye (blepharitis, keratoconjunctivitis, and dry eyes). In one of those studies, the strength of the association increased when eye diseases first manifested around the fifth and sixth decades. Some authors proposed that this age range, together with the beginning of the physiological decline in the dopaminergic control over the trigeminal blink reflex circuit, might represent a temporal window of relative vulnerability to ocular diseases triggering BSP. A multicenter case control study in Italy, found that coffee drinking was associated with reduced likelihood of BSP.

Clinical Features

Clinical features of ICCD syndrome are fairly uniform. Most commonly, it begins in the upper face producing BSP. It may remain localized, but most frequently extends to other cranial muscle groups with variable rate and extent. When BSP is not associated with known etiologies, the term benign essential blepharospasm (BEB) is commonly used. Typically symptoms evolve gradually, reaching maximal disability after several months and then tend to remain stable. Occasionally, it can have a more abrupt onset and fluctuations can be seen during its evolution. Even though ICCD is a chronic disorder, spontaneous improvement may occur and there is a small potential of about 10% of remission of symptoms, particularly within the first 5 years. The clinical spectrum is wide causing variable degrees of social and occupational incapacity. Patients with BSP usually complain of eye discomfort, uncontrollable closing of the eyes or excessive blinking. It often interferes with the ability to read, drive, watch television, and other activities of the daily living. Sometimes this condition can be so severe, that it causes functional blindness.

BSP may coexist with apraxia of eyelid opening which is important to recognize as the latter condition does not respond well to botulinum toxin (BTX) injections.

Patients with involvement of the lower face and the oromandibular region complain of difficulty in speaking, chewing or swallowing and are socially most embarrassed. When vocal cords are involved a harsh, raspy voice, interrupted by voiceless pauses can be observed (spasmodic dysphonia). OMD may appear only when the patient attempts to eat, producing jaw opening or closing (trismus); as a result of lingual dystonia the food may be pushed out of the mouth. The severity of all these symptoms is influenced by various factors. For example, bright light, wind, or smoke tend to worsen BSP and patients generally like to use dark glasses. Other actions that frequently worsen symptoms include looking upward, walking, and reading. Various maneuvers called 'sensory tricks' may temporarily alleviate symptoms. These maneuvers include pulling at an upper eyelid, pinching the neck, talking, singing, humming, chewing, or opening the mouth, among others. Dental prosthetic devices may relieve jaw spasms. Patients with ICCD may have postural hand tremor and jerky movements in the arms. Sometimes they may seem talkative and anxious, but association with overt psychopathology has not been demonstrated. Intellect is normal and the remainder of the neurological exam is expected to be normal. In secondary forms additional neurological findings may be observed, depending on the disease entity. There are multiple reports of secondary CCD; potential etiologies include vascular or demylinating focal insults, head trauma, mass lesions, several neurodegenerative disorders such as Huntington's, Wilson's, and Parkinson's disease, neuroacanthocytosis, progressive supranuclear palsy, pantothenate kinase-associated neurodegeneration, and other metabolic, mitochondrial, and infectious disorders. Virtually all kinds of lesions, particularly those involving basal ganglia, thalamus, and rostral brainstem, may be associated with this syndrome. Tardive dystonia, produced by chronic neuroleptic administration, is a common cause of secondary CCD. The orofacial region is preferentially involved in tardive syndromes. Cases of tardive dystonia may resemble primary forms, but the presence of other hyperkinetic movements such as stereotypies, tics, akathisia, and respiratory dyskinesias are suggestive of prior neuroleptic exposure. CCD may also be induced by metoclopramide, levodopa, selective serotonin reuptake inhibitors, and more rarely by antihistaminics and stimulant drugs.

Pathophysiology

The underlying mechanisms of primary dystonia are still not well understood, but progress has been made based on different study results. The role of peripheral mechanisms

in focal dystonias has been studied in animal and human models. Schiatno and colleagues proposed a two factor model in which artificial dopamine depletion disinhibits the trigeminal blink circuits creating a permissive environment so that a prolonged external ophthalmic insult could precipitate BSP. Defazio, Martino, and colleagues found a significant association between disease of the anterior segment of the eye and BSP.

Pathology data have been scarce in cranial dystonia. Normal or nonspecific findings were present in nearly all specimens of idiopathic forms, except for increased contents of norepinephrine or copper and manganese in few autopsies. Recently, Defazio and colleagues reviewed the role of genetic factors in adult focal dystonia. They found an inheritance pattern compatible with an autosomal dominant trait and reduced penetrance in a few large families. More often the number of ascertained affected relatives was small, and inheritance did not appear to be Mendelian. Only DYT7 and DYT13 have been associated with cranial dystonia. The association of DYT1 and DRD5 polymorphisms with lifetime risk for focal dytonia is still controversial.

Novel neurophysiological and imaging studies in patients with cranial dystonia found: (1) impaired inhibitory control of motor mechanisms (at various levels of central nervous system) extending beyond affected muscles; (2) abnormally raised somatosensory spatial and temporal discrimination threshold; (3) increased excitability of brainstem interneurons mediating the blink reflex; (4) enlargement of putamen; (5) hyperechogenic lesions in the lenticular nucleus; (6) reduced postsynaptic dopamine D2 receptor binding in the striatum; (7) increased grey matter density in the primary sensory cortex and putamen; (8) overactivity of the primary sensorimotor cortex and the caudal part of supplementary motor area (SMA) in fMRI studies performed in the absence of a dystonia-inducing task; (9) overactivity of the primary sensorimotor cortex and SMA and deficient activation of primary motor and ventral premotor cortex within the mouth representation area; (10) abnormally reduced activity of the primary sensorimotor cortex after vibrotactile stimulation of affected and unaffected body regions.

Lots of the abnormalities described above for cranial dystonia are shared with other types of dystonia, suggesting common pathophysiologic mechanisms. Virtually in all cases of primary dystonia, there is dysfunction of the thalamus, frontal cortex, and basal ganglia. New data suggest that the cerebellum might also play an important role in this disorder. Physiological and imaging studies reflect an overactivation of sensory motor cortices that might be secondary to reduced inhibition. It seems that abnormalities in sensory processing accompany most types of dystonia, including cranial ones, and are concomitant with motor system modifications. These results have introduced the concept that patients with cranial dystonia also have impaired 'sensorimotor integration.' Animal models reinforce these observations and suggest that a disruption anywhere in the sensorimotor circuit can produce dystonia. The different localizations of the lesions producing secondary cranial dystonia also support the idea that any structure involved in these circuits can alter the activity patterns of all the others. Genetic susceptibility factors combined with certain environmental factors may enable these dysfunctional circuits to develop, leading to the expression of this movement disorder.

Differential Diagnosis

BSP should be differentiated from other conditions that can lead to eyelid closure, such as ptosis due to weakness of the levator palpebrae or Muller muscles. Ptosis may be seen in various disorders such as Myasthenia Gravis, third nerve lesions, or sympathetic denervation. Some patients are unable to open their eyes because of failure of the levator palpebrae to contract; this is called apraxia of eyelid opening. Vigorous frontalis contraction associated with delayed eye opening suggests this entity. EMG demonstrates an inactivity of the levator muscle despite the attempt to open the eyes. This entity is common in Parkinson's disease and other parkinsonian disorders, but can also be seen in isolation. Its treatment is difficult because it does not respond to BTX injections. Surgical approaches and special glasses may help.

Hemifacial spasm is typically characterized by unilateral, mostly clonic, facial muscle contractions. Twitching frequently begins in the OO and subsequently involves the lower face, including the platysma. Very rarely (3–5%) this condition can be bilateral, but usually there is a long latency before it affects the contralateral side. In contrast, BSP is typically bilateral. Commonly it is preceded by increased blinking and progresses to tonic, synchronous, OO contractions. Facial tics are multifocal, often suppressible, abrupt movements frequently preceded by a premonitory sensation. Hemimasticatory spasm consists of a unilateral contraction of muscles innervated by the motor trigeminal nerve resulting in painful jaw closing. Facial myokymia refers to continuous, undulating contractions of muscle fascicles.

Diagnostic Work-up and Tests

Diagnostic evaluation in adults presenting with dystonia should begin with a careful history. Although the majority of the cases of CCD are idiopathic in nature, physicians should be alert not to miss a reversible cause such as Wilson's disease. Review of all medications should query possible exposures to dopamine receptor blocking agents. If this is negative and the history suggests a gradual onset,

while there is no evidence of atypical features, such as rapid progression, abrupt onset, or onset at early age, imaging tests may not be required. All patients with possible heredodegenerative or secondary dystonia should undergo MRI imaging. The rest of the exams should be focused on the suspected etiologies. Genetic and functional imaging studies in CCD are not used routinely. Diagnosis remains largely based on careful clinical assessment. Referral to a movement disorder expert is recommended.

Management

Treatment of dystonia should be directed at the underlying cause. If no reversible etiologies are found, symptomatic treatment is the next step. Relief from pharmacotherapy is usually partial and short-lived. Anticholinergic agents (such as trihexyphenidyl), benzodiazepines (including clonazepam) and baclofen, are most commomly used. Recent communications reported improvement with clozapine and zolpidem. Levetiracetam showed inconsistent results. Tetrabenazine may benefit patients with tardive syndromes.

Periodic local injection of BTX is considered the therapy of choice for CCD. Side effects are local, and the duration of benefit is usually 2–6 months (average of 3 months). The pretarsal region of OO, particularly the Riolan muscle, seems to be the best place to inject BTX for BSP. If mild lower face spasms are associated with BSP, injections of BTX in periorbital muscles and slightly lower could be enough, otherwise, additional injections should be applied in the overflowing regions. Treating OMD with BTX is more challenging because of the risk of inducing dysphagia. In general, jaw-closing dystonia responds better than jaw-opening dystonia. Optimal doses reduce local side effects such as ptosis, diplopia, lower facial palsy, and dysphagia. For nonresponders to BTX in whom BSP is the main problem, myectomy is an option. Tinted lenses, in particular FL-41, may also help. Many patients benefit from combination therapies.

Sometimes this condition can be disabling and its medical treatment disappointing. Interest in the use of deep brain stimulation (DBS) for refractory forms of dystonia is thus increasing. Several recent case reports have suggested that this therapy may also be effective for CCD. Earlier communications in ICCD showed mild positive effects, but more recently Foote, Ostrem, Blomstedt, and Zauber showed more promising results, with improvements of around 70–75% in Burke-Fahn-Marsden (BFM) scores. It is important to note, that despite improvement in dystonia, some patients experienced mild and occasionally considerable worsening of motor function in previously nondystonic body regions. Other points of interest were that bilateral stimulation was necessary to achieve good results concerning axial symptoms; the latency of the benefit was shorter than in generalized dystonia; some patients developed stimulation induced dyskinesias, and speech and swallowing improvements were less significant.

Acknowledgments

I would like to thank Dr. T Arakaki and Dr. M Nogues for critical reading of the text and Dr. M Kauffman for his contribution on genetics in craniocervical dystonia.

Glossary

Complex I – Also called 'NADH-ubiquinone reductase,' an enzyme complex localized in the inner mitochondrial membrane. A part of the mitochondrial electron transport chain composed of complexes I–IV, which produce a proton 'gradient,' and transfer electrons to complex V (ATP synthase) producing ATP. In Parkinson's disease, Complex I activity is reduced.
***S*-Glutathionylation** – A term for the formation of 'mixed' disulfide bindings between reduced glutathione (GSH) and protein cysteine. *S*-Glutathionylation is catalyzed by reactive oxygen and nitrogen species (ROS–RNS), and this reversible posttranscriptional modification regulates various protein functions related to intracellular energy synthesis, signal transduction, and transcriptional activation.
Mitochondrial permeability transition (mPT) – The initial event in mitochondria-dependent intrinsic apoptosis. The permeability of the mitochondrial outer membrane is increased, leading to the release of proteins, such as apoptogenic molecules (cytochrome *c*, Smac/Diablo, HtrA2, etc.) from the intermembrane space into cytoplasm, accompanied by a decline of the membrane potential, $\Delta\Psi_m$, and Ca^{2+} influx. The mPT pore is a conductance pore spanning the inner and outer membrane, and consists of various membrane elements, the opening of which is regulated by the Bcl-2 protein family, cyclophilin D, and the mitochondrial redox state.
Ubiquitin–proteasome system – An intracellular macromolecular complex degrading misfolded, mutated, or oxidatively damaged proteins. Proteins are marked by covalent attachment of a polyubiquitin chain to lysine residues of protein and degraded in a large proteolytic complex, the 26S proteasome. The dysfunction of this system causes accumulation of inclusion bodies in neurodegenerative disease.

Characteristics of Melanin and Neuromelanin (NM) – Similarity and Dissimilarity

Melanin is a black pigment synthesized nonenzymatically or enzymatically from dopamine, L-DOPA and L-tyrosine. Melanin-containing cells, including catecholaminergic (CA) cells in the brain and melanocytes of the hair and skin, pigment cells in the inner ear, iris, and choroid of the eye, originate from the neural crest. However, the synthesis pathway, chemical structure, and function of melanin are quite different in the neural versus peripheral cells. In adult CA neurons of the substantia nigra (SN), locus coeruleus (LC), and additional brain stem loci, NM is produced in the cytoplasm mainly by autooxidation of dopamine. However, enzymatic synthesis of NM by tyrosine hydroxylase, peroxidase, prostaglandin H synthase, and macrophage migration inhibitory factor has also been proposed. In melanocytes, tyrosinase synthesizes L-DOPA and then DOPA-quinone from L-tyrosine in melanosomes. Tyrosinase mRNA and promotor activity are detected in the SN, but the tyrosinase-dependent synthesis does not occur in human brain, even though it does occur in the retinal pigmented epithelium.

NM isolated from the human SN is present in a large, aggregated structure, composed of three major components, melanin, protein, and lipid, with different electron density. Melanin polymer has the highest density and the protein component shows intermediate density, whereas the third lipid component is translucent. Melanin component is a mixture of melanin classes, black–brown 'eumelanin' and yellow–red 'pheomelanin' in a ratio of 4∼3 to 1. Eumelanin is composed of indole derivatives produced by autooxidation of dopamine, whereas pheomelanin contains benzothiazine molecules from incorporated cysteine or GSH with dopamine–quinone derived from dopamine by autooxidation. The protein components are covalently bound to NM, make up 5–15% of the isolated molecule, and include mostly lysosomal proteins, in addition to mitochondria-, cytosol-, and endoplasmic reticulum-associated protein, as detected by subcellular proteomics. The protein components are derived from a reaction of melanin polymer and proteins, or dopamine (quinone) bound to cysteinyl residue of peptide chains. The lipid components account for up to 20% of the mass and are identified to be 1% cholesterol and 14% polyisoprenoid dolichol. The lipid component is adsorbed to NM, not integrated in the structure. It was proposed that NM granules originate from lipofuscin, a lipid-containing pigment, but this hypothesis is now challenged by the fact that lipofuscin is localized in the lysosomes and produced also in glia and distributed ubiquitously in the brain.

The higher structure of the NM molecule is a multilayer three-dimensional structure similar to synthetic and naturally occurring melanin, as shown by X-ray diffraction studies. More recently, atomic force microscopy has revealed a spherical structure of NM granules with a diameter of ∼30 nm. The spherical structure of NM is composed of a pheomelanin core with a higher oxidation potential and a less redox-reactive eumelanin surface. However, this model cannot explain the occurrence of free sulfhydryl (SH) residues on the NM surface.

NM binds iron most strongly, and zinc, copper, manganese, chromium, cobalt, mercury, lead, and cadmium for 1.5% of the mass, and other 2–5% is due to sodium, potassium calcium and other inorganic compounds. Iron binds to NM at two distinct sites, the catechol groups forming metal centers in a lattice and the small-sized iron–oxygen frameworks in an insoluble NM matrix. In dopamine neurons of the SN, iron binds mainly to NM and accounts for 10–20% of the total iron, and the remainder is stored in microglia as bound to ferritin.

Physiological Function of NM

NM has been considered an inert waste product of dopamine autooxidation. However, recently, NM was found to function more actively in the brain. NM sequesters redox-active metals and toxic compounds, such as MPP^+, paraquat, and dopamine-(semi) quinone, preventing neuronal damage. NM also functions as an antioxidant and protects biomembranes from lipid peroxidation by scavenging ROS–RNS, such as hydroxyl radicals. Under physiological conditions, NM reduces ferric to ferrous iron and inactivates iron by accumulation as oxyhydroxide iron cluster. In addition, NM is ∼50% saturated with ferrous iron and can function as an iron-binding molecule to regulate iron homeostasis in NM-containing neurons.

NM in Aging and Parkinson's Disease

NM is first detected at 3–5 years of age as small, brown granules in the SN, and the size, number, and color of NM granules increase steadily until age 20. Thereafter, the NM color continues to darken until NM reaches its maximal levels around the sixth decades, when NM fills ∼47% of the cytoplasm. After then, the levels are relatively sustained in normal aging brains at 2.3–3.7 $mg\,g^{-1}$ of the SNpc in 50–90-year-old individuals. The number of NM-containing cells in normal SNpc is ∼95% of dopamine neurons, and decreases with age. With the onset of Parkinson's disease (PD), NM contents are reduced to 1.2–1.5 $mg\,g^{-1}$ of SNpc, suggesting that NM-containing dopamine neurons are more vulnerable than less-pigmented cells. The reduction of NM can be detected in vivo in the SN and LC of PD patients by use of 3 T MRI. Other studies indicate that NM contents decrease in the surviving neurons of SN, either because of reduced synthesis or increased degradation of NM.

NM isolated from PD patients contains highly cross-linked, proteasome-resistant lipoprotein with reduced NMR resonance. In PD (but not in control) brains, α-synuclein, a component of Lewy bodies, is cross-linked with dopamine *ortho*-quinone, aggregated and associated with NM lipid. In NM from PD SN, lipid composition also changes with reduced cholesterol, as shown by large volume of nonoxidized lipids in NM. In sporadic PD patients, insoluble extraneuronal NM granules released from dying neurons are detected and phagocytozed by microglia, the activation of which contributes to the inflammatory reaction observed in PD.

NM induces apoptosis in cellular models of dopamine neurons by activation of the mitochondrial apoptotic pathway, and it also deteriorates the ubiquitin–proteasome system. The cytotoxicity of NM depends on its protein component, since protease K treatment of NM completely reduces the cytotoxicity. NM liberates reduced glutathione (GSH) from mixed disulfide binding with SH residues of protein cysteine (*S*-glutathionylation) in mitochondria, and dissociates the higher structure of complex I. In PD, iron content increases by 30–35%, and GSH and antioxidant capacity reduce markedly, which induces oxidative stress. Increased ROS–RNS modify NM, activate SH residues in

NM protein, reduce the iron-binding capacity, and release sequestered iron in cytoplasm. These events finally induce the selective cell death of NM-containing neurons in the SNpc and the accumulation of Lewy bodies, the major pathological characteristics of PD.

Mercury

C G Goetz, Rush University Medical Center, Chicago, IL, USA

Glossary

Mercury – An element that in organic and inorganic forms can be toxic to the nervous system.
Neurasthenia – A neurological condition marked most prominently by fatigue and lassitude. Many other symptoms may accompany these feelings including headache and other, often vaguely localized pains.
Tremor – A to-and-fro movement around a joint.

Mercury Compounds and the Nervous System

Human mercurial intoxication results from exposure to the metal, to its inorganic salts, to organic mercury-containing compounds that are degraded to the inorganic metal. Another form of mercurialism, with different chemical and clinical manifestations, results from intoxication with alkyl compounds, particularly methyl and ethyl mercury.

Inorganic mercury poisoning occurs as an industrial disease during paper manufacture, in the preparation of chlorine, and as a result of exposure to certain other chemical processes. Historically, mercurialism was associated with the hat manufacturing industry, because mercuric nitrate was used for processing felt. Acute poisoning has also followed the use of mercuric chloride as a local antiseptic, the excessive use of calomel as a diuretic, and following merthiolate ear irrigations. Dental amalgams release small amounts of mercury, available data do not indicate that this exposure represents a significant clinical risk of neurological intoxication.

The chief atmospheric source of mercury pollution is through the burning of coal and other fossil fuels. Metallic

mercury volatilizes at room temperature and condenses on skin and respiratory membranes. It is absorbed from the skin and the gastrointestinal and respiratory tracts. Elemental, nonionized mercury is transported in the blood, bound to plasma proteins and hemoglobin. Inorganic mercury has remarkable affinity for the kidney; as a result, symptoms of intoxication relate predominately to that organ. Brain uptake varies, depending on chemical form, but under appropriate conditions, the brain incorporates mercury rapidly. Once incorporated into the nervous system, mercury is very slowly eliminated.

Toxic Mechanisms

Serum concentrations are unreliable indicators of inorganic mercury toxicity, but toxic symptoms are usually present when concentrations exceed $500\,\mathrm{mg\,l^{-1}}$. Blood concentrations below $100\,\mathrm{mg\,l^{-1}}$ are considered to be safe. Urinary excretion is similarly an untrustworthy measure of toxicity. Inorganic mercury produces its toxic effects by altering membranes, particularly through combination with sulfur-containing bonds. Mercury inhibits energy metabolism by interacting with several enzyme systems that contain sulfur and by effects on chemicals including lipoic acid, coenzyme A, and pantetheine. Unlike lead, however, mercury forms complexes with amino groups of proteins.

Clinical Syndromes of Intoxication

Acute poisoning does not cause movement disorders but is associated with neurological signs that include emotional irritability, weakness in the lower limbs, psychosis with delirium, hallucinations, and locomotor hyperactivity when weakness does not occur. The chronic form of mercurialism is more common and occurs in industries that use mercury in low doses. The onset of illness may be subtle with postural and kinetic tremor, accompanied by weakness of the limbs and often a progressive personality change. The presence of tremor has been frequently associated with exposure to mercury, but tremor intensity and frequency had not been definitely correlated with current urinary levels of mercury. Other involuntary movements are described but have been poorly characterized in the literature. Muscle cramps and convulsions may develop. Occasionally a clinical picture resembling Parkinson's disease with slowness, gait difficulty, rigidity, and tremor develops, but in a large case–control study, no association between chronic mercury exposure and Parkinson's disease was found. Personality changes that can accompany or precede the motor phenomena include fatigue, apathy, and insomnia, often termed historically as *mercurial neurasthenia*. These symptoms may be interrupted or accompanied by periods of excitability and irritability, as typified in Lewis Carroll's Mad Hatter. The hyperirritability can be associated with violent behaviors, with some descriptions of assaultive and homicidal aggression.

Ataxia and gait instability has also been described in the context of chronic mercury exposure, and this syndrome can be associated with additional signs that include vertigo, nystagmus, blurred vision, narrowing of the visual fields, optic neuritis and atrophy of the optic nerve, and peripheral neuropathy. In children, far more often than in adults, chronic inorganic mercurialism is associated with acrodynia, but this syndrome involves generalized irritability and dysautonomia and has no associated movement disorder. Organic mercury readily enters the brain from the blood, and brain turnover is slow. In chronic exposure, ~10% of the body burden localizes in the brain. With acute intoxication, less than 3% is degraded into inorganic brain mercury, but this rate may change with chronic exposure. Specifically, inorganic mercury levels may account for 82–100% of brain mercury after organic mercury exposure if the autopsy is done several years after exposure. Once biotransformation to inorganic mercury occurs, excretion rates are extremely low since inorganic mercury cannot leave the brain easily. Anatomic changes in the brain involve especially the primary visual cortex and cerebellum followed by the putamen and frontal/parietal lobes. Peripheral nerves are also damaged. Because organic mercury is converted to inorganic metal, the intoxication syndrome seen after organic mercury exposure largely mimics the signs seen with inorganic exposure.

Alkyl mercury poisoning has followed the ingestion of contaminated sea food or exposure to alkyl mercury used in seed grain as an antifungal additive. Massive intoxication occurred in individuals living in the vicinity of Minamata Bay, Japan, as a result of ingestion of fish and shellfish containing methyl mercury. After effluent containing inorganic mercury from an adjacent chemical plant was deposited in sea water, mercury was methylated by microorganisms in the sediment, and methyl mercury so formed was incorporated into the protein of fish and shellfish. Alkyl mercury remains bound to protein for long periods as the half-life is several years. The intoxication occurred after humans consumed contaminated sea food. In 1972, another catastrophic epidemic of methyl mercury poisoning occurred in Iraq. Over 6000 patients were hospitalized for treatment, and 459 known fatalities occurred, principally as a result of eating homemade bread prepared from seed treated with a methyl mercury fungicide. At the cellular level, alkyl mercury compounds share many of the biochemical effects of their inorganic counterparts and form complexes with sulfhydryl radicals. The blood–brain barrier provides little impediment to the crossing of alkyl mercurials.

The primary neurological syndrome of this form of intoxication involves neuropathy, visual field defects, and blindness, many patients demonstrate evidence of cerebellar involvement, with unsteady gait, slurred speech, and poor coordination. Less frequent movement disorders include resting or postural tremor, chorea, athetosis, myoclonus, and rigidity. Prominent behavioral problems include labile affect, mental deterioration, comatose states, and even akinetic mutism.

Diagnosis

It is difficult to diagnose mercury toxicity from laboratory data because of variability of blood and urine measurements. While measurements in blood and hair are less variable than those in urine, these do not accurately reflect the degree of mercury toxicity. In urine, levels higher than $35\ \mu g\ g^{-1}$ creatinine are considered elevated. Hair samples must be collected according to specific protocols. For example, head samples must be taken close to the scalp and then washed to remove contaminants such as hair dyes or hair treatments. The advantage of hair samples is that they provide exposure information for the past year. Pubic hair has the advantage of being more likely free of mercury-containing surface contaminants. Subclinical slowing of finger tap speed has been detected in subjects with regular high fish consumption and levels of urinary organic and inorganic mercury that were higher than controls, but still far lower than the levels cited above.

Treatment

For treatment, mercury-binding compounds augment excretion of the metal in intoxicated patients regardless of the type of mercury exposure. The agents employed include D-penicillamine, *n*-acetyl-DL-penicillamine, and thiol resins. Dimer-caprol (BAL) is no longer utilized, because it increased the cerebral mercury concentrations in animals experimentally receiving the methyl form. Administration of chelating agents results in only irregular removal of mercury from the body. When chelating agents are administered, mercury concentrations of blood increase for 1–3 days, presumably as a result of rapid mobilization from the tissues and a slower rate of urinary and fecal excretion. After this period, blood concentrations decline. Thiol resins are not absorbed from the gastrointestinal tract, so they can be administered orally to bind mercury in bile and other fluids within the intestine. Fecal excretion is then enhanced by preventing reabsorption of methyl mercury so that redistribution of mercury in the body will not occur. Because thiol resins cannot reenter the body, they have no potentially adverse systemic effects. Spironolactone has also been employed in the experimental treatment of inorganic mercury poisoning. The protective effect appears to be related to increasing stool excretion through a yet unknown mechanism.

Prognosis

Most patients with severe mercury poisoning die within a few weeks of symptom onset, and those who survive have major neurological disability. In those with mild or moderate neurological symptoms, especially children and young adults, improvement may occur within the first 6 months. Examples have also been reported of ataxic, bedridden individuals who regained the ability to walk, and some children who were totally blind regained vision.

Metachromatic Leukodystrophy

A L Fluharty, University of California at Los Angeles, Los Angeles, CA, USA

Glossary

Auditory and visual evoked potentials – Evoked potential measurements record the time and strength of nerve responses to auditory (BAER) or visual (VER) stimulation.
Autosomal recessive – A genetic trait on one of the 22 nonsex chromosomes (autosomes) which requires the trait be present on both chromosome pairs to be expressed.
CSF protein – Protein content of the cerebral spinal fluid which is often elevated in the later stages of MLD.
EEG – An electroencephalogram (EEG) records brain electrical activity via electrodes on the scalp.
Heterozygote – An individual with a genetic trait on only one of a chromosome pair – a carrier.
Mucopolysaccharidosis – A genetic disorder in which the breakdown of one or more of a group of acidic carbohydrate polymers, the mucopolysaccharides or glycosaminoglycans, is impaired.
Nerve conduction velocity – The speed at which a nerve impulse is conducted along a peripheral nerve in the arm or leg.
Oligodendrocytes – Brain cells which provide the myelin sheath around axons in the central nervous system.
Periventricular – A brain imaging finding occurring next to or around the ventricles, usually on both sides of the brain.
Polyneuropathy – A generalized disorder of the peripheral nerves.
Schwann cells – Cells in the peripheral nervous system which provide the myelin sheath around axons.

Definition and History

Metachromatic leukodystrophy (MLD) is a group of genetic disorders resulting from defects in the catabolism of sulfated glycolipids commonly referred to as sulfatides or cerebroside sulfates. This leads to losses of myelin and results in motor, cognitive, and behavioral problems. Both central and peripheral nervous systems are impacted. Sulfatides occur throughout the body but are found in abundance in nervous tissue, kidneys, and testes. MLD is most often due to a profound deficiency of the lysosomal enzyme arylsulfatase A. The onset of symptoms can occur at any age beyond 1–2 years, but is preceded by a period of apparently normal development. MLD is generally divided into late-infantile, juvenile, and adult subtypes, based on the age of onset, which is an arbitrary classification. Sulfatide accumulation and MLD-like pathology also occur in two genetically distinct conditions: Saposin B deficiency and multiple sulfatase deficiency.

Metachromatic staining in the nervous system of individuals with neurodegenerative disease was noted as early as 1910, but a reliable staining protocol was only reported in 1955. Sulfatides, being the component responsible for the metachromasia, were not recognized until 1958. The gene for human arylsulfatase A was sequenced in1990, and a number of mutations and polymorphisms were recognized soon thereafter. The arylsulfatase A crystal structure was reported in 1998 and a unique active site structure revealed. A mouse model for arylsulfatase A deficiency was developed in 2000 and subsequently subjected to an extensive series of studies.

Pathogenesis/Pathophysiology

In the nervous system, sulfatides are most prevalent in white matter where they constitute 4–5% of the myelin lipids. In MLD, myelin appears to be formed normally by the oligodendrocytes and Schwann cells, but myelin turnover and repair are impaired resulting in the accumulation of excess sulfatides. This eventually leads to the disintegration of myelin and cell death. The cell debris is taken up by macrophages where the sulfatide accumulates. Neurons and axons tend to be relatively unaffected, and attempts at remyelination are evidenced by thin and poorly compacted residual myelin.

The cerebellum can be much more severely affected with a substantial loss of Purkinje cells and axonal tracts. Sulfatides are also increased in a variety of extraneural tissues and excreted in the urine. Liver and kidney sulfatides are substantially increased without apparent clinical consequences. The accumulation of sulfatides may occur in the gallbladder and may interfere with its function.

Epidemiology/Risk Factors

MLD is an autosomal recessive genetic disorder with a one in four chance of an affected child if both the parents are carriers (heterozygotes). The carrier frequency for the arylsulfatase A deficiency form of MLD ranges somewhere between one in 100 and one in 200 in the most studied European and European-derived populations. A number of inbred populations such as the Habbanite Jews in Israel have been described, in which the carrier frequency (1 in 6) and the incidence of MLD (>1%) are much higher. Saposin B and multiple sulfatase deficiency forms of MLD are rare, and reasonable estimates of the carrier frequencies have not been made. MLD occurs throughout the world, but reliable estimates of incidence in African and Asian populations are lacking.

Clinical Features and Diagnostic Criteria

MLD is characterized by a loss of motor and cognitive functions after a period of apparently normal development. The clinical subtypes are differentiated by the age of onset.

Late infantile: 1–2 years
Juvenile: 4–12 years
Adult: after sexual maturity

In late-infantile MLD, acquired skills such as walking and speech begin to deteriorate with a fairly rapid progression over a period of several months. There may be alternating periods of stabilization and decline. The patient eventually becomes bedridden, unable to speak or feed oneself. There may be seizures, and hypotonia eventually evolving to painful contractures is common. The child remains able to respond to the parents for a period, but eventually becomes nonresponsive. Swallowing becomes difficult, and tube feeding is usually recommended. With current levels of care, the child may survive for many years, but a secondary infection such as pneumonia eventually results in death.

Juvenile MLD (which is sometimes divided into early and late subforms) is usually detected during early schooling by a decrease in academic performance, difficulty in following directions, and behavioral abnormalities. This is typically followed by gait difficulties and slurred speech. Incontinence, abnormal postures, and loss of the ability to walk follow. The final stages of the disease are similar to the late-infantile form with survival for many years possible.

The initial indications of adult MLD occur after sexual maturity, but can range from 14 to >60. Initial symptoms can be clumsiness and loss of ambulation with the retention of intellectual processes or may be a change in personality, emotional labiality, and deteriorating job or school performance. Initial diagnoses such as MS on the one hand and psychiatric conditions such as schizophrenia on the other are common. Alcohol and drug abuse are frequent early signs. Eventually, there is a slow progressive loss of both motor and cognitive functions, which may extend over a period of 1–3 decades.

Multiple sulfatase deficiency has a clinical course similar to juvenile MLD, but may initially be diagnosed as a mucopolysaccharidosis due to mucopolysaccharide excretion and skeletal abnormalities.

The cases of saposinB deficiency recognized are too few to define a typical course, but the onset has ranged from infantile to adult, a juvenile MLD-like clinical course being most common.

Differential Diagnosis

In MLD, there is a period of normal development before symptoms emerge. Stumbling and loss of walking and/or speech regression in a 1–2 year old are typical of the late-infantile form. Gait problems and/or behavioral difficulties and emotional liability are the initial signs in juvenile or adult cases. It is difficult to distinguish MLD from a large spectrum of neurological and neuromotor disorders of genetic, environmental, and infectious etiology.

Diagnostic Work-Up/Tests

After a period of diagnostic uncertainty, the worsening of symptoms typically leads to a brain scan (CT or MRI) and indications of a leukodystrophy. In late-infantile cases, posterior periventricular white matter changes and severe bilateral polyneuropathy are noted. In later onset cases, anterior white mater changes are more common and polyneuropathy is often milder or completely absent. A series of enzymatic tests on white blood cells would reveal a profound deficiency of arylsulfatase A, leading to a preliminary diagnosis of MLD. Care must be exercised as there is a relatively common arylsulfatase A gene polymorphism with a substantially reduced enzyme expression, referred to as pseudodeficiency (PD). PD provides 5–10% of normal enzyme, enough to avoid clinical MLD even when present with a MLD-related gene. It is therefore necessary to show sulfatide storage or excretion to substantiate the diagnosis. In the past, this was a finding of sulfatide metachromasia in a brain or a nerve biopsy, and more recently, of sulfatide excretion into urine.

A number of additional tests are often included in the MLD work-up. CSF protein levels rise as the disease progresses in late-infantile and some juvenile cases reaching high levels in the later stages of the disease. Nerve conduction velocity is often decreased, and auditory- and visual-evoked potentials changes are commonly found. EEG alterations occur, sometimes before clinical symptoms are noted, and there may be seizures.

Management

Management mostly consists in the treatment of particular manifestations: Physical therapy is important for maintaining neuromuscular function and mobility. Contractures are treated with muscle relaxants. An enriched and challenging environment, memory training, and facilitated communication help sustain intellectual functioning. Seizures are treated using antiepileptic drugs. Genetic councilors and family support groups can be extremely valuable in helping parents and/or caregivers to anticipate when to employ walking aids, wheelchairs, feeding tubes, and other management needs.

Hematopoietic stem cell and bone marrow transplantation are the only therapies presently available for limiting the progression of central nervous system manifestations. This involves substantial risk and shows effects only after a period of continued regression. The best outcomes have been when the transplant is performed with later onset patients and before a substantial loss of function has occurred. Transplants do not correct peripheral nervous system manifestations, and long-term effects remain uncertain.

Prognosis

There is presently no cure for MLD, which eventually leads to immobility, dementia, and a loss of all but the most basic contact with the surroundings. Survival is correlated with the age of onset, but individual clinical courses can be variable, particularly with later onset cases. Death is usually due to pneumonia or some other infectious disease. The quality of care can substantially increase survival and enhance the quality of life.

Micrographia

J C Cabassa and W J Weiner, University of Maryland Medical Center, Baltimore, MD, USA

Glossary

Basal ganglia – A collection of nuclei in the deep white matter of the brain, which is involved in motor control, cognition, emotions, and learning.
Bradykinesia – Slowness in movement, with the loss of voluntary and spontaneous movement.
Levodopa – Dopamine precursor produced by the brain, which is used as the best treatment for bradykinesia and rigidity in Parkinson diseases.
Micrographia – An acquired reduction in handwriting size, resulting in smaller amplitude strokes from slow and hypokinetic hand movements.
Parkinson's diseases – Degenerative disorders caused by loss of dopaminergic neurons from the substantia nigra parts compacta, commonly causing muscle rigidity, bradykinesia, resting tremor, and postural instability.

Definition and History

Micrographia is an acquired reduction in handwriting size, caused by hypokinetic hand movements resulting in smaller than normal sized strokes. It is more commonly associated with neurodegenerative diseases of the basal ganglia (BG), such as Parkinson's diseases (PD), but has also been described in focal BG lesions. This common clinical sign of parkinsonism can be the earliest manifestation of the syndrome. James Parkinson might have been aware of this feature in the first description of PD, when explaining 'the hand failing to answer with exactness to the dictates of the will' in *An Essay on the Shaking Palsy* (1817). Arnold Pick provided the first report of micrographia in 1903, in a patient with a syphilitic infarct involving the left thalamus and the genu of the internal capsule, and Froment was the first to associate it with PD.

Micrographia is usually defined by visual inspection of the patient's handwriting, and by comparing it to previous samples of their handwriting. Most often in PD micrographia worsens with continued writing. Recently, there has been an effort to further classify micrographia into two distinct types: constant micrographia (CM) and progressive micrographia (PM); and there also has been an effort to standardize an objective way to measure this clinical sign. CM was defined by the average size of the letter or figure written or copied by the patient, being two standard deviations below controls' size. PM was defined by the slope of reduction in size of letters as a function of the serial positioning of the letters/figures below two standard deviations of the mean. To better define and quantify micrographia, copying tasks instead of free writing should be used. There are currently no standard guidelines.

Pathogenesis/Pathophysiology

Micrographia is considered a component of bradykinesia in PD, and is thought to result from decreased pallidothalamic signals, secondary to dopamine depletion in the substantia nigra pars compacta. In this model, bradykinesia results from BG output failure. Cortical mechanisms cannot be reinforced in preparation and execution of movement, which then suffers and results in slow micrographic handwriting. This results in insufficient recruitment of muscle force during initiation of movement, leading to patients undershooting their targets and having to approach it using several smaller steps. In PD patients with micrographia, bradykinesia has been shown to result in decreased upstroke duration, thus in slower handwriting. However, upstroke amplitude (letter size) is unaffected with levodopa treatment, while stroke duration decreased, suggesting that other possible nondopaminergic components of micrographia and bradykinesia may exist.

It is thought that the overall deficit of reduced motor output in PD patients affects the modulation of upstroke amplitude and results in smaller handwriting. This deficit also results from focal lesions of the BG, and from lesions of the subcortical (thalamic and internal capsule) connections to the frontal lobe, especially to the supplementary motor cortex (which is involved in force modulation). Theoretically, in the absence of other lesions affecting the pyramidal system, patients with micrographia could have the force to increase handwriting amplitude, but they are less efficient at modulating force parameters given a compromised frontal–subcortical circuit. This resultant cortical abnormality may involve the underactivation of the supplementary motor cortex, which can specifically affect the 'open loop' circuit that is normally responsible for automatic motor programs, such as handwriting.

Despite this proposed primary cortical deficit in micrographia, frontal lobe function may also play a role in its improvement. This has been demonstrated in studies in which micrographia in PD patients significantly improved

with visual targets or constant auditory reminders. This is also described in bradykinesia, in which deficits can be ameliorated with external cues given to guide movement. Given that the underscaling of movement in automatic motor patterns improves with attention, the proposed mechanism involves the activation of the lateral premotor cortex (part of the 'closed loop' circuit) which can compensate, if attention is paid at preparing for movement or learning a motor task. The emergence of micrographia, despite compensatory mechanisms with improved attention, might suggest that in conditions such as PD, more extensive cortical dysfunction or other contributing cognitive processes maybe occurring.

Another possible mechanism for micrographia in PD suggests more extensive cortical dysfunction. In this model, micrographic handwriting is due to reduced motor output coupled with distortions in visual feedback. This was demonstrated in PD patients who initially produced smaller strokes (from reduced motor output), but then failed to recognize their micrographia secondary to reduced kinaesthesia, and subsequent strokes were produced to match the size of previously undersized strokes. Micrographia resulting from a sensory-motor deficit was also shown in a recent study in which simple eye closure eliminating distorted visual feedback significantly improved micrographia in PD patient during their 'off' periods.

Another theoretical mechanism for micrographia in PD could be that the dopamine depleted globus pallidus neurons result in a 'noisy' BG output, which reduces the signal-to-noise ratio in motor systems. The patient is more sensitive to any additional motor processing, and any additional simultaneous movement or additional motor load results in poorer handwriting. The deficit itself may be a compensation for this 'noisy' BG output, in which patients reduce their stroke size when other processing demands increase. Deep brain stimulation efficacy in PD may work in part by reducing or eliminating 'noisy' BG output.

Epidemiology/Risk Factors

The prevalence of micrographia ranges from severe micrographia in 15% to some micrographia in 75–90% of all PD patients. The self-reported prevalence of micrographia has been 6–14% in the elderly population, and 65–90% in PD cases.

Clinical Features and Diagnostic Criteria

Handwriting is an important skill in daily life. Any disease state that affects it will have a significant impact on the patient. When patients present with an initial complaint of micrographia, studies have shown that this symptom significantly increases the likelihood of having PD (with positive likelihood ratios of 3–6). The diagnosis of PD has to be considered, and other signs of Parkinsonism need to be searched for. Secondary causes of micrographia need to be considered.

Differential Diagnosis

Neurodegenerative

Parkinson's diseases (PD)
Secondary parkinsonism
Parkinson plus syndromes
Huntington's disease

Vascular

Ischemic (BG, left thalamus and genu of internal capsule)
Lenticular hematoma.

Toxic Exposure

Manganese poisoning.

Malignancy

BG tumors.

Immunologic

Multiple Sclerosis
Systemic lupus erythematosus (SLE)

Diagnostic Work-up/Tests

The most common etiology for micrographia is Parkinsonism. A complete history and neurological exam is essential to evaluate micrographia. Focus should be on determining if other features of parkinsonism including resting tremor, decreased hand and finger dexterity, cogwheel rigidity in the affected limb, and/or decreased arm swing when walking on the affected side exist. If a diagnosis of parkinsonism is made, then the diagnostic workup focuses on the syndrome. If no other associated signs are found in the presence of micrographia, then imaging of the brain with a computerized tomography (CT) or magnetic resonance imaging (MRI) is indicated.

Management

There is no specific treatment for micrographia. The same modalities used to treat bradykinesia in PD are utilized.

In one small study, handwriting was analyzed in PD patients across one levodopa treatment cycle. It showed that upstroke duration decreased when upstroke size was unchanged, 1 h after levodopa administration.

This suggested that at least one component of micrographia results from a nondopaminergic system. This is in keeping with the many reported cases of micrographia from focal subcortical lesions. Other treatments have improved stroke size including external application of weak electromagnetic fields, with resultant reversal of micrographia. Deep brain stimulation with high-frequency stimulation of the subthalamic nucleus made handwriting movements faster and smoother, perhaps indicating a partial restoration of 'open loop' automatic performance. Mean stroke length also increased demonstrating a stimulation-related reduction in micrographia in PD.

Prognosis

The prognosis in micrographia depends on the etiology. If part of parkinsonism, it may be partially treatable with drugs used to treat PD. However, there has been no clear correlation between motor scores on the Unified Parkinson's Disease Rating Scale (UPDRS) and micrographia. Therefore, prognosis is hard to predict with treatment. In other syndromes, micrographia can be the result of focal lesions of the BG, thalamus, internal capsule, and parietal lobe. If irreversible, as in the case of most ischemic or demyelinating lesions, the prognosis in terms of improvement may depend on the extent of the lesion and its potential to improve with physical/occupational therapy.

Milkmaid's Grip

A L Barba, Albany Medical College, Albany, NY, USA
D S Higgins, Samuel S Stratton VA Medical Center, Albany, NY, USA

Glossary

Asterixis – Recurrent arrhythmic movement of the limbs typically occurring as a result liver failure.
Chorea – Jerky spasmodic movements of the limbs, trunk, and facial muscles common to diverse diseases of the central nervous system that involve the basal ganglia.
Encephalopathy – A disease of the brain.
Extrapyramidal – Situated outside of the pyramidal tracts, especially pathways involved in the control of motor function.

Motor impersistence – Inability to sustain a voluntary motor act despite the ability to perform the act briefly.
Myasthenia gravis – An autoimmune disease characterized by progressive weakness and fatigability of voluntary muscles caused by antibodies recognizing the acetylcholine receptor in the neuromuscular junction.
Myoclonus – Irregular, rapid, and typically multifocal involuntary muscle contraction.

Definition and History

Although the origin of the term 'milkmaid's grip' is difficult to define, this phenomenon is a characteristic feature of choreiform movement disorders such as Huntington's disease. Describing continuous and capricious increases and decreases in the pressure of handgrip; the terms 'milkmaid's grasp' or 'milking sign' have also been applied.

Pathogenesis/Pathophysiology

Striatal projections comprising the indirect pathway are believed to suppress undesired movements. Impairment/degeneration of this projection reveals movements that would ordinarily be inhibited. Hyperkinetic involuntary movements in Huntington's disease are thought to reflect the selective loss of medium spiny neurons of the indirect pathway. Functional alteration likely accounts for the occurrence of milkmaid's grip in other disorders. In addition, deficits in sensorimotor control during fine hand movements have been described in Huntington's disease and may contribute to the waxing and waning strength of grip.

Epidemiology/Risk Factors

Factors influencing the expression of milkmaid's grip depend upon the underlying diagnosis. Primarily genetic factors modulate risk in the autosomal dominant disorder Huntington' disease. Antecedent streptococcal infection and family history of chorea augment the risk of Sydenham's chorea and milkmaid's grip.

Clinical Features and Diagnostic Criteria

Considered a manifestation of motor impersistence, milkmaid's grip is often accompanied by impairment in sustained protrusion of the tongue and closure of the eyelids. While a precise description of milkmaid's grip was not included in George Huntington's monograph, 'On Chorea' (1872) he did recognize dyskinesia of the hands characterizing this as '. . .rolling – first the palms upward, and then the backs.' It is not only with the diagnosis of Huntington's disease that 'milkmaid's grip' has been reported. In post-infectious chorea, also identified as Sydenham's chorea or St. Vitus dance, an antecedent streptococcal illness has yielded milkmaid's grip. A precise description of this phenomenon is derived from the clinical notes of W.B. Cheadle at the Great Ormond Street Hospital. Describing a boy of 7 years and 9 months with endocarditis and chorea, Cheadle noted; '. . .when told to grasp the hand he is unable to give more than a spasmodic grasp and then looses it [while] the hand wanders round the object making ineffective attempts to hold it as constantly supinating and pronating the forearm' (1890). Milkmaid's grip has also been identified as a manifestation of the extrapyramidal syndrome that can complicate treatment with dopamine antagonists (i.e., tardive dyskinesia).

Differential Diagnosis

While commonly associated with choreiform disorders, milkmaids grip has been described in neuromuscular disorders. For example, handgrip fluctuating between weak and normal strength in myasthenia gravis has been characterized as milkmaid's grip. In the context of hepatic encephalopathy rhythmic squeezing when asked to grip the fingers, suggestive of milkmaid's grip, has been reported and considered a manifestation of asterixis (negative myoclonus) that complicates liver dysfunction.

Diagnostic Work-up/Tests

Elucidation of the etiology of milkmaid's grip is accomplished through determination of CAG repeat number ($\geq$37 CAG repeats) in the huntingtin gene, examination of immune measures to suggest prior streptococcal infection (i.e., antistreptolysin O titers) and magnetic resonance imaging of the brain to define basal ganglia anatomy. Laboratory assessment of hepatic function (asterixis) and determination of acetylcholine receptor antibodies (myasthenia gravis) will exclude uncommon causes.

Management

When symptoms are grave enough to require treatment, medications that curb choreiform movements can modulate the severity of milkmaid's grip. The most commonly utilized medications are dopamine antagonists. Most often an atypical neuroleptic will be prescribed due to the diminished risk of emergent tardive involuntary movements. Antagonism of the disinhibited, glutamatergic projection

from the subthalamic nucleus to the medial globus palidus with amantadine has also proven beneficial.

Prognosis

The natural history of milkmaid's grip is determined by the context in which it occurs. In Huntington's disease, improvement is unlikely given the degenerative nature of this diagnosis. In contrast, Sydenham's chorea is a self-limited disorder for which improvement is the rule. For toxic and metabolic etiologies of milkmaid's grip correction or improvement of the inciting imbalance will often result in restoration or resolution.

Mitochondrial Dysfunction

A H Schapira, Institute of Neurology, University College London, London, UK
S Przedborski, Columbia University, New York, NY, USA

Glossary

Complex I – One of the polysubunit complexes of the mitochondrial electron transport chain.
DJ-1 – Protein of uncertain function whose gene mutations are found in rare forms of familial PD.
Haplotypes – Combination of alleles at multiple loci that are transmitted together on the same chromosome.
Lewy bodies – Intraneuronal proteinaceous inclusions found in affected brain regions, mainly in PD.
MPTP – Potent parkinsonian neurotoxin.
mtDNA – Mitochondrial DNA.
Parkin – E3 ubiquitin ligase whose gene mutations are found in rare forms of familial PD.
PINK1 – Mitochondrial kinase whose gene mutations are found in rare forms of familial PD.
Ubiquitin – Highly conserved regulatory protein of 76 amino acids that participates in the degradation process mediated by the proteasome complex.

Introduction

The second most common neurodegenerative disorder of the aging brain after the dementia of Alzheimer is Parkinson's disease (PD). This disease is progressive with a mean age at onset of 61, and exhibits an incidence that increases markedly with age. The cause of almost all occurrences of PD remains unknown. PD arises essentially as a sporadic condition, that is, in absence of any apparent genetic linkage, but occasionally the disease is inherited due to mutations in a variety of genes, including DJ-1 and PINK1. In both sporadic and familial (i.e., genetically inherited) PD, the primary hallmark is the degeneration of the nigrostriatal dopaminergic pathway, which, in depleting the brain of dopamine, leads to the emergence of abnormal motor manifestations such as resting tremor, rigidity, slowness of voluntary movement, and postural instability. At the onset of these manifestations, striatal dopamine has been depleted ~80%, and ~60% of substantia nigra dopaminergic neurons have been lost. However, the neuropathology of PD is far from limited to the nigrostriatal pathway, and histological changes can be found in many other dopaminergic and even nondopaminergic cell groups, including locus coeruleus, raphe nuclei, nucleus basalis of Meynert, and dorsal motor nucleus of the vagal nerve. Because a host of distinct neurological conditions share PD clinical features, a definite diagnosis of PD can only be achieved at autopsy and is customarily based not only on the loss of nigrostriatal dopaminergic neurons, but also on the identification of intraneuronal inclusions called Lewy bodies (LBs). These inclusions are spherical eosinophilic cytoplasmic aggregates composed of a variety of proteins, such as α-synuclein, parkin, ubiquitin, and neurofilaments, and

they can be found in every affected brain region. Whether identification of LBs should still be considered as necessary for the diagnosis of PD is controversial, since cases of inherited PD linked to parkin mutations typically lack LBs and are still regarded as cases of PD.

Why a Mitochondrial Defect Was Sought in PD

As mentioned above, the cause of sporadic PD is currently unknown. Over the years, a variety of pathogenic scenarios have been proposed to explain why and how neurodegeneration occurs in PD. The idea of mitochondrial dysfunction as a pathogenic mechanism in PD seems to have emanated from the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) story. Indeed, in the early 1980s, some drug users developed a rapidly progressive parkinsonian syndrome almost indistinguishable from PD. In these individuals, even the beneficial response and development of long-term motor complications from the administration of L-DOPA were virtually identical to those seen in PD patients. This cluster of patients with a young-onset PD-like syndrome was traced to intravenous use of a street preparation of 1-methyl-4-phenyl-4-propionpiperidine (MPPP), an analogue of the narcotic meperidine (Demerol). MPTP is the responsible neurotoxic contaminant, inadvertently produced during the illicit synthesis of MPPP in a basement laboratory. Subsequently, it was established that 1-methyl-4-phenylpyridinium (MPP^+), the active neurotoxic metabolite of MPTP, accumulates in the mitochondrial matrix where it inhibits oxidative phosphorylation. The use of several MPP^+ analogs and cationic inhibitors has demonstrated that MPP^+ binds at two distinct sites within the mitochondrial complex I of the electron transport chain comprised between N2 and ubiquinone. It is believed that, in response to MPP^+ binding to complex I, the flow of electrons along the respiratory chain is hampered, leading to an energy crisis, oxidative stress, and ultimately to cell death.

In light of the phenotypic similarity between PD and MPTP-induced parkinsonism in humans and the fact that the MPP^+ is a poison of the oxidative phosphorylation, many investigators have been prompted to search for mitochondrial respiratory defects in PD patients. Despite the fact that parkinsonism is hardly associated with genuine mitochondrial diseases, less than a decade later, as discussed in the next section, this idea has gained major enthusiasm among PD researchers.

Mitochondrial Dysfunction in PD

The direct relationship between mitochondrial dysfunction and PD came from the postmortem description of complex I deficiency in the substantia nigra of patients with PD. Subsequently, the deficiency was also reported in several tissues of PD patients including skeletal muscles and platelets. Notably, complex I deficiency in the substantia nigra and platelets has been consistently detected while the mitochondrial abnormality in skeletal muscle has been more difficult to identify reliably. Also worth noting is the fact that the substantia nigra samples used in the aforementioned studies were obtained from autopsies, which typically originate from very advanced cases of PD. We can, thus, safely assume that, in these PD samples, most of the neurons of interest, such as the dopaminergic neurons, are gone, and the number of glial cells, in contrast, has grown due to neurodegeneration-associated gliosis. Consequently, it is legitimate to posit that it is unlikely that the reported complex I deficit could have emanated from dopaminergic neurons only, since the vast majority of the cells contained in the studied samples are probably nondopaminergic neurons.

Mitochondrial complex I deficiency is not present in all patients with PD, either in the brain, platelets, or other tissues. The severity of the defect is about a 35% reduction in activity when the patient group is compared with control populations. At this point, in absence of a molecular marker, we cannot exclude that what we call sporadic PD is in fact not a disease per se (i.e., a single entity) but rather a syndrome made of heterogeneous pathological conditions sharing the same clinical phenotype. This view may have several significant implications. First, the aforementioned mitochondrial studies report on an etiologically heterogeneous population (e.g., patients with PD who had severe complex I deficiency and patients with PD who had healthy complex I activity). Second, there may be patients with a substantial complex I defect in whom the defect is directly related to their etiology, whereas other pathogenetic factors are important in other patients with PD. The small and unselected sample groups might explain why, for example, the mitochondrial abnormality has not been seen consistently in skeletal muscle. The complex I deficiency in the substantia nigra and platelets implies that this is a systemic defect in a proportion of cases (25% on the basis of platelet activities) and that this defect might be due to genetic or environmental (endogenous or exogenous) causes.

As for how the complex I defect may provoke neurodegeneration, it is important to mention that such a defect appears to be associated with a recruitment of the mitochondrial-dependent apoptotic pathway in intact cells. However, in isolated brain mitochondria, complex I dysfunction, caused by either pharmacological or genetic means, fails to directly activate this cell death pathway and to kill cells. Instead, defects of complex I lower the threshold for activation of mitochondrial-dependent apoptosis by Bax, thereby, rendering compromised neurons more prone to degeneration.

Mitochondrial DNA in Patients with PD

Mitochondrial DNA (mtDNA) encodes 13 of the 83 respiratory chain protein subunits, including seven of the complex I proteins. Thus, mutations in mtDNA were an obvious early target for analysis. The number of mtDNA deletions in individual neurons in the substantia nigra is substantially increased in PD patients older than 65 years. The deletions within a neuron are clonal and are associated with decreased cytochrome oxidase activity, as seen with histochemistry. While a high proportion of mtDNA deletions can be seen in controls, which increased with age, more mtDNA deletions are found in patients with parkinsonism and dementia. These results support the proposal that the human substantia nigra is a site of free-radical-mediated damage to mtDNA, and that this damage is enhanced in parkinsonism.

Sequencing of mtDNA from patients with PD has generally been done in unselected groups, with and without a mitochondrial deficiency. Although the results of some reports have suggested increased frequency of specific mtDNA polymorphisms in patients with PD, others have not. For instance, certain mtDNA haplotypes influence PD expression, and haplotype J has been associated with both a decreased and an increased risk of developing PD. Some evidence suggests that mtDNA haplotypes might influence cytosolic pH and mitochondrial calcium regulation which could influence neuronal function and integrity over time.

Genetic transplantation has been used to investigate the possibility that mtDNA from patients with PD is the origin of the complex I defect. Here, platelets from unselected patients with PD were fused and grown in mixed cultures or patients with PD were selected on the basis of a peripheral complex I deficiency and cells from these patients were fused with cells that lacked mtDNA (rho−) and grown in mixed or clonal cultures. In both instances, the mtDNA that was transferred from the patients with PD caused a complex I defect in the recipient cybrid cells, which suggests that the mtDNA in these patients caused the complex I deficiency through inherited or somatic mutations.

Finally, a mutation in mtDNA 12S RNA was found in a patient with maternally inherited, early-onset PD, deafness, and neuropathy, and a deletion in the gene encoding cytochrome b was found in a patient with parkinsonism. However, these mutations have not been identified in other patients with PD.

Mitochondrial Function and Familial PD

As indicated in the introduction, in rare instances, PD is linked to genetic defects and relevant to this review, some of these, including parkin, PINK1 and DJ-1, may affect mitochondrial function.

The Ubiquitin Ligase, Parkin

Parkin is transcribed ubiquitously, and intracellular localization studies have reported the association of parkin with the endoplasmic reticulum, Golgi apparatus, synaptic vesicles, and mitochondria. The function of parkin is unknown but the protein contains several domains for protein–protein interactions and E3 ligase activity. The ligase activity is a function of the ubiquitin proteasomal pathway, and several putative substrates for parkin have been reported, but whether any of these are bona fide parkin substrates remains to be established.

Recessive loss-of-function mutations in *parkin* were first reported in patients with juvenile-onset parkinsonism and have subsequently been shown to be the most common cause of PD in people younger than 20 years, although patients with later-onset cases have also been reported. An increase in striatal extracellular dopamine concentrations, reduced synaptic excitability, and mild, nonprogressive motor deficit at 2–4 months were described in a *parkin* knockout mouse line. However, no loss of dopaminergic neurons and no inclusion formations were noted. It has been reported that *parkin* knockout mice have decreased mitochondrial respiratory chain function in the striatum and reductions in specific respiratory chain and antioxidant proteins. More striking is the fact that *parkin* knockout *Drosophila* develop muscle pathology, abnormal mitochondrial morphology, and apoptotic cell death.

PINK1 (PTEN-Induced Putative Kinase 1)

The gene encoding PINK1 comprises 8 exons and encodes an insoluble, ubiquitously expressed, 581 amino acid, 63 kDa protein with an amino-terminal, mitochondrial-targeting sequence. There is some evidence that PINK1 is, at least in part, localized to the inner mitochondrial membrane, while its carboxy-terminus is exposed to the cytoplasm. The serine–threonine kinase domain of PINK1 has substantial homology with the CG4523 protein in drosophila. CG4523 interacts with a protein in the fly that is a homologue of the mammalian mitochondrial translation-initiating factor 3 (MTIF3), which makes this a candidate protein for interacting with PINK1. Analysis of genetic variants of MTIF3 in patients with PD found an allelic association between the C798T polymorphism and PD.

Mutations in *PINK1* are a cause of autosomal recessive PD. Mutations have been reported within and outside the kinase domain; however, the localization of PINK1 to the mitochondria is not affected by these mutations. Patients harboring the causative *PINK1* mutations have features typical of young-onset PD.

PINK1 knockout flies are viable but sterile or hypofertile, have a motor deficit, a shorter lifespan, an abnormal flight muscle with impaired function, disorganized mitochondrial morphology, reduced mitochondrial mass, lower

concentrations of ATP, and a small reduction in the number of dopaminergic neurons. This phenotype is very close to that seen in the *parkin* knockout flies. Relevant to these characteristics is the fact that parkin overexpression can rescue the mutant PINK1-related phenotype in flies, suggesting that parkin and PINK1 participate in the same pathogenetic pathway. While more work needs to be done to elucidate the role played in mitochondria by both PINK1 and parkin, mounting evidence indicates that, at least in insect cells, both proteins modulate the mitochondrial dynamics, including the fusion/fission.

Oncogene DJ-1

DJ-1 is a 23 kDa protein that is expressed in peripheral tissues and in parts of the brain, including the striatum, substantia nigra pars compacta, and reticulata in neurons and in glia, but is highly expressed in the cerebellum, hippocampus, and olfactory bulb. Studies of the intracellular distribution of DJ-1 show that it is found in several pools, including the mitochondria, where it is present presumably in the intermembrane space and matrix.

Thus far, studies on DJ-1 function have yielded confusing results, and its role at the level of the mitochondria remains enigmatic. DJ-1 seems to posses several functions, including that of an oncogene, a modulator of androgen-receptor-dependent transcription, and as a sensor of oxidative stress. More troubling is the fact that some studies have reported that oxidative stress and PD-associated mutations do not increase the mitochondrial localization of DJ-1, while others show that DJ-1 might translocate to the outer mitochondrial membrane during oxidative stress. The deletion or silencing of DJ-1 has been reported to sensitize cells to oxidative stress, and overexpression of DJ-1 protects cells. DJ-1 forms a nuclear complex with both RNA- and DNA-binding proteins that regulate gene transcription and can prevent apoptotic cell death by α-synuclein or oxidative stress.

Mutations in the gene encoding DJ-1 are a rare cause of autosomal recessive PD. Patients with mutations in *DJ-1* have young-onset PD that progresses slowly, responds well to levodopa, and might be coupled with dystonia. Mutations in *DJ-1* that cause familial PD lead to protein instability or decreased nuclear localization, decreased transcriptional activation, and decreased protection against apoptosis. The L166P mutation is also associated with increased mitochondrial localization, although this was not confirmed in other studies.

Conclusion

In the past decade, there have been some major discoveries on the role of mitochondria in neurodegenerative diseases in general and PD in particular. We now understand that through depletion of ATP, generation of ROS, and release of apoptogenic proteins, mitochondria may hold a key role in neurodegenerative processes. Initiation of these events, either individually or, more likely, in combination, would potentially lead to neuronal death. We also understand that the potential role of mitochondrial dysfunction in PD may not be restricted to a defect in respiration but may involve alterations in mitochondrial dynamics, which is increasingly recognized as a pathogenic factor. Some aspects of mitochondrial genetics, such as heteroplasmy, mitotic segregation, and the threshold effect, may contribute to our difficulty in linking common neurodegenerative diseases to mitochondrial defects. It is also important to remember that most studies on the mitochondrial link to neurodegeneration have been mainly performed in autopsy material, which often originates from terminally ill patients and is devoid of almost all neurons of interest, those that are proposed to die from mitochondrial dysfunction. Thus, many, if not all of these studies reflect analyses performed on a population of surviving cells (e.g., glia) not necessary representative of the actual neuronal death mechanism. Finally, it is also crucial to remember that mitochondrial defects reported in postmortem tissues may simply reflect nonspecific alterations that occur in dying neurons. The development of better in vivo experimental models of neurodegenerative diseases may provide us with the necessary tools to appropriately examine the mechanistic relationship between neurodegeneration and mitochondrial dysfunction and to address once and for all many of the pending issues that cloud the field of sporadic *mitochondrial* neurodegenerative diseases.

Mitochondrial Encephalopathies

D K Simon, Beth Israel Deaconess Medical Center, Boston, MA, USA

Glossary

Dystonia – A movement disorder that causes involuntary sustained muscle contractions, repetitive twisting movements, and abnormal postures of the trunk, neck, face, or arms and legs.
LHON (Leber's hereditary optic neuropathy) – A disorder consisting of acute or subacute painless visual loss in one or both eyes due to optic atrophy, usually caused by a point mutation in one of the mitochondrial DNA encoded complex I genes.
MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) – This is a disorder caused by various mitochondrial DNA mutations, most commonly an A to G point mutation at position 3243 in the tRNA-Leu(UUR) gene.
MERRF (myoclonus epilepsy with ragged-red fibers) – MERRF is characterized by myoclonus, generalised epilepsy, ataxia, and ragged-red fibers in muscle biopsy.
MPTP (1-methyl 4-phenyl 1,2,3, 6-tetrahydropyridine) – A toxin that inhibits the activity of complex I of the mitochondrial electron transport chain.
3-NP (3-nitropropionic acid) – A toxin that inhibits the activity of complex II of the mitocohondrial electron transport chain.

Mitochondria are the 'energy factories' of our cells. They generate ATP through the mitochondrial electron transport chain, which includes a series of protein complexes within the inner mitochondrial membrane that transfer electrons to molecular oxygen. This process is coupled to the generation of a proton gradient, and the energy stored in this proton gradient is used to generate ATP. Mitochondrial dysfunction can result in several deleterious consequences (**Table 1**) that may contribute to the pathogenesis of mitochondrial encephalomyopathies.

Table 1 Potential consequences of mitochondrial dysfunction

Low ATP levels
Increased reactive oxygen species (ROS)
Impaired calcium buffering
Opening of the mitochondrial permeability transition pore → release of pro-apoptotic factors

The mitochondrial encephalomyopathies, sometimes also referred to as mitochondrial encephalopathies or simply mitochondrial disorders, represent a diverse set of disorders involving abnormalities of mitochondrial function. Classic mitochondrial genetic disorders are associated with mutations in mitochondrial DNA (mtDNA), which are inherited strictly along the maternal line. MtDNA mutations also can be acquired during life (somatic mtDNA mutations), a phenomenon hypothesized to play a role in some age-related disorders. The situation is complicated by the fact that a predisposition to accumulating somatic mtDNA mutations can be inherited (see discussion of Polg mutations later in this section). A total of 13 proteins are encoded on the mtDNA, each of which is a component of the mitochondrial electron transport chain, along with 22 tRNAs and 2 rRNAs. Thus, most of the estimated 1500 proteins that function within the mitochondria are encoded on the nuclear genome. Not surprisingly, many disorders caused by mutations in nuclear genes have been associated with mitochondrial dysfunction, including Friedreich's ataxia and Huntington's disease. However, this section focuses on disorders associated with mtDNA mutations. Inherited mitochondrial genetic disorders are relatively rare, and the literature on movement disorders associated with these disorders is even rarer.

Classic mitochondrial encephalopathies are relatively rare, and not all physicians are familiar with the range of clinical presentations of these disorders. Recognition of the potential for prominent movement disorders in mitochondrial encephalopathies can help to avoid delays in diagnosis. This review briefly summarizes the movement disorders reported in association with some of the classic mitochondrial disorders.

Leber's Hereditary Optic Neuropathy Plus Dystonia

The first human disease demonstrated to be caused by a mtDNA mutation was Leber's hereditary optic neuropathy (LHON), most commonly caused by a point mutation in one of the mitochondrial genes encoding a subunit of complex I of the mitochondrial electron transport chain, either G3460A, G11778A, or T14484C in most cases. LHON is associated with acute or subacute painless visual loss in one or both eyes due to optic atrophy. Subsequently, rare families were identified in which LHON occurred in some family members and dystonia, either alone or together with LHON, in others. This syndrome

Table 2 mtDNA mutations associated with dystonia

Syndrome/disease	*Gene*	*Site of mutation*	*Types of mutations*
MELAS	tRNA-Leu(UUR)	3243	A to G substitution
Dystonia + cataracts	ND1 (complex I)	3308	Frame shift
LHON	ND1 (complex I)	3460	Missense
	ND4 (complex I)	11778	Missense
LHON + Dystonia	ND4 (complex I)	11696	Missense
	ND6 (complex I)	14459	Missense
	ND6 (complex I)	14596	Missense
Leigh's syndrome	tRNA-Lys	8344	A to G substitution
	ATP-6 (complex V)	8993	Missense
Kearns–Sayr	Multiple		5.9 kb deletion

of LHON plus dystonia can be caused by a point mutation at position 14459 in the ND6 subunit of complex I. Subsequently, other mtDNA mutations have been linked to a similar syndrome (**Table 2**).

LHON associated mtDNA mutations also rarely can be associated with other neurological features. For example, we reported a family with maternally inherited parkinsonism plus dystonia and dementia in association with a heteroplasmic G11778A 'LHON' mutation. Others have reported postural tremors, tics, parkinsonism, chorea, and dystonia, as well as other neurological findings.

Mitochondrial Encephalopathy, Lactic Acidosis, and Stroke-Like Episodes

Another mitochondrial syndrome, MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes), as the name implies, typically is characterized by stroke-like episodes as well as seizures, myopathy, ataxia, headaches, and recurrent vomiting. An A3243G point mutation in the tRNA-Leu(UUR) gene accounts for about 80% of cases. Dystonia also can be a feature of MELAS, and Sudarsky et al. reported a patient with MELAS for whom dystonia was the predominant presenting symptom. Some patients have been reported to have myoclonus as well, though myoclonus is more typical of myoclonus, epilepsy, ragged-red fiber (MERRF) (see below). Chorea also can occur in MELAS.

Leigh Syndrome

Maternally inherited Leigh syndrome (MILS) is a severe usually infantile- or early childhood-onset mitochondrial disorder associated with bilateral basal ganglia and brainstem degeneration that is genetically diverse, and can be caused by various different mtDNA mutations and also by autosomal recessive or X-linked mutations in nuclear encoded genes leading to mitochondrial dysfunction. Because of the propensity for basal ganglia pathology, it is not surprising that MILS can be associated with many different movement disorders, including prominent dystonia, myoclonus, chorea, parkinsonism, and tics.

Myoclonus, Epilepsy, Ragged-Red Fibers

Myoclonus, epilepsy, ragged-red fibers (MERRF) is a syndrome characterized by myoclonus, generalized seizures, ataxia, and myopathy, usually due to a point mutation in the tRNA-Lys gene (A8344G, T8356C, or G8363A). In addition Rita Horvath et al. reported a patient with parkinsonism as a prominent clinical feature in a patient harboring the 8344 'MERRF' mutation.

Treatment of myoclonus in MERRF is complicated by the fact that valproic acid can inhibit cytochrome oxidase activity and has been reported to cause ultrastructural changes in mitochondria. A case report has been published of improvement in myoclonus with levetiracetam in a patient with MERRF. Unfortunately, controlled trials are lacking regarding treatment of movement disorders specifically in MERRF or in other classic mitochondrial disorders.

Multiple mtDNA Deletions Associated with Parkinsonsism

Familial parkinsonism can result from an inherited predisposition to accumulating multiple somatic mtDNA deletions. This form of parkinsonism, associated with progressive external ophthalmoplegia (PEO) and premature ovarian failure, results from a mutation in the mtDNA polymerase γ (Polg) gene, resulting in increased errors during mtDNA replication. Polg is a nuclear encoded gene, and thus this predisposition to accumulating mtDNA deletions is inherited in an autosomal dominant manner.

mtDNA Mutations and Mitochondrial Toxins in Parkinson's Disease and Dystonia

Mitochondrial complex I activity is deficient in the substantia nigra in Parkinson's disease (PD). Cell lines expressing mtDNA from PD patients also manifest

complex I deficiency, suggesting that mtDNA mutations may account for the defect in PD, though specific mutations have yet to be identified that definitively account for the complex I defect in PD. Large mtDNA deletions have been found to accumulate with age in substantia nigra neurons with modestly higher levels in PD compared to controls, but the significance of these deletions in the pathogenesis of PD remains uncertain. Interestingly, patients with adult-onset idiopathic dystonia also are reported to have a defect in mitochondrial complex I activity, but the significance and origin of mitochondrial dysfunction in such cases remains unknown.

Though this review focuses on mtDNA mutations, it is worth noting that mitochondrial toxins also can cause parkinsonism and dystonia. The mitochondrial complex I inhibitors 1-methyl 4-phenyl 1,2,3,6-tetrahydropyridine (MPTP) and rotenone (a pesticide) can induces loss of dopaminergic neurons resulting in parkinsonism in animal models. MPTP also induces transient dystonia in baboons. Another mitochondrial toxin, 3-nitropropionic acid (3-NP) inhibits complex II and induces behavioral changes and striatal lesions similar to those of Huntington's disease. 3-NP also can induce a delayed-onset progressive dystonia following systemic injections in monkeys. Accidental exposure in humans following ingestion of 3-NP contaminated sugar cane is reported to have induced a transient encephalopathy followed by a progressive movement disorder including dystonia and chorea.

MMSE - Mini-Mental State Examination

B A Bernard and J G Goldman, Rush University Medical Center, Chicago, IL, USA

Glossary

Factor analysis – A statistical method for reducing correlational data to a smaller number of factors which are regarded as the basic variables that account for the interrelationships among the data.

Reliability – The regularity with which a test produces the same score under similar retest conditions, or the regularity with which different parts of a test provide similar findings.

Validity – The degree to which a test measures what it purports to measure.

Definition and History

The Mini-Mental State Examination (MMSE), published by Folstein et al. in 1975, is a widely used test for screening and scaling cognitive impairment. The MMSE was initially developed as a simplified, quick, scored form of cognitive mental status since the batteries available at that time to evaluate mental status were lengthy and time-consuming. In the original article, Folstein et al. administered the MMSE to a total of 206 patients with dementia syndromes and other psychiatric diagnoses (affective disorder, affective disorder with cognitive impairment, mania, schizophrenia, and personality disorders) and 63 normal, elderly controls. Comparing 69 psychiatric inpatients (diagnosed with dementia or affective disorder with or without cognitive impairment) and 63 normal, elderly controls, the authors reported that the MMSE significantly differentiated the three diagnostic groups of patients from each other and from the normal group. Based on the examination of an additional 137 psychiatric inpatients for standardization, Folstein et al. found scores of 20 or less in their patients with dementia, delirium, schizophrenia, or affective disorder but not in the normal elderly or in patients with neurosis or personality disorder. The MMSE scores demonstrated high concurrent validity with the Weschler Adult Intelligence Scale, Verbal and Performance scores. In a subset of patients retested after 28 days, there was no significant difference in scores. Folstein et al. acknowledged that the MMSE did not replace a complete clinical evaluation for diagnostic purposes, but highlighted its reliability and validity, clinical pertinence, and usefulness in training residents in skillful evaluation of cognitive aspects of mental status.

Over time, the MMSE has remained a brief test of mental status that is easy to administer and score. Administration time is approximately 10 min. There are authorized translated versions of the MMSE in many languages. In addition, population-based normative data such as age and years of education are available for interpreting the MMSE scores; total scores are affected by increased age and low education (especially education less than 8 years), which may represent psychometric bias.

Scale Structure

The total possible score is 30, and a score of 23 and below is generally considered to be within the impaired range. In patients with significant physical or sensory limitations, not all items can be administered (e.g., patient may be unable to copy the design due to motor impairment, or may be unable to name objects because of visual defect). In this case, the score is out of the number of items which are administered (e.g., out of 28 or 29). Items on the MMSE assess a number of domains, including orientation (10 points), registration of three words (3 points), attention (5 points), recall of three words (3 points), language (8 points), and visuoconstruction (1 point).

Psychometric Properties

The MMSE demonstrates moderately high levels of reliability. It has been reported to be internally consistent. The MMSE has been found to have short-term test–retest reliability in patients with dementia, as well as long-term reliability in cognitively intact individuals. The MMSE has been shown to have construct validity, since it is moderately correlated with other dementia screening exams (e.g., Blessed Orientation-Memory-Concentration Test), as well as measures of general cognitive abilities (e.g., Wechsler Intelligence Scale).

The MMSE has been found to be sensitive to the severity of dementia in patients with Alzheimer's disease (AD). The total score is useful in documenting cognitive change over time. Patients with AD typically show an annual decline of 3 points on the MMSE. The MMSE is not used as the sole criterion for diagnosing dementia, since there are nonneurological reasons that lead to low scores (e.g., low education, difficulty with the English language, visual or auditory defects). Rather, the score is used in conjunction with the clinical history, the neurological examination, and other neuropsychological tests in order to establish a diagnosis of dementia. Besides being routinely used in clinical practice, the MMSE has been used to assess cognition in epidemiological studies of dementia. The MMSE also has been used in clinical trials as an exclusion–inclusion criteria (e.g., screening for cognitive impairment) and as part of neuropsychological test batteries in research studies.

Since individual items of the MMSE load on different factors across factor analytic studies, caution should be used in interpreting performance on individual items. For example, there is a tendency to associate not recalling the three words with cortical, generalized dementia, and difficulty spelling WORLD backwards with frontal–subcortical dysfunction. However, the items of the MMSE should not be substituted for a detailed neuropsychological evaluation for differential diagnosis.

Use in Movement Disorders

The MMSE has been used to detect cognitive decline in patients with Parkinson's disease (PD). For example,

researchers followed 69 patients with idiopathic PD who initially scored within the normal range (MMSE $\geq$ 24). At two-year follow-up, 12 patients (17%) had significant cognitive decline, as defined as a decline of $\geq$4 points on the MMSE.

A score of less than 24 on the MMSE in patients with parkinsonism is generally supportive of dementia; however, the MMSE does not differentiate coexisting AD versus dementia with Lewy bodies in patients with parkinsonism and dementia. In a study of 115 newly diagnosed patients with Parkinson's disease, subjects were excluded who had possible dementia, as defined by a MMSE score of less than 24. Of these patients, 24% had mild cognitive impairment, as defined as impairment on at least three tests from a neuropsychological test battery. In a recent study of 106 patients with PD who had normal MMSE scores, mild cognitive impairment was found in 29.2% of the patients, as defined as impairment on at least two tests within a cognitive domain. These findings have led some researchers to suggest that the MMSE has a ceiling effect when assessing the mild cognitive changes associated with PD.

The MMSE has also been used with patients with of Huntington's disease (HD). In a study comparing 145 patients with AD and 84 patients with HD, the HD patients were generally impaired in performing serial subtractions, while the AD patients had more difficulty recalling the three words.

Criticisms and Strengths

The MMSE has been criticized as being not very effective in separating patients with mild dementia from normal subjects, as well as being insensitive to mild cognitive impairment. Recently, the Montreal Cognitive Assessment (MoCA) has been proposed as a screening instrument that is sensitive to mild cognitive impairment and the early cognitive changes of Parkinson's disease. The MoCA assesses a broader range of domains affected in PD, including attention, executive functions, and visuoperception. In a study of 131 patients with PD, 52% of patients with normal MMSE scores had mild cognitive impairment, as suggested by a score of less than 26 on the MoCA.

In addition, the MMSE has received criticism for being a highly verbal based test, for all items not being equally sensitive to cognitive impairment, for lacking assessment of subcortical functions, and for being limited in the evaluation of change in more severely demented patients. There also may be influences of age, education, and cultural background; some of these factors such as age or education can be accounted for with use of normative data.

However, the MMSE has several strengths including that it can be readily and quickly administered in both clinical and research settings. It has demonstrated utility in its widespread and long-standing use as a cognitive screening test. Translations into multiple languages are available, as are age and education-based normative data. Its psychometric properties and use in studies of dementia demonstrate that the test largely meets its proposed goals as a screening instrument of cognitive function and serial measurement of cognitive change.

Monoamine Oxidase Type B Inhibitors

J J Chen, Loma Linda University, Loma Linda, CA, USA

Introduction

The monoamine oxidase type B (MAO-B) inhibitors, rasagiline and selegiline, have been studied extensively in regard to both symptomatic and possible neuroprotective or disease-modifying properties in Parkinson's disease (PD). Selegiline and rasagiline are propargylamine pharmacophores and irreversibly inhibit the MAO-B isozyme, but they differ substantially in chemical scaffolding and metabolic by-products. Considering the pharmacological differences between the two compounds, it cannot be assumed that selegiline and rasagiline demonstrate similar clinical benefits.

In addition to rasagiline and selegiline, other MAO-B selective inhibitors (e.g., lazabemide and mofegiline) have been tested in clinical trials for the treatment of PD. However, these agents have not made it to the market.

MAO Inhibitor Pharmacology

MAO are ubiquitous enzymes that exist in mammalian tissues in two genetically distinct forms, referred to as MAO-A and MAO-B. The physiologic role of MAO is to catalyze the biotransformation of a variety of arylalkylamine neurotransmitters, such as dopamine, norepinephrine, and serotonin as well as to detoxify biogenic amines, such as tyramine. The overall reaction involves oxidative deamination and can be characterized as: $RCH_2NH_2 + H_2O + O_2 \rightarrow RCHO + NH_3 + H_2O_2$. Each isozyme demonstrates distinct substrate specificity, inhibitor selectivity, and a unique tissue distribution. MAO-A is primarily responsible for degrading serotonin and norepinephrine, as well as exogenous monoamines such as tyramine. MAO-B is primarily responsible for degrading dopamine. Both MAO isoenzymes are present in the tissues of the brain, gastrointestinal tract, and liver; however, MAO-A predominates in the gastrointestinal and hepatic tissues and in the human basal ganglia, MAO-B is more abundant than MAO-A, accounting for 80% of total MAO activity.

Although the mechanism by which MAO-B inhibitors exert beneficial effects in PD are multifactorial, the main pharmacologic activity is the selective inhibition of MAO-B resulting in a reduced deamination of dopamine and thus in a greater dopaminergic activity. Both drugs contain a propargylamine moiety that is essential for conferring irreversible inhibition of MAO-B.

Medical interest in MAO inhibitors initially emerged in the early 1950s for the treatment of psychiatric disorders (i.e., depression). The nonselective MAO inhibitors, such as phenelzine and tranylcypromine, were shown to be associated with an increased incidence of hypertensive crisis, which was initially observed in association with the consumption of aged cheese. This 'cheese reaction' is known to be due to the increased bioavailability of tyramine, a dietary sympathomimetic amine, into the systemic circulation due to MAO-A inhibition in the gut. Subsequently, inhibitors selective for the MAO-B isozyme were developed and are nowadays used to treat PD. Despite the proven safety of selective MAO-B inhibitors, concerns persist regarding unlikely interactions with tyramine-containing foods/beverages and drugs with serotonergic augmentation. Practically speaking, at therapeutic doses, these selective MAO-B inhibitors are unlikely to induce a 'cheese reaction' (transient hypertension, headache) unless extraordinary amounts of dietary tyramine (400 mg or greater) are ingested, unlike the nonselective MAO-A/B inhibitors, which require as little as 10 mg or less of dietary tyramine. Studies in rasagiline-treated patients receiving a tyramine challenge test did not yield significant findings on blood pressure or heart rate changes. It should also be noted that there were no dietary restrictions with respect to tyramine in the rasagiline clinical trials. Thus, rasagiline 0.5–1.0 mg daily can be used safely without over concern regarding dietary tyramine restrictions.

Additionally, the potential for a hypertensive effect resulting from concomitant administration of sympathomimetic agents (e.g., ephedrine, phenylephrine, pseudoephedrine), which are substrates of MAO, is low and the available data demonstrate that the risk of a severe hypertensive episode associated with occasional administration of over-the-counter sympathomimetic agents (e.g., cold products, weight-reducing agents) appears to be minimal.

Concomitant use of MAO-B inhibitors with meperidine and other selected analgesics is contraindicated due to a small risk of serotonin syndrome. Concomitant use of serotonergic antidepressants is not contraindicated (with the exception of rasagiline and mirtazapine) and they can be used together safely. In one survey, the frequency of serotonin syndrome in patients on concomitant selegiline and a selective serotonin reuptake inhibitor (SSRI) was reported to be only 0.24%, with 0.04% of patients experiencing serious symptoms.

Selegiline

At daily doses of <20 mg, selegiline (*N*-propargyl-methamphetamine), also known as L-deprenyl, is an irreversible inhibitor of the MAO-B isozyme. For treatment in PD, conventional selegiline is administered 5 mg twice daily and orally disintegrating selegiline 1.25–2.5 mg once daily. Synthesized in 1961, selegiline was the first selective MAO-B inhibitor. It is a propargylamine derivate of methamphetamine and able to selectively and irreversibly block MAO-B activity in the brain. The inhibition of MAO-B activity results in a reduced oxidative deamination of dopamine and phenylethylamine.

Several randomized, controlled trials, including the large Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism (DATATOP), demonstrate that selegiline monotherapy provides a symptomatic benefit and is well tolerated. As monotherapy, the side effects of selegiline include nausea, benign cardiac arrhythmias, dizziness, and headache. The outcomes data for conventional selegiline as an adjunct to levodopa are conflicting. Several studies have demonstrated improvements in motor symptoms and reduction in off-time. However, several other studies, have shown minimal or no benefit from adjunctive selegiline therapy. When used in combination with levodopa or dopamine agonists, treatment emergent side effects include nausea, dizziness, fatigue, constipation, insomnia, peak-dose dyskinesias, psychiatric complications (e.g., hallucinations), and orthostatic hypotension.

The clinical value of conventional selegiline is compromised by low bioavailability as >90% of an orally administered dose undergoes first-pass metabolism by hepatic microsomal P-450 dependent monooxygenases before reaching the systemic circulation. This extensive hepatic first-pass effect not only reduces the systemic exposure to selegiline, but is also associated with the production of metabolites, namely *N*-desmethylselegiline (DMS), L-methamphetamine (*m*-amph), and L-amphetamine (amph) (**Figure 1**). The latter two metabolites have been implicated in contributing towards adverse cardiovascular and psychiatric side effects during selegiline treatment (e.g., orthostatic hypotension, hallucinations, insomnia, vivid dreaming).

The putative neuroprotective effects of selegiline and its metabolite, DMS, have been investigated clinically as well as in cell culture and animal models. Selegiline and DMS prevent neurotoxin-induced cell death by virtue of their ability to induce antiapoptotic molecules and down-regulate proapoptotic molecules. In fact, the protective efficacy of DMS may be greater than that of selegiline, as it is active at lower concentrations and provides significantly greater levels of protection at the same concentrations, suggesting that DMS might be the active compound responsible for the neuroprotective properties of selegiline. Despite preclinical evidence of neuroprotection, the amphetamine-like metabolites of selegiline may actually be neurotoxic and counteract any disease-modifying effect of selegiline.

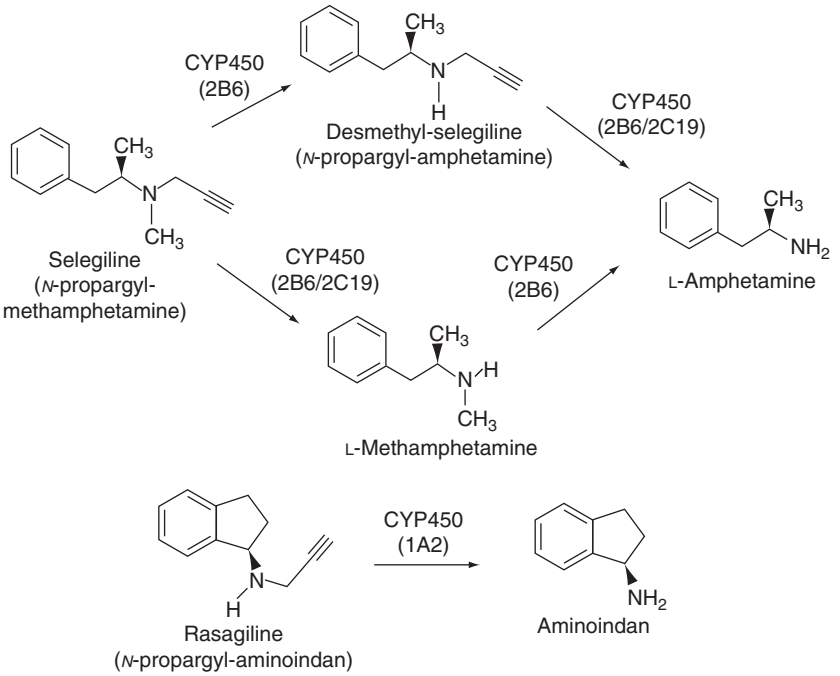

Figure 1 Molecular structure and metabolic pathways of rasagiline and selegiline.

Since the selegiline molecule can be absorbed transbuccally, selegiline is also formulated as an orally disintegrating tablet that dissolves in the mouth on contact with saliva. Subsequent transbuccal absorption minimizes first-pass hepatic metabolism and provides higher plasma concentrations of selegiline and lower levels of metabolites (DMS, *m*-amph, amph). In pharmacokinetic studies, about one-third of the dose of an oral disintegrating tablet was absorbed pregastrically within a minute, and selegiline plasma levels were approximately 5 fold higher than those achieved with the same dose of the conventional oral formulation.

Rasagiline

Rasagiline (*N*-propargyl-1(*R*)-aminoindan) is a nonamphetamine propargylamine and at doses of up to 1 mg once daily is a selective and irreversible MAO-B inhibitor. Results from in vitro and in vivo preclinical studies have demonstrated that rasagiline increases the release of dopamine in the striatum. Large, randomized, clinical studies have demonstrated that rasagiline is effective as monotherapy in patients with early PD and that earlier initiation of rasagline is associated with improved long-term outcomes compared with delayed therapy. As an adjunct to levodopa, rasagiline reduces off-time in patients experiencing motor fluctuations (e.g., wearing off).

In a clinical trial, patients initiated on rasagiline monotherapy early in PD had less functional decline than patients whose treatment was delayed for 6 months. Using a delayed-start onset design, the TVP-1012 in Early Monotherapy for Parkinson's Disease Outpatients (TEMPO) study indicated that rasagiline might furthermore have neuroprotective properties in addition to its symptomatic effects. In this study, patients treated with 1 mg rasagiline per day for 12 months showed less functional decline than subjects whose treatment with rasagiline was delayed for 6 months. This suggests that early initiation with rasagiline (even before the onset of functional impairment) is associated with better long-term outcomes.

For the management of patients with motor fluctuations, the efficacy of rasagiline appears similar to that of entacapone as demonstrated in the Lasting Effect in Adjunct Therapy with Rasagiline Given Once Daily (LARGO) study. Thus, when an adjunctive agent is required for managing motor fluctuations, rasagiline is considered as a first line agent. Rasagiline has an absolute bioavailability of 36% and its major metabolite is 1-R-aminoindan (**Figure 1**), which is devoid of amphetamine-like effects. Accordingly, clinical studies demonstrated good tolerability of rasagiline treatment and found no difference in the frequency of cardiovascular and psychiatric adverse events between rasagiline and placebo-treated patients.

Overall, the data associated with rasagiline for reducing 'off' time are of high quality. In addition to demonstrated efficacy in reducing 'off' time in patients experiencing motor fluctuations while receiving levodopa, rasagiline has demonstrated good tolerability in patients receiving numerous other adjunctive therapies (e.g., dopamine agonists, catechol–*O*–methyl–transferase (COMT) inhibitors): a common scenario in the real-world management of PD. The use of conventional selegline for reducing 'off' time is supported by less robust quality of data. However, the orally disintegrating selegiline tablet appears to offer a similar benefit in reducing 'off' time to that by rasagiline, albeit no direct comparative data are available.

Clinical Neuroprotection or Disease Modification

MAO-B inhibitors with a propargylamine molecular scaffolding, such as rasagiline and selegiline, have been investigated for neuroprotective (disease-modifying) properties. These agents exhibit several mechanisms that either protect neurons from toxic insults or attenuate neuronal degeneration. The published literature is abundant with data on the antioxidant and antiapoptotic properties of rasagiline and selegiline. Clinically, results of randomized, placebo-controlled studies in patients with early PD suggests that either agent may provide positive disease-modifying effects, in addition to symptomatic effects. However, due to disagreement regarding the validity of neuroprotection study methodologies, the medical and scientific community remains hesitant to confirm or refute the disease-modifying properties of MAO-B inhibitors.

The DATATOP clinical trial represents one of the earliest attempts to identify a neuroprotective benefit in PD. Untreated patients with early PD were randomized to receive treatment with either placebo, selegiline, vitamin E, or the combination selegiline and vitamin E. The primary outcome was the time it took patients to develop sufficient disability to require L-dopa. Individuals treated with selegiline reached this endpoint nearly 9 months later than individuals not treated with selegiline. Although initially lauded as a major breakthrough in PD therapeutics, it soon became clear that the effect of selegiline on progression was at least in part accounted for by a symptomatic benefit of selegiline. Several subsequent studies have also attempted to demonstrate the clinical neuroprotection-like effects associated with selegiline; but all have been confounded by methodological or interpretive issues. Thus, despite the availability of clinical data, the matter of whether selegiline confers neuroprotection remains unsettled.

The TEMPO (rasagiline mesylate TEMPO) study employed a delayed-start design to evaluate early treatment with rasagiline versus delayed treatment in an

attempt to elucidate a potential neuroprotective benefit over a 1-year period. Untreated patients with early PD were randomized to receive treatment with either placebo, rasagiline for 1 year, or placebo for 6 months and then rasagiline for the remaining months (delayed treatment group). The primary outcome was the change in the total Unified Parkinson Disease Rating Scale (UPDRS) score from baseline to 1 year. Individuals randomized to early treatment with rasagiline showed a statistically significant benefit at 1 year compared with those in the delayed treatment arm, albeit the effect was small (~2 points on the total UPDRS). Overall, the TEMPO study and its open-label follow-up demonstrate that early intervention in patients with PD can be associated with measurable benefits that endure for several years. Subsequently, the Attenuation of Disease Progression With Azilect Once Daily (ADAGIO) study was conducted. The ADAGIO 18-month study was a randomized, delayed-start, multicenter, double-blind, placebo-controlled, parallel-group study that prospectively examined the potential disease-modifying effects of rasagiline. The delayed-start protocol was based on recommendations and input from the FDA. More than 1100 patients with early and untreated PD were enrolled, making it one of the largest of its kind. Patients were randomized to early-start treatment (18 months of rasagiline 1 or 2 mg once daily) or delayed-start treatment (9 months placebo phase followed by 9 months rasagiline phase). The three primary analyses of the trial were based on the change in total UPDRS (baseline vs. end of study) as well as slope superiority of rasagiline over placebo in the placebo-controlled phase (i.e., if the rate of disease progression in the rasagiline-treated group is lower vs. the placebo-treated group) and noninferiority of early-start versus delayed-start slopes during weeks 48–72 of the active phase (i.e., if the rate of disease progression is at least similar once both groups are on active treatment). The rasagiline 1 mg group met all the three primary end points for statistical significance while the rasagiline 2 mg group did not satisf the predefined criteria for disease modification.

Utilizing a design that is somewhat similar to a delayed-start methodology, a follow-up of the controlled trial DATATOP, evaluated 310 patients (of the originally 800 enrolled) who did not reach the primary end point of disability requiring levodopa therapy. After a 2-month washout and while maintaining the blindness of the original treatment (selegline or placebo), the 310 patients were administered selegiline 5 mg twice daily and were monitored for up to 18 months. The primary end point was the need for levodopa. During this extended trial, there was no statistically significant difference in the time for levodopa initiation between the 189 patients who had been assigned originally to active selegiline and the 121 patients who delayed the start of selegiline. Thus, earlier treatment with selegiline did not lead to superior survival with respect to the end point of disability requiring levodopa. However, since this was an open-label extension, an important limitation of the between group comparison is that patients were not matched for the level of disability at the beginning of this open-label extension period. This contrasts with the rasagiline delayed-start studies in which patients were randomized a priori to the early- and delayed-start groups, thus minimizing the potential confounding effects of mismatches in functional level. It is also important to note that the main outcome measures of the delayed-start rasagiline studies (i.e., change in total UPDRS score and/or slope analyses) are different than that of the extended selegline study (i.e., time required for addition of levodopa).

Summary

Rasagiline and selegiline are irreversible inhibitors of MAO-B but differ substantially in molecular and pharmacologic characteristics. In spite of chemical differences between the two compounds current, evidence supports the use of either agent as symptomatic monotherapy in early stage PD and as adjunctive therapy for the management of motor fluctuations. Additionally, the fully published results of the ADAGIO study suggest that rasagiline. 1mg perday provides benefits that are consistent with a possible disease-modifying effect. However, given the negative findings for the 2mg dose, it cannot be definitively concluded that rasagiline has disease modifying effects.

Motor Evoked Potential

G Abbruzzese, University of Genoa, Italy

Definition and History

The term 'motor evoked potential' (MEP) most commonly refers to the action potential elicited by noninvasive stimulation of the motor cortex through the scalp. MEPs were originally reported following electrical stimulation (high voltage: 1000/1500 V, and short duration: 50/100 μs, pulses) of the motor cortex, first introduced by Merton and Morton. Subsequently, magnetic stimuli (rapidly transient fields with variable flow direction and intensity up to 1.5/2.5 Tesla) were introduced by Barker and collaborators to evoke MEPs. The latter method, transcranial magnetic stimulation (TMS), is largely preferred since magnetic fields pass unattenuated through the skull and scalp, without nociceptive activation, and penetrate easily into the brain generating an electrical current that activates the neural tissue.

Origin of MEPs

In humans, MEPs can be recorded using surface electromyography from all skeletal muscles. They are characterized by a preferential contralateral distribution, short latency with proximo-distal progression, a variable amplitude (larger in distal muscles), and sensitivity to voluntary contraction. Such features support the notion that MEPs are mainly mediated by fast-conducting corticomotoneuronal connections projecting monosynaptically to the alpha-motoneurons in the contralateral spinal cord. It has been suggested that MEPs probably reflect the transynaptic activation of corticospinal neurons (including large pyramidal neurons and intracortical interneurons). Indeed, the recorded MEP is the sum of multiple descending volleys produced by a single high-intensity TMS pulse: a shorter latency direct D-wave (reflecting the *direct* excitation of the corticospinal axon) is followed by several later indirect I-waves (reflecting the *indirect* excitation of tangentially oriented axons in the deep cortical layers).

MEP Parameters

MEP recordings are largely used in clinical practice as well as in experimental research and several parameters can be considered. The threshold refers to the lowest intensity of the magnetic stimulus able to evoke a MEP of minimal size during either muscle relaxation or contraction. MEP threshold reflects the excitability of the corticospinal connections. The latency of the response, expressed in milliseconds, indicates the time taken by descending impulses to reach the target muscle. MEP latencies, therefore, vary as a function of the muscle distance (or subject height) and may be used to assess conduction along the central motor pathways (central motor conduction time, CMCT) by subtracting the peripheral conduction time. The peak-to-peak amplitude of the response is usually expressed as a percentage of the amplitude of the maximum response (direct M-wave) recorded in the same muscle on supramaximal electrical stimulation of the corresponding peripheral nerve. MEP size provides a measure of the portion of the spinal motoneurons discharged by TMS. This is clearly demonstrated by the observation that the MEP amplitude can be differently modulated by various motor tasks (reach, grasp, locomotion) and even by motor imagery and observation.

When TMS is delivered during a voluntary contraction of the target muscle, the MEP is followed by a pause of the ongoing electromyogram (EMG) activity lasting up to 200–300 ms. This period of inhibition is defined 'cortical silent period' and depends on GABA-mediated mechanisms controlling cortical excitability. Finally, when a focal coil is used for TMS, MEP recordings can be used for noninvasive and painless mapping of the somatotopic representation of muscles within the motor cortex. The cortical maps are constructed by stimulating different points on the scalp at a constant intensity and analyzing the number of sites from which MEPs can be elicited in the target muscle.

Applications of MEPs

Immediately after the introduction of the techniques of single-pulse TMS, it became evident that recording the MEP represented a reliable method to detect abnormalities of impulse propagation along the corticospinal tract. Afterwards, new techniques of paired-pulse or repetitive TMS have been progressively introduced to test the excitability of motor cortical areas. TMS, therefore, represents a noninvasive neurophysiological technique that allows studying both 'conductivity' and 'excitability' of the corticospinal system in man and may be regarded as an important new tool in clinical and experimental neurology.

Several abnormalities of standard MEP parameters can be documented in clinical studies. The MEP can be

absent, the onset-latency can be delayed, and the amplitude can be decreased together with a raised threshold. Different mechanisms may underlie such changes: failure of conduction due to damage to the corticospinal tract, dispersion of multiple descending volleys causing desynchronization of alpha-motoneurons discharges, depression of cortico-motoneuronal excitability, or intracortical conduction block. MEP recordings are currently used in routine clinical practice in order to document the functional impairment (even subclinical) of central motor conduction in various neurological conditions such as demyelinating syndromes, amyotrophic lateral sclerosis, myelopathies, stroke, and cerebrovascular disorders. On the other hand, central conduction is usually normal in neurodegenerative disorders not involving the corticospinal tracts.

Changes of the MEP size may reflect the efficiency of inhibitory systems within the human motor cortex. Using paired-pulse stimulation, it has been shown that the test MEP can be suppressed by subthreshold or suprathreshold conditioning stimuli delivered respectively a few milliseconds or 50–200 ms before (short- or long-interval intracortical inhibition – SICI or LICI). All these inhibitory phenomena are thought to depend on the activation of intracortical circuits, which are able to suppress the corticospinal output. The modulation of MEP amplitude by conditioning-test paradigms has been largely used to investigate motor cortical excitability in movement disorders (Parkinsonism, dystonia, chorea, dyskinesias).

Motor Fluctuations

K A Chung and J G Nutt, Oregon Health & Science University, Portland, OR, USA

Glossary

COMT – An enzyme that catalyzes the degradation of catecholamines, including the neurotransmitters dopamine, epinephrine, and norepinephrine.
MAOI – The brain and liver enzyme that normally breaks down the catecholamines norepinephrine, serotonin, and dopamine.
Pharmacodynamics – The study of how drugs act at target sites of action in the body.
Pharmacokinetics – The study of the uptake, distribution, metabolism, biotransformation, and elimination of drugs by the body.

Definition and History

Motor fluctuations are defined as variations in motor ability or performance over time, typically measured in

minutes to hours. This problem was recognized shortly after oral levodopa (LD) was introduced for the treatment of Parkinson's disease (PD). In 1969, Barbeau described 'a marked variation in individual performance from day to day or within the same day. Occasional short-lasting refractory periods varying from a few minutes to 3 or 4 h will occur in patients who are otherwise perfectly controlled.' The problem of fluctuating motor ability is not a small one. In a review of the literature from 1966 to 2000, Ahlskog and Muenter determined that by the 4–6 year of LD therapy, ~40% of patients will have developed motor fluctuations. Risk factors for developing fluctuations include younger age at disease onset, longer disease duration, greater disease severity, longer time of treatment, and higher LD intake.

Pharmacological Basis of Motor Fluctuations

Although subtle motor fluctuations may occur with other antiparkinsonian medications such as dopamine agonists, the vast majority of fluctuations are related to LD. The most important pharmacokinetic property of LD is its short plasma half-life of ~90 min. It follows that the dopamine produced from this short-lived precursor is also available relatively briefly. Coupled with progressive loss of functional dopaminergic nerve terminals in the striatum, it is not surprising that the response to single doses of LD in advanced PD as demonstrated in F^{18} fluorodopa PET studies is equally short. Furthermore, in the setting of the dopaminergically denervated striatum in PD, the relative rise and fall of dopamine concentrations are much larger than in the normal striatum.

The short plasma half-life of LD and the dependence of striatal dopamine synthesis on external LD in PD mean that alterations in absorption, metabolism, and distribution to brain of LD will translate into clinical effects. To understand how this impacts on PD patients, one must be familiar with the concept of the 'short duration effect.' This is the short-duration antiparkisonian response that approximates the plasma LD concentration and by extension, the striatal synaptic levels of dopamine. Most recognize that it is this phenomenon that underlies motor fluctuations and in the more severely affected, the ON–OFF cycle.

LD is absorbed through the small bowel, and thus, any interference with the delivery of drug to the intestinal region will also delay the rise in plasma levels of drug and, therefore, the production of dopamine by the brain. At the level of the brain, LD entry is limited by the capacity of an amino acid transporter that is responsible for moving several dietary-derived amino acids into the brain. Competition with LD here can also reduce dopamine production overall. These latter-described factors can be best thought of as contributors to the unpredictability of fluctuations, but they are important to recognize, because they are also more amenable to treatment.

Evolution of Motor Fluctuations

It is clear that at the beginning of treatment, patients are often unaware of their variable motor performance despite being detectable with careful observation. At some point, however, patients will notice that their medication effect wanes as the hours pass, and the etiology of this evolving awareness of motor fluctuations is the subject of some debate. One attractive view because of its simplicity is that an earlier finishing of the short-duration response due to disease progression leads to motor fluctuations. Another hypothesis is that the shortening of the response is not the largest factor, but that the alteration in the magnitude of the response (difference between OFF and ON motor function) is the most important etiologic factor. More specifically, the absolute magnitude of the short-duration response increases, because the trough or worst motor function related to disease severity becomes deeper over time and additionally because the peak response may increase with ongoing LD treatment. These two causal theories about the evolution of motor fluctuations suggest two treatment approaches, which can be complementary.

The first approach is perhaps more intuitive and widely applied with the aim of using pharmacokinetic manipulation to prolong the action of each dose of LD. This is achieved by either lengthening the absorption time with controlled release preparations or inhibiting the loss of LD outside the CNS by inhibiting aromatic amino acid decarboxylase (i.e., carbidopa, benserazide) and catechol-*O*-methyltransferase, as well as augmenting the effects of centrally produced dopamine with dopamine agonists or monoamine oxidase inhibitors. More directly, attempting to continuously administer drug to the brain via duodenal LD infusions or a subcutaneous/transcutaneous application of dopamine agonists will also reduce motor fluctuations. A second approach utilizes pharmacodynamic principles in attempting to lessen the amplitude of motor disability and is discussed later.

Clinical Phenomenology and Types of Motor Fluctuations

In their extreme, fluctuations can be one of the most dramatic phenomena witnessed in clinical medicine. A PD patient may be profoundly immobile or frozen, slumped in a wheel chair, even unable to control drooling. After a dose of dopaminergic medication, the patient may suddenly find it easy to rise, walk independently, and perform normal activities. When this dramatic, the mobile phase is often accompanied by dyskinesia or excessive unwanted movements of the body that most often appear

choreiform or jerky. After minutes to hours, the effect wanes and the patient returns to the wheelchair-bound state. These transitions between parkinsonism, (often referred to as the OFF state), and the more mobile or active ON state may occur over seconds, making them all the more striking in appearance. It has been likened to turning a light switch on and off; hence, the descriptive term 'ON-OFF' phenomenon has gained widespread use. Although most motor fluctuations are not this dramatic, patients with fluctuations are aware of, and observers can perceive, clear variations in motor ability. Often, the less severe motor fluctuations are seen as the 'wearing off' of the effects of a dose of medication or 'end of dose' effect. While motor fluctuations are often associated with dyskinesia, this association is not absolute.

Other types of motor fluctuations have been recognized. Delayed onset of responses to single (especially first morning) doses of LD was detailed by Melamed over 20 years ago and has become known as the 'delayed ON.' The complete failure of a drug dose to reverse parkinsonism has been termed 'no ON' or dose failure. Other types of motor fluctuations have been described in PD, including the 'sleep benefit' or diurnal fluctuation, and the more rarely observed paradoxical kinesia. This refers to the unexpected motor improvement that comes with extraordinary situations such as being able to easily mobilize in a dangerous setting.

Nonmotor fluctuations have been described and may or may not coincide with motor fluctuations. Nonmotor symptoms may be cognitive/psychiatric, visceral, or dysautonomic in nature and could involve pain or fatigue. For some patients, these nonmotor fluctuations can be more disruptive than motor fluctuations. It is worth exploring for coincidental timing of motor and nonmotor fluctuations, because if they do occur together, there is a good chance that both will be improved using strategies to smooth motor fluctuations. There is much less understanding of how to improve nonmotor fluctuations that do not respond to dopaminergic manipulation.

Diagnosis

It is critical for clinicians to recognize motor fluctuations, because not addressing this problem will inevitably lead to undertreatment of the patient and dissatisfaction. One way to probe the patient for the appearance of fluctuations is to ask whether he or she experiences changes in stiffness, slowness, walking, or tremor lasting minutes to hours. Another good question to ask is what the effects are of missing one or two doses of LD. During the beneficial period of a fluctuation, PD symptoms will be lessened; patients may report that shuffling is much better; they feel more fluid in their movements; or their movements are faster overall. Tremor can respond in this fashion as well, although it may not respond as consistently as rigidity or bradykinesia. The transition from OFF to ON can be gradual and hardly perceptible in the early stages of the disease and treatment. In this early period, fluctuations also tend to be more predictable. For example, a patient may report his/her symptoms worsening only if he/she missed a dose of medication several hours earlier. As months to years pass, the gradual nature of the transitions becomes steeper or abrupt, and to the patient, it appears that ON-time shortens. In other words, during early disease, a dose of medicine causes long-lasting benefit, but in advanced stages, the dose benefit can last as short as an hour or two. Accompanying these changes in the rate of a fluctuation comes the deepening of the 'trough' or the extent of parkinsonian symptoms while in the OFF state. For example, an early fluctuator may notice that walking slows mildly or tremor returns if one or sometimes, even several doses in a row are missed. The advanced fluctuator described earlier can suffer a profound loss of movement ability within moments of drug levels dropping below a critical threshold. In addition, during advancing stages, the duration of fluctuations can become more unpredictable, and this feature can be quite bothersome to daily life.

Although the diagnosis of motor fluctuations can usually be made with careful questioning of the patient, at times, the picture is unclear and some clinicians then prefer to examine the patient after a dose of medication is withheld for hours or even overnight and compare it with an examination an hour or so after medication is taken. On the other hand, frequent dosing with LD as well as other drugs can make the picture very confused; putting the patient on 3-h dosing may make the pattern clear.

Management of Motor Fluctuations

Treatment goals for motor fluctuations need to be realistic. The principles most likely to lead to improvements begin with transforming unpredictable fluctuations into predictable ones (so that interventions will in turn predictably succeed). The next goal is to try and make an ON-cycle as long as possible. However, it is impossible to lengthen ON-cycles and diminish troughs enough to abolish fluctuations in most cases, because inevitably, it leads to the escalation of antiparkinsonian medication usage and severe dyskinesia, psychiatric adverse events, or other toxicity.

Treatment options range from changing dietary intake to altering the pattern of medication use or using additional medications to improve ON time and/or reduce dyskinesia (as dyskinesia can be provoked by strategies that improve ON time). Currently, surgical options are mostly used for medically refractory fluctuations.

Improving Systemic Absorption of LD

Making motor responses more predictable can be achieved by altering the absorption of LD. For example, speeding up absorption by adding in or switching to regular release LD (versus the controlled release formula), suspending LD in liquid, and making doses large enough to attain therapeutic thresholds all can increase consistent results. In fact, a complicated fluctuating pattern of response can be converted into a stable, predictable wearing off pattern by giving adequate doses at 3 or 4 h intervals. Then, the wearing off pattern is much more rationally approached with methods to prolong or overlap ON time.

It has been demonstrated that dietary protein intake can reduce the effectiveness of LD because of competition with other amino acids at the large neutral amino acid transporter site in the gut and at the blood brain barrier. This effect is not important for other classes of PD medication. As patients become more advanced in their condition and especially if their fluctuations are brittle in nature, a meal with even modest amounts of protein can cause dose failures. If the patient adopts a low protein meal strategy or is able to time medication intake such that LD is taken on an empty upper GI tract, he or she may have more reliable responses and fluctuate less. This can take a toll on the patient who is taking medication very frequently, as it may be hard to find a window where protein delivery will not come close to dose times. Nevertheless, many more PD patients will find this to be an inexpensive change that makes a noticeable difference.

A poor absorption of the drug through the small intestine can obviously worsen fluctuations. Methods of improving this absorption include crushing the drug and consuming it in the form of a suspension with or without acidification, that is, ascorbic acid. Iron supplements must be administered at alternate times, as iron will bind to and, thus, contain LD in the GI tract, decreasing drug absorption and reducing benefit.

Improving Constancy of Dopaminergic Stimulation

It is generally thought that a smoother delivery of medication is beneficial to reducing fluctuations and dyskinesia. This concept has become codified as 'continuous dopaminergic stimulation' with the aim of constantly delivering medication to the striatum and avoiding troughs of medication and, thereby, periods of reduced dopaminergic stimulation. This constancy of stimulation is believed to reduce the sensitization that underlies both motor fluctuations and dyskinesia. A continuous delivery of LD or apomorphine will reduce 'OFF' time, but as this benefit occurs immediately, it is likely that this is achieved through pharmacokinetic means, by maintaining drug delivery above a threshold level throughout the day. It is important to note that patients will sometimes turn OFF despite having adequate plasma levels of LD or apomorphine, indicating that the constant delivery of drug to the systemic circulation is not the only factor determining if a patient is ON or OFF. The effects of continuous dopaminergic stimulation on dyskinesia is less clear. It is important to note that no controlled trials have demonstrated the efficacy of continuous dopaminergic stimulation over months.

Despite these reservations, in practical terms, most patients will benefit from trying to simulate a more constant drug level in the brain. This is not very important in early disease, as patients will begin medications two or three times a day initially and perceive no troughs. Over time, the troughs appear as a given dose wanes in effect. Patients will then alter medication intake to bridge the OFF periods. It is not unusual for some patients to require taking doses every few hours. The complexity arises in the number of strategies that is available to choose from to achieve the steady benefit.

The most obvious method is to decrease the interval between drug doses. For example, if a patient finds that the motor worsening occurs often an hour before the next dose is due, the natural remedy is to take subsequent doses an hour earlier than before. The disadvantage of this strategy is that more doses in a day translate into more inconvenience and chances of forgetting a dose.

This early wearing off phenomenon is well recognized with LD use, and the advent of dopamine agonists was heralded by the observation that the experience of wearing off was muted and delayed in those who began agonist therapy in favor of LD. Examples of dopamine agonists include pramipexole, ropinerole, rotigotine (24 h-transdermal patch), lisuride, and apomorphine. Pergolide and bromocriptine are not often used anymore due to the concerning risk of cardiac valvulopathy and other possible connective tissue abnormalities. All of these agonists with the exception of apomorphine are united in their relatively long half-life. For example, the LD $T_{1/2}$ is 45–90 min, whereas the plasma half-life of pramipexole is 8 h. Although the duration of benefit is not explained fully by pharmacokinetics alone, it is likely that the longer persistence of the agonist benefit is at least partly associated with its more durable half-life. Thus, it is not an uncommon strategy for patients to begin a dopamine agonist as monotherapy in the earliest stages of disease requiring symptomtic treatment. In a Cochrane review of dopamine agonists, the authors determined that the odds ratio of developing motor fluctuations was 0.75 (95% CI 0.63–0.9, $p = 0.002$) compared with LD-treated early PD subjects. On the other hand, the results of the PDRG-UK study published in 2008 indicated that initial treatment with an agonist may delay the onset of motor complications, but over time, the benefit is not sustained and may be at the expense of therapeutic benefit. Still, other investigators have explored the ability

of dopamine agonists not only to delay the onset of fluctuations but also to reduce them once fluctuations have become established. Some studies have shown that continuous infusions of lisuride or apomorphine with or without low dose LD supplementation can reduce fluctuations and dyskinesia, although blinded studies are lacking. Adverse skin reactions can be expected in a substantial minority of patients using a subcutaneous administration system.

Another promising effort to achieve more continuous dopaminergic stimulation is to deliver LD in novel ways. The controlled release preparation of carbidopa/LD was introduced with the hope that it would smooth motor fluctuations. Studies showed that initial use of the controlled release preparation (versus the regular release formulation) was equally or more effective in delaying the onset of fluctuations. In established fluctuators, however, the results have been mixed. More recently, continuous duodenal or jejunal infusions, which create more steady plasma drug levels, have been reported to reduce OFF time significantly and to possibly reduce dyskinesias, although device problems were not uncommon. Other formulations, including prodrug transdermal species and more reliable controlled release preparations of LD, are also in development.

Catechol-*O*-methyltransferase inhibitors (COMTI) have become established adjunct therapies to prolong the LD effect. This class of medication works by inhibiting the loss of LD peripherally by conversion to an inert compound 3-*O*-methyldopa (3-OMD), thus, allowing more LD to enter the brain. Two inhibitors are available commercially: entacapone and tolcapone. The former is a peripheral inhibitor of COMT; the latter is able to penetrate the CNS and may also inhibit the O-methylation of dopamine, and thus, may, extend its effect. With tolcapone, individuals can rarely develop transaminase elevation and liver failure; therefore, periodic monitoring of liver enzymes is recommended, especially during the initial months of use. Generally, side effects necessitating the discontinuation of COMTI are unusual, but may include diarrhea or a harmless alteration in urine color. More frequently, adverse effects as a result of too much dopaminergic stimulation may occur; thus, it is not unusual to concomitantly reduce the LD dose. A Cochrane review of COMTI concluded that entacapone increased clinically meaningful ON time by $1\,\mathrm{h\,day^{-1}}$, while tolcapone results were approximately twice of that. With repeated doses throughout the day, the peak levels of LD can also rise and result in the problems of excessive dopamine effect if not compensated for by LD dose reductions.

Monoamine oxidase type B (MAO-B) inhibitors, including selegiline and rasagiline, have been investigated for their ability not only to provide benefit against PD symptoms but also to reduce motor fluctuations. The initial hope for MAO-B inhibition was to serve as a neuroprotectant; however, this effect has still not yet been definitively proved, and these medications are currently not FDA approved for this indication. On the other hand, the inhibition of MAO-B has proved beneficial against motor fluctuations, while providing some relief from parkinsonian symptoms.

There are important limitations to these approaches, which cannot be ignored. Not surprisingly, these strategies can be associated with more dopaminergic adverse events such as worsened dyskinesia, orthostasis, sleep disruption, and psychiatric toxicity. Around-the-clock administration of dopaminergic drugs is generally avoided to reduce psychiatric complications, although it has been used successfully in a few patients. Another interesting consideration is that even with continuous administration of drugs like LD or apomorphine, there is NOT complete amelioration of OFF states, even when plasma levels of LD or apomorphine are in the therapeutic range. In addition, there is the question of tolerance developing to continuous dopaminergic stimulation. While the evidence for tolerance to LD is not persuasive in PD subjects, in humans, there is certainly other evidence of tolerance to drugs that alter dopamine levels, for example, cocaine, and also animal evidence of tolerance to long-acting dopamine D-1 agonists. Therefore, to avoid any possibility of developing tolerance to continuous dopaminergic stimulation, it may be beneficial to restrict it to the daytime and if possible, establish a drug-free interval overnight.

While the wide variety of medications to sustain dopaminergic stimulation has been clearly helpful (especially in reducing OFF time), more continuous drug delivery has not eliminated the problem, underscoring the idea that pharmacokinetics alone cannot explain motor fluctuations. A second, more pharmacodynamic approach toward the treatment of motor fluctuations is to improve the trough or OFF motor function.

An interesting phenomenon called the 'long-duration response' (LDR) to LD has been discovered, and in contradistinction to the short-duration response, which in broad terms parallels the plasma level of drug, the LDR builds up over weeks and likewise dissipates slowly. The LDR improves trough function and may partially account for why motor fluctuations are not appreciated early in LD therapy.

Methods to augment the LDR would likely diminish motor fluctuations. Unfortunately, since the underlying mechanisms for the LDR are poorly understood, there have been only few strategies or therapies to address it. Deep brain stimulation (DBS) of the globus pallidus (GP) or the subthalamic nucleus (STN) has been the most important advance that appears to reduce motor fluctuations by augmenting the LDR, or in other words, by improving trough function. In most cases, surgery will reduce the magnitude of fluctuations, and hence, they may be less clinically apparent, keeping in mind that most patients will still require medication for the optimal functioning.

The benefit seen with DBS is due to the reduction of the depth of the OFF symptomatology, or in other words, the shallowing of the troughs. DBS does not increase the peak or ON-benefit of LD, or increase the duration of benefit. In this setting, STN stimulation with its prokinetic effect often results in a reduced medication use and subsequently in less dyskinesia. With GP stimulation, there is a direct antidyskinetic effect in addition to the reduction in motor fluctuations; this effect is less dependent on the reduction in medication intake.

Other means to improve trough motor function remain experimental and utilize neural grafting, neurotrophic factors, and gene therapy.

Conclusion

The problem of motor fluctuations is extremely common in PD treatment. It is critical that the medical provider is aware of and alerted to the appearance of this evolving motor variability, as treatment options are numerous and usually successfully lead to improved patient outcomes and satisfaction. In general, using pharmacokinetic and pharmacodynamic principles, one can try to achieve a smoother overlap of therapeutic cycles to maximize ON time and minimize OFF time by altering LD absorption through the gut and into the brain, retarding the breakdown of synthesized dopamine and by use of other classes of dopaminergic medications or surgery. The advancing fluctuator presents a treatment challenge however, and options become more complex to employ due to the ceiling limitations of dyskinesia and psychiatric and other adverse effects, coupled with the increasing disability associated with deepening OFF periods. Surgery is applicable for some PD patients who have reached the limits of medical optimization.

Motor Impersistence

A L Barba, Albany Medical College, Albany, NY, USA
D S Higgins, Samuel S Stratton VA Medical Center, Albany, NY, USA

Glossary

Anosagnosia – Unawareness of the presence of disease or deficit.
Apraxia – Inability or impaired ability to plan and execute motor acts in the absence of muscle or sensory impairment.
Hemiplegia – Paralysis affecting one side of the body.
Motor impersistence – Inability to sustain a voluntary motor act despite the ability to perform the act briefly.

Definition and History

Coined by Fisher, motor impersistence describes an inability to sustain voluntary motor acts (i.e., eyelid closure or tongue protrusion) despite the ability to briefly perform the act. In his observation of hemiplegic patients, Fisher described an inability to (a) take a deep breath, hold one's breath, or say 'ah' for a prolonged period; (b) exert steady pressure during hand grip; (c) keep the eyes fixed centrally during visual fields testing; (d) hold the eyelids shut; and (e) hold the mouth open or tongue protruded. He also described other gaze disturbances, including conjugate deviation to the side of the lesion, gaze restriction to the hemiplegic side, and inability to maintain steady conjugate gaze.

Fisher viewed impersistence as being akin to the limb kinetic form of apraxia, while others have speculated that symptoms of impersistence reflect a reversion to primitive drives (i.e., maintenance of vigilance and a defensive posture). Joynt and colleagues suggested that motor impersistence represents the oscillation of function typically seen following cerebral damage.

Pathogenesis/Pathophysiology

Available evidence suggests that right hemisphere dysfunction is crucial. In reviewing ten cases with right hemisphere damage, Fisher noted motor impersistence in all, and although four of the ten studied had prior left hemisphere or bihemispheric injury, he suggested that this past damage did not meaningfully affect the syndrome's expression. He viewed cortical injury as vital with variable expression reflecting lesion location.

In 16 patients (15 with right hemisphere lesions and one with bilateral lesions), Berlin found signs of impersistence in all. In 14, right parietal structures were involved. He did not observe impersistence in patients with right hemiplegia.

Kertesz and colleagues compared the performance of 45 acute stroke patients (31 right and 14 left hemisphere, matched for lesion size) and 17 control subjects on 11 tasks assessing motor impersistence. They found that right hemisphere lesions showed significantly more impersistence and suggested an essential role for frontal and central structures.

Although impersistence occurred more often in patients with bilateral or right hemisphere lesions in Joynt's sample, the authors cautioned that evidence did not strongly support localization to the right hemisphere, in contrast to prior opinion.

Contrasting with other authors, Garfield found that pathological impersistence was more common in children with right (75%)-versus-left hemiplegia (20%), although the difference was not statistically significant.

Epidemiology/Risk Factors

As motor impersistence is a symptom not a diagnosis, the underlying disorder defines the epidemiology and risk factors. Many cases reported in the literature result from hemispheric vascular insults. Therefore, factors associated with enhanced stroke risk (i.e., hypertension, dyslipidemia, etc.) need to be considered. Family history modulates risk in Huntington's disease, while antecedent streptococcal infection is important in Sydenham's chorea.

Joynt and colleagues examined impersistence in a sample of 101 patients with hemispheric dysfunction and 74 control subjects. 'Pathological' impersistence (defined performance worse than 97% of controls) was observed in 23% of patients.

In Garfield's sample, when children with hemispheric lesions were compared with a larger normative sample for impersistence, 68% met criteria (as against 3% of uninjured children).

Clinical Features and Diagnostic Criteria

In his sample, Fisher noted an inability to keep the eyelids closed and the tongue protruded as being most central. Left hemiplegics with impersistence were said to show more significant cognitive dysfunction with memory impairment, confusion, and anosagnosia observed in most. In Joynt's sample, motor impersistence was related to mental impairment and a trend was apparent between marked motor impersistence (performance worse than all controls) and advancing age.

Berlin reported an impersistence triad (i.e., an inability to maintain the mouth open, the tongue protruded, and the eyelids closed), but unlike Fisher, orientation and memory were preserved.

Kertesz reported that an inability to maintain the mouth open, tongue protruded, eyelids closed, and gaze fixed right best discriminated right from left hemisphere lesions. A correlation was noted between impersistence and performance on spatial tasks (all patients) and on a measure of apraxia (right hemisphere lesions only).

In Garfield's pediatric sample, there was no apparent relationship between impersistence and age, sex, or IQ.

Differential Diagnosis

In addition to hemispheric injury, motor impersistence is commonly associated with hyperkinetic movement disorders such as Huntington's disease and Sydenham's chorea.

Diagnostic Work-up/Tests

The imaging of the brain is central to the evaluation of motor impersistence to examine hemispheric anatomy and evaluate the integrity of the basal ganglia. Specific testing for Huntington's disease examines CAG repeat number ($\geq$37 CAG repeats) in the huntingtin gene. Immune markers can suggest prior streptococcal infection (i.e., antistreptolysin O titers) in Sydenham's chorea.

Management

The nature of motor impersistence is such that treatment is not usually warranted. This is good, since efforts to treat the dyskinesia have met with limited success. Dopamine receptor antagonists may diminish the frequency and severity with atypical agents being most often prescribed.

Prognosis

Impersistence has been observed acutely but also years after the initial insult. DeRenzi and colleagues studied the incidence of eyelid movement disorders in a large sample of acute stroke patients on ten impersistence tasks. In some cases, the left eye was the only affected, and impersistence persisted 3 months post-stroke in 26% of right hemisphere strokes.

In his sample, Berlin found that with clinical improvement, impersistence of eye closure was often modified; first, the eye on the hemiplegic side (usually the left) would open before the second eye, and the left eye would open only later, and finally both eyes would remain closed for 30 s or more.

When noted in hyperkinetic movement disorders, prognosis is defined by the primary diagnosis. In Huntington's disease, improvement is doubtful, while for Sydenham's chorea resolution is the rule.

Motor Output Variability

E A Christou, Texas A&M University, Collage Station, TX, USA

Glossary

Force variability – The involuntary inconsistency in the force output.
Motor-output variability – The involuntary inconsistency in the output of voluntary muscle contractions.
Noise – Motor-output variability is assumed to be noise superimposed on the motor command at any level of the nervous system (e.g., synaptic noise).
Trial-to-trial variability – The involuntary variability of a motor-output characteristic (e.g., peak force or time to peak force endpoint variability) among different trials.
Within-trial variability – The involuntary inconsistency in the output within a trial (e.g., trajectory variability).

Definition and History

Motor-output variability refers to the involuntary inconsistency in the output of voluntary muscle contractions. The variability in the motor output can be observed within a trial (e.g., trajectory variability) and from trial to trial (e.g., end-point variability). Initial studies on

motor-output variability were performed by Fullerton and Cattell (1892).

It is generally accepted that within-trial and trial-to-trial variability increases with force level; however, most studies suggest that this increase in variability is not proportional to the level of force. In addition to force, the amplitude of motor-output variability is influenced by numerous other factors including the input–output properties of the motor neurons, the muscle group performing the task, the type of contraction performed, and the age of the individual. For example, acute elevations of physiological arousal can increase the gain of input–output relations of the motor neurons and increase the variability in force exhibited by the same individual attempting to maintain a constant force. Similarly, lower limb muscles display greater trial-to-trial variability compared with the upper limb muscles and eccentric contractions exhibit greater within- and between-trial variability compared with isometric and concentric contractions. Finally, a number of studies have focused on the effects of age on motor-output variability. It is generally accepted that the within-trial variability is greater for older adults compared with young adults, especially, for intensity levels lower than 20% of maximum. These age-associated impairments appear to be even greater for trial-to-trial variability. Interestingly, older adults appear to exhibit greater variability in the temporal characteristics of movement (time-to-peak force, impulse duration) than force.

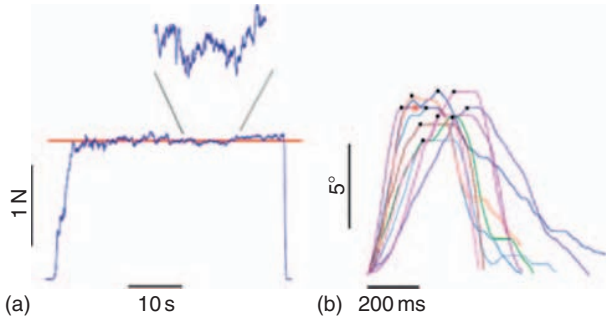

Figure 1 Within-trial and trial-to-trial motor-output variability. The recording on the left (a) demonstrates the involuntary variability in the force output despite the efforts of a young adult to exert a constant isometric contraction with no variations. This variability is dominated by low-frequency oscillations (inset). The recording to the right (b) demonstrates the trial-to-trial variability during goal-directed movements exerted by a young adult. It is evident from the 10 trials graphed that variability exists across trials for both the spatial and time components of movement.

Theoretically, motor-output variability is assumed to be noise superimposed on the motor command at any level of the nervous system. The neural activation of muscle appears to interact with the noisy motor command in the following three ways: first, increased variability in motor unit discharge, which has been shown to be related with synaptic noise, appears to be a major contributor to force variability during constant isometric contractions. Second, changes in the rhythmical discharge of motor units, which has been attributed to oscillatory input from higher centers, can influence the variability of motor performance. Third, increasing coactivation of the antagonist muscles can reduce trajectory variability possibly by minimizing the influence of noise to the antagonist muscles via joint stiffness and damping. Nonetheless, further research is needed to understand the neural mechanisms that contribute to within-trial and trial-to-trial motor-output variability.

Independent of the exact causal mechanisms, the functional significance of motor-output variability is that it can impair the ability of humans to perform accurate movements. Recent findings provide evidence that during aiming isometric contractions, older subjects who exhibit greater trajectory (within-trial) and end-point (trial-to-trial) variability exhibit impaired accuracy in force and time. Therefore, these findings demonstrate that both forms of motor-output variability are strongly associated with functional performance in humans (see **Figures 1** and **2**).

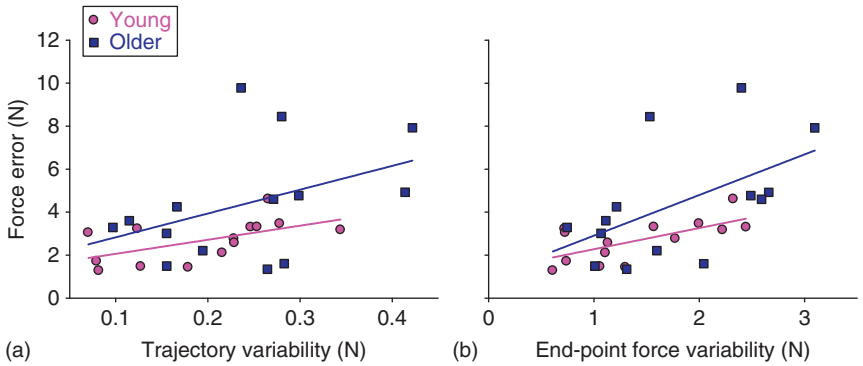

Figure 2 Functional significance of motor-output variability. The variability in the force trajectory (left; within-trial variability) and end-point (right; trial-to-trial variability) is associated with the end-point accuracy of force. In this example, subjects that exerted smoother force trajectories (left) and lower peak force variability (right) exhibited greater end-point accuracy in force. In addition, this example demonstrates the age-associated increases in motor-output variability and the associated impairment in end-point accuracy.

Motor Unit

M Weinberger and J O Dostrovsky, Department of Physiology, University of Toronto, Toronto, ON, Canada

Glossary

α-Motor neurons – Neurons that innervate extrafusal muscle fibers of skeletal muscles to directly control their contraction. Also known as lower motor neurons; they are grouped in nuclei in the anterior horn of the spinal cord or in brainstem nuclei.
Innervation ratio – The number of muscle fibers innervated by a single motor neuron.
Motor unit – A single α-motor neuron together with all the muscle fibers it innervates.
Neuromuscular junction – The synaptic linkage between the axon terminal of a motor neuron and the excitable region (end plate) of the innervated muscle fiber.
Tetanic contraction – A condition of continuous contraction in a skeletal muscle caused by a steady high rate of firing of motor units.

Definition and History

In mammals, each skeletal muscle fiber is innervated by only one motor neuron. An individual motor axon, however, branches to innervate several muscle fibers. Sir Charles Sherrington (1857–1952) was the first to recognize that a single motor neuron and the colony of muscle fibers which it innervates constitute the basic unit of contraction, and in 1925 he coined the term *motor unit* to describe it (**Figure 1**). By definition, all the muscle fibers belonging to a single motor unit contract together. These fibers are always within the same muscle but are generally distributed over a relatively wide area within the muscle to ensure a uniform contraction. Such organization also decreases the probability that damage to one or a few motor neurons will significantly alter the action of a muscle.

The transmission mechanisms in the neuromuscular junction are very similar to those at central synapses. Upon the arrival of an action potential at the axon terminal, voltage-dependent calcium channels open and Ca^{2+} ions flow into the terminal. The influx of Ca^{2+} triggers the exocytosis of neurotransmitter called acetylcholine (Ach) into the synaptic cleft. The Ach then diffuses across the neuromuscular junction to bind at nicotinic receptor sites located on the end plate. These receptors are ligand-gated ion channels so when bound by Ach they open, allowing sodium and potassium ions to flow in and out. This results in a local depolarization of the end plate, which then spreads across the surface of the muscle fiber to trigger muscle contraction. The action of Ach is terminated by the enzyme acetylcholinesterase which hydrolizes the neurotransmitter.

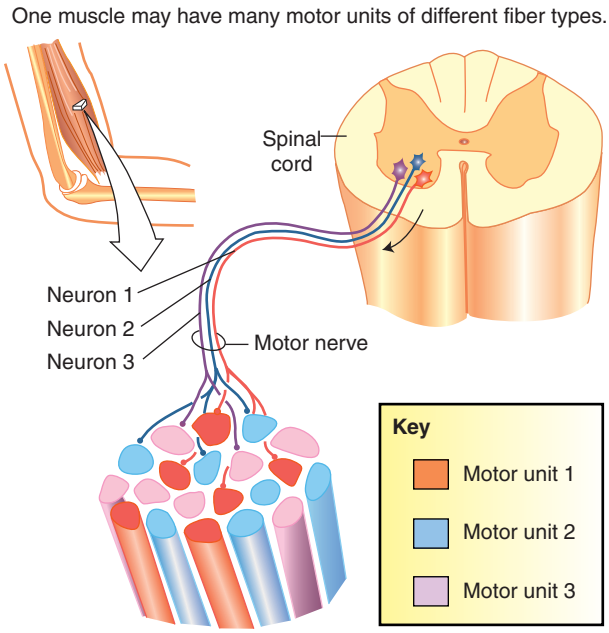

Figure 1 Diagram illustrating the motor unit components.

Innervation Ratio

The number of muscle fibers innervated by a single motor neuron varies across motor unit types and muscles. The variation in innervation ratio is the most significant factor that contributes to differences in motor unit force. A low innervation ratio allows for finer grading of the muscle total force by the nervous system. Thus, muscles used for fine motor control have low innervation ratios (e.g., 5:1 for the lateral rectus muscle of the eye). In these muscles, activation of one motor unit elicits a relatively small response because only a few fibers contract. On the other hand, muscles used for gross motor actions, such as standing or walking, have high innervation ratios (e.g., 2000:1 for the gastrocnemius muscle in the leg).

Types of Motor Units

During embryological development, each motor neuron secretes a growth factor which aids the differentiation of all muscle fibers in their motor unit so that they develop into the same fiber type. Thus, motor units can be categorized according to the physiological and biochemical properties of their muscle fibers. There are three types of motor units: *Slow fatigue-resistant* motor units consist of comparatively small muscle fibers (type I) that contract slowly and generate relatively small forces. These fibers are red due to rich blood supply and myoglobin content. With plentiful mitochondria, they rely exclusively on oxidative metabolism and are highly resistant to fatigue. Slow motor units are important for activities that require sustained muscle contraction, such as the maintenance of upright posture. *Fast fatigable* motor units, on the other hand, consist of larger fibers (type IIb) that contract rapidly and generate the greatest force. Their force is 10–100 fold greater than the force of type I fibers. These fibers are pale due to limited blood supply and have sparse mitochondria. They rely on anaerobic glycolysis and are therefore easily fatigued. Fast fatigable motor units are especially important for brief exertions that require great forces, such as jumping. The third type of motor unit is the *fast fatigue-resistant* that has physiological properties that lie between those of the other two. In this motor unit, the fibers (type IIa) are of intermediate size and are only slightly slower than type IIb fibers. However, because they have more mitochondria and better blood supply, they have greater capacity for oxidative metabolism and are more resistant to fatigue. These fibers can generate about twice as much force as the type I fibers.

All three types of motor units can be found in most muscles, but in different proportions that are appropriate for different muscle functions. For example, slow motor units are prevalent in muscles that participate in motor acts that require sustained effort, such as the soleus muscle that is important for posture.

Regulation of Muscle Force

Although each motor unit in a skeletal muscle contracts in an all-or-none fashion, the nervous system can regulate the contraction force of a muscle. The force produced by a single muscle can be regulated in two ways. The first is *orderly recruitment*. The force of muscle contraction can be increased by recruiting additional motor units. However, the motor units within a muscle are not activated in a random manner. As a general rule, motor units are recruited in the order of their size. When muscle is initially activated, small motor units are the first to be recruited since they require the lowest threshold for activation. When more force is needed, the synaptic input increases in strength to progressively recruit lager motor units. The sequential recruitment of larger motor units results in a smooth increase in muscle force. This principle, known as the *size principle*, is functionally important as it simplifies the task of modulating muscle force by the nervous system. Instead of selecting specific combinations of motor units to produce the needed amount of force, higher brain centers only need to determine the strength of synaptic drive to be delivered to the motor neuron pool as a whole.

The second mechanism for force regulation is *rate coding*. The rate at which motor neurons discharge action potential has a pronounced influence on the force that the motor unit exerts. The contraction and relaxation time for a muscle twitch is much longer than that of an action

potential. Thus, an increase in the frequency of firing allows the forces of successive twitches to summate. This effect is typically characterized by a sigmoidal association between firing frequency and force. For a motor unit, the force–frequency relationship depends on the time course of its twitch response and the quantity of contractile proteins.

In a given motor unit, firing rates stay within a relatively narrow range (about 6–30 Hz). The force that a single motor unit can exert will vary by ~3–15 times when discharge rate is increased from a minimum to a maximum. When the frequency of action potentials is relatively low, successive stimuli activate the fibers only after the peak force of each twitch, in the relaxation phase, so that individual twitches can still be distinguished. This is called *unfused tetanus*. As the firing rate increases the individual twitches merge and can no longer be observed giving rise to a constant increase in force. This is called *fused tetanus*. The muscle as a whole contracts smoothly even in cases of unfused tetanus because individual motor units are activated at different times allowing individual twitches to be averaged out.

Motor Unit Disorders

Damage to or dysfunction of the motor unit due to genetic or acquired (e.g., toxic, traumatic, infectious) conditions can result in various disorders. The distinctive features of these disorders vary depending on which of the functional components of the motor unit is primarily affected. Disorders that primarily affect the cell body of the motor neurons or its axon are classified as *neurogenic* diseases. In these diseases, death of motor neurons results in the associated denervated muscle fibers becoming spontaneously active (termed fibrillation), and the muscle gradually becomes weak and wasted. The axons of the remaining motor neurons give off small branches that innervate some of the denervated muscle fibers, resulting in an increased innervation ratio of the surviving motor units. In addition, visible muscle twitches (fasciculations) can occur resulting from spontaneous activity of motor neurons. Changes in reflexes (e.g., tendon reflexes) may also be observed. Dysfunction of the neuromuscular junction can also occur and lead to impaired motor unit function (e.g., myasthenia gravis).

Disorders that mainly affect the muscle fibers are called *myopathic* diseases. The main symptoms of myopathic diseases (e.g., muscular dystrophies) are due to weakness of the skeletal muscle which often includes difficulty in walking or lifting. Other infrequent symptoms include myotonia (inability of the muscle to relax), cramps, and pain. In these diseases, the number of muscle fibers in each motor unit is reduced, but there is no change in the number of motor units firing during a contraction.

Motor Unit Synchronization

M Weinberger and J O Dostrovsky, Department of Physiology, University of Toronto, Toronto, ON, Canada

Glossary

Electromyography (EMG) – A technique for recording muscle signals in order to evaluate the activation of a muscle. EMG is performed using surface electrodes to record the electrical activity generated by muscle fibers both at rest and during contraction.

Intramuscular recordings – A technique for recording the action potentials of muscle fibers using fine-wire electrodes that are inserted into the muscle. Intramuscular recordings are often used in nerve

conduction studies involving deep or proximal muscles and in other electrodiagnostic tests.

α-Motor neurons – Neurons that innervate extrafusal muscle fibers of skeletal muscles to directly control their contraction. Also known as lower motor neurons; they are grouped in nuclei in the anterior horn of the spinal cord or in brainstem nuclei.

Motor unit synchronization – The simultaneous or near-simultaneous discharge of motor units that occurs more often than would be expected by chance.

Motor unit – A single α-motor neuron together with all the muscle fibers it innervates.

Neuromuscular junction – The synaptic linkage between the axon terminal of a motor neuron and the excitable region (end plate) of the innervated muscle fiber.

Measurement of Motor Unit Synchronization

The excitability of motor neurons can be measured in humans by inserting fine-wire electrodes into the muscle and recording the action potentials of the muscle fibers belonging to the same motor unit (intramuscular recordings). This technique provides a reliable indication of the firing properties of the motor neuron due to the high synaptic efficacy at the neuromuscular junction, where an action potential in a motor neuron will consistently produce an action potential in its associated muscle fibers. Synchronization between motor neurons can be consequently quantified by time- and frequency-domain analyses of the discharge times of pairs of motor units.

The most direct method to measure the level of motor unit synchronization in human is by cross-correlation of discharge times from pairs of concurrently active motor units, where the discharge times of one motor unit are used as a reference, and a histogram is constructed based on the perievent discharge times of the second motor unit. In case of a tendency toward synchronization, a peak in the cross-correlation histogram is observed. Theoretically, if there is no difference in conduction velocities between the two motor neurons, the cross-correlation peak will be centered around time zero, which is the time of firing of the reference motor unit. The size of the central peak in the cross-correlation histogram is proportional to the strength of the common input to the two motor neurons.

Additional information about the properties of the shared input responsible for motor unit synchronization can be acquired from coherence analysis, the frequency-domain equivalent measure of cross-correlation. While cross-correlation approximates the strength of the shared input between the two motor neurons, coherence also provides its frequency when the synchronization varies periodically in time. For example, when applied to human hand muscle, significant coherence was detected between pairs of motor units at frequencies of 1–12 and 16–32 Hz during isometric abduction of the index finger. The presence of coherence between motor unit pairs indicates common periodicity at the presynaptic input.

Mechanisms of Motor Unit Synchronization

The most widely accepted explanation for motor unit synchronization is that branched inputs delivered by presynaptic neurons at the level of the spinal cord generate a common input that increases the probability of simultaneous discharge in the motor neurons sharing this input. It is important, however, to note that such input can be responsible only for 'short-term' synchronization, which is characterized by a narrow central peak in the cross-correlation histogram with duration of less than 10 ms. Based on the models of branched-axon input, direct common input is likely to evoke action potentials that occur within a few milliseconds of each other. Thus, central peaks with broader durations must involve indirect common inputs to the motor neurons via interneurons that are themselves synchronized by a common input. This type of synchronization is termed as 'broad-peak' synchronization. In most human studies, the duration of the central peak varies between 10 and 20 ms, perhaps reflecting a combination of these two forms of input.

Several observations in humans suggest that short-term synchronization is likely to be generated by branched input from supraspinal centers. For example, in patients with sporadic amyotrophic lateral sclerosis, a progressive degenerative disorder that involves the loss of large diameter corticospinal neurons and decreased conduction velocity of the surviving axons, almost no motor unit synchronization could be detected in the dominant extensor carpi radialis muscle. This is in contrast to strong synchronization normally seen in healthy subjects. Another interesting study was conducted on a patient with Klippel–Feil syndrome, who had abnormally branched, fast-conducting corticospinal tract fibers that projected to motor neuron pools bilaterally. In this patient, peculiar synchronization was detected between motor units from the two hands – a phenomenon that was never observed in normal subjects. These studies suggest that branched corticospinal axons are an important cause of short-term synchrony in motor units. Conversely, strong vibration of a hand muscle, which is known to activate muscle spindle afferents, has no effect

on the strength of motor unit synchronization, indicating that peripheral afferents are unlikely to contribute to its generation.

It is important, however, to note that the branched common input theory fails to account for certain observations. In 1993, De Luca and colleagues reported the existence of 'long-term' synchronization that, compared to short-term synchronization, is characterized by lower amplitude peaks that are centered at long latencies ranging from 8 to 76 ms. These long latencies of synchronization cannot be explained by common presynaptic branches, considering the conduction velocity differences and the distances involved. An alternative mechanism is that such synchronization might be the product of synchronous oscillatory activity of the pairs of cortical neurons that synapse on two or more motor neurons. Indeed, activities that are likely to involve synchronized oscillations in higher order neurons, such as attention-demanding tasks, are often accompanied by increased motor unit synchronization. Motor cortical neurons themselves can also be synchronized. This is particularly evident during precision tasks or following training.

Functional Significance of Motor Unit Synchronization

It was initially postulated that synchronization of motor-units can temporarily increase the force generated by the muscle due to a superposition of motor-unit force twitches. However, several studies failed to find a relation between the level of synchronization and net force output, and this hypothesis remains controversial. Nevertheless, this does not indicate that motor unit synchronization does not have a significant physiological function. Various studies have demonstrated that the level of motor unit synchronization can be altered significantly depending on the task conditions. For example, correlated motor unit activity can be altered in human limb muscles during the performance of an action that requires significant attention, or during the changes in muscle length (lengthening vs. shortening contraction). In addition to the task-related changes, it has been shown that certain types of exercise can alter motor unit synchronization. In 1975, Milner-Brown and colleagues carried out one of the earliest and most influential studies on the functional role of motor unit synchronization in the control of movement. They found that weight lifters exhibited greater motor unit synchronization in the first dorsal interosseus muscle than the control subjects. Their study also demonstrated an increase in synchronization following 6 weeks of strength-training program in control subjects. It was therefore suggested that supraspinal inputs from motor cortex directly to spinal motor neurons are enhanced as a result of training to the point where they produce a significant synchronization of motor units. However, this study utilized an indirect method in which averaging the surface electromyography (EMG) signal with respect to motor unit discharge provided a global estimate of synchronization, and the validity of this technique has been challenged.

In a later study, Semmler and Nordstrom (1998) used the more direct method of cross-correlation of motor unit discharges, to compare motor unit synchronization between highly trained musicians, weight lifters, and untrained subjects. Similar to the earlier Milner-Brown et al. findings, strength-trained weight lifters displayed the highest level of synchronization in both hands during a simple index finger abduction task. Furthermore, the amount of motor unit synchronization was lowest in both hands of the musicians and the dominant hand (usually used for skilled movements) of untrained subjects. These findings further support the idea that motor unit synchronization may be a form of adaptation that occurs as a consequence of strength training, allowing for greater force production. However, in a more recent study carried out by the same group, it was shown that significant increases in strength of a hand muscle after several weeks of training were not accompanied by alterations in motor unit synchronization, suggesting that correlated motor unit activity is not important for the expression of muscle strength. Alternatively, the divergent level of motor unit synchronization observed in weightlifters and musicians might reflect reduced motor unit synchronization due to long-term skill training, rather than an increase in synchrony that is caused by strength training. It has been therefore suggested that the weak motor unit synchronization in musicians might reflect a neural adaptation that occurs to lower the strength of common inputs to motor neurons in order to promote the accurate performance of skilled tasks.

Although increased motor unit synchronization is not directly associated with the development of muscle strength, it has been shown to contribute to larger force fluctuations and to increase the rate of force development during rapid contraction. In addition, motor unit synchronization has been implicated in the coordination of the activity of multiple muscles. Evidence for this view comes from cross-correlation analysis of single motor units related to functionally linked, but anatomically distinct muscles. For example, motor unit synchronization has been shown to exist between left and right masseter muscles during jaw clenching and left and right rectus abdominus muscles during trunk curl, but not for the coactivation of homologous muscles of the left and right upper limbs. The functional significance of the motor unit synchronization may therefore lie in the selection and activity of common inputs between muscles. It is possible that the increase in motor unit synchronization observed in a single muscle of weightlifters may also reflect increased common inputs between muscles. This might be a nervous system adaptation to facilitate the

coactivation of many muscles to produce force rapidly. Conversely, the weaker synchronization in musicians may reflect minimal common inputs between muscles to promote independent and skilled muscle synergies.

Movement Disorders: Overview

S Fahn, Columbia University College of Physicians & Surgeons, New York, NY, USA

Glossary

Basal ganglia – The basal ganglia are that group of gray matter nuclei lying deep within the cerebral hemispheres (caudate, putamen, and pallidum), the diencephalon (subthalamic nucleus), and the mesencephalon (substantia nigra).
Dyskinesia – Abnormal, unnatural movement.
Hyperkinesias – Involuntary movements where there is an excess of movement.
Hypokinesias – Involuntary movements where there is a paucity or poverty of movement.

Definitions

Movement disorders are neurological syndromes in which there is either an excess of movement or a paucity of voluntary and automatic movements, unrelated to weakness or spasticity. The former are commonly referred to as hyperkinesias (excessive movements), dyskinesias (unnatural movements), and abnormal involuntary movements). These terms are used interchangeably. The five major categories of dyskinesias, in alphabetical order, are chorea, dystonia, myoclonus, tics, and tremor. The list of the hyperkinetic disorders is presented in **Table 1**.

The syndromes with a paucity of movement are referred to as hypokinesias (decreased amplitude of movement), bradykinesias (slowness of movement), and akinesias (loss of movement), and these terms are also used interchangeably. The list of the hypokinetic diosorders is presented in **Table 2**. The parkinsonian syndromes comprise the vast majority of such paucity of movement. Other hypokinetic disorders represent only a small group of patients.

Conveniently, movement disorders can be divided into parkinsonism and all other types. There are about an equal number of patients in each of these two groups,

Table 1 Hyperkinetic disorders

as seen from the perspective of movement disorder specialty clinics. It should be noted that this listing is merely a categorization of movement phenomenolgy and not etiology. There are usually multiple etiologies for each of them, including a psychogenic etiology.

Neurologists, neurosurgeons, and nurses who specialize in these disorders are known as movement disorder specialists; their international professional society is The Movement Disorder Society, Inc. (www.movementdisorders.org), which holds annual meetings and publishes a scholarly journal that includes videotape demonstrations of various conditions.

The Origins of Abnormal Movements

Most movement disorders originate within the central nervous system (CNS), particularly the basal ganglia or their connections. The basal ganglia are that group of gray matter nuclei lying deep within the cerebral hemispheres (caudate, putamen, and pallidum), the diencephalon (subthalamic nucleus), and the mesencephalon (substantia nigra). There are some exceptions to this general rule. Pathology of the cerebellum or its pathways typically results in an impairment of coordination (asynergy, ataxia), misjudgment of distance (dysmetria), and intention tremor. Myoclonus and some forms of tremors do not appear to be related primarily to basal ganglia pathology, and often arise elsewhere in the CNS, including cerebral cortex (cortical reflex myoclonus), brainstem (cerebellar outflow tremor, reticular reflex myoclonus, hyperekplexia, and rhythmical brainstem myoclonus such as palatal myoclonus and ocular myoclonus), and spinal cord (rhythmical segmental myoclonus and nonrhythmic propriospinal myoclonus). The peripheral nervous system can give rise to abnormal movements also, such as the moving toes-painful legs syndrome. It is not known for certain which part of the brain is associated with tics, although the basal ganglia and the limbic structures have been implicated. Certain localizations within the basal ganglia are classically associated with specific movement disorders: substantia nigra – bradykinesia and rest tremor; subthalamic nucleus – ballism; caudate nucleus – chorea; and putamen – dystonia.

Evaluation of a Dyskinesia

Not all postures and movements should be considered abnormal and therefore a movement disorder. One must consider whether the suspected movements might be purposeful voluntary movements, such as exaggerated gestures, mannerisms, or compulsive movements, or whether sustained contracted muscles might be physiologic reflex muscle tightness to reduce pain, so-called guarding. It should also be noted that, as a general rule, abnormal involuntary movements are exaggerated with anxiety and stress, and most diminish or disappear during sleep. They may or may not lessen with amobarbital or with hypnosis.

Once it has been decided that abnormal movements are present, the next question is to determine the category of the involuntary movement, such as chorea, dystonia, myoclonus, tics, and tremor. To do so, one evaluates features such as rhythmicity, speed, duration, pattern (e.g,. repetitive, flowing, continual, paroxysmal, diurnal), induction (i.e., stimuli-induced, action-induced, exercise-induced), complexity of the movements (complex vs. simple), suppressibility by volitional attention or by sensory tricks, and whether the movements are accompanied by sensations such as restlessness or the urge to make a movement that can release a built up tension.

After the type of hyperkinesia is determined, the neurologist then tries to determine their etiology, namely, whether the movement disorder is hereditary, sporadic, or secondary to some known neurological disorder. As a general rule, the etiology can be ascertained on the basis of the history and judicially selected laboratory tests. Once the type of disorder and its etiology have been determined, the neurologist determines how best to treat it.

Phenomenology of Hyperkinesias (as listed in Table 1)

Abdominal Dyskinesias

Abdominal dyskinesias are continuous movements of the abdominal wall or sometimes the diaphragm. The movements persist, and their sinuous, rhythmic nature has led to their being called belly dancer's dyskinesia. They may be associated with abdominal trauma in some cases, and a common result is segmental abdominal myoclonus. Another common cause is tardive dyskinesia. Hiccups, which is regularly recurring diaphragmatic myoclonus, does not move the abdomen and umbilicus in a sinewy fashion, but with sharp jerks and typically with noises as air is expelled by the contractions, and hence should not present a problem in diagnosis.

Akathitic Movements

Akathisia (from the Greek, meaning unable to sit still) refers to a feeling of inner, general restlessness, which is reduced or relieved by moving about. The typical akathitic patient, when sitting, may caress his scalp, cross and uncross his legs, rock his trunk, squirm in the chair, get out of the chair often to pace back and forth, and may even make noises such as moaning. Akathisia can be generalized or focal; the latter often produces a sensation of burning or pain, again relieved by moving that body part. Common sites for focal akathisia are the mouth and vagina.

The most common cause of akathisia is iatrogenic. It is a common complication of antidopaminergic drugs, including those that block dopamine receptors (such as antipsychotic drugs) and those that deplete dopamine (such as reserpine and tetrabenazine). Akathisia can occur when drug therapy is initiated (acute akathisia), subsequently with the emergence of drug-induced parkinsonism, or after chronic treatment (tardive akathisia). Acute akathisia is eliminated upon withdrawal of the medication. Tardive akathisia is usually associated with the syndrome of tardive dyskinesia. Like tardive dyskinesia, tardive akathisia is aggravated by discontinuing the neuroleptic.

Asynergia/Ataxia/Dysmetria

Asynergia or dyssynergia refers to decomposition of movement due to breakdown of normal coordinated execution of a voluntary movement. It is one of the cardinal clinical features of cerebellar disease or of lesions involving the pathways to or from the cerebellum. Instead of a smooth, continuous movement; the limb wanders off its trajectory attempting to reach a target, with corrective maneuvers that resemble oscillations of the limb. The limb usually misses the target (dysmetria). Ataxia of gait is typified by unsteadiness on walking with a wide base, the body swaying, and an inability to walk on tandem (heel-to-toe). Asynergia of a limb is also called limb ataxia.

Athetosis

Athetosis has been used in two senses: (1) to describe a class of slow, writhing, continuous, involuntary movements and (2) to describe the syndrome of athetoid cerebral palsy. This syndrome commonly occurs as a result of injury to the basal ganglia in the prenatal or perinatal period or during infancy. When producing abnormal posture, athetosis blends with dystonia. When the speed of athetosis is high, it blends with those of chorea, and the term choreoathetosis is used. Pseudoathetosis refers to distal athetoid movements of the fingers and toes due to loss of proprioception, which can be due to sensory deafferentation (sensory athetosis) or due to central loss of proprioception.

Ballism

Ballism refers to very large amplitude choreic movements of the proximal parts of the limbs, causing flinging and flailing limb movements. Ballism is most often unilateral, which is referred to as hemiballism. This is often the result of a lesion in the contralateral subthalamic nucleus or its connections, or to multiple small infarcts (lacunes) in the contralateral striatum.

Chorea

Chorea refers to involuntary, irregular, purposeless, nonrhythmic, abrupt, rapid, unsustained movements that seem to flow from one body part to another. A characteristic feature of chorea is that the movements are unpredictable in timing, direction, and distribution (i.e., random). The prototypical choreic movements are those seen in Huntington's disease, in which the brief and rapid movements are irregular and occur randomly as a function of time. In Sydenham chorea and in the withdrawal emergent syndrome, the movements have a restless-like appearance.

Choreic movements can be partially suppressed, in which the movements are incorporated into semipurposeful movements, known as parakinesia. Chorea is usually accompanied by motor impersistence ('negative chorea'), the inability to maintain a sustained contraction. A common symptom of motor impersistence is the dropping of objects. Motor impersistence is detected by examining for the inability to keep the tongue protruded and by the presence of the 'milk-maid' grip due to the inability to keep the fist in a sustained tight grip.

Dystonia

Dystonia refers to twisting movements that tend to be sustained at the peak of the movement, are frequently repetitive, and often progress to prolonged abnormal postures. In contrast to chorea, dystonic movements

repeatedly involve the same group of muscles, that is, they are patterned. Agonist and antagonist muscles contract simultaneously (cocontraction) to produce the sustained quality of dystonic movements. The speed of the movement varies widely from slow (athetotic dystonia) to shock-like (myoclonic dystonia).

When dystonia first appears, the movements typically occur when the affected body part is carrying out a voluntary action (action dystonia) and are not present when that body part is at rest. With the progression of the disorder, dystonic movements can appear at distant sites (overflow) when other parts of the body are voluntarily moving, such as occurs also in athetosis and in dopa-induced dyskinesias. With further progression, dystonic movements become present when the body is 'at rest.' Even at this stage, dystonic movements are usually made more severe with voluntary activity. Primary dystonia often begins as action dystonia and may persist as the kinetic (clonic) form, whereas secondary dystonia often begins as sustained postures (tonic form). Rarely, primary dystonia can appear initially at rest and clears when the affected body part or some other part of the body is voluntarily active; this type has been called paradoxical dystonia.

One of the characteristics and almost unique features of dystonic movements is that they can often be diminished by tactile or proprioceptive 'sensory tricks' (geste antagoniste). Thus, touching the involved body part or an adjacent body part can often reduce the muscle contractions.

When a single body part is affected, the condition is referred to as focal dystonia. Common forms of focal dystonia are spasmodic torticollis (cervical dystonia), blepharospasm (upper facial dystonia), and writer's cramp (hand dystonia). The involvement of two or more contiguous regions of the body is referred to as segmental dystonia. Generalized dystonia indicates the involvement of one or both the legs, the trunk, and some other part of the body. Multifocal dystonia involves two or more regions, not conforming to segmental or generalized dystonia. Hemidystonia refers to the involvement of the arm and leg on the same side.

Sustained contractions of ocular muscles, resulting in tonic ocular deviation, usually upward gaze, is referred to as oculogyric crisis. It is most common today as a complication of dopamine receptor blocking agents. Paroxysmal tonic upgaze can be seen in infants and children and often eventually subsides.

In contrast to this continual type of classical torsion dystonia, a variant of dystonia also exists in which the movements occur in attacks, with a sudden onset and limited duration – known as paroxysmal kinesigenic dyskinesias (PKDs) and paroxysmal nonkinesigenic dyskinesias (PNKDs). These are categorized among the paroxysmal disorders (see below). Among the other disorders to be differentiated from dystonia are tonic tics (also called dystonic tics), which also appear as sustained contractions.

Hemifacial Spasm

Hemifacial spasm, as the name indicates, refers to unilateral facial muscle contractions. Generally, these are continual rapid, brief, repetitive spasms, but can also be more prolonged sustained tonic spasms, mixed with periods of quiescence. Often the movements can be brought out when the patient voluntarily and forcefully contracts the facial muscles; when the patient then relaxes the face, the involuntary movements appear. The disorder involves the facial nerve, and sometimes it is due to compression of the nerve by an aberrant blood vessel.

Hyperekplexia

Hyperekplexia ('startle disease') is an excessive startle reaction to a sudden, unexpected stimulus. The startle response can be either a short 'jump' or a more prolonged tonic spasm causing falls. This condition can be familial or sporadic.

Hypnogenic Dyskinesias

Most dyskinesias disappear during deep sleep, although they may emerge during light sleep. The major exception is symptomatic rhythmical oculo-palatal myoclonus, which persists during sleep, in addition to being present while the patient is awake. There are, however, a few movement disorders that are present only when the patient is asleep. The most common hypnogenic dyskinesia is the condition known as periodic movements in sleep. They appear as slow flexor contractions of one or both legs, with dorsiflexion of the big toe and the foot, and flexion of the knee and hip. They occur in intervals, approximately every 20 s. Periodic movements in sleep are a frequent component of the restless legs syndrome.

Another rare nocturnal dyskinesia is hypnogenic paroxysmal dystonia or other dyskinesias that occur only during sleep. Hypnogenic dystonia can be complex and with sustained contractions, similar to that occurring in torsion dystonia. As depicted in its name, such movements occur as a paroxysm during sleep and last only a few minutes. They may or may not awaken the patient. Some may be frontal lobe seizures.

Jumping Disorders

Jumping disorders are similar-appearing syndromes with names like Jumping Frenchmen of Maine, latah, myriachit, and Ragin Cajun. The names were coined for the ethnic groups in different parts of the world, although their clinical features are similar. All of these appear to be influenced by social and group behavior. After the initial jump to the unexpected stimulus, there is automatic speech or behavior, such as striking out. In some of these, there is automatic obedience to words as 'jump' or 'throw.'

Jumpy Stumps

Jumpy stumps are uncontrollable and sometimes exhausting chaotic movements of the stump remaining from amputated limbs. When they occur, it is after a delayed period of time after the amputation.

Moving Toes and Fingers

The painful legs, moving toes syndrome refers to a disorder in which the toes of one foot or both feet are in continual flexion-extension with some lateral motion, associated with a deep pain in the ipsilateral leg. The constant movement has a sinusoidal quality. The movements and pain are continuous, and both occur even during sleep, although they may be reduced and the normal sleep pattern may be altered. The leg pain is much more troublesome to the patient than are the constant movements. In some patients with this disorder, there is evidence for a lesion in the lumbar roots or in the peripheral nerves. An analogous disorder, 'painful arm, moving fingers,' has also been described.

Myoclonus

Myoclonic jerks are sudden, brief, shock-like involuntary movements caused by muscular contractions (positive myoclonus) or inhibitions (negative myoclonus). The most common form of negative myoclonus is asterixis, which commonly accompanies various metabolic encephalopathies. In asterixis, the brief flapping of the outstretched limbs is due to a transient inhibition of the muscles that maintain posture of those extremities.

Myoclonus can appear when the affected body part is at rest or when it is performing a voluntary motor act, so-called action myoclonus. Myoclonic jerks are usually irregular (arrhythmic), but can be rhythmical (such as in palatal myoclonus or in ocular myoclonus, with a rate of $\sim$2 Hz). Rhythmical ocular myoclonus due to a lesion in the dentato-olivary pathway needs to be distinguished from arrhythmic and chaotic opsoclonus or dancing eyes. Rhythmic myoclonus is typically due to a structural lesion of the brainstem or spinal cord (therefore also called segmental myoclonus), but not all cases of segmental myoclonus are rhythmic, and some types of cortical epilepsia partialis continua can be rhythmic. Oscillatory myoclonus is depicted as rhythmic jerks that occur in a burst and then fade. Spinal myoclonus, in addition to presenting as segmental and rhythmical, can also present as flexion axial jerks triggered by a distant stimulus that travels via a slow-conducting spinal pathway, and called propriospinal myoclonus. Respiratory myoclonus can be variable and has been called diaphragmatic flutter and diaphragmatic tremor.

Myoclonic jerks occurring in different body parts are often synchronized: a feature that may be specific for myoclonus. The jerks can often be triggered by sudden stimuli such as sound, light, visual threat, or movement (reflex myoclonus). Myoclonus has a relationship to seizures in that both seem to be the result of hyperexcitable neurons.

Action or intention myoclonus is often encountered after cerebral hypoxia-ischemia (Lance–Adams syndrome) and with certain degenerative disorders, such as progressive myoclonus epilepsy (Unverricht–Lundborg disease) and progressive myoclonic ataxia (Ramsay Hunt syndrome). In the opsoclonus–myoclonus syndrome, originally described by Kinsbourne and subsequently called both 'dancing eyes, dancing feet' and 'polymyoclonia' by Dyken and Kolar, the amplitude of the myoclonus is usually very tiny, resembling irregular tremors. Because of the small amplitudes of the continuous, generalized myoclonus, these are called minipolymyoclonus.

Myokymia

Myokymia is a fine persistent quivering or rippling of muscles. Electromyography reveals regular groups of motor unit discharges, especially doublets and triplets, occurring with a regular rhythmic discharge. Myokymia occurs most commonly in facial muscles. Most facial myokymias are due to pontine lesions, particularly multiple sclerosis, and less often due to pontine glioma. Myokymia is also a feature of neuromyotonia (see stiff muscles, below). Myokymia can persist during sleep.

Myorhythmia

The term, myorhythmia, has been used in different ways over time. Herz used it to refer to the rhythmical movements seen in patients with torsion dystonia. Today, this is recognized as a patterned feature of dystonic movements and not as a separate phenomenon. Monrad-Krohn and Refsum and Masucci et al. used the term myorhythmia to label what is called rhythmical myoclonus today, such as palatal myoclonus. Fahn and Jankovic advocate using the term to represent a somewhat low frequency ($<$3 Hz), prolonged, rhythmical or repetitive movement, in which the movement does not have the sharp square wave appearance of a myoclonic jerk. Therefore, it would not apply to palatal myoclonus. Myorhythmia would also not be applied to the sinusoidal cycles of most tremors (parkinsonian, essential, cerebellar), because the frequency of these tremors is higher than what is defined for myorhythmia.

The most typical disorder in which the term myorhythmia is applied is in Whipple disease, in which there are slow-moving, repetitive, synchronous, rhythmical contractions in ocular, facial, masticatory, and other muscles, so-called oculo-facio-masticatory myorhythmia. The abnormal movements of facial and masticatory muscles can persist in sleep.

Paroxysmal Dyskinesias

The paroxysmal dyskinesias represent various types of dyskinetic movements, particularly choreoathetosis and dystonia, that occur 'out-of-the-blue' and then disappear after being present for seconds, minutes, or hours. The patient can remain normal for months between attacks, or there can be many attacks per day.

PKD is the best described and easiest to diagnose, because it is characteristically triggered by a sudden movement, and the abnormal movements last only seconds to a few minutes. PKD can be hereditary or symptomatic and is usually successfully treated with anticonvulsants. The abnormal movements easily habituate, that is, they fail to recur if the sudden movement is immediately repeated. These movements can be dystonic, ballistic, and choreic. There may be many brief paroxysmal bursts of movements each day.

PNKD can be familial, sporadic, or symptomatic; is triggered by stress, fatigue, caffeine, or alcohol; and can last minutes to hours. Sporadic PNKD is more often a psychogenic movement disorder, particularly if it is a combination of both paroxysmal and continual dystonias.

Paroxysmal exertional dyskinesia (PED) can be due to glucose transporter 1 deficiency or can be sporadic. The attacks of dyskinesias occur about 30 min after exercising.

When the paroxysmal dyskinesias consist of ataxia or tremor, they have been called episodic ataxias and tremors. They are usually familial, and may include vestibular signs and symptoms.

Restless Legs

The term restless legs syndrome refers to more than just the phenomenon of restless legs, where the patient has unpleasant crawling sensations in the legs, particularly when sitting and relaxing in the evening, which then disappear on walking. The complete syndrome consists of several parts, in which one or more may be present in any individual. While the unpleasant dysesthesias in the legs are the most common symptom, the clinical spectrum may also include periodic movements in sleep (see hypnogenic dyskinesias), myoclonic jerks, more sustained dystonic movements, or stereotypic movements that occur while the patient is awake, particularly in the late evening.

Stereotypy

Stereotypy refers to coordinated movements that repeat themselves continually and identically. However, there may be long periods of minutes between movements, or they may be very frequent. When they occur at irregular intervals, stereotypies may not always be easily distinguished from motor tics (see below), compulsions, gestures, and mannerisms. In their classic monograph on tics, Meige and Feindel distinguished between stereotypies and motor tics by describing the latter as acts that are impelling but not impossible to resist, whereas the former, while illogical, are without an irresistible urge. Stereotypies typically occur in patients with tardive dyskinesia and with schizophrenia, mental retardation, and autism.

Compulsions are repetitive, purposeless, usually complex movements seen in patients with obsessive-compulsive disorder (OCD). They are associated with an irresistible urge to make the movement. Patients realize they are making the movements in response to this 'need to do so.' In this respect, compulsions resemble tics, and not stereotypies, which are not accompanied by any urge. Like stereotypies, compulsions could be carried out in a uniform repetitive fashion for long periods of time, but do so at the expense of all other activities because compulsions may be impossible to stop. In contrast, stereotypies can usually be stopped on command, and the patient will have normal motor behavior until they start up again, usually as soon as the patient is no longer paying attention to the command.

Gestures are culturally developed, expressive, voluntary movements calculated to indicate a particular state of mind and which may also be used as a means of adding emphasis to oratory. Mannerisms are sets of movements that include gestures plus more peculiar and individualistic movements not considered as bothersome. Mannerisms can be considered to represent a type of motor signature that individualizes a person. Sometimes mannerisms can be bizarre, and these could be considered as tics or on the borderline with tics. Since gestures and mannerisms rarely continually repeat themselves, they would not likely be confused with stereotypies, but they may have problems at times being distinguished from tics.

Tics

Tics consist of abnormal movements (motor tics) or abnormal sounds (phonic tics). When both types of tics are present, the designation of Gilles de la Tourette syndrome or Tourette syndrome is commonly applied. Tics vary in severity over time and can have remissions and exacerbations.

Motor and phonic tics can be simple or complex and occur abruptly for brief moments from a background of normal motor activity. Thus, they are paroxysmal in occurrence unless so severe as to be continual. A single simple motor tic may be impossible to distinguish from a myoclonic or choreic jerk; each of these would be an abrupt, sudden, isolated movement. Examples include a shoulder shrug, head jerk, blink, dart of the eyes, and twitch of the nose. Most of the time such simple tics are repetitive, such as a run of eye blinking or a sequence of several simple tics in a row. In this more complex pattern, tics can be easily distinguished from the other

hyperkinesias. Even when tics are simple jerks, more complex forms of tics may also be present in the same patient, allowing one to establish the diagnosis by 'the company it keeps.' One type of simple tic is quite distinct, namely ocular. Eye movements are not a feature of chorea or myoclonus, but are common in tics.

Complex motor tics are very distinct, consisting of coordinated patterns of sequential movements that can appear in different parts of the body and are not necessarily identical from occurrence to occurrence in the same body part. Examples of complex tics include such acts as touching the nose, touching other people, head shaking with shoulder shrugging, kicking of legs, and jumping. Obscene gesturing (copropraxia) is another example.

Like akathitic movements, tics are usually preceded by an uncomfortable feeling or sensory urge that is relieved by carrying out the movement, that is, like 'scratching the itch.' Thus, the movements and sounds can be considered 'unvoluntary.' Unless very severe, tics can be voluntarily suppressed for various periods of time, but when suppressed, inner tension builds up and is only relieved by an increased burst of more tics.

Tics can vary in speed, from being as rapid as myoclonic jerks to being slow and sustained contractions, resembling dystonic movements. The complex sequential pattern of muscular contractions in dystonic tics makes the diagnosis obvious in most cases. Moreover, torsion dystonia is a continual hyperkinesia, whereas tics are paroxysmal bursts of varying duration.

Phonic tics can range from simple throat-clearing sounds or grunts to verbalizations and the utterance of obscenities (coprolalia). Sniffing can also be a phonic tic, involving nasal passages rather than the vocal apparatus. Like motor tics, phonic tics can also be divided into simple and complex. Throat-clearing and sniffing represent simple phonic tics, whereas verbalizations are considered complex phonic tics.

Tremor

Tremor is an oscillatory, usually rhythmical and regular, movement affecting one or more body parts, such as the limbs, neck, tongue, chin, or vocal cords. Jerky, irregular 'tremor' is usually a manifestation of myoclonus. Tremor is produced by rhythmic alternating or simultaneous contractions of agonists and antagonist muscles. The rate, location, amplitude, and constancy vary depending on the specific type of tremor and its severity. It is helpful to determine whether the tremor is present at rest (with the patient sitting or lying in repose), with posture-holding (with the arms or legs extended in front of the body), with action (such as writing or pouring water), or with intention maneuvers (such as bringing the finger to touch the nose). Tremors can, thus, be classified as tremor-at-rest, postural tremor, action tremor, or intention tremor, respectively. Some tremors may be present only during a specific task (such as writing) or with a specific posture, such as standing as in orthostatic tremor. These are called task-specific or position-specific tremors, respectively, and may overlap with task-specific and position-specific action dystonias, which may also appear as tremors (dystonic tremor). Etiologies and treatment of tremors differ according to the type of tremor phenomenology it fits.

Phenomenology of Hypokinesias (as listed in Table 2)

Akinesia/Bradykinesia

Akinesia, bradykinesia, and hypokinesia literally mean absence, slowness, and decreased amplitude of movement, respectively. The three terms are commonly grouped together for convenience and usually referred to under the term of bradykinesia. These phenomena are a prominent and most important feature of parkinsonism, and are often equated as a *sine qua non* for parkinsonism. Although akinesia means lack of movement, the label is often used to indicate a very severe form of bradykinesia. Bradykinesia is mild in early Parkinson disease (PD) and becomes more severe in advanced PD and other forms of parkinsonism. Parkinsonism is a neurological syndrome manifested by any combination of six cardinal features: tremor-at-rest, bradykinesia, rigidity, flexed posture, freezing, and loss of postural reflexes.

Akinesia/bradykinesia/hypokinesia can be detected in various parts of the body. Cranially, it is manifested by masked facies (hypomimia), decreased frequency of blinking, impaired upgaze, impaired ocular convergence, soft speech (hypophonia), loss of inflection (aprosody), and drooling of saliva due to decreased spontaneous swallowing. In the arms, bradykinesia is manifested by slowness in shrugging the shoulder and lowering the shrugged shoulder; slowness in raising the arm; loss of spontaneous movement such as gesturing; smallness and slowness of handwriting (micrographia); decreased armswing when walking; slowness and decrementing amplitude of repetitively opening and closing the hands, tapping a finger, and twisting the hand back and forth; and difficulty with hand dexterity for shaving, brushing teeth, and putting on make-up. In the legs bradykinesia is manifested by slowness and decrementing amplitude in repetitively stomping the foot or tapping the toes; by slowness in making the number eight with the foot; and by a slow, short-stepped, shuffling gait with reduced heel strike when stepping forward. In the trunk, bradykinesia is manifested by difficulty in arising from a chair, getting out of automobiles, and turning in bed.

Bradykinesia encompasses a loss of automatic movements, slowness in initiating movement on command, and reduction in amplitude of the voluntary movement. An early feature of reduction of amplitude, besides the

decrementing of the amplitude with repetitive finger tapping or foot tapping, there is also a breakdown of the smooth, regular rhythm of the tapping. Carrying out two activities simultaneously is impaired, and this difficulty may be a manifestation of bradykinesia. With the stimulation of a sufficient sensory input, bradykinesia, hypokinesia, and akinesia can be temporarily overcome (kinesia paradoxica).

Akinesia needs to be distinguished from the freezing phenomenon (see below), both of which are features of parkinsonism.

Apraxia

Apraxia is a cerebral cortex, not a basal ganglia, dysfunction. Apraxia is traditionally defined as a disorder of voluntary movement that cannot be explained by weakness, spasticity, rigidity, sensory loss, or cognitive impairment. It can exist and can be tested for in the presence of a movement disorder provided that akinesia, rigidity, or dystonia is not so severe that voluntary movement cannot be executed. There are three classical categories of apraxia:

1. In ideational apraxia, the concept or plan of movement cannot be formulated by the patient. Some examiners test for ideational apraxia by asking the patient to perform a series of sequential movements such as filling a pipe, lighting it, and then smoking; or putting a letter into an envelope, sealing it, and then affixing a stamp. Ideational apraxia is due to parietal lesions, most often diffuse and degenerative.
2. In ideomotor apraxia, the concept or plan of movement is intact, but the individual motor engrams or programs are defective. Ideomotor apraxia is commonly tested for by asking patients to undertake specific motor acts to verbal or written commands, for example, wave goodbye, salute like a soldier, comb their hair, or use a hammer to fix a nail, etc. The patients with ideomotor apraxia often improve their performance if asked to mimic the action when the examiner shows them what to do or when given the object or tool to use. Ideomotor apraxia usually does not interfere with normal spontaneous motor actions, but requires specific testing for its demonstration. It is usually, but not always, associated with aphasia, and is due mainly to lesions in the dominant hemisphere, particularly in the parietotemporal regions, the arcuate fasciculus, or the frontal lobe; such ideomotor apraxia is bilateral, providing there is not a hemiplegia. Lesions of the corpus callosum can cause apraxia of the nondominant hand.
3. Limb-kinetic apraxia is the least understood type. It refers to a higher order motor deficit in executing motor acts that cannot be explained by simple motor impairments. It has been attributed to lesions of premotor regions in the frontal lobe, such as supplementary motor area.

Blocking (Holding) Tics

Blocking (or holding) is a motor phenomenon that is seen occasionally in patients with tics and is characterized as a brief interference of social discourse and contact. There is no loss of consciousness, and although the patient does not speak during these episodes, he/she is fully aware of what has been spoken. They appear in two situations: (1) as an accompanying feature of some prolonged tics, such as during a protracted dystonic tic or during tic status and (2) as a specific tic phenomenon in the absence of an accompanying obvious motor or vocal tic. The latter occurrences have the abruptness and duration of a dystonic tic or a series of clonic tics, but they do not occur during an episode of an obvious motor tic; it can be considered as a negative motor phenomenon, that is, a 'negative' tic.

Cataplexy and Drop Attacks

Drop attacks can be defined as sudden falls with or without loss of consciousness, due either to collapse of postural muscle tone or to abnormal muscle contractions in the legs. There are many neurological and nonneurological causes of symptomatic drop attacks, but most are of unknown etiology. Neurological disorders include leg weakness, sudden falls in parkinsonian syndromes including those due to freezing, transient ischemic attacks, epilepsy, myoclonus, startle reactions (hyperekplexia), paroxysmal dyskinesias, structural CNS lesions, and hydrocephalus. In some of these, there is a loss of muscle tone in the legs, and in others, there is excessive muscle stiffness with immobility, such as in hyperekplexia. Syncope and cardiovascular disease account for nonneurological causes.

Cataplexy is another cause of symptomatic drop attacks that does not fit the categories listed earlier. Patients with cataplexy fall suddenly without loss of consciousness, but with an inability to speak during an attack. There is a precipitating trigger, usually laughter or a sudden emotional stimulus. The patient's muscle tone is flaccid and remains this way for many seconds. Cataplexy is usually just one feature of the narcolepsy syndrome, which also includes sleep paralysis and hypnagogic hallucinations, in addition to the characteristic feature of uncontrollable falling asleep.

Catatonia, Psychomotor Depression, and Obsessional Slowness

About catatonia:

> "... the patient remains entirely motionless, without speaking, and with a rigid, mask like facies, the eyes focused at a distance; he seems devoid of any will to move or react to any stimuli; there may be fully developed "waxen" flexibility, as in cataleptic states, or only indications, distinct, nevertheless, of this striking phenomenon.

> The general impression conveyed by such patients is one of profound mental anguish. . ."
> Karl Ludwig Kahlbaum, 1874
> from Bush et al., 1996

Catatonia is a syndrome characterized by catalepsy (abnormal maintenance of posture or physical attitudes), waxy flexibility (retention of the limbs for an indefinite period of time the positions in which they are placed), negativism, mutism, and bizarre mannerisms. Patients with catatonia can remain in one position for hours and move exceedingly slowly to commands, usually requiring the examiner to push them along. However, when moving spontaneously, they move quickly, such as when scratching themselves. In contrast to patients with parkinsonism, there is no concomitant cogwheel rigidity, freezing, or loss of postural reflexes. Classically, catatonia is a feature of schizophrenia, but it can occur with severe depression. Gelenberg also stated that catatonia can appear with conversion hysteria, dissociative states, and with organic brain disease.

Depression is commonly associated with a general slowness of movement, as well as of thought, so-called psychomotor retardation, and catatonia can be considered as an extreme case of this problem. Although depressed patients are widely recognized to manifest slowness in movement, some, particularly children, may not have the more classical symptoms of low mood, dysphoria, anorexia, insomnia, somatizations, and tearfulness. In this situation, slowness due to depression can be difficult to distinguish from the bradykinesia of parkinsonism; like catatonia, lack of rigidity and preservation of postural reflexes may help to differentiate psychomotor slowness from parkinsonism.

Some patients with OCD may present with extreme slowness of movement, so-called obsessional slowness. The major differential diagnosis is parkinsonism.

Freezing

Freezing refers to transient periods, usually lasting several seconds, in which the motor act is halted, being stuck in place. It commonly develops in parkinsonism and is one of its six cardinal signs. The freezing phenomenon has also been called motor blocks, 'pure akinesia' and 'gait ignition failure.' In freezing, the voluntary motor activity being attempted is halted, because agonists and antagonist muscles simultaneously and isometrically contract, preventing the normal execution of voluntary movement. The motor blockage, therefore, is not one of lack of muscle tone or flaccidity, but rather is analogous to being glued to a position so that the patient exerts an increased effort to overcome being 'stuck.' The stuck body part attempts to move to overcome the block, and muscle force (isometric) is exerted. Hence, with freezing of gait, by far the most common form of the freezing phenomenon, as the patient attempts to move the feet, short, incomplete steps are attempted, but the feet tend to remain in the same place ('glued to the ground'). After a few seconds, the freezing clears spontaneously, and the patient is able to move at his/her normal pace again, until the next freezing episode develops. Often the patient has learned some trick maneuver to terminate the freezing episode sooner; stepping over an 'inverted cane' when the legs begin to freeze is one method by which patients can manage to ambulate.

Freezing of speech also occurs; speech is 'arrested' with the patient repeating a sound until it finally becomes unstuck, and speech then continues. This can be considered a severe form of parkinsonian palilalia, which usually refers to a repetition of the first syllable of the word trying to be verbally expressed. Parkinsonian palilalia differs from the palilalia seen in patients with Tourette syndrome, in which there is repetition of entire words or a string of words.

Freezing of the arms can affect handwriting, shaving, or teeth-brushing. Difficulty in opening the eyes can be another target of freezing. This eyelid freezing was originally called 'apraxia of eyelid opening,' which is a misnomer, because the problem is not an apraxia. Eyelid freezing has also been called 'levator palpebrae inhibition' and even a form of dystonia.

Freezing of gait can sometimes appear as a disorder without other features of parkinsonism, except for loss of postural reflexes and mild bradykinesia; most commonly as this disorder worsens over time, features of progressive supranuclear palsy become manifest.

Hesitant Gaits

Hesitant gaits or uncertain gaits are seen in a number of syndromes. The cautious gait seen in some elderly people is slow on a wide base with short steps and superficially may resemble that of parkinsonism except there are no other parkinsonian features. Fear of falling, either because of perceived instability or realistic loss of postural righting reflexes, produces an inability to walk independently without holding onto people or objects. Since this abnormal gait disappears when the person walks holding onto someone, it is often considered to be a psychiatric disorder, a phobia of open spaces (i.e., agoraphobia). However, because previous falls usually play a role in patients developing this disorder, it is likely a true fear of falling and should be distinguished from agoraphobia, which is a separate syndrome. Fear of falling should be differentiated from psychogenic gait disorders.

The senile gait disorder (or gait disorder of the elderly) is a poorly understood condition that comprises a number of different syndromes. In gait ignition failure, also called

primary freezing gait, the problem is one of getting started. Once underway, such patients walk fairly briskly, and equilibrium is preserved. In frontal gait disorders, there is also start-hesitation, and walking is with slow, small, shuffling steps, similar to that in PD. However, there are few other signs of parkinsonism, and equilibrium is preserved. Such a gait can occur with frontal lobe tumors, cerebrovascular disease, and hydrocephalus, all causing frontal lobe damage. This pattern has been incorrectly called frontal ataxia or gait apraxia.

Other hesitant gaits are those due to severe dysequilibrium. These types of gait have been associated with frontal cortex and deep white matter lesions (frontal disequilibrium) or thalamic and midbrain lesions (subcortical disequilibrium).

Hypothyroid Slowness

Along with decreased metabolic rate, cool temperature, bradycardia, myxedema, loss of hair, hoarseness, and myotonia, severe hypothyroidism can also feature motor slowness, weakness, and lethargy. These signs could be mistaken for the bradykinesia of parkinsonism, but the combination of the other signs of hypothyroidism, along with lack of rigidity and loss of postural reflexes, should aid the correct diagnosis.

Rigidity

Rigidity is characterized as increased muscle tone in the presence of passive motion. It is distinguished from spasticity in that it is present equally in all directions of the passive movement, equally in flexors and extensors, and throughout the range of motion, and it does not exhibit the clasp-knife phenomenon nor increased tendon reflexes. Rigidity can be smooth (lead-pipe) or jerky (cogwheel). Cogwheeling occurs in the same range of frequencies as action and resting tremor and appears to be due to superimposition of a tremor rhythm. Cogwheel rigidity is more common than the lead-pipe variety in parkinsonism (nigral lesion), and lead-pipe rigidity can be caused by a number of other CNS lesions, including those involving corpus striatum (hypoxia, vascular, neuroleptic malignant syndrome), midbrain (decorticate rigidity), medulla (decerebrate rigidity), and spinal cord (tetanus).

An increase in passive muscle tone can sometimes lead to impaired motor performance or even immobility. Before there was a clear understanding of bradykinesia, rigidity was considered to be responsible for the paucity of movement in parkinsonism, but rigidity is clearly distinct from bradykinesia; the former is more easily treated by levodopa therapy or by stereotactic thalamotomy and can be relieved while bradykinesia with residual paucity of movement persists. When rigidity is extremely severe so that the examiner can barely move the limbs, as in patients with neuroleptic malignant syndrome, the patient is virtually unable to move. The extended neck occasionally seen in progressive supranuclear palsy may be due to rigidity (vs. dystonia); the neck can be immobile in this disorder, and other axial muscles are also rigid.

Stiff-Muscles

Stiff muscles are defined as being due to continuous muscle firing without muscle disease and not due to rigidity or spasticity. There are four major categories of stiff-muscle syndromes: continuous muscle fiber activity or neuromyotonia, encephalomyelitis with rigidity, the stiff-limb syndrome, and the stiff-person syndrome. Neuromyotonia is a syndrome of myotonic failure of muscle relaxation plus myokymia and fasciculations. Clinically, it manifests itself as continuous muscle activity causing stiffness and cramps. The best-known neuromyotonic disorder is Isaacs syndrome.

Encephalomyelitis with rigidity manifests itself with marked rigidity and muscle irritability, with increased response to tapping the muscles, along with myoclonus. It is now recognized as a severe manifestation of stiff-person syndrome and may respond to steroid therapy.

Stiff-person syndrome refers to a rare disorder in which many somatic muscles continuously contract isometrically, resembling 'chronic tetanus,' in contrast to dystonic movements, which produce abnormal twisting and patterned movements, and postures. The contractions of stiff-person syndrome are usually forceful and painful and most frequently involve the trunk and neck musculature. The proximal limb muscles can also be involved, but rarely does the disorder first affect the distal limbs. Benzodiazepines and valproate are usually somewhat effective. Withdrawal of these agents results in an increase of painful spasms. This disorder has now been recognized to be an autoimmune disease, with circulating antibodies against the GABA-synthesizing enzyme glutamic acid decarboxylase and also other type of antibodies, including against insulin. Diabetes is a common accompanying disorder. The diagnosis can now be aided by laboratory testing for these antibodies. The so-called 'stiff-baby' syndrome is actually due to infantile hyperekplexia, in which the muscles continue to fire repeatedly and so frequently that the muscles appear to contract continuously.

Movement Time

T L Davis and J Y Fang, Vanderbilt University, Nashville, TN, USA

Glossary

Movement time – The time to complete a discreet predefined motor task.

Definition and History

Movement time may be defined as the time to complete a discreet predefined motor task. The timing of the task starts at the initiation of movement rather than at the start of a prompt as in reaction time. Movement time is a measure of bradykinesia and has been used as an outcome measure for therapeutic trials of agents designed to improve motor function. Movement time is task specific and, for this reason, care must be taken to control all variables to standardize the test for clinical trials.

A number of instruments have been used to measure movement time. Many of these require the subject to place their hand on a button and then at a prompt move their hand to another button. In this model, the time from the prompt to releasing the first button is simple reaction time, and the time from releasing the button to depressing the second button is movement time. Movement time increases with age, but there is no difference between men and women. In a model using a stopwatch to measure the movement time, there is no significant difference between the nondominant and dominant hands. In another model using other instruments, movement time is slower on the nondominant side than on the dominant side.

Several studies demonstrate that movement time measures, like reaction time measures, are dependent on a number of variables, and great care must be taken to control for these when comparing studies. Movement time has been utilized in a number of studies as a quantifiable measure of bradykinesia. As expected, most of these have been investigations of Parkinson's disease (PD) and related disorders.

Movement Time – PD

Patients with PD are slower to react and to move than the normal subjects, and disease severity more highly correlates with movement time than reaction time. In subjects with PD and asymmetrical signs, both responses were longer on the more affected side and bradykinesia is the clinical symptom that best correlates with the objective measurements. Levodopa significantly improves both the responses, whereas anticholinergic agents are less effective. There is evidence to suggest that movement time may be a more sensitive outcome measure than the motor

examination part of the Unified Parkinson's Disease Rating Scale (UPDRS-III) in predicting the magnitude of long-term dopaminergic responsiveness from a short-term dopaminergic challenge. Interestingly, abnormalities in movement time found in patients with PD more closely correlate with abnormalities in color vision than reaction time. This suggests that movement time and abnormalities in color vision may be more closely tied to dopaminergic dysfunction than reaction time.

Movement time has been successfully used as an outcome measure in surgical trials for PD. These studies typically have limited numbers of subjects making a sensitive outcome measure more attractive. The effectiveness of deep-brain stimulation of the subthalamic nucleus on bradykinesia has been examined by the analysis of movement time. After turning off stimulation, movement time progressively increases, reaching a plateau after ~30 min. Upon pulse generator reactivation, movement time shows a dramatic shortening, already significant after 2 min. In these studies, a significant correlation between movement time and the severity of PD exists. Reaction time and movement time have been used to gauge the change in motor performance in patients with PD who received embryonic tissue implants. The physiological measures detected significant changes in patients undergoing embryonic nigral cell implants and correlated directly with clinical outcome measures. In this model, reaction time and movement time analysis could document subtle changes in motor performance over time, suggesting utility as outcome measures in therapeutic trials of PD.

Movement Time – Other Conditions

Movement time has been studied in essential tremor patients. Using a test paradigm around metacarpophalangeal, wrist, elbow, and shoulder joints, there was no significant difference in movement time between essential tremor and normal controls.

Fast voluntary neck movements have been studied in patients with cervical dystonia before and after therapy with botulinum toxin type-A (BoNT-A). Before receiving BoNT-A, patients perform pro- and antidystonic movements with lower peak angular velocity than control subjects. Prodystonic movements show a reduced angular amplitude, and antidystonic movements show an abnormally long movement time. Flexion and extension movements require longer movement times, but other kinematic variables are normal. After BoNT-A injections, prodystonic movement amplitude and antidystonic movement peak angular velocity increase, whereas flexion and extension movement times remain unchanged.

In Huntington's disease, a series of methods to measure voluntary movement (reaction time, tapping speed, and movement time) have been studied. Despite identifying several abnormalities, none are specific to Huntington's disease.

Conclusion

Movement time is a quantifiable measure of subtle bradykinesia that may have utility both in clinical and research settings. It is a better predictor of dopaminergic responsiveness in PD than the reaction time. Movement time measures are very task specific, and care must be taken to standardize the recording protocol.

MPTP

J W Langston and I Irwin, The Parkinson's Institute and Clinical Center, Sunnyvale, CA, USA

Glossary

Levodopa-induced dyskinesias (LIDs) – Abnormal involuntary movements such as tics, chorea, or spasm or distortion of voluntary movements which are a side effect of L-DOPA therapy.
MPP+ (1-methyl-4-phenylpyridinium) – The positively charged fully oxidized metabolite of MPTP.
MPTP (1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine) – A small molecule neurotoxin that selectively damages nigrostriatal dopamine neurons and induces parkinsonism in humans and nonhuman primates.
Parkinson's disease – A neurodegenerative disease that involves loss of nigrostriatal dopamine neurons and that is characterized clinically by bradykinesa, rigidity, and tremor.

Definition and History

MPTP (1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine) is a small molecule that selectively damages nigrostriatal dopamine neurons and induces parkinsonism in humans and nonhuman primates. Since 1982, when the parkinsonogenic effects of MPTP were first recognized in humans, this simple chemical and the experimental models that it made possible have provided transformative insights into our understanding of the etiology, natural history, and treatment of Parkinson's disease. In this entry, we review the history of MPTP and its impact on PD research and focus on how experimental studies in MPTP-treated monkeys have lead to new treatments for PD. Unlike the development of many models of human disease that exploit the toxicity of a chemical agent in experimental animals, the effects of MPTP were first observed as an outbreak of parkinsonism among relatively young drug-abusers in northern California in 1982. This outbreak was traced to the intravenous use of a street drug produced by a clandestine laboratory. The laboratory operator was synthesizing, 1-methyl-4-phenyl-4-propionoxy-piperidine (MPPP), a synthetic opiate related to the narcotic analgesic meperidine. MPTP is a by-product of the process used in the synthesis of MPPP. Probably as a result of using either too much heat or acid, the clandestine chemist managed to produce a batch of drug that was primarily made up of MPTP. While the target compound, MPPP, had been selling briskly as 'China White' or 'synthetic heroin,' when this 'bad batch' reached the streets, its users rapidly developed a series of untoward effects, the worst of which was enduring and profoundly disabling parkinsonism. On the basis of the analysis of heroin bindles used by these patients, their clinical picture, and an autopsy study of the earlier reported case in which the offending agent had never been clearly identified, we concluded that MPTP was the culprit and that it was selectively toxic to the substantia nigra: a conclusion that has subsequently and repeatedly been confirmed in nonhuman primates, as well as in other species, including mice and even invertebrates. As a result, this discovery opened up an entirely new research era in Parkinson's disease. It is important to note that it did not emerge from a research laboratory, but rather from clinical observation, reminding us of the power of clinical observation when it comes to advancing medical research.

As the effects of MPTP occurred in a human cohort, it was possible to compare directly the clinical, physiological, therapeutic, and eventually the neuropathological features of MPTP-induced parkinsonism in humans with those seen in the idiopathic disease. These rare, if not unprecedented, circumstances provided two important insights. The first was that the key motor features (bradykinesa, rigidity, and tremor) can result solely from a lesion of the substantia nigra. This conclusion is based on two findings: (1) our patients with MPTP-induced parkinsonism exhibited these cardinal motor features of PD, including rest tremor and (2) clear-cut pathologic evidence that MPTP induces a selective lesion of the zona compacta of the substantia nigra in humans. The observation regarding tremor resolved long-standing and considerable controversy over the neuroanatomic origins of rest tremor and whether a purely nigral lesion can induce it. Interestingly, the results of recent physiological studies in a case of MPTP-induced human parkinsonism undergoing deep brain stimulation (DBS) were consistent with recordings from MPTP-treated primates and humans with PD, thus providing further validation for the MPTP model in the study of the neurophysiology of the nigrostriatal dopaminergic deficit in PD. Furthermore, DBS in this patient provided similar clinical benefit as what is usually seen in patients with idiopathic PD. Ironically, much of the preclinical work that led to the development of DBS of the subthalamic nucleus came from the MPTP primate model, which in turn was based on the original observations in these human cases. It is also

interesting to note that our MPTP patients demonstrated mild cognitive deficits seen in nondemented patients with the disease and facial seborrhea, suggesting that these features are dopaminergic as well.

A second observation in patients with MPTP-induced parkinsonism relates to the side effects of therapy. Although the response of our patients to dopaminergic therapy was dramatic, they rapidly experienced all of the side effects typically encountered with chronic levodopa treatment. For example, a short-duration response was seen almost immediately after starting treatment and dyskinesias were encountered within days to weeks of initiating treatment. It is possible that the relative youth of these patients could be responsible for the early onset of dyskinesias, since these are well known to begin earlier in younger idiopathic patients. However, the short-duration response is not known to be age-dependent, suggesting that this phenomenon is related to disease severity: an observation that is consistent with the hypothesis that diminishing storage at the level of the synaptic vesicles may be a key feature underlying this phenomenon.

Neuropathologic studies have been conducted on three of MPTP cases, who subsequently died. The time from exposure to MPTP until death in these three cases ranged from 3 to 14 years. Surprisingly, in each of these individuals, there was neuropathologic evidence of active, ongoing nerve cell death. Specific findings included microglial proliferation and clustering with clear-cut neuronophagia, and in two of the cases, abundant extraneuronal melanin. The mechanism by which a fixed insult might induce and maintain an ongoing active neuropathologic process is presently not clear, but might include enhanced oxidative stress from increased dopamine turnover in remaining dopaminergic neurons, ongoing effects propagated by protein misfolding, or an active inflammatory process that has become self-sustaining. Whatever the underlying cause(s) of these observations, they may be precedent setting, as they provide compelling evidence that a time-limited exposure to an exogenous toxin can induce an active neurodegenerative process that can persist for many years.

MPTP-Induced Parkinsonism in Nonhuman Primates: A Proving Ground for New Therapy

The epidemic of MPTP-induced parkinsonism in humans gave birth to an immediate quest to use this neurotoxicant to create new animal models for PD. Indeed, the drug has been given to organisms ranging from baboons to yeast to study its biological effects and to produce PD models. As would be expected, the first studies were in rats, which at the time was the primary model for neurobiological study. However, this animal turned out to be completely refractory to the effects of the toxin. Since that time, the models that have been most widely used are the mouse and the nonhuman primate, and most of what we know about the mechanism of action of MPTP has come from these studies. Mice and monkeys are quite different in their response to MPTP. While mice develop significant nigrostriatal damage, they do not develop the full-blown parkinsonism, whereas MPTP-lesioned monkeys faithfully reproduce the motoric features of idiopathic PD. For this reason, the development of pharmacological, surgical, and other symptomatic treatments for PD has relied on the MPTP-lesioned monkey.

Dopamine Agonist Therapy

While dopamine agonists of the ergoline class were in use at the time of discovery of MPTP, investigation of dopaminergic receptors in the MPTP-lesioned monkey greatly expanded our insight into the role of receptor subtypes involved in nigrostriatal denervation and behaviorally overt parkinsonism and served as a 'proving ground' for many of the nonergoline dopamine agonists introduced into clinical practice in the past 2 decades. D2 receptors are consistently upregulated in MPTP-treated monkeys, suggesting that the brunt of presynaptic damage is proximal to these receptors. Consistent with these changes in D2 receptors, D2 and D2-like agonists (D2, D3, D4) have been found to reliably reverse parkinsonism in MPTP-monkeys and PD patients. The fate of D1 receptors in MPTP-treated monkeys has been variable, that is, either unchanged, increased, or decreased after nigrostriatal denervation. The anti-parkinsonian effects of selective D1 agonists have been moderate and variable in MPTP-treated primates. These preclincal findings have been predictive of the clinical outcomes of investigational D1 agonists. Thus, the MPTP-treated monkey work has led to the emergent view that the pathophysiology of Parkinson's disease may relate primarily to the D2 like dopamine receptors. The MPTP-lesioned primate has played a key role in the development of most of the dopamine agonists in current use, including ropinerole, rotigotine, and pramipexole.

Levodopa-Induced Dyskinesias (LIDs)

Dopamine replacement (L-DOPA) and agonist therapy are effective at reversing the majority of motoric deficits early in PD. With chronic use, a variety of motor complications occurs, including abnormal involuntary movements (dyskinesias) and these present a challenge to the long-term management of therapy. As expected from the experience with MPTP-exposed humans, MPTP-lesioned monkeys quickly developed classic, levodopa-induced dyskinesias (LIDs) virtually identical to those

seen in humans with PD. This model has become the 'gold standard' for investigating dyskinesias and the ability to faithfully model LIDs has led to an intensive search for agents to treat LIDs. The more severe the lesion, the more likely animals are to develop dyskinesias, lending credence to the hypothesis that the development of dyskinesias in PD is related to severity of disease. Another potentially important observation is that these animals never develop dyskinesias on their first dose of levodopa, thus confirming the need for so-called 'priming.' The availability of this model provides an opportunity to dissect the changes that occur during 'priming,' which may itself lead to an understanding of the cause(s) of dyskinesias.

Dopamine agonists and LIDs

D1- and D2-like agonists both produce dyskinetic movements in MPTP-lesioned monkeys, but D1 and D2 agonists together cause more prominent dyskinesias than either alone. This observation is consistent with the 'mixed' agonism of levodopa, Studies in the MPTP-lesioned primate showing that D2 agonists are less likely than levodopa to produce dyskinesias lead to the widespread clinical practice of starting with agonist therapy in order to forestall the onset of dyskinesias and motor fluctuations.

The greater likelihood that pulsatile rather than continual administration of agonists to MPTP-lesioned monkeys is associated with dyskinesia development has led to the testing of constant delivery forms of dopamine agonists including the percutaneous administration (patch) of rotigotine, subcutaneous administration of apomorphine, and modifications of L-DOPA itself, including extended release formulations or new routes of delivery such as duodenal infusion. A number of new drugs are L-DOPA prodrugs that promise more sustained absorption and stable levels of L-DOPA. Additional approaches have sought pharmacokinetic control over L-DOPA concentrations by modulating L-DOPA metabolism with the catechol-*O*-methyltransferase inhibitor entacapone. Each of these has been pioneered in the preclinical monkey model before introduction to clinical practice.

Serotonergic agonists and LIDs

Further, serotonin terminals have been shown to take up and decarboxylate L-DOPA and potentially store and release the dopamine formed and this process has been implicated in LIDs. Combinations of 5HT1A and 5HT1B agonists have been reported to reduce LIDs without diminishing the antiparkinsonian effects of L-DOPA in the MPTP monkey. A number of other clinical candidates with more complex pharmacological profiles that include 5HT agonism among their properties have been tested in this model as well. While to our knowledge no pure serotonergic agonists have been studied in the clinic, drugs such as sarizotan, quetiepine, and clozapine that possess 5HT activity in their pharmacological profile have all followed this pathway from monkey to man with somewhat mixed results. Clozapine appeared efficacious, while quetiepine and sarizotan failed to show efficacy in the larger clinical trials. While the complex pharmacology of these agents (both clozapine and quetiepine are D2 antagonists and possess 5HT2, histamine, and adrenergic action in their profile) 'muddies the waters' as to the role of serotonin, future trials with more selective agents may shed light on this. ACP-103 (primavanserin), a selective 5HT2A inverse agonist, reduced LIDs in the monkey model and is currently under study in a clinical trial.

Glutamate receptors and LIDs

Recently, there has been increasing interest in the possibility that both NMDA and AMPA subtypes of glutamate receptors might be involved in LIDs. Altered phosphorylation of these receptors and downstream changes in their function might produce enhanced glutamatergic transmission and drive dyskinesias, possibly through increased D1 activity.

Perhaps the most convincing evidence of the antidyskinetic effects of NMDA antagonists and the utility of the MPTP-lesioned monkey comes from the clinical use of amantadine to treat dyskinesias in patients and the observation that amantidine reduces dyskinesias by 40% without increasing motor impairment in MPTP-lesioned monkeys receiving high-dose L-DOPA monkeys. Other nonselective NMDA receptor antagonists, including currently available compounds such as dextromethorphan, attenuate LIDs in the MPTP-lesioned monkeys, and several have been studied with variable success in phase II clinical trials.

Nicotinic receptors and LIDs

Nicotine has long been of interest to those investigating PD, since abundant studies have established that smokers are significantly less likely to develop PD than nonsmokers. One of the most recent and interesting findings that have emerged from the MPTP-monkey model of dyskinesias is the observation that nicotine reduces LIDs in monkeys with MPTP-induced parkinsonism. Several small clinical studies examining the effect of nicotine patch and gum formulations on motor symptoms in PD have been reported. However, the results have been conflicting and none of the studies to date has specifically examined the effect of nicotine on dyskinesias. Clinical trials to examine this indication are in the planning stages.

Deep Brain Stimulation (DBS) and the Subthalamic Nucleus (STN)

The MPTP-lesioned monkey has also opened a window into a better understanding of the basal ganglia circuitry and the neurophysiologic changes that occur in the

presence of parkinsonism induced by a dopaminergic nigrostriatal deficit. One of the seminal observations using the MPTP-primate model is that, in the presence of a nigrostriatal deficiency, there is a decrease in striatal inhibitory output to the STN. As the output of the STN to the internal segment of the pallidum is excitatory, the result appears to be an overstimulation of the globus pallidus, thus altering outflow to the thalamus and cortex. Lesioning the subthalamic nucleus results in the reversal of akinesia, rigidity, and tremor in MPTP-treated primates and the subsequent demonstration that high-frequency stimulation of the STN in MPTP-lesioned monkeys reversed parkinsonism led to the successful introduction of DBS: a procedure that is now widely used to treat patients with PD.

Neurotransplantation

The MPTP-lesioned primate, with its full array of parkinsonian features, has proved to be an excellent testing ground for the effectiveness of this approach. Intraputaminal implantation of fetal mesencephalic tissue in this model provided the feasibility, efficacy, and safety data to translate this approach into human trials. However, while human open label studies have shown some encouraging results, including transplanted neuronal survival and some clinical improvement, randomized, sham-surgery controlled studies have not demonstrated the anticipated benefit. Of note is that the fetal grafting procedure was used on three human cases of MPTP-induced parkinsonism and that all the three subjects experienced substantial improvement. These individuals may have done slightly better than patients with the idiopathic disease because of their young age or because they have more selective lesions of the substantia nigra. Nonetheless, the MPTP-lesioned monkey will remain the standard for developing modifications of the surgical procedures (e.g., nigral delivery of grafts) as well as improvements in substrates for cell therapy such as stem cells.

Gene Therapy

MPTP-lesioned monkeys have provided a rich proving ground for various approaches to in vivo gene therapy. At least 3 separate 'therapeutic genes' (encoding for): (1) aromatic amino acid decarboxlyase (AADC); (2) the growth factor neurturin (CERE120); and (3) glutamic acid decarboxylase (GAD)) have been studied with the goal of greatly increasing the expression of their target proteins in the brain. In each case, the genes are transfected into either the putamen (AADC, CERE120) or STN (GAD) using an adeno-associated viral vector (AAV); in each case the preclinical results in the MPTP-lesioned monkey have provided sufficient proof of concept data to advance to human trials. While it is still too early to predict the ultimate outcomes of these approaches in patients, the successful translation of the approach has provided an avenue to evaluate and deliver candidates for gene therapy.

Mechanism of Action and the Advent of Neuroprotective Therapy

The striking similarities between the effects of MPTP and the idiopathic disease in humans, and the fact that the toxin and the disease both targeted the dopaminergic cells of the substantia nigra raised the possibility that the processes involved in MPTP-induced cell death might mirror, or shed light on, the underlying processes that occur in the disease produced tremendous interest in exploring its mechanism of action. Several of the key steps in a concerted process that is ultimately responsible for selectivity and cell death were quickly elucidated, with MAO-mediated biotransformation of MPTP, the dopamine uptake system, and mitochondrial respiration emerging as central players. This information produced the experimental evaluation of a range of strategies designed to protect against MPTP toxicity that has now been tested at almost every level of biologic complexity, ranging from tissue culture to patients with PD. Indeed, it would not be an overstatement to say that these studies ushered in a new age of research on 'neuroprotection' or disease-modifying strategies aimed at stopping or slowing the progress of PD. While there have been numerous studies of putative neuroprotective agents in the MPTP primate model, we focus on those that have lead to clinical trials for idiopathic PD.

The Biotransformation of MPTP

The first investigations to define the distribution and fate of MPTP in primates revealed that the parent compound was short lived and most of it was converted into the metabolite MPP+ and that high and persistent concentrations of MPP+ were present in the nigrostriatal regions of the brain. Interestingly, although the administration of MPTP to mice also produces high striatal concentrations of MPP+, this metabolite is rapidly cleared from the CNS: an observation that may explain the fact that mice are less sensitive to toxin than primates. Perhaps one of the most surprising and interesting observations was that the conversion of MPTP to MPP+ is mediated by monoamine oxidase B (MAO B). Investigators wasted little time demonstrating that blocking this enzyme with MAO B inhibitors prevented both dopamine depletion in mice and nigral cell degeneration in primates.

These observations had several exciting implications, both practical and theoretical. First, the chemical structure of the metabolite MPP+ was very similar to that of

paraquat, a widely used and highly toxic herbicide, triggering a renaissance of research on possible environmental risk factors for PD. Second, the role of MAO in the bioactivation of MPTP stimulated a renewed interest in MAO and its role in the human nervous system. Generally considered a housekeeping enzyme, these new data raised the possibility that MAO might play a role in the bioactivation of other possible agents and that the inhibition of MAO B might slow or stop the progression of PD: a possibility suggested by previous clinical studies with the MAO B inhibitor selegiline. Testing this hypothesis in a clinical trial was especially attractive, because selegiline had already been approved for human use in Europe. For these reasons, we initiated a prospective controlled trial in patients with PD to assess the effect of selegiline on disease progression. Shortly thereafter, planning for a much larger trial was initiated that included an additional arm to measure the effect of vitamin E on disease progression. Newly diagnosed patients, who did not yet require L-DOPA therapy, were enrolled and the primary endpoint was the need for L-DOPA. In addition, the rate of progression was measured using standard rating scales for PD. As far as we are aware, this was the first prospective trial evaluating a therapeutic intervention to slow or halt disease progression. In 1988, the results of both studies showed that the need for L-DOPA therapy could be delayed nearly twofold with the initiation of early selegiline treatment in de novo patients. Furthermore, based on clinical evaluation, the drug appeared to slow disease progression by about 50% and this effect persisted after a 2 month 'wash out' of selegiline. Subsequent recognition that a small but statistically significant symptomatic benefit was derived from selegiline was seen by some as a confounding factor that might mask disease progression and that the 2 month wash out was inadequate to rule out this possibility.

The recent clinical development of a second generation MAO-B inhibitor for Parkinson's disease, rasagiline has renewed interest in MAO-B inhibitors. While approved for both the early and late treatment of PD, clinical studies are now also evaluating its neuroprotective properties, using a novel 'delayed start' design. This design was chosen to address the two issues that marred the selegiline study as described earlier: (1) the symptomatic benefit masking possible disease modifying effects and (2) the washout period. According to this design, one group of subjects receives active drug from the beginning of the study, while the other group is not exposed to the drug until after several months. If the investigational drug has only symptomatic effects, then the delayed start group should quickly 'catch up' with the first (early start) group. On the other hand, if the drug indeed has neuroprotective properties, then the delayed start group should never completely catch up. Preliminary analyses suggest that this indeed appeared to be the case in the rasagiline study. Importantly, a much larger study has now been completed using this same designed, the results of which should be announced shortly to see whether these results can be replicated.

MPP± and Dopaminergic Uptake

While the MAO-B-mediated conversion of MPTP to MPP+ was the first step and required for toxicity, it did not explain the selectivity for dopaminergic neurons. This would come, at least in part, with the observation that MPP+ (but not MPTP) was a substrate for the dopamine transporter – thus the nerve cells own uptake system proved to be the mechanism for the selective accumulation of the toxin within dopaminergic neurons. It was quickly shown that inhibitors of the dopamine uptake transporter protected against MPTP toxicity in rodents, but protection in primates was more difficult to achieve, probably because of the long half-life of MPP+ in this species and difficulties in maintaining constant uptake inhibition with available agents. Perhaps for this reason there has yet to be an evaluation of dopamine uptake inhibitors in a neuroprotective trial in PD.

If one considers this aspect of MPTP toxicity, it could be argued that it exemplifies an unfortunate 'alignment of the stars,' in which several factors combine to predispose the dopaminergic system to damage. This is particularly true, since we now know that the MAO B generation of MPP+ occurs primarily in glia. Thus, MPTP must enter the brain and gain access to glia, which then convert a nontoxic substance into a toxin that cannot be further metabolized or conjugated, but rather is retained within the brain by virtue of its positive charge (see **Figure 1**). Next, the dopamine

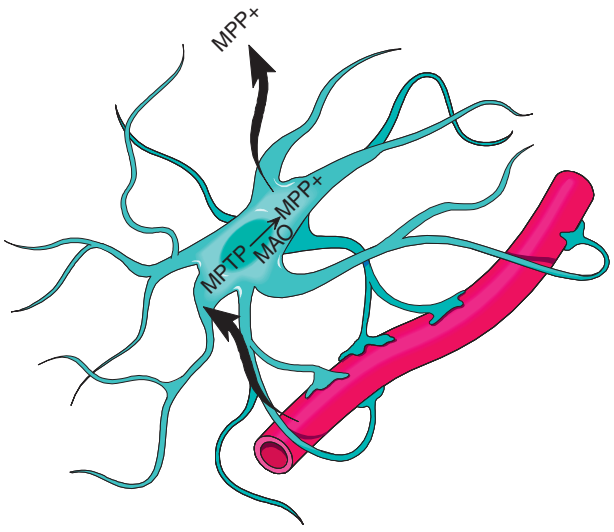

Figure 1 Glial cell: After absorption, circulating MPTP crosses the blood brain barrier by diffusion and enters the glial cell. MPTP is oxidized to MPP+ by monoamine oxidase B within the glia and diffuses into the extracellular space.

uptake carrier mistakes this toxic metabolite for the normal substrate (i.e., dopamine) and transports it intracellularly, where it causes cell death (this has been referred to as a Trojan horse effect). One of the more interesting questions to address is "is this remarkable sequence of events a rare aberration?" or "is it a much more common scenario that plays a role in other human neurodegenerative diseases as well?".

MPP± and Mitochondria

While the multistep mechanism described earlier explains the means by which MPTP selectively delivers high concentrations of a toxic product to dopaminergic neurons, there is still the question of what is the ultimate 'coup de grace' that kills the cell. MPP+ has a number of potentially toxic properties that might be involved but most studies point toward a direct effect on mitochondria. MPP+, by virtue of its positive charge is driven by the energy-dependent gradient across the mitochondrial membrane to accumulate within mitochondria. There, MPP+ inhibits Complex I of the electron transport chain and this derangement leads to the potential production of reactive oxygen species and a rapid loss of cellular energy as a consequence of ATP depletion (see **Figure 2**). These observations led to the search for similar deficits in PD itself, where a complex I deficiency was in fact found. Indeed, the mitochondrial hypothesis of PD, which was largely precipitated by MPTP-related discoveries, continues to be one of the most viable hypotheses regarding potential mechanisms that may underlie cell death in PD.

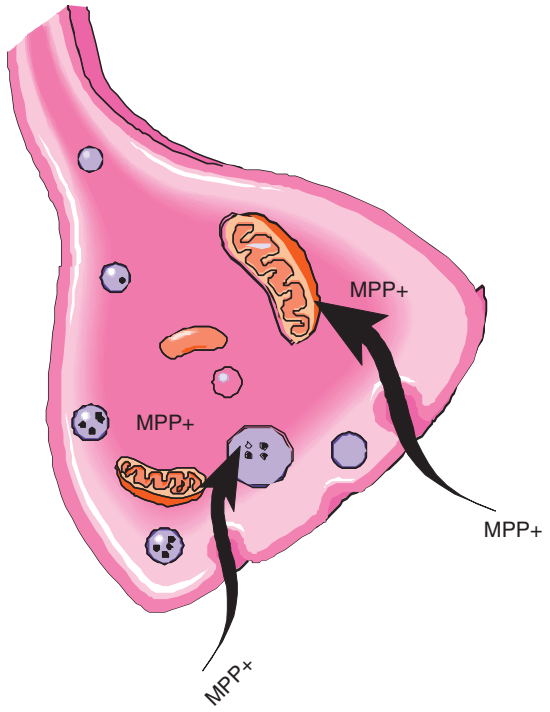

Figure 2 Dopaminergic neuron: MPP+ is actively taken up by dopaminergic neurons. Once inside the cell, it is concentrated by mitochondria where it inhibits complex 1 leading to derangement of electron transport and loss of ATP production.

While much is still unknown, there is near-universal agreement that a complex I deficit is present in the substantia nigra of patients with PD and that the deficit is also present in platelets. This aspect of the MPTP story has again launched a number of experimental studies targeting mitochondrial function and several clinical trials in PD are underway. Perhaps since most of the agents under consideration are nutrients and are expected to have an acceptable safety profile for human use, few studies have been done in primates and most of the preclinical data have been generated in MPTP-treated mice. Nonetheless, there are several large and long-term clinical trials examining agents such as creatine, which may increase phosphocreatine buffering against ATP depletion, and coenzyme Q10, which would be expected to improve or supplement the function of mitochondrial complex I. Both of these agents have shown protection against the effects of MPTP in mice.

Conclusion

Since recognition of the biological effects of MPTP, this small molecule neurotoxin has propelled an extensive array of scientific research in Parkinson's disease. Studies have encompassed the full spectrum of disciplines from molecular biology to epidemiology and have yielded insights into both the disease process and putative agents for its treatment.

Multiple System Atrophy

C Colosimo and D Tiple, Sapienza University of Rome, Rome, Italy

Glossary

Camptocormia – An abnormal flexion of the thoracolumbar spine during standing and walking that abates in the recumbent position.
Dysautonomia – A medical term utilized for a group of complex conditions that are caused by a dysfunction of the autonomic nervous system.
Multiple system atrophy-parkinsonian-type (MSA-P) – Implies parkinsonism with or without some degree of cerebellar dysfunction.
Multiple system atrophy-cerebellar type (MSA-C) – Indicates primarily cerebellar defects with minor degrees of parkinsonism.
Red-flags – Clinical clues that could distinguish between MSA-P and PD in the early differentiation of two entities.

Definition and History

The term multiple system atrophy (MSA) was introduced by Graham and Oppenheimer in 1969 to denote a neurodegenerative disease characterized clinically by any combination of autonomic, parkinsonian, cerebellar, or pyramidal symptoms and signs, and pathologically by cell loss and gliosis in the basal ganglia and olivopontocerebellar system. Previous cases of MSA were reported under the terms of olivopontocerebellar atrophy (OPCA), Shy–Drager syndrome (SDS), and striatonigral degeneration (SND). Recent studies describing the patterns of pathological involvement of gray matter are generally an extension of the original accounts, noting neuronal loss and gliosis in the striatum, substantia nigra, locus ceruleus, inferior olivary nucleus, pontine nuclei, cerebellar Purkinje's cells, intermediolateral cell column in the thoracic spinal cord, and Onuf's nucleus in the sacral cord. Depending upon which part of the central nervous system is affected first, MSA may present in different ways. According to the most recent diagnostic criteria, MSA is divided into two main clinical categories: (1) MSA-parkinsonian type (MSA-P) which implies parkinsonism with or without some degree of cerebellar dysfunction (SND) and (2) MSA-cerebellar type (MSA-C) which indicates primarily cerebellar deficit with minor degrees of parkinsonism (OPCA). In both conditions, autonomic failure is a frequently associated manifestation of the clinical spectrum of the disease.

Pathogenesis

The discovery of glial cytoplasmic inclusions (GCIs) and α-synuclein immunostaining as a sensitive marker of MSA is the major milestone in the definition of MSA as a clinicopathological entity. Concentration of GCIs in MSA in cerebral structures is variable (**Table 1**). How the expression and aggregation of α-synuclein in glial cells affects their biology as well as the glia–neuron interactions, which might be a critical step in the

Table 1 Concentration of glial cytoplasmic inclusions (GCI) in MSA

High concentration	*Low concentration or absence*
Primary motor cortex	Visual pathways
Supplementary motor cotex	Auditory pathways
Putamen: dorsolateral portion	Olfactory system
Caudate: dorsolateral portion	Somatosensorial system
Globus pallidum	Limbic areas
Internal and external capsula	
Substantia nigra	
Basis pons	
Medial cerebellar peduncle	
Cerebellar white matter	

pathogenesis of all α-synucleinopathies, is not yet elucidated. Whether environmental factors influence α-synuclein aggregation, and the survival of glial and neuronal cells remains unknown as well. MSA is a sporadic disease, and no confirmed familial cases of MSA have been described yet; notwithstanding, it is conceivable that genetic factors may play some role in the etiology of the disease.

Clinical Picture

MSA-P

MSA patients may present with parkinsonism that often responds poorly to levodopa. This has been identified as the most important early clinical discriminator of MSA and PD, although a subgroup of MSA patients may show a good, but usually short-lived, response to levodopa. Bradykinesia, rigidity, postural tremor as well as disequilibrium, and gait unsteadiness characterize parkinsonism associated with MSA. Jerky postural tremor, and less commonly tremor at rest may be superimposed and, frequently, patients exhibit a characteristic quivering high-pitched mixed dysarthria. It has been suggested that a symmetrical atremulous picture might distinguish MSA-P from PD. However, motor disturbance was asymmetrical in 74% of patients in a clinical series, and unilateral at onset in 47% of the literature cases. Also, some sort of tremor is present in 64–80% of cases and, tremor present at rest is observed in 29–40% of cases. Even so, a classical pill-rolling resting tremor may be observed in only 7–9% of subjects. Therefore, the differential diagnosis of MSA-P and PD may be quite difficult in the early stages due to a number of overlapping features such as rest tremor or asymmetrical akinesia and rigidity. Levodopa-induced dyskinesia affecting orofacial and neck muscles occurs in 50% of MSA-P patients, sometimes in the absence of motor benefit. This feature seems typical of MSA.

MSA-C

Progressive ataxia may also be a presenting feature of MSA, and this variant of MSA appears to be more common than the parkinsonian variant in Japan compared to Western countries.

The cerebellar disorder comprises gait ataxia, limb kinetic ataxia, and scanning dysarthria as well as cerebellar oculomotor disturbances. Quite common is a wide-based ataxic gait; however, a subgroup of patients present with narrow-based unsteady gait due to more marked impairment of the postural reflexes. The finding of a mixed dysarthria with combinations of hypokinetic, ataxic, and spastic components is consistent with both the overall clinical and the neuropathologic changes of MSA.

Dysautonomia

Dysautonomia is a characteristic of both MSA subtypes, primarily including urogenital and orthostatic dysfunction. Urogenital dysfunction manifesting with urinary incontinence (71%) or retention (27%), often early in the course or as presenting symptoms, is very frequent. In men, the urological symptoms of pollakiuria, urgency, nicturia, and incontinence together with hesitancy and incomplete emptying or chronic retention may simulate those of prostatic outflow obstruction. Early impotence is virtually universal in men with MSA. In a series of 62 MSA patients, impotence occurred in 96% of the men and was the first symptom alone in 37%. In addition, MSA patients may note severe constipation and hypo or anhydrosis.

Orthostatic dysfunction characterized by recurrent syncopal attacks is commonly regarded as a typical feature of MSA. However, severe orthostatic hypotension with recurrent (more than three) syncopes was only reported in 15% of subjects whereas postural faintness was present, but only to a mild or moderate degree, in up to 53% of cases. The analysis of a detailed questionnaire and autonomic function tests in a series of 121 patients with clinically diagnosed MSA showed that urinary symptoms (96%) were more common than orthostatic symptoms (43%). Orthostatic hypotension is frequently associated with impaired or absent reflex tachycardia upon standing and, dopaminergic drugs may provoke or worsen its manifestation.

Pyramidal Signs

Although pyramidal signs may be elicited in up to 61% of MSA patients, obvious spastic paraparetic gait or significant pyramidal weakness should cast doubt upon the clinical diagnosis of MSA.

Other Clinical Features

MSA-P can be difficult to differentiate from idiopathic PD because of the lack of clear pathognomic features between the two disease states. Besides the poor response to levodopa, and the additional presence of pyramidal or cerebellar signs or severe autonomic failure as major diagnostic clues, certain other features may either raise suspicion of MSA, or at least suggest that one might not be dealing with PD. Diagnostic clues that distinguish between the two entities could assist in the early differentiation of MSA-P from PD in a clinical setting. A recent multicenter study by the European MSA Study Group (EMSA-SG) evaluated the diagnostic role of potential 'red flags' in MSA-P versus PD in order to better raise clinical suspicions of MSA-P. The initial list of potential

'red-flags' included the following items: instability and early falls, rapid progression of the disease, camptocormia (prolonged episodes of forward trunk flexion), Pisa syndrome (prolonged episodes of lateral trunk flexion), orofacial dystonia, disproportionate antecollis, contractures of joints, jerky tremor, diurnal and nocturnal inspiratory stridor, severe dysphonia, severe dysarthria, severe dysphagia, sleep dysfunction (including REM sleep behavior disorder and sleep apnea), emotional incontinence, and history of hypertension. Red-flags signs were then further grouped into six categories: early instability, rapid progression, abnormal postures, bulbar dysfunction, respiratory dysfunction, and emotional incontinence. All these categories were significantly found to occur more frequently in MSA than in PD. Larger studies of the identified red flags in patients with possible MSA-P would be useful to further establish the predictive value of this system.

Progression

MSA is a chronically progressive disease characterized by the gradual onset of neurological symptoms and rapid accumulation of disability reflecting involvement of the systems initially unaffected. Thus, patients who present initially with extrapyramidal features commonly progress to develop autonomic disturbances, cerebellar disorders, or both. Conversely, patients who begin with symptoms of cerebellar dysfunction often progress to develop extrapyramidal or autonomic disorders, or both. Patients whose symptoms initially are autonomic may later develop other neurological disorders. In a study looking at the progression of Hoehn and Yahr (HY) stages in different parkinsonian disorders, patients with PD showed significantly longer latencies to each HY stage than patients with atypical parkinsonian disorders such as MSA. In fact, development of a HY-III within 1 year of motor onset accurately predicted MSA. Once patients with PD and MSA became wheelchair-bound, both had equally short survival times. Although therapeutic options are limited at present, there is a real hope for a radical change of our approach to this devastating illness. A few trials with possible neuroprotective agents are already ongoing.

Multiple System Atrophy: Animal Models

N Stefanova, Innsbruck Medical University, Innsbruck, Austria

Glossary

3-NP (3-nitropropionic acid) – A mycotoxin and an inhibitor of succinate dehydrogenase that induces selective neurodegeneration of striatal GABAergic medium spiny neurons.

6-OHDA (6-hydroxydopamine) – A neurotoxin that is closely related to dopamine and is readily taken into dopaminergic and noradrenergic neurons via their normal reuptake mechanism, whereupon it destroys the neuron terminals, causing loss of function.

MPTP (1-methyl 4-phenyl 1,2,3,6-tetahydropyridine) – A neurotoxin that causes permanent symptoms of Parkinson's disease by killing dopaminergic neurons in the substantia nigra pars compacta.
Multiple system atrophy – An adult onset neurodegenerative disorder with features of levodopa resistant parkinsonism, cerebellar ataxia, pyramidal signs, and autonomic failure.
Quinolinic acid (QA) – An *N*-methyl-D-aspartate receptor agonist that may cause selective excitotoxic cell death of striatal GABAergic medium spiny neurons.
Spinocerebellar ataxias – A group of autosomal dominant ataxic disorders caused by degeneration of the cerebellum and its afferent and efferent connections.

Neurotoxin Models of MSA

The first effort to model multiple system atrophy (MSA) in rodents occurred in 1996 with the unilateral double lesion rat model. Wenning et al. based the idea of reproducing striatonigral degeneration (SND) in rats by applying selective nigral and striatal neurotoxins. To do this, 6-hydroxydopamine (6-OHDA) is administered into the medial forebrain bundle to induce an almost complete lesion of the substantia nigra pars compacta (SNc), and is followed by intrastriatal injection of quinolinic acid (QA) into the ipsilateral striatum to target GABAergic medium spiny neurons of the striatum. The unilateral 6-OHDA lesion results in ipsilateral rotation to amphetamine-induced dopamine release and contralateral rotation to apomorphine (dopamine receptor agonist). Following the subsequent striatal lesion, amphetamine-induced ipsilateral rotation persists, but apomorphine-induced contralateral rotation is reduced or abolished. The unilateral double lesion rat model has demonstrated a complex interaction of nigral and striatal lesions depending on the lesion sequence. Further, it has reproduced the typical levodopa-unresponsive motor disability accompanied by levodopa-induced dyskinesia correlating with striatal FosB/ΔFosB upregulation in the remaining striatum.

The unilateral double lesion rat model has been widely used to test the neuroprotective and neurorestorative strategies for the parkinsonian variant of MSA (MSA-P). Riluzole, an antiglutamatergic drug, demonstrated striatal, but no nigral protection in the double-lesion rat model of MSA-P. Minocycline, which has been demonstrated to have a significant neuroprotective effect in Parkinson's disease (PD) and Huntington's disease (HD) models, was ineffective in the MSA-P rat model in terms of sparing neurons in the striatum and SNc; nevertheless, there was efficient suppression of microglial and astroglial activation. Finally, caspase inhibition failed to exert neuroprotection in the MSA-P rat model. Grafting in the double-lesion rat model has demonstrated that embryonic allografts of mesencephalic and striatal origin survive transplantation in SND with, however, poor dopaminergic reinnervation of the lesioned striatum. Yet, striatal grafts could restore the apomorphine-induced contralateral rotation suggesting a possibility to restore the dopamine response in the lesioned striatum of SND.

In an attempt to better reproduce the symmetric lesion pattern in MSA-P, selective neurotoxins have been used to develop systemic models of MSA-P with bilateral striatal and nigral lesions. 3-Nitropropionic acid (3-NP) and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) have been intraperitoneally injected in mice and primates in various sequence- and dose-paradigms. The studies confirm the complex integrative mechanisms that likely regulate the vulnerability of the striatum and SNc to cell death in MSA-P. Again, neuroprotective studies with riluzole provided limited 'neuronal rescue' with subtle motor improvement in the systemic MSA-P mouse model.

In conclusion, all neurotoxin models, whether stereotaxic or systemic, reproduce the neuronal cell loss in the striatum and SNc, and thus model the SND pathology of MSA-P. These models are useful to study the neuronal circuitry interactions with possible pathogenic contribution in the striatonigral system as well as to explore therapeutic approaches for neuroprotection. The neurotoxin double lesion rodent models prove to be valuable preclinical tools for testing neurotransplantation with restoration of dopamine response as a possible strategy in MSA treatment.

Transgenic Models of MSA

In 2000, Zuscik et al. suggested that overexpression of α_{1B}-adrenergic receptors might cause MSA. Overexpression of α_{1B}-adrenergic receptors in transgenic mice induced apoptotic neurodegeneration of SNc with a levodopa responsive Parkinson-like motor disorder, autonomic dysfunction, and α-synuclein inclusion formation. However, the authors also observed recurrent grand mal seizures, which are atypical for MSA. In addition, the pattern of brain lesions, beginning in cortex, hypothalamus, and cerebellum, and then progressing with age to encompass all brain areas, was only partially consistent with the neuropathology of MSA. For all these reasons as well as the limited information on the expression of adrenergic receptors in MSA, it has been difficult to correlate the disease

pathogenesis with the mouse model overexpressing α_{1B}-adrenergic receptors.

Further, after detecting specific oligodendroglial α-synuclein pathology in MSA, efforts have focused on reproducing glial cytoplasmic inclusions (GCIs) in transgenic mice with targeted overexpression of human α-synuclein in oligodendrocytes. The proteolipid protein (PLP) promotor was first used to express human α-synuclein in mouse oligodendrocytes. The transgenic α-synuclein demonstrated high insolubility and hyperphosphorylation at serine 129, like in human MSA. Behavioral studies indicated stride length shortening in these animals associated with mild loss of dopaminergic neurons in SNc and extensive region-specific and age-related microglial activation that at least partly mediates neurodegeneration. Later on, two other transgenic mouse models applied either the 2′, 3′-cyclic nucleotide 3′-phosphodiesterase (CNP) promotor or the myelin basic protein (MBP) promotor for oligodendroglial overexpression of α-synuclein; these models suggested that GCI-like pathology may initiate neurodegeneration associated with secondary axonal degeneration and mitochondrial dysfunction, yet without achieving the selective neurodegeneration pattern of MSA.

Further, transgenic mice with oligodendroglial α-synuclein pathology showed increased susceptibility to exogenous oxidative stress. When systemically applied, 3-NP led to severe SND with striatal shrinkage, loss of striatal GABAergic medium spiny neurons, loss of dopaminergic neurons in the substantia nigra pars compacta, and loss of dopaminergic nigrostriatal fibers. Additionally, 3-NP exposure of (PLP)-α-synuclein transgenic mice affected the cerebellar cortex, pons, and inferior olives, thereby reproducing human olivopontocerebellar atrophy (OPCA) with cerebellar shrinkage and loss of Purkinje cells, neuronal loss in pons and inferior olives. In addition to the transgenic oligodendroglial pathology with insoluble and hyperphosphorylated α-synuclein-positive inclusions, the degenerating areas included prominent astrogliosis and microglial activation. This has been the first complete phenotypic animal model of MSA which completely reproduces the selective neurodegeneration of the human disease by a combination of genetic predisposition (oligodendroglial α-synuclein expression) and induction of exogenous oxidative stress. It has recently proven to be successfully applicable in preclinical neuroprotection studies. High doses of rasagiline, a selective monoaminoxidase-B (MAO-B) inhibitor used in the symptomatic therapy of PD, achieved significant motor improvement in MSA mice. This correlated with neuroprotection at a striatonigral and olivopontocerebellar level, thereby suggesting rasagiline as a potent neuroprotective candidate for MSA. Furthermore, this combined MSA mouse model has proven to be a valuable tool for studying the role of oligodendroglial α-synuclein pathology, embryonic striatal graft survival, and functional activity as these will be important determinants in potential clinical trials of neurotransplantation in MSA patients.

In conclusion, despite their imperfection, the transgenic mouse models with oligodendroglial α-synuclein expression are useful tools that reveal pathogenic mechanisms related to GCI-like pathology. The combined α-synuclein+3-NP mouse model provides an excellent phenotypic system with both behavioral and neuropathological outcome parameters that may serve to evaluate novel therapeutic strategies for MSA.

Animal Models of SCAs

Spinocerebellar ataxias (SCAs) are a group of genetically determined neurodegenerative disorders. The experimental animal models typically target the affected gene either by transgenic or knockin approaches. SCA 1, SCA 2, SCA 6, SCA 7, and SCA 17 are members of the group of the polyglutamine (polyQ) diseases. However, excluding the CAG repeat, the gene products associated with these SCAs share no significant homology and in most cases, have partly unknown function. The use of animal models has been crucial to understand the disease pathogenesis in SCA 1 and the affected protein, ataxin-1. Numerous SCA 1 models have emphasized the importance of the subcellular localization of the mutated protein, the role of the nuclear inclusions, protein folding, as well as the clearance and posttranslational modification in the disease. SCA 2 is a neurodegenerative disorder caused by the expansion of an unstable CAG repeat in the ataxin-2 gene with a phenotype of progressive ataxia accompanied by slow saccadic eye movements. Transgenic mice expressing mutant ataxin-2 show progressive functional and pathological deficits, namely shortened stride length and abnormal rotarod performance combined with loss of Purkinje cells. SCA 7 is caused by CAG trinucleotide expansion within the coding region of the gene coding ataxin-7. All SCA 7 mouse models express full-length ataxin-7 with different sizes of polyQ expansion in different targeted neuronal types. In knockin and transgenic mice, widespread expression of mutant ataxin-7 in the CNS causes adult onset and progressive neurological phenotype usually with gait ataxia, motor incoordination, and premature death regardless of the phenotypic differences.

In summary, the animal models of SCAs allow insights into the regional susceptibility and main pathogenic mechanisms related to the various genetic mutations associated with SCA. Therapeutic strategies have now been addressed in animal models of SCA by overexpression of chaperones, such as HSP70, HSP40/HDJ1, DNAJ1, and HSP104, or reduction of acetylation through histone deacetylase inhibitors.

Myoclonic Epilepsy with Ragged Red Fibers (MERRF)

M Hirano, Columbia University Medical Center, New York, NY, USA

Glossary

Cytochrome *c* oxidase (COX) – Complex IV of the mitochondrial respiratory chain.
Cybrids – Cytoplasmic hybrid cells usually generated by fusing cytoplasm from patient cells harboring a mtDNA mutation with cells lacking mtDNA (rho-zero cells).
Heteroplasmy – A mixture of different forms of multicopy DNA molecules (e.g., mtDNA).
Homoplasmy – A uniform population of multicopy DNA molecules.
Maternal inheritance – Vertical transmission of DNA from mother to progeny.
Mitochondrial DNA (mtDNA) – A small (16 569 base pair) circular DNA molecule within mitochondria and encoding 37 genes.
Ragged-red fibers – Abnormal muscle fibers with subsarcolemmal reddish appearance by modified Gomori trichrome stain.
Respiratory chain – A set of four multisubunit enzymes (complexes I–IV) embedded in the mitochondrial inner membrane that transfers reducing equivalents (electrons) to generate a transmembrane proton gradient.
Succinate dehydrogenase (SDH) – Complex II of the mitochondrial respiratory chain, and a component of the tricarboxylic acid cycle.
Transfer RNA – A small RNA molecule that transfers an amino acid to a growing polypeptide.

Definition and History

Myoclonus epilepsy with ragged-red fibers (MERRF) is a multisystem mitochondrial disorder defined by myoclonus, generalized epilepsy, ataxia, and ragged-red fibers (RRFs) in muscle biopsies. In 1921, Ramsay Hunt described six patients with a disorder resembling Friedreich ataxia characterized by ataxia, myoclonus, and epilepsy, which he called 'dyssynergia cerebellaris myoclonica.' Several different disorders have been associated with this clinical triad, but nearly 60 years passed before Fukuhara and colleagues

reported two patients with a syndrome that they named 'myoclonus epilepsy associated with ragged-red fibers,' but has also been called Fukuhara disease.

Pathogenesis and Pathophysiology

In 1990, Shoffner and colleagues identified a mitochondrial DNA (mtDNA) point mutation, m.8344A > G, in a large pedigree with maternally inherited MERRF. This mutation in the tRNA-Lys (MTTK) gene has been found in about 80% of patients with MERRF. Three additional MTTK gene mutations (m.8356T > C, m.8361G > A, and m.8363G > A) have been identified in MERRF patients as well as a tRNA-Phe (MTTD) mutation (m.611G > A). It is unclear why the MTTK gene is a hot-spot of MERRF mutations.

Studies of cultured myoblasts from patients and cybrid cells (cytoplasmic hybrid cells containing different mtDNA species against a uniform nuclear DNA background) have demonstrated that the m.8344A > G mutation impairs molecular modification (addition of a 5-taurinomethyl-2-thiouridine to the anticodon wobble base) of $tRNA^{Lys}$, and leads to reduced levels of the native and aminoacylated $tRNA^{Lys}$. At high levels (>85%) of the m.8344A > G or m.8356T > C mutant $tRNA^{Lys}$ cause reduction of mitochondrial protein synthesis and mtDNA-encoded proteins leading to respiratory chain defects, particularly cytochrome *c* oxidase (COX) deficiency and decreased oxygen consumption.

Clinical expression of the mutation depends on three factors: (1) mtDNA heteroplasmy, (2) mtDNA tissue distribution, and (3) tissue threshold. Skeletal muscle biopsies typically demonstrate mitochondrial abnormalities; by histochemistry a mosaic pattern of RRFs and COX and by biochemistry, respiratory chain defects, particularly COX deficiency, are often detected. The RRF and COX-deficient fibers harbor higher levels of mtDNA mutations supporting pathogenicity and accounting for the mosaic pattern. Pathological studies of brain have revealed neuronal loss in the dentate nucleus, inferior olivary nucleus, degeneration of the posterior columns of the spinal cord, and diffuse gliosis of the cerebellar white matter and of the brain.

Epidemiology/Risk Factors

MERRF patients have been found worldwide. The disorder has no known ethnic predilection. Three epidemiological studies in northern European countries have estimated prevalence of the A8344G mutation to be 0–1.5 out of 100 000.

Clinical Features and Diagnostic Criteria

MERRF is defined clinically by: (1) myoclonus, (2) generalized epilepsy, (3) ataxia, and (4) RRFs in the muscle biopsy. Onset of the disease is usually in childhood, but adult onset has been described. Besides the defining criteria, other common clinical manifestations include impaired hearing, dementia, peripheral neuropathy, short stature, exercise intolerance, optic atrophy, and lactic acidosis. Other less frequent manifestations include optic nerve atrophy, cardiomyopathy, electrocardiographic preexcitation syndrome, pigmentary retinopathy, pyramidal tract signs, ophthalmoparesis, pes cavus, and multiple lipomatosis. Most patients have a family history of mitochondrial encephalomyopathy, although not always the full MERRF syndrome. Occasional patients that fulfill the clinical criteria for MERRF also have had strokes similar to mitochondrial encephalomyopathy lactic acidosis and stroke-like episodes (MELAS). Maternally inherited spinocerebellar degeneration, atypical Charcot–Marie-Tooth disease, and Leigh disease have been reported as unusual manifestations in a MERRF pedigree while one patient presented with parkinsonism without myoclonus, epilepsy, or ataxia.

Differential Diagnosis

The differential diagnosis of syndromes characterized by myoclonus epilepsy and ataxia includes Unverricht–Lundborg disease, Lafora body disease, neuronal ceroid lipofuscinosis, and sialidosis. When no etiology is found, the diagnosis of Ramsay Hunt syndrome is made.

Diagnostic Work-up/Tests

Screening patients for MERRF should begin with routine blood tests including complete blood count, serum electrolytes, liver function tests, blood urea nitrogen, creatinine, lactate, and pyruvate. These tests may reveal kidney or liver dysfunction. Lactate and pyruvate at rest are commonly elevated in MERRF patients and may increase dramatically after moderate exercise. Blood leukocyte or urinary sediment DNA should be screened for an mtDNA point mutation because identification of an mtDNA mutation will obviate the need for a costly and invasive muscle biopsy.

Electrocardiograms may reveal preexcitation. Lumbar puncture may show elevated cerebrospinal fluid protein, but generally $<100\,mg\,dl^{-1}$. Electromyography and nerve conduction studies are typically consistent with a myogenic process, although a neuropathy may also be present. Typically, there are decreased amplitudes of compound muscle or nerve action potentials indicating axonal degeneration. Electroencephalography may show atypical generalized spike and wave discharges, with abnormal background slowing; focal epileptiform discharges may also be seen. Somatosensory-evoked responses often reveal giant cortical-evoked responses. Brain imaging with CT or MRI may show basal ganglia calcification and generalized atrophy.

Finally, muscle biopsy can be performed to confirm the diagnosis. RRFs on modified Gomori trichrome stain are the hallmark histological feature and a defining criterion. In addition, a mosaic pattern of COX-deficient fibers is typically seen; however, some MERRF patients with the A8344G mutation lack RRFs and COX-deficient fibers. Mitochondrial enzyme activities can be measured in whole muscle homogenate or in isolated mitochondria and usually demonstrate multiple respiratory chain defects, particularly in complex IV. When the clinical and muscle histological abnormalities indicate MERRF, mtDNA should be screened for the mutations.

Management

The seizures of MERRF can be treated with conventional anticonvulsant therapy. There are no controlled studies to compare efficacy of different antiepilepsy regimens. Aerobic exercise can reverse deconditioning in MERRF and other mitochondrial diseases.

No treatment for the genetic defect is currently available. Coenzyme Q10 (50–200 mg tid) and L-carnitine (300 mg qd) have been used to improve mitochondrial function.

Prognosis

The disease gradually progresses over years. The age of death has ranged from 7 to 79 years. The major complications are seizures and, less commonly, blindness and cardiac failure.

Myoclonus

M A Thenganatt and S J Frucht, Columbia University Medical Center, New York, NY, USA

Glossary

Cortical myoclonus – Myoclonus arising from a hyperexcitable focus within the sensory-motor cortex.

Essential myoclonus – A syndrome of isolated myoclonus or a syndrome accompanying dystonia and no other neurologic abnormalities.

Lance–Adams syndrome – Myoclonus following hypoxic encephalopathy.

Negative myoclonus – Brief losses of muscle tone in the agonist muscles followed by a compensatory jerk of antagonist muscles.

Palatal myoclonus – Myoclonus that presents as rhythmic movements of the palate at a frequency of

2 Hz. This form of myoclonus may be primary or secondary.
Propriospinal myoclonus – Myoclonus resulting from a thoracic cord generator that is notable for the relatively slow spread of impulses up and down the cord.
Reticular reflex myoclonus – A form of brainstem myoclonus that causes flexor jerks of the proximal limbs and trunk and is stimulus sensitive.
Spinal segmental myoclonus – A form of spinal myoclonus derived from several adjacent segments of the spinal cord, usually the cervical or thoracic cord.
Subcortical myoclonus – Myoclonus not associated with a cortical discharge. An example is thalamic myoclonus.

Definition and History

Myoclonus is defined as brief, involuntary lightning-like muscle jerks that arise from the central or peripheral nervous system. These movements correlate with brief electromyographic discharges lasting for 10–100 ms in duration. Positive myoclonic jerks are contractions of a muscle or group of muscles which are most noticeable during voluntary movements such writing, using utensils, or walking. Negative myoclonic jerks are brief losses of muscle tone in the agonist muscles followed by a compensatory jerk of antagonist muscles. Examples of negative myoclonus include asterixis seen in hepatic encephalopathy, and loss of postural tone seen in posthypoxic myoclonus and stiff person syndrome. Myoclonus was first defined by Friedrich in 1881, through a case report of a patient with essential myoclonus.

Pathogenesis and Pathophysiology

Myoclonus can originate from the cerebral cortex, subcortical structures, brainstem, spinal cord, or peripheral nerve. Determining the origin of myoclonus is important in guiding the treatment. Cortical myoclonus arises from a hyperexcitable focus within the sensory-motor cortex. Thalamic myoclonus, an example of subcortical myoclonus, is not associated with a cortical discharge. There are three types of myoclonus that arise from the brainstem – startle, palatal myoclonus, and reticular reflex myoclonus. Palatal myoclonus may be primary or secondary. The secondary form is caused by a lesion within the Guillain–Mollaret triangle which includes the dentate, red, and inferior olivary nuclei. Such a lesion interrupts the dentato-olivary pathway, leading to olivary denervation and hypertrophy. Spinal myoclonus can be further subdivided into two types, segmental and propriospinal. Spinal segmental myoclonus is derived from several adjacent segments of the spinal cord, usually the cervical or thoracic cord. Propriospinal myoclonus usually results from a thoracic cord generator and is notable for the relatively slow spread of impulses up and down the cord. Myoclonus resulting from peripheral nerve injury, for example hemifacial spasm, is limited to the involved motor unit.

Epidemiology and Risk Factors

Myoclonus is one of the most common movement disorders that neurologists encounter in the hospital and outpatient setting. However, myoclonus has received less attention than other hyperkinetic disorders such as dystonia, tremor, chorea, and tics. This may be in part due to the fact that myoclonus is typically transient in the hospital setting, and often overshadowed by other associated medical problems. Myoclonus is also seen in the outpatient setting. In the community, chronic myoclonus has a prevalence rate of 8.6 per 100 000. Negative myoclonus is more common in the inpatient setting, while positive myoclonus is more prevalent in the outpatient clinic.

The causes of myoclonus are varied and include physiologic phenomena, epileptic syndromes, and metabolic disturbances. Physiologic myoclonus is a normal phenomenon exemplified by hiccups (myoclonus of the diaphragm) and hypnic jerks upon falling asleep. Essential myoclonus or myoclonus-dystonia is a syndrome of isolated myoclonus or with accompanying dystonia and no other neurologic abnormalities. This is a rare disorder and is inherited in autosomal dominant fashion with maternal imprinting. Most cases of inherited myoclonus-dystonia are exquisitely sensitive to alcohol, and the disorder has been linked to mutations in the ε-sarcoglycan gene located on chromosome 7, and in other families to chromosome 18. There is probably a higher incidence of obsessive–compulsive disorder in patients with myoclonus-dystonia. Myoclonus may be associated with epileptic syndromes such as juvenile myoclonic epilepsy and Lennox–Gastaut syndrome. Progressive myoclonic epilepsy is a term used to describe a group of degenerative disorders characterized by epilepsy, myoclonus, and progressive neurologic deterioration. Examples of progressive myoclonic epilepsy are neuronal ceroid lipofuscinosis, Lafora body disease, MERRF, MELAS, sialidoses, and Unverricht–Lundborg disease. Symptomatic myoclonus can occur in the setting of metabolic encephalopathy such as renal, hepatic, or pulmonary dysfunction; these movements are generally negative myoclonus such as asterixis. Posthypoxic myoclonus is classically described post cardiac arrest but can be seen after asthmatic attacks, obstructed airways, or accidental intubation of the esophagus.

The latter is less common now with end-tidal CO_2 monitoring. Drug toxicity, such as the serotonin syndrome, is another cause of myoclonus. Myoclonus is associated with a variety of degenerative diseases such as Huntington's disease, Alzheimer's disease, Creutzfeldt–Jakob disease, corticobasal ganglionic degeneration, multiple system atrophy, and subacute sclerosing panencephalitis. Common causes of secondary palatal myoclonus are multiple sclerosis and cerebrovascular disease. The infectious encephalopathy of Whipple's disease features facial myoclonus referred to as oculofacial-masticatory myorhythmia; other common features include supranuclear vertical gaze palsy and cognitive changes. Encephalomyelitis with rigidity is a severe, sudden-onset variant of the stiff-person syndrome, denoted by stiffness, excessive startle, and stimulus-triggered myoclonic jerks; it often responds to steroid therapy. An uncommon form of myoclonus is polymini-myoclonus, in which the jerks are of small amplitude, resembling irregular tremor that is continuous, and generalized. The term opsoclonus is applied when the eyes are involved with spontaneous, irregular, chaotic saccades. First described as part of an encephalopathic picture in infants, particularly in association with neuroblastoma, it also has been found in adults, usually as a paraneoplastic or postviral syndrome. The latter disorder is self-limiting after months or years. The paraneoplastic syndrome is associated with antineuronal antibodies and may remit with removal of the tumor.

Clinical Features and Diagnostic Criteria

Myoclonic jerks may occur singly or repetitively, and they may be focal, segmental, or generalized. Their amplitude ranges from mild contractions that do not move a joint, to gross contractions that move limbs, the head, or the trunk. Myoclonic jerks range in frequency from rare isolated events to many events each minute; they may occur at rest, with action or with intention. Commonly myoclonic jerks are stimulus sensitive; they can be induced by sudden noise, movement, light, visual threat, or pinprick. Most often myoclonic jerks occur irregularly and unpredictably, but some occur in bursts of oscillations and may even be rhythmic, as in palatal myoclonus. Rhythmical myoclonus almost always denotes a segmental origin, either brainstem or spinal cord. An uncommon rhythmical form, cortical tremor, originates in the cerebral cortex.

Cortical myoclonus is triggered by action or intention and is typically stimulus sensitive. Examples of stimuli include sound, touch, or startle. It is classically arrhythmic and involves an arm, leg, or face; however, in the case of epilepsia partialis continua, myoclonic jerks may be rhythmic. Thalamic myoclonus, an example of subcortical myoclonus often presents as asterixis. Myoclonus originating from the brainstem can be either generalized (reticular myoclonus) or segmental (e.g., ocular-palatal-pharyngeal myoclonus).

Palatal myoclonus presents as rhythmic movements of the palate at a frequency of 2 Hz. Primary palatal myoclonus disappears during sleep, while secondary myoclonus may persist. Primary palatal myoclonus is of unknown etiology and is often associated with annoying constant clicking sounds in the ear caused by contractions of the tensor veli palatini muscles which open the eustachian tubes. Secondary palatal myoclonus is often associated with rhythmic vertical ocular movements, also occurring at 2 Hz, called ocular myoclonus.

Reticular reflex myoclonus causes flexor jerks of the proximal limbs and trunk, and is stimulus-sensitive. Spinal segmental myoclonus is rhythmic and stimulus-insensitive and persists during sleep. Propriospinal myoclonus causes flexor jerks of the trunk and is sensitive to stimuli such as when eliciting the knee jerk. The muscles in the torso are commonly activated first and then spread rostrally and caudally. Myoclonus resulting from peripheral nerve injury, such as hemifacial spasm, is irregular and typically stimulus-insensitive.

Myoclonus following hypoxic encephalopathy is known as the Lance–Adams syndrome and was first observed by Dr. James Lance in survivors of cardiac arrest in the 1960s. Most patients with this syndrome are between the ages of 15 and 60. This probably reflects the relative resistance of the young brain to hypoxia and the poor survival of older adults after cardiac arrest. Myoclonus in this syndrome may be cortical, subcortical, or both. Similarly, it may be action and intention myoclonus, negative myoclonus with postural lapses, or both. The myoclonus may be stimulus-sensitive and have a distal predominance. Myoclonic jerks are triggered by voluntary movements such as reaching for an object, drinking from a glass, or feeding oneself. Affected patients have a tendency to fall due to failed sustained contraction of antigravity muscles. Negative myoclonus may involve the hamstring and quadricep muscles, producing a characteristic "bouncing" gait that may be misinterpreted as psychogenic by an untrained observer. Another peculiar tendency of these patients is their susceptibility to startle. One misstep or stumble could result in myoclonic jerks or loss of postural tone resulting in a fall. Other associated neurological features include dysarthria, dysmetria, and ataxia. Patients also suffer from difficulties with attention, memory, and executive function which are recognized with formal neuropsychological testing. Patients with posthypoxic myoclonus are usually in a coma for up to 7 days and seizures are common during this stage. These patients may be noted to startle easily to sounds. Of patients who emerge from coma and enter the chronic phase of this disorder, at least one third will have dysarthria and ataxia and more than two thirds have difficulty walking. Seizures are frequent but are usually well controlled by anti-epileptic medications. Many patients who develop the Lance–Adams syndrome are left with significant permanent disability.

Differential Diagnosis

Myoclonus is usually easily distinguished from other hyperkinetic movement disorders. In contrast to dystonia, tics, chorea, and tremor, myoclonus is one of the few movement disorders that persists during sleep. Dystonia is slower, sustained, and results in twisting postures. Tics are brief, stereotyped movements, which are suppressible – a distinguishing feature from myoclonus. Chorea is fragmentary, flowing, and associated with motor impersistence; however, patients with chorea of the distal extremities may occasionally mimic myoclonus. Tremor is rhythmic and oscillatory, present at rest, posture, or action, and is slower than myoclonus.

Diagnostic Work-Up/Tests

Surface EMG

The principal diagnostic test of myoclonus is surface EMG recording of myoclonic movements. Recording simultaneously from as many muscles as possible allows one to determine the distribution and spread of myoclonus. Band pass filters of 30–1000 Hz are adequate. Cortical myoclonus is associated with an EMG discharge of abrupt onset and short duration, lasting less than 50 ms. In most cases, agonist and antagonist muscles contract simultaneously. It may spread from proximal to distal muscles at the speed of about $50\,m\,s^{-1}$, which approximately corresponds to the conduction velocity of α-motor fibers.

EEG–EMG Polygraph

Simultaneous recording of EEG with the surface EMG is especially useful for the confirmation of cortical myoclonus. The EEG is recorded by placing electrodes according to the International 10–20 System. The referential derivation with ipsilateral earlobe reference or bipolar derivation is used. Band pass filter of 1–500 Hz is usually used. The demonstration of spikes or multiple spikes on EEG highly suggests a cortical origin of myoclonus. The spikes may be associated with myoclonic jerks, or they may not. Absence of EEG spikes, however, does not exclude cortical myoclonus, because small spikes may not be detected by scalp recording because of attenuation of the electric potential by the skull.

Jerk-Locked Back Averaging of EEG

The technique of jerk-locked back averaging can be used for detecting spikes associated with myoclonus that are otherwise not detectable on the conventional EEG–EMG polygraph. It can also be used for investigating the time and spatial relationship between the EEG spikes and myoclonus. EEGs and EMGs are simultaneously recorded just like the conventional polygraph, and the onset of EMG discharges associated with myoclonus is used as a fiducial point for back-averaging the EEG. The EMG may be rectified to avoid the canceling effect by averaging, integrated, and then its onset used as a fiducial point for back averaging. In order to obtain a record of good quality, it is important to choose the most appropriate muscle for obtaining the fiducial point, to distinguish the myoclonic discharges from the background EMG activities, and to avoid artifacts such as head movements. In the case of hand myoclonus, the positive peak or the onset of the negative peak of the EEG spike leads the myoclonus by 20 ms on average, and is localized to the central region of the contralateral head.

Somatosensory Evoked Potential (SEP)

The SEP is recorded by delivering electric shocks to the median nerve at wrist with the pulse duration of 0.2–0.3 ms and the stimulus intensity of 10% above the motor threshold. The initial peak of the cortical SEP, N20/P20, is not significantly enlarged, but the subsequent peaks (P25, N30/P30, N35) are extremely enlarged in patients with cortical reflex myoclonus.

Long-Loop Reflex

It is convenient to record the long-loop reflex at the time of SEP recording. While the median nerve is electrically stimulated for recording SEP, the surface EMG can be simultaneously recorded from the thenar muscle of that hand by a pair of surface electrodes. In cortical reflex myoclonus, the transcortical reflex (C reflex) at the latency of about 45 ms is enhanced, while in normal subjects it is not detectable under the resting condition. In the case of severe cortical reflex myoclonus, the reflex EMG response is seen not only in the thenar muscle, but also from other muscles of the same limb and also from the thenar muscle of the contralateral hand. In this case, the C reflex of the contralateral hand occurs 10–15 ms later than that of the stimulated hand.

Management

Several general principles apply to the selection of antimyoclonic therapy. There are few placebo-controled trials of antimyoclonic treatments, and even fewer double-blind trials. As a result therapy is empiric. The choice of agents is dictated by the underlying diagnosis, the likely origin of the myoclonus, and the side effect profile of the antimyoclonic agents. Positive myoclonus is more likely to respond to treatment, while negative myoclonus has more limited treatment options. In practice, after precipitants of

myoclonus are identified and corrected, one treats the positive myoclonus and hopes that negative myoclonus will respond partially as well, or resolve spontaneously.

Unlike the treatment of epilepsy, antimyoclonic agents are usually used in combination, and it is rare for one agent to achieve complete control of myoclonus. It is important to begin one drug at a time, starting slowly and titrating to tolerance or efficacy. The choice of agents is dictated by the underlying diagnosis, the likely origin of the myoclonus, and the side effect profile of the antimyoclonic agents.

There are nine drugs that are used to treat myoclonus: clonazepam, valproic acid, acetazolamide, primidone, L-5-hydroxytryptophan, piracetam, levetiracetam, zonisamide and sodium oxybate. L-5-Hydroxytryptophan is rarely used due to the risk of eosinophilia–myalgia syndrome, and piracetam is not available in the United States. Primidone and acetazolamide are not widely used for the treatment of myoclonus, but in occasional patients these drugs are useful. Sodium oxybate is approved in the United States for the treatment of narcolepsy – while there is preliminary evidence to support its use in select myoclonus patients, it should be considered investigational. This leaves clonazepam, valproic acid, levetiracetam, and zonisamide as the major four drugs used to treat patients with myoclonus in clinical practice.

Clonazepam is used in cortical, subcortical, and spinal myoclonus, and is probably the drug of choice for spinal myoclonus. Clonazepam is available in 0.5, 1, and 2 mg tablets, and is usually prescribed three times per day. It is wise to begin with a small dose, typically 0.5 mg, and to titrate until there is control of symptoms or side effects appear. Most patients require doses of at least 2 mg day^{-1}. Clonazepam is contraindicated in patients with hepatic dysfunction or narrow angle glaucoma. Drug interactions between clonazepam and other drugs are not significant. Clonazepam may potentiate the sedative effect of other medications. The most common side effect is drowsiness, although occasional patients experience ataxia or personality changes. After prolonged use, the dose should be tapered off if discontinuation is required in order to avoid withdrawal symptoms.

Valproic acid was the first drug specifically used for the treatment of myoclonus. It has been shown to be effective in cortical and subcortical myoclonus. A recent open-label study of valproic acid in myoclonic Huntington's disease showed significant improvement in myoclonus with good tolerability. Valproic acid is available in 125, 250, and 500-mg tablets, and is also available in 125-mg capsules. Valproic acid is usually begun at 125 mg BID, and titrated to clinical response. Doses of 750–1000 mg day^{-1} are usually required to achieve antimyoclonic effect. Valproic acid blood level monitoring is available, but is usually not necessary unless patient compliance is at issue. Valproic acid should not be administered to patients with hepatic disease or significant hepatic dysfunction. The drug is also contraindicated in patients with urea cycle disorders. Valproic acid may cause neural tube defects, craniofacial defects and cardiovascular malformations if taken during pregnancy. Drugs that increase levels of hepatic enzymes may decrease serum levels of valproic acid. Phenytoin, carbamazepine, and phenobarbital may decrease levels of valproic acid. Valproic acid may increase levels of warfarin, lamotrigine, phenobarbital, and phenytoin. Fatal hepatic failure may occur in patients taking valproic acid, usually within the first 6 months of treatment. This may occur in individuals who have no history of hepatic impairment. Liver function tests should be monitored frequently in patients taking valproic acid. Valproic acid may also trigger potentially life-threatening pancreatitis in adults and children. Dose-related thrombocytopenia is also possible. Action tremor, alopecia, and reversible parkinsonism are not uncommon. Valproate's extensive side effect profile and potential life-threatening adverse events have relegated this drug to second-line status in our opinion.

Piracetam is a nootropic agent that is available in Europe. It is not FDA-approved and is unlikely to be made available in the United States. Piracetam has been shown to be effective in patients with cortical myoclonus. Tablets are formulated by pharmacies, usually in 400 or 800 mg strength, and it is generally prescribed three times a day. The usual target dose is 16–24 g day^{-1}. Piracetam is contraindicated in patients with renal insufficiency or hepatic dysfunction. Piracetam is excreted unchanged and is not protein bound. There are no major drug interactions. Piracetam is generally well tolerated. There have been case reports of reversible thrombocytopenia and leukopenia. Piracetam should not be abruptly discontinued, as this may precipitate withdrawal seizures.

Levetiracetam is a novel antiepileptic agent, introduced into the United States in early 2000. Levetiracetam has been reported in several studies to be effective in patients with cortical myoclonus, including patients with posthypoxic myoclonus and progressive myoclonic epilepsy. Levetiracetam is probably ineffective in subcortical myoclonus. It is available in 250, 500, and 750 mg tablets. The standard initial dose for epilepsy is 500 mg twice daily, and this dose typically provides adequate seizure control. In contrast, patients with chronic myoclonic disorders may experience side effects from an initial dose of 1000 mg daily, and it is wise to begin initially with 250 or 500 mg day^{-1}, with gradual titration by 500 mg $week^{-1}$. The maximum recommended dose is 3000 mg day^{-1}, although doses as high as 4000 mg day^{-1} have been used. Pediatric doses are 20–40 mg kg^{-1} day^{-1}. Levetiracetam should be used cautiously in elderly patients and in those with decreased renal function. Levetiracetam's great advantage is its pharmacokinetics. It is minimally protein bound and excreted in the urine. There are virtually no interactions with other drugs. Levetiracetam is

exceptionally well tolerated. In placebo-controlled trials, the most commonly reported side effects were dizziness, somnolence, and asthenia. The most troublesome side effects, which occur uncommonly, are psychosis and ataxia.

Sodium oxybate (Xyrem) is used in certain European countries for the treatment for of alcohol withdrawal and in maintaining abstinence from alcohol. It is a schedule III agent in the United States, strictly regulated and approved for the treatment of cataplexy and excess daytime sleepiness in patients with narcolepsy. In one report, alcohol-sensitive myoclonus-dystonia was successfully treated with $6.125\,g\,day^{-1}$. Sodium oxybate has recently been shown to be effective in several patients with posthypoxic myoclonus and myoclonus-dystonia. Sodium oxybate may cause respiratory depression when used along with other CNS depressants. High doses (more than $10\,mg\,kg^{-1}$) may produce CNS depression. Patients with sodium oxybate toxicity may be agitated and combative despite profound CNS depression. Use of sodium oxybate should be considered experimental.

Rarely a first-line antimyoclonic drug, primidone is sometimes used in patients with cortical or subcortical myoclonus. Primidone is available in 50, 125, and 250 mg tablets. Unlike patients with epilepsy, patients with myoclonus do not tolerate rapid titration of primidone. It is wise to start with $25\,mg\,day^{-1}$, gradually increasing no faster than 25 or $50\,mg\,week^{-1}$. The dose is usually increased to tolerance, with a target of $500–750\,mg\,day^{-1}$. Primidone should be used with caution in the elderly, because of the risks of sedation, depression, and mental slowness. Primidone is contraindicated in patients with porphyria. Primidone is metabolized to phenobarbital and phenylethylmalonamide (PEMA). Phenobarbital induces hepatic enzymes and may decrease the levels of drugs metabolized in the liver. Primidone lowers the levels of warfarin and steroids, and may either decrease or increase levels of phenytoin. Sodium valproate decreases phenobarbital metabolism. The most common adverse reaction is drowsiness although tolerance to this side effect usually develops. Primidone may cause significant neurobehavioral and subtle cognitive side effects. It may exacerbate existing behavioral problems and trigger irritability. It may also impair memory and tasks requiring prolonged periods of attention.

Treatment of Specific Myoclonic Syndromes

Posthypoxic myoclonus

A review of posthypoxic myoclonus from 2000 summarized the effects of various agents on myoclonus. Clonazepam significantly improved posthypoxic myoclonus in 24 of 47 patients in whom it was prescribed, and valproate was similarly effective in 10 of 22 patients. L-5-Hydroxytryptophan was effective in only 17 of 43 patients, often with intolerable side effects. Piracetam was effective in three of six patients. Drugs that did not produce significant benefit in even one patient include nitrazepam, primidone, phenobarbital, phenytoin, and tetrabenazine. In March of 2000, the novel antiepileptic agent levetiracetam was released in the United States. Several case reports and series have reported good to dramatic benefit in patients with posthypoxic myoclonus treated with levetiracetam in doses of $1000–1500\,mg\,day^{-1}$. A pilot study to test the tolerability and efficacy of levetiracetam in patients with chronic myoclonus, including four patients with posthypoxic myoclonus, showed that levetiracetam was well tolerated and beneficial in at least two patients. A significant number of patients with posthypoxic myoclonus demonstrate dramatic benefit with alcohol, although benefits are short-lived. Some of these patients may benefit from treatment with sodium oxybate. As patients emerge from coma, myoclonic jerks are probably best managed with clonazepam. This drug has a short half-life, and its sedative properties may be welcome in an encephalopathic, agitated patient. Piracetam is available in Europe and Canada, is well tolerated and is effective in many patients with cortical myoclonus. Side effects are minimal, although patients must be able to swallow pills as the effective dose ranges from 16.8 to $24\,g\,day^{-1}$ (a liquid formulation is available). It is unknown whether piracetam or levetiracetam is more effective in treating cortical myoclonus. Therefore it seems reasonable to choose either drug for patients with proven or suspected cortical posthypoxic myoclonus. If a patient does not respond to one drug, the other should be tried as there have been anecdotal reports of patients responding to only one agent. Once treatment with levetiracetam or piracetam has begun, patients should be weaned off clonazepam in order to minimize its potential side effects (sedation, depression, personality change, and impotence). For patients who do not obtain adequate relief from these drugs, valproic acid is another option. However, its side effect profile and its potential effects on hematologic and liver function parameters make this a less desirable drug.

Posthypoxic myoclonus patients who are afflicted with reticular reflex myoclonus pose a particular challenge. Clonazepam is often helpful; however, drugs that are effective in cortical myoclonus are generally of little benefit. In these patients, and in patients with cortical myoclonus who do not respond to any of the drugs mentioned before, consider using L-5-Hydroxytryptophan. This agent requires pretreatment with carbidopa, and even then nausea and gastrointestinal upset is a major nuisance. The drug can be found in many health food stores, although the purity of the preparation is unknown. In the past, an impurity in one lot of L-5-Hydroxytryptophan triggered a potentially lethal eosinophilia myalgia syndrome, raising concern about the source of the agent. At present, few patients take the drug, and ideally it should be used only with an institutional review board-approved protocol that includes written informed consent.

Progressive myoclonic epilepsy (PME)

Zonisamide has been reported to be particularly effective in PME at doses of 400–600 mg day^{-1}. Other medications that have been used are sodium valproate, topiramate, levetiracetam, baclofen, L-5-hydroxytryptophan, clonazepam, piracetam, and primidone. Phenytoin and carbamazepine should be avoided because of their tendency to worsen cerebellar signs. In a series of four patients with PME, seizures were reported to improve with *N*-acetylcysteine (NAC), without change in myoclonus or ataxia. In the reported cases NAC was used at doses of 3.0–3.6 g day^{-1}. Higher doses may cause neutropenia. One recent series demonstrated the use of chloral hydrate to control daytime myoclonic exacerbations in three patients with PME. Patients were treated with doses ranging from 500–1500 mg day^{-1}. The liquid formulation was found to be more effective and better tolerated that the capsule form. Several open-label trials have shown levetiracetam to be effective in forms of progressive myoclonic epilepsy, including MERRF, Unverricht-Lundborg, Lafora body disease, and in benign adult familial myoclonic epilepsy.

Myoclonus-dystonia

Although alcohol suppresses myoclonus in these patients, it should be avoided because of the risk of abuse and dependence. Repetitive transcranial magnetic stimulation has been tried with empiric benefit in patients with myoclonus-dystonia. One case improved with high frequency deep brain stimulation of the ventral intermediate thalamic nucleus (VIM). Clonazepam, benztropine, anticholinergics, valproic acid, and piracetam have also been reported to be effective in selected patients. Recently, sodium oxybate has been shown to be effective in several patients with ε-sarcoglycan-linked myoclonus-dystonia.

Intractable hiccups

Hiccups require treatment only if they do not remit with conventional treatments. Baclofen, amitryptiline, and valproic acid remain the most commonly used medications. Neuroleptics should be avoided because of the risk of tardive dyskinesia.

Palatal myoclonus

Asymptomatic palatal myoclonus does not require treatment. In a case report from 2002, lamotrigine improved ear clicking from palatal myoclonus. Carbamazepine, L-5-hydroxytryptphan, phenytoin, barbiturates, diazepam, and trihexyphenidyl have been used in selected patients. In one report, injection of botulinum toxin into the levator veli palatini and tensor veli palatini muscle was beneficial. A second study of five patients showed resolution of symptoms in four patients, with transient velopharyngeal insufficiency in one patient.

Opsoclonus-myoclonus

This paraneoplastic or parainfectious disorder may spontaneously resolve, especially when it follows a viral infection. Various immunomodulatory approaches have been used in patients with persistent debilitating opsoclonus-myoclonus. High-dose intravenous immunoglobulin has been reported to be effective as has high-dose methylprednisone, but a recent randomized clinical trial of Piracetam in pediatric opsoclonus-myoclonus found it ineffective. Plasmapheresis has also been found to be beneficial. There have been isolated case reports of response to thiamine and clonazepam.

Spinal myoclonus

Keshwani described three patients with symptomatic spinal myoclonus who improved with levetiracetam. One report mentioned a good response of spinal myoclonus to apomorphine. Botulinum toxin injections have also been used to treat stimulus-sensitive spinal segmental myoclonus. Clonazepam, tetrabenazine, trihexyphenidyl, baclofen, carbidopa/levodopa, valproic acid, and L-5-HTP are the most commonly used medications.

Prognosis

The prognosis of myoclonus is dependent on the underlying cause. For example, drug-induced myoclonus tends to be transitory. Posthypoxic myoclonus, as well, improves with time. Myoclonus in progressive myoclonic epilepsy and degenerative disorders, on the other hand, is typically progressive.

Myoclonus, Animal Models

D D Truong, The Parkinson's and Movement Disorder Institute, Fountain Valley, CA, USA

Glossary

Myoclonus – Myoclonus is defined as a brief, sudden, shock-like, involuntary movement caused by muscular contractions or inhibitions.
Posthypoxic myoclonus – Myoclonus induced after cardiac or pulmonary arrest or after anesthesia accidents during surgery.

Introduction

Myoclonus is defined as a brief, sudden, shock-like, involuntary movement caused by muscular contractions or inhibitions. Myoclonus can be caused by many pathological conditions affecting the central nervous system. For example, neurodegenerative disorders involving the basal ganglia, dementias, cerebral hypoxia, and drug intoxications can cause myoclonus. Posthypoxic myoclonus (PHM) is the most severe form of myoclonus and was first well-described in 1963 by Lance and Adams. PHM is caused by brain injury that results from lack of oxygen as the blood flow is interrupted during cardiac or pulmonary arrest or during anesthesia accidents related to surgery. PHM is characterized by action-triggered jerking, myoclonic movements affecting the normal daily activities of patients. Although the mechanism underlying PHM is not fully understood, the development of medications to manage this movement disorder has been challenging. An animal model of PHM is thus a valuable tool to elucidate the mechanism underlying this movement disorder.

A Rat Model of Cardiac Arrest-Induced PHM

Early attempts to develop animal models of PHM were mostly induced by chemicals instead of transient hypoxic insults. Because the method of myoclonus induction in these animal models is toxic rather than hypoxic, the results from these animal models may have limited direct relevance to PHM in humans. Truong and colleagues have developed an animal model of PHM by mechanical obstruction of the major cardiac vessels for 8.5 min. This method was first introduced by Kawai and colleagues. Cerebral ischemic insult is induced as a result of low arterial blood pressure. Resuscitation is initiated by mechanical ventilation and an injection of an intravenous bolus of epinephrine ($20\,\mu g\,kg^{-1}$) and sodium bicarbonate ($4\,mEq\,kg^{-1}$), followed by manual thoracic compression until the systemic arterial blood pressure returns to the preoperative level. Mechanical ventilation continues until the animal is capable of initiating spontaneous breathing. This mechanical method of inducing PHM mimics the events that occur during anesthesia accidents, allowing the biochemical and pharmacological findings from this animal model to be directly relevant to PHM in humans.

Movement Behavior in the Animal Model

Subjects with severe cardiac arrest-induced cerebral ischemic insults usually go through a deep coma phase before action-induced myoclonus develops. These animals are most susceptible to auditory stimuli, but myoclonic jerks can also be triggered by other stimuli such as

flashing lights. In this animal model, rats are in a coma for 2–3 h after cardiac arrest surgery, and after awakening, they are prone to seizures that may be spontaneous but are more often preceded by running movements. Seizures can also be evoked by external stimuli such as noise. Two days after cardiac arrest, the seizures subside and myoclonic jerks become the predominant movement disorder. The severity of myoclonic jerks reaches its peak on the fourth day after cardiac arrest and thereafter, they gradually subsides over ~1 month.

Evaluation of Myoclonic Jerks in the Animal Model

For evaluating myoclonic jerks, rats are given auditory stimulation of 45 clicks from a metronome recorded on audiotape. The involuntary muscle jerks of rats in response to each click are scored with the following rating scale: 0, no reaction; 1, ear twitch; 2, ear and head jerk; 3, ear, head, and shoulder jerk; 4, whole animal jerk, and 5, whole body jerk causing the animal jump. The sum of the cumulative scores in response to the 45 clicks yields a total myoclonus score for the animal, and this score is the primary outcome measure for most studies. The severity of myoclonus is age-dependent, and older rats consistently show higher myoclonus scores than younger rats. Further, younger animals have a faster recovery from hypoxia so that the number of days they have myoclonus is shorter than that of older animals. However, the mortality rates from the surgery increase with the age.

Pharmacology of the Animal Model of PHM

Early clinical studies showed that an array of antiepileptic agents can reduce myoclonic jerks in humans. In this animal model, antimyoclonic activity of these antiepileptics has been evaluated, and valproate, clonazepam, 5-hydroxytrytophan (5-HTP), and felbamate dose-dependently reduce auditory-induced myoclonic jerks of the posthypoxic animals when compared with animals treated with vehicle alone. Newer generation antiepileptic drugs such as levetiracetam and brivaracetam are also effective in this model. In addition, ketogenic diets, a nutritional treatment used in humans for controlling seizure resistant to antiepileptic drugs, are also effective in reducing seizure and audiogenic myoclonic jerks in this animal model. The antimyoclonic activity of other antiepileptic agents, which work by interfering with excitatory synaptic glutamatergic neurotransmission, has also been evaluated. Lamotrigine, which inhibits voltage-gated sodium channels in the deactivated state and thus reduces presynaptic release of the excitatory transmitter, glutamate, has antimyoclonic activity in the animal model. Similarly, riluzole, another antiepileptic agent with a similar mechanism of action to lamotrigine, reduces myoclonic activity in this animal model.

Histological Features of the Animal Model

Fluoro-jade staining in coronal brain sections from posthypoxic rats with myoclonus reveals that the cerebral hypoxia-induced neurodegeneration is confined to the hippocampal CA1 region, the cerebellum, and the thalamic reticular nucleus (TRN) (**Figure 1**). Using specific neuron phenotype markers, researchers have identified injuries in regions of the brain involved in normal functioning of motor coordination. Specifically, excitatory amino acid carrier expression in the Purkinje cell layer of the cerebellum is reduced. Glutamate decarboxylase, a marker for GABAergic neurons, is also significantly reduced in the TRN of the posthypoxic rats, indicating injury of the GABAergic neurons. These findings are consistent with a study in which fos protein expression, an immediate early gene product, was detected in the TRN and in specific areas in the brainstem of the

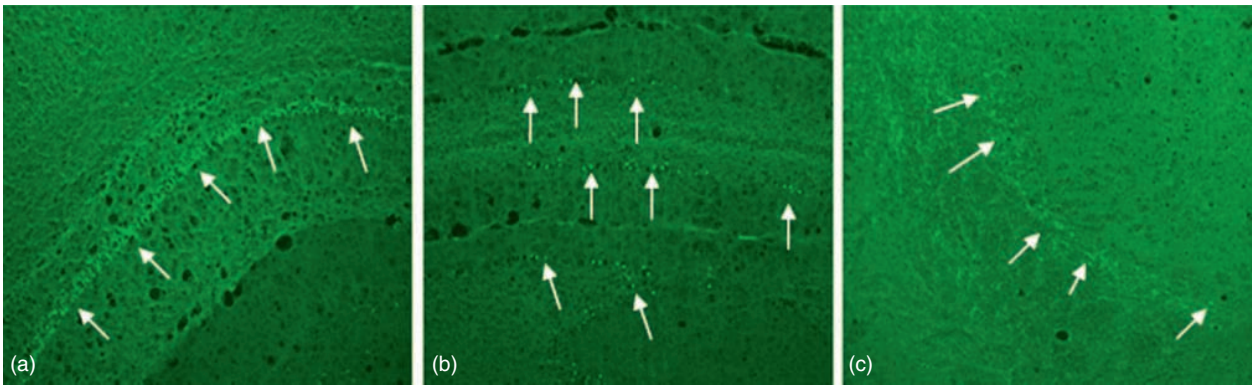

Figure 1 Neurodegeneration of a rat subjected to cardiac arrest-induced cerebral hypoxia for 8.5 min. (a) Hippocampus CA1, (b) cerebellum, and (c) thalamic reticular nucleus. The arrows indicate fluoro-jade-positive degenerating neurons.

posthypoxic myoclonic rats, suggesting that activity of this nucleus is associated with PHM. This hypothesis was verified by the finding that electrolytic lesion of the TRN reduced PHM in this animal model.

Serotonin (5-HT) Neurotransmission Dysfunctions in the Animal Model of PHM

Early clinical observations suggested that chemical imbalances in the serotonin (5-HT) neurotransmitter system could be the underlying cause of PHM. Studies detected low levels of the 5-HT metabolite, 5-hydroxyindol acetic acid (5-HIAA), in the cerebrospinal fluid of patients with PHM. This notion is further supported by the observation that 5-HTP in combination with an oral aromatic amino acid decarboxylase inhibitor such as carbidopa, which increases plasma 5-HTP significantly, abated myoclonus in humans with PHM. Myoclonic jerks in this animal model also improve with 5-HTP treatment. Further, the level of 5-HT metabolites in different areas of the brains of posthypoxic rats with myoclonus including the cortex, cerebellum, striatum, and hippocampus are significantly reduced when compared with nonhypoxic rats. The reduction in striatal 5-HT, cortical 5-HIAA, and mesencephalic 5-HIAA appears to most relevant to the development of PMH, as the correlation between myoclonus scores and the levels of indoles in these brain regions are particularly high. These results suggest that dysfunctions in serotonergic transmission in the cortical and the extrapyramidal ascending pathways are involved in the pathophysiology of PHM. Given the complexity of the 5-HT system and the existence of many types of 5-HT receptors, the animal model has tested the antimyoclonic efficacy of different 5-HT receptor agonists and antagonists. Myoclonus can be attenuated by a 5-HT1B/1C/2 agonist, a 5-HT2 agonist, and a 5-HT3 agonist. In contrast, 5-HT1A agonists, 5-HT1B agonists, and 5-HT2 antagonists are ineffective. These results suggest that enhancement of the serotonergic transmission in particular via the 5-HT2 and 5-HT3 receptors can reduce PHM in this animal model. This conclusion is consistent with observations in human PHM. A study by Pappert et al. (1999) using the same animal model of PHM showed that a 5-HT1B/1D/2 receptor antagonist and a 5-HT2A/2B antagonist dose-dependently reduced myoclonic jerks. Results from their study suggested that 5-HT1B, 5-HT2A/2B, and 5-HT1D receptor subtypes are likely to play a role in PHM.

Future Research Directions

Myoclonus is a common movement disorder but is difficult to manage clinically due to the lack of understanding of the pathophysiological basis of this movement disorder. The animal model of PHM replicates the essential features seen in patients with PHM. The model has been proven experimentally to be a valuable tool for evaluation of new antimyoclonic agents and to study the mechanism underlying this movement disorder. With the advent of new pharmacological products, preclinical testing with this model offers an inexpensive screening tool for the development of agents to be studied in prospective double-blind randomized clinical trials of new treatments for humans with PHM.

Myoclonus, Epileptic

A Balabanov, Rush University Medical Center, Chicago, IL, USA

Glossary

Electroencephalogram (EEG) – A noninvasive test for epilepsy during which electrodes are placed on a patient's scalp to record electrical impulses from the brain.
Electromyogram (EMG) – Recording of electric currents associated with muscle contractions; it is done by placing a small needle into the muscle.
Epileptic syndrome – A seizure disorder characterized by a pattern of findings, such as the age of onset, cause, EEG data, family history, precipitating factors, and prognosis.
Myoclonus – A sudden brief involuntary muscle jerk.
Progressive myoclonic epilepsy (PME) – A rare form of epilepsy, often hereditary, characterized by myoclonic and other types of seizures and progressive neurological impairment.
Somatosensory-evoked potentials (SSEP) – Recording of electrical signals along the somatosensory pathways after stimulation of peripheral nerves.

Definition and History

Myoclonus is a quick involuntary movement that can be seen in a large variety of disorders. The term myoclonus comes from two Greek words: myo meaning muscle and clonus meaning turmoil. It was used by Nikolaus Friedreich in 1881 to describe a movement known today as essential myoclonus. Throughout the years, the term myoclonus was used by different authors with different meanings, leading to nosological confusion. Uverrich, Lundborg, Herpin, and Rabor contributed to a further definition of myoclonus by adding their own descriptive terms, most of which are still used. In the 1980s, there was a notion that the term myoclonus must be used only in the context of CNS disorders and not to describe muscle jerks due to peripheral nerve and plexus lesion or fasciculations due to motor neuron disease. Today, the term myoclonus is used to describe a sudden, involuntary, shock like muscle contraction, and anatomic or etiological considerations help to define the subclasses of myoclonus.

Epileptic myoclonus is a form of myoclonus that occurs as an ictal phenomenon related to several epilepsy syndromes. The epileptic myoclonic movements can be unilateral or bilateral, symmetric or asymmetric, or single or repetitive. They can be violent, leading to large amplitude movements of the arms and legs or very small in amplitude and not noticeable to an observer. Based on the area involved, the myoclonus can be further subdivided into generalized (generalized epilepsies), focal or regional (partial seizures), and isolated (epilepsia partialis continua). Myoclonus can also be defined as positive, caused by muscle contractions and negative, caused by muscle inhibitions. The brief lapses of muscle tone during an atonic seizure caused by an epileptic discharge in the brain is an example of negative myoclonus.

Epidemiology/Risk Factors

The only epidemiological study of myoclonus in a defined population was done in Olmstead County, Minnesota and published in 1999. The study reported the lifetime prevalence of myoclonus to be 8.6 cases per 100 000 population. Symptomatic myoclonus was most commonly seen (72%), followed by epileptic myoclonus (17%) and essential myoclonus (11%). It appears that postanoxic insults, neurogenerative disorders, and epileptic syndromes are the most common causes of myoclonus, frequencies that concur with observation based on day-to-day practice.

Pathogenesis/Pathophysiology

The pathophisiology of myoclonus is best studied by using the correlation between cortical discharges as recorded by EEG and the actual muscle movement as recorded by EMG. Based on this methodology, Halliday described three types of myoclonus:

1. *Pyramidal myoclonus* – originates from a stimulus in the cerebral cortex that is transmitted to the muscle trough the pyramidal tract. There is a definite correlate between the EEG discharge and the myoclonic movement, in which the action potential seen on EMG follows the EEG discharge by a few milliseconds.
2. *Extrapyramdal myoclonus* – originates from the subcortical regions. There is no correlation between the EEG discharge and the EMG action potential.
3. *Segmental myoclonus* – occurs due to hyperactive apha motor neurons in the spinal cord or brain stem that have lost their normal inhibitory inputs.

Epileptic myoclonus is a pyramidal myoclonus that can be further subdivided into

1. *Cortical reflex myoclonus* – originates from hyperexitable cerebral sensory-motor cortex and each jerk represents a discharge from that area. These types of movements are particularly seen in focal seizures involving the facial muscles.
2. *Reticular reflex myoclonus* – originates from the hyperexcitable caudal brain reticular formation. The EEG shows a generalized spike and wave discharge that follows the EMG signs of myoclonus, suggesting that the stimulus travels from the brain stem to the cortex.
3. *Primary generalized epileptic myoclonus* – originates diffusely from the cerebral cortex. The impulses travel down the brain stem and induce muscle movements. The movements are usually bilateral, involving primarily the muscles of the upper extremities and the face. The myoclonic jerks are locked in with the EEG discharges of generalized polyspike, spike-wave and polyspike-wave activity.

Clinical Features/Diagnostic Criteria

Epileptic myoclonus is usually seen as a part of an epileptic syndrome. Myoclonus can be only one component of a seizure, the only seizure manifestation (myoclonic seizure), or as one of multiple seizure types within an epileptic syndrome. The cause may be idiopathic, genetic, or a static encephalopathy.

Epileptic myoclonus can also be seen as a result of defined pathologic process, and in this case, falls into the category of symptomatic myoclonus. Focal cortical myoclonus can be seen to be associated with many cortical lesions such as tumors, angiomas, hemorrhage, and infections.

In this article, we describe several epileptic syndromes that have the common feature of having myoclonic movements as part of their semiology. While doing that, our primary goal is to emphasize the clinical features of the myoclonic seizures.

Juvenile Myoclonic Epilepsy (JME)

This is one of the most commonly seen epileptic syndromes associated with myoclonus. It consists of a combination of absence seizures, myoclonic seizures, and generalized tonic–clonic seizures (GTCS) in the absence of any neurological deficits. The myoclonic seizures of JME are the true presentation of pure myoclonic seizures. Myoclonic seizures usually occur early in the morning, soon after awakening. They involve most commonly the upper extremities, extensor muscles more than flexors, leading to the patient's dropping utensils during breakfast or for 'the cereal to fly.' The myoclonic jerks frequently involve the muscles of the face and shoulders and less commonly the muscles of the legs. The jerks can be single or repetitive. When repetitive, a generalized tonic–clonic convulsion can follow. The myoclonic seizures are very sensitive to sleep deprivation or alcohol use the night before. They can be precipitated by photic stimulation in some cases. The EEG pattern is very characteristic and shows generalized polyspike discharge, which is synchronous to the myoclonic jerks. Interictal EEG has a normal background with fast (4–6 Hz) generalized spike and wave, polyspike, and wave activity. The seizures are usually easy to control with antiepileptic drugs (AED), but life-long treatment is needed in most cases.

Benign Myoclonic Epilepsy of Infancy

This is a rare condition characterized by generalized myoclonic seizures occurring in otherwise normal children during the first or second year of life. No other seizure types are seen. The myoclonic jerks are characterized by head drops and sudden movements of upper extremities upwards, while the legs are flexed. The

amplitude of the movements varies and may cause a fall if severe enough. The myoclonic jerks usually last one to three seconds. Consciousness does not appear to be affected. No precipitant factors have been identified. The EEG shows generalized irregular 3-Hz, spike wave, or polyspike wave discharges, synchronous with the muscle activity on the EMG. The seizures are easy to control with AED, and the prognosis is good if treatment is started early, which is important in order to prevent deterioration of intellectual development.

Severe Myoclonic Epilepsy of Infancy (SMEI)

This is a rare syndrome, first described by Charlotte Dravet in 1978. It starts during the first year of life with febrile generalized or focal seizures. Soon after, myoclonic seizures appear in addition to complex partial and simple partial motor seizures. The myoclonic seizure can be violent leading to a fall, but they can also be subtle. EEG during the myoclonic seizures shows generalized fast spike-wave and polyspike-wave discharges. Cognitive impairment, psychomotor delay, and ataxia develop gradually after the onset of the seizures.

Doose and colleagues described an epileptic syndrome with myoclonic astatic seizures and strong genetic predisposition. The onset is between 1 and 5 years of age, usually with a generalized febrile seizure. Characteristically, boys are affected twice as often as girls. The patients can have multiple types of seizures, including absence, generalized tonic, generalized tonic–clonic in addition to myoclonic and myoclonic–astatic and astatic seizures. Myoclonic seizures consist of symmetric jerking of the arms, head, and shoulders. Some myoclonic seizures can be violent and lead to falls, other may not be evident to the observer. In myoclonic–astatic seizure, myoclonic jerks of arms and face precede the loss of tone. EEG during the myoclonic seizures shows generalized polyspike wave discharges. The prognosis differs from being favorable with spontaneous remission, to being poor with severe mental deterioration and medically intractable seizures.

Progressive Myoclonic Epilepsies (PME)

The syndrome of PME consists of myoclonic seizures, tonic–clonic seizures and progressive neurological dysfunction, particularly ataxia and dementia, which leads to severe mental impairment and death in many cases. PME is rare and usually genetic in etiology. The syndrome of PME is clearly heterogeneous. The onset is usually in late childhood or adolescence, but it can be at any age. Unverricht–Lundborg syndrome, Baltic myoclonus, Lafora body disease, and Myoclonic Epilepsy with Ragged Red Fibers (MERRF), among others, are representative of PME.

Myoclonus in PME is very characteristic, being multifocal and usually precipitated by posture, action, or external stimuli such as light, touch, or sound. Facial and distal limb muscles are typically involved. However, massive myoclonic jerks involving arms and legs leading to falls can also be seen. The origin and generators of myoclonus in PME is one confusing and still controversial issue. Neurophysiological studies document that most, but not all, myoclonic jerks are cortical in origin. When the myoclonic jerks are cortical in origin, they are accompanied by obvious discharges on EEG such as burst of spikes, polispikes, and spike wave complexes. Some of the myoclonic jerks are bilateral, which means that they are either generated in the cortex unilaterally and then spread contralaterally via the corpus callosum, or they are generated in a source in the brain stem, therefore representing a reticular reflex myoclonus. Clearly, however, some myoclonic jerks are not accompanied by any EEG changes, leading to the conclusion that those are 'nonepileptic' in etiology. From a pragmatic point of view, in this particular disorder, the patients are diagnosed with epileptic myoclonus when most, even if not all, of the myoclonic jerks are accompanied by EEG discharges. In PME, the prognosis is poor, with seizures that are difficult to control and cognitive deterioration in most patients.

Diagnostic Work-up/Tests

Assessment of patients with epileptic myoclonus should start with obtaining a good clinical history: age of onset, presence of other seizure types or neurological problems, family history, toxin or drug exposure, etc. Physical examination should concentrate on the myoclonic movement-distribution as well as the temporal and activation profile. These steps are followed by basic ancillary testing, brain imaging, and clinical neurophysiological testing, including EEG–EMG correlation studies, SSEP, and CSF examination in selected cases. Genetic testing and mitochondria function studies, lactate levels, and muscle biopsy are needed for inherited disorders. Neuropsychological testing is used to detect cognitive deterioration. Recognition of the epileptic syndrome may be delayed for a while due to the fact that some of its clinical features can develop slowly over time.

Management

The best strategy in treating epileptic myoclonus is to treat the underlying epileptic disorder. The treatment

usually targets the deficient cortical inhibition, which is thought to be at least one of the mechanisms behind the seizures. Studies done on CSF from patients with PME have shown 25–40% reduction of GABA concentration. Sodium valproate is considered to be the drug of choice due to its capacity to increase cortical GABA concentration and to potentate GABA postsynaptic inhibitory activity. Valproate can be given in IV load when needed at a dose of $20\,mg\,kg^{-1}$ or can be started gradually orally. Benzodiazepines also facilitate GABAergic transmission by effects on GABA receptor complex. Clonazepam is usually effective in the treatment of myoclonus; however, tolerance can develop over time. While effective in the treatment of myoclonic seizures, clonazepam is not effective in preventing other types of seizures such as generalized tonic–clonic seizures that can be part of the same epileptic syndrome. Levetiracetam is an AED with unknown exact mechanisms of action that has been very effective in the treatment of myoclonus. Levetiracetam can be used up to $3–4000\,mg\,day^{-1}$. It can also be used in IV load when needed. Zonisamide was also reported to help with myoclonic seizures. Depending on the epileptic syndrome, myoclonic seizures can be very refractory to medical treatment and using a combination of AED is sometimes needed. Some polytherapy regiments such as valproate and clonazepam, while effective in the treatment of the myoclonus, can lead to severe sedation and encephalopathy. Vagal nerve stimulation and ketogenic diet have been reported to be useful as adjunctive treatment in some patients. The medical treatment of atonic seizures is often unsatisfactory. Corpus callosotomy may be effective in well-selected cases, especially after a trial of VNS treatment had failed.

It is important to note that commonly used AEDs such as carbamazepine, phenytoin, lamotrigine, vigabatrin, and even gabapentin have been associated with the worsening of myoclonic seizures. In addition, drugs commonly used in patients with epilepsy to treat comorbid conditions such as SSRIs or tricyclic antidepressants can cause myoclonus. Quinolone antibiotics can cause myoclonus in the presence or absence of seizure disorder. In most cases, withdrawal of the drug precipitating the myoclonus is enough to resolve the disorder.

Prognosis

The prognosis of the myoclonic seizures depends on the 'company they keep.' Patients with myoclonic seizures due to benign epileptic syndromes such as JME have a normal life span, intelligence, and good seizure control as long as they are compliant with the treatment. It is essential to sensitize patients to the fact that JME is a life-long condition with a highly favorable prognosis, but there is a very high recurrence of seizures (including myoclonic) when treatment is withdrawn. In contrast to JME, patients with progressive myoclonic epilepsies, in general, have poor prognosis. When symptomatic, the prognosis of the epileptic myoclonus depends on the cause.

Myoclonus-Dystonia/Essential Myoclonus

E MJ Foncke, VU medical center, Amsterdam, The Netherlands
M AJ Tijssen, Academic Medical Center, Amsterdam, The Netherlands

Glossary

***DYT11* MC** – *DYT11* mutation carriers: carriers of a mutation in the *SGCE* gene, causing M–D.
Myoclonus–dystonia (M–D) – Autosomal dominantly inherited movement disorder characterized by myoclonic jerks and dystonic movements/postures.
SGCE – ε-sarcoglycan gene, on chromosome 7q21, causing M–D.

Definition and History

Myoclonus–dystonia (M–D) is a movement disorder characterized by myoclonic jerks and dystonic movements or postures. Myoclonus is a rapid, brief contraction ('fast lightning jerk') of one muscle or a group of muscles. Dystonia is characterized by sustained twisting and repetitive movements that may result in abnormal postures. The abnormal movements most often affect the neck, trunk, and the upper limbs. M–D has an autosomal dominant inheritance with reduced penetrance because of maternal imprinting and is caused by mutations in the ε-sarcoglycan gene (*SGCE*) on chromosome 7q21.

M–D was described by Friedreich in 1881 as 'paramyoclonus multiplex' but since then, a large variety of terms have been used to describe the movement disorder: 'hereditary essential myoclonus,' 'essential familial myoclonus,' 'familial essential myoclonus,' 'dominantly inherited myoclonic dystonia with dramatic response to alcohol,' hereditary myoclonic dystonia, and M–D and inherited M–D syndrome. The hyphenated combination of the two terms 'myoclonus' and 'dystonia' with the specific order of presentation is now considered to be the appropriate term for M–D. However, it should be noted that myoclonus, or rarely, dystonia is the sole symptom of the disorder. Although M–D is a predominantly myoclonic syndrome associated with often mild dystonia, M–D has been classified as *DYT11* among the hereditary forms of dystonia since the detection of the *SGCE* on chromosome 7q21 in several M–D families, and it is considered as a dystonia-plus syndrome.

A patient with clinically typical M–D is shown in Video 1.

Pathogenesis and Pathophysiology

Pathogenesis: Function of the *SGCE* Protein

SGCE is a member of the sarcoglycan family of transmembrane proteins that are part of the dystrophin-associated glycoprotein complex. This complex links the cytoskeleton to the extracellular matrix in skeletal and cardiac muscle. α-, β-, γ-, and δ-sarcglycan are predominantly expressed in muscles, and mutations cause different forms of autosomal recessive limb girdle muscular dystrophies. *SGCE* is highly homologous to the α-sarcoglycan. However, expression of *SGCE* in the membrane of skeletal muscles in M–D patients is normal, which is reflected by the normal morphological and immunohistological investigations of muscle tissue and the normal muscle strength at neurological examination. Unlike the other sarcoglycans, *SGCE* is widely expressed in different tissues including the brain. *SGCE* is found in neurons of the cerebral cortex, basal ganglia, cerebellum, hypocampus, and the olfactory bulb, but the molecular function of the protein in human neurons is still elusive.

In *SGCE* knock-out mice with a deletion of exon 4, impaired motor skills and anxiety-like behavior have been observed. These mice exhibited an altered monoamine metabolism in the striatum with an increase in dopamine, 3,4-dihydroxy-phenlacetic acid (DOPAC) and 3-methoxy-4-hydroxyphenylacetic acid (HVA) levels in the striatum. These findings suggest that increased endogenous dopamine levels may be involved in the pathophysiology of M–D. This is further supported by a recent IBZM (iodobenzamide) SPECT imaging study that showed reduced dopamine receptor availability in the striatum of *DYT11* MC.

Mutations in the *SGCE* gene are thought to result in loss of function of the *SGCE* protein. Loss of *SGCE* function at the plasma membrane of neurons may lead to changes in the excitability of the neuronal membrane. This loss of function may be due to the mechanism of nonsense-mediated decay, which is a mRNA surveillance mechanism that detects premature stopcodons on mutant mRNA and prevents expression of a truncated protein. Lack of expression of the *SGCE* protein is then believed to be the disease-causing mechanism. Another possible mechanism is the altered intracellular trafficking of mutant *SGCE* to the plasma membrane. Recently, torsin A, mutated in *DYT1* dystonia, has been implicated in promoting degradation of intracellular mutant *SGCE* by the proteasome when both proteins are coexpressed.

Pathophysiology

The pathophysiology of M–D is largely elusive. Myoclonus in M–D is considered to be of subcortical origin due to the usual lack of stimulus-sensitivity of the myoclonus, the absence of giant somato-sensory-evoked potentials, the negative C-reflex and the absence of a cortical potential on EEG jerk-locked back averaging. The mean duration of myoclonic burst is 90–100 ms and is in line with these findings. Several functional studies point to a primary dysfunction of the basal ganglia. Study of the local field potentials (LFP) of the internal globus pallidus (GPi) in *DYT11* MC who underwent deep brain stimulation because of invalidating motor symptoms showed significantly increased coherence in the low (3–15 Hz) frequency band between GPi activity and the muscles, with the LFP leading the muscles. In addition, an EEG–EMG coherence study demonstrated that the normal cortical drive to the muscles in the beta band during weak isometric contraction is replaced by a similar low-frequency drive which correlates with dystonic muscle activity. These findings suggest that the basal ganglia, most specifically, GPi, are involved in the pathophysiology of M–D, which is supported by the dramatic effect of GPi stimulation on the symptoms of myoclonus and dystonia. Suppression of increased oscillatory activity in the low-frequency band is believed to be the mechanism responsible for the clinical effect of GPi stimulation.

A recent fMRI study detected hyperactivity of different cortical structures in symptomatic and nonsymptomatic *DYT11* MC which is likely to be secondary to dysfunction of the basal ganglia. However, short- and long-interval cortical inhibition was normal in different transcranial magnetic stimulation (TMS) studies, suggesting normal cortical inhibition in M–D.

Epidemiology

M–D is considered rare, although no clear prevalence data are available. Nonetheless, M–D may be much more common than previously thought for different reasons: the clinical picture of M–D is often mild and many patients do not come under medical attention; the disorder is not very well known among pediatricians nor neurologists, leading to likely underdiagnosis; although known to be hereditary, because of reduced penetrance, M–D may appear sporadically and therefore not be considered by many clinicians.

Phenotype–Genotype Characteristics

Phenotypical Characteristics

The myoclonic jerks in M–D are brief, lightning-like jerks usually affecting the neck, trunk, and the proximal upper limbs. The legs and distal upper limbs are less commonly involved. However, characterization of the motor symptoms in a Dutch M–D family revealed that slight jerky movements of the fingers may be the only presentation of myoclonus in M–D. Myoclonus is often the presenting symptom, but in 20% of the patients, dystonia may be the first symptom.

The myoclonic jerks are frequently elicited or worsened by active movements of the affected or a remote body part. Other factors negatively influencing the myoclonic jerks are fatigue, emotional stress, anxiety, nervousness, sound, touch, startle, and caffeine. Myoclonus and dystonia disappear during sleep.

A positive effect of alcohol on the symptoms of myoclonus, and to a lesser extent, dystonia is commonly reported but not invariably present. Some patients experience a rebound phenomenon after alcohol withdrawal.

Focal or segmental dystonia is present in half of the affected patients and often consists of cervical dystonia and/or writer's cramp. Involvement of the legs is rare in contrast to primary generalized dystonia. Dystonia in M–D does not tend to generalize. Rarely, dystonia is the only manifestation of the disease.

The onset is usually in childhood or adolescence (mean age of 6 years). Late age of onset, up to the eighth decade, can occur. Gender may influence the age of onset: the onset occurs earlier in girls than in boys in 42 *DYT11* MC from 11 families.

Psychiatric comorbidity is common in M–D patients but so far, it remains unclear whether psychiatric symptoms are part of the phenotypic spectrum of M–D or are secondary to the debilitating motor symptoms. Psychiatric symptoms include obsessive compulsive disorder, alcohol dependence, depression, anxiety, and panic attacks. Uniform standardized assessment of a larger number of symptomatic and asymptomatic *DYT11* MC may give more conclusive insights on whether such signs are implicit to the disorder or secondary social adjustment effects.

Unusual features have been described in selected families with a mutation in the *SGCE* gene and include postural or other forms of tremor. Alcohol withdrawal seizures may occur because of the relieving effect of alcohol on the motor symptoms but epileptic seizures in the absence of alcohol abuse have been observed in a few families.

Cognitive function is considered normal in M–D patients. An extensive neuropsychological test battery in a large Dutch M–D family showed no differences between *DYT11* MC and controls on any of the examined cognitive domains. However, mild cognitive abnormalities, including impaired verbal learning and memory, have been reported in a limited number of patients. In one M–D report, mental retardation has been observed. Mutation analysis showed an interstitial deletion of chromosome 7q21 completely removing

the *SGCE* and surrounding genes. It has been hypothesized that the mental retardation is due to the absence of surrounding genes.

Genotypical Characteristics

The SGCE *gene on chromosome 7q*

Linkage to chromosome 7q was observed in several M–D families in the late 1990s. In 2001, the *SGCE* gene encoding the ε-sarcoglycan protein was identified on chromosome 7q23. Subsequently, *SGCE* gene mutations have been identified in many individuals with familial M–D and occasionally in sporadic M–D cases. The mutations that have been described in literature up to the present can be found on *http://www.dmd.nl/sgce_seqvar.html*. In only one-third of the total number of genetically investigated M–D, a *SGCE* mutation can be demonstrated. This suggests genetic heterogeneity.

Recently, exonic deletions, not detected with direct sequence analysis, have been identified in several M–D families, indicating that *SGCE* mutations may account for a larger amount of the genetic cases of M–D than was previously thought and stresses the importance of performing gene dosage analysis.

De novo mutations in apparently sporadic M–D have been reported indicating that *SGCE* mutations must be considered in M–D patients with a negative family history.

Mutations in two other genes have been associated with M–D, that is, a missense mutation in the dopamine receptor 2 gene in a single family and an 18-bp deletion in the *DYT1* gene usually associated with early-onset primary torsion dystonia, in another single family. In both the families, however, an additional mutation in the *SGCE* gene was subsequently identified, which makes the pathological involvement of these genes in M–D uncertain. A large Canadian M–D family shows linkage to chromosome 18p (*DYT15*), but the contribution of this locus to the genetic heterogeneity of M–D remains unclear until the gene is identified.

Reduced penetrance due to maternal imprinting

The reduced penetrance in *DYT11* positive M–D patients is due to the mechanism of maternal imprinting. This implies that when inheriting the mutation from your mother the mutated maternal allele is silenced and the wild-type paternal allele is expressed leading to clinically unaffected mutation carriers. Silencing of the mutated maternal allele is probably due to differential methylation of CpG nucleotides which have been demonstrated in the *SGCE* gene. However, about 5–10% of affected individuals inherit the mutation from their mother, indicating an escape from maternal imprinting. The underlying mechanism for the loss of imprinting is unclear. Coexpression of the mutated and the wild-type allele or a different level of imprinting in brain compared to peripheral blood leucocytes (imprinting mosaicism) has been suggested as possible mechanisms.

Genotype–Phenotype Correlation

Considerable inter- and intrafamilial heterogeneity has been observed. However, no genotype–phenotype correlations have been found. An association between the localization or the type of the reported mutations and the described phenotype is not obvious, since *SGCE* mutations are likely to result in a loss of function of the *SGCE* gene.

Because mutational testing of the *SGCE* gene is expensive and laborious, several *SGCE* mutational screening studies have tried to identify distinct phenotypic features that could predict the presence of a *SGCE* mutation in M–D patients. Except for onset before the age of 20 years and truncal myoclonus, no other predictive factors could be identified.

Diagnostic Criteria

Several descriptions of M–D were reported in the literature before 1967, but Mahloudji and Pikielny were the first to formulate diagnostic criteria for M–D, which they called 'hereditary essential myoclonus.' These criteria have been modified by Gasser and recently by Klein on the basis of the findings in genetically proven *DYT11* M–D patients.

Since epileptic seizures and/or EEG changes have been found in mutation-positive M–D families, presence of seizures and an abnormal EEG are no longer considered as exclusionary criteria for M–D. In **Table 1**, the modified diagnostic criteria are displayed.

Differential Diagnosis

The clinical picture with myoclonus, dystonia, or both is quite distinct in M–D. Most other conditions in which myoclonus is a prominent feature are characterized by a variety of other neurological symptoms making a diagnosis of M–D unlikely. Genetically confined conditions with myoclonus as a major component include progressive myoclonus epilepsy and myoclonus epilepsy associated with ragged-red fibers. In rare cases, myoclonus can be a prominent feature of primary dystonia syndromes,

Table 1 Diagnostic criteria of M–D

Diagnostic criteria
Onset of myoclonus usually in the first or second decade of life; dystonic features are observed in more than half of the affected in addition to myoclonus and may rarely be the only manifestation of the disorder
Males and females about equally affected
A relatively benign course, often variable but compatible with an active life of normal span in most cases
Autosomal dominant mode of inheritance with variable severity, and incomplete pentrance, which is dependent on the parental origin of the disease allele; affected individuals usually inherit the disease from their father
Absence of dementia, ataxia and other neurological deficits
Normal SSEP, normal results of neuroimaging studies (CT or MRI)
Optional diagnostic criteria
Alleviation of symptoms (particularly of the myoclonus and to a lesser degree of the dystonia) with alcohol use
Various psychiatric symptoms

including *DYT1* and *DYT5* dystonia. It should be noted that myoclonus in these syndromes is often restricted to the body part affected by dystonia and the typical lightning-like character is usually absent. Benign hereditary chorea may be sometimes difficult to distinguish from M–D, especially when choreic movements are jerky.

Diagnostic Workup

The diagnosis of M–D is established on clinical grounds and can be confirmed by genetic analysis of the *SGCE* gene. By definition, additional tests are normal.

Laboratory tests (including lactate, pyruvate, serum copper, ceruloplasmin, and red cells) and neuroimaging studies (including brain CT and MRI) should be performed to exclude secondary causes of myoclonus(–dystonia).

Management

There is no etiological therapy for M–D. Pharmacological therapy is often ineffective. Various drugs have been tried including benzodiazepines (clonazepam), anticholinergics (trihexyphenidyl), antiepileptics (valproate, levetiracitam), L-dopa, dopamine agonists, neuroleptics, serotonergic agents, and β-blockers. Trihexiphenydyl may improve the dystonia, whereas clonazepam is sometimes effective to treat the myoclonus. Botulinum toxin can be used to treat focal dystonia, especially cervical dystonia. Alcohol often induces a dramatic relief of the symptoms of myoclonus and dystonia, but due to the risk of addiction to alcohol, this appears an unacceptable treatment option. Motor symptoms in some patients are severe and may lead to considerable disability. In selected patients deep brain stimulation of the internal GPi or the ventral intermediate thalamic nucleus has shown to substantially improve the motor symptoms. The effect of deep brain stimulation on the commonly associated psychiatric symptoms is unknown.

Prognosis

The course of the disease is usually benign with a normal lifespan of active life. Very often, stabilization of the condition is reached in adulthood, with most patients functioning independently in the activities of daily life. In selected cases, spontaneous remissions of myoclonus (and dystonia) have been reported. In contrast, some patients worsen progressively during the course of the disease, also at older age. Increase in frequency and intensity of the myoclonus or dystonia and the involvement of body parts that had been previously unaffected have been reported. This may lead to considerable functional disability.

Myokymia

S Zimnowodzki, Rush University Medical Center, Chicago, IL, USA

Glossary

Ephaptic transmission – Transmembrane spread of an action potential from motor axon to motor axon (as is suspected in myokymia), or sensory axon to sensory axon or muscle cell to muscle cell.
Entrapment neuropathies – Compression of individual named nerves, such as median mononeuropathy at the carpal tunnel.
Motor unit – The anterior horn cell, its lower motor neuron axon, its surrounding myelin, terminal axon sprouts, neuromuscular junction, and the respective skeletal muscle fibers.
Myokymia – An involuntary movement disorder characterized by continuous, undulating skin movements.
Myokymic discharges – Spontaneous grouped motor unit action potentials, generated at the level of motor units, with suspected ephaptic spread to other motor units, down to their respective muscles cells, causing continuous wormlike movements of the skin.

Definition

Myokymia is an involuntary movement disorder with a distinctive appearance best described as earthworms moving continuously under the skin.

Pathophysiology

The source of these vermicular (wormlike) movements originate somewhere along the course of the motor units, usually distally or proximally in the anterior horn cells, depending on the cause of the myokymia. Pathophysiologically, spontaneous depolarization of axons or anterior horn cells occur – perhaps via ephaptic transmission – thereby sending an action potential down the various motor units to their respective skeletal muscles fibers. And since each motor unit innervates several hundred muscle fibers (fewer in the face), there is a visible movement of skin overlying the contracting muscle cells.

Clinical Presentation

There is a clinical value in recognizing myokymia, as it results from a limited number of pathological conditions, and fewer physiological conditions.

Moreover, myokymia may be generalized or localized, which further assists in determining its cause.

One of the typical examples of physiological myokymia is something most of us have experienced: eyelid twitching. But because the eyelids are so thin, myokymia has the appearance of an eyelid twitch rather than the undulating skin movements common to facial or limb myokymia.

Myokymia may be observed in both peripheral nervous system and central nervous system disorders.

Clinical myokymia may appear in several patterns of distribution:

1. Focal myokymia limited to the face (generally observed in the chin) occurs in conditions such as multiple sclerosis, brainstem neoplasm, Bell's palsy, Guillain–Barre syndrome, or in individuals with no abnormalities (physiological).
2. Limb (segmental) myokymia may be seen in syringomyelia, cervical or lumbar radiculopathies, chronic entrapment neuropathies such as median neuropathy at the wrist, or in the classic condition associated with myokymia: postirradiation brachial plexopathy.
3. Generalized myokymia has been seen in acute inflammatory neuropathies such as Guillain–Barre (which as stated above can present with facial myokymia) or chronic inflammatory neuropathies such as Chronic Inflammatory Demyelinating Polyneuropathy (CIDP). Other conditions causing myokymia include uremia, thyrotoxicosis, Isaac's syndrome, postexercise induced myokymia, timber rattlesnake venom, gold therapy, or hereditary episodic ataxia.

Diagnosis

When a needle electromyogram (EMG) is inserted into muscles demonstrating clinical myokymia, the potentials generated are referred to as myokymic discharges. These are spontaneous discharges of grouped motor unit potentials, with an average of 2–10 motor unit potentials per burst, and an intraburst frequency of 20–150 Hz. The frequency of burst discharges ranges from 0.1 to 10 Hz, and these bursts discharge with a periodicity that is often referred to as marching shoulders (on the auditory portion of the EMG exam).

In the author's opinion, the diagnosis of myokymia should be made in conjunction with a needle EMG test, since other conditions may potentially mimic generalized myokymia. These conditions include blepharospasm, facial myoclonus, myotonia, or spasticity.

Treatment

Treatment of myokymia includes eliminating the source of the causative factor. Reducing the symptoms may be improved with medicines such as anticonvulsants.

Myorhythmia

R J Elble, Southern Illinois University School of Medicine, Springfield, IL, USA

Glossary

Guillain–Mollaret triangle – A triangular neural circuit from the cerebellum (dentate nucleus), through the superior cerebellar peduncle to the contralateral red nucleus and inferior olive, and back to the cerebellum via the inferior cerebellar peduncle.
Holmes tremor – A combined rest, postural, and intention tremor at 2–5 Hz, which is produced by lesions in the vicinity of the red nucleus or neighboring ventrolateral thalamic and subthalamic area.
Myorhythmia – An unusually slow 1–3 Hz tremor that affects various combinations of the face, jaw, throat, tongue, head, eyes, torso, and extremities.
Oculomasticatory myorhythmia – A synchronous myorhythmia of the face and eyes, which is regarded by many as a pathognomonic sign of Whipple disease.
Olivary hypertrophy – A degenerative enlargement of the inferior olive that occurs in response to lesions in the dentatorubro–olivary pathway.
Palatal tremor – A rhythmic 1–3 Hz movement of the soft palate caused by lesions in the dentatorubro–olivary pathway.
Whipple disease – A rare systemic infectious disease caused by *Tropheryma whipplei.*

Definition and History

Myorhythmia is an unusually slow 1–3 Hz tremor that affects various combinations of the face, jaw, throat, tongue, head, eyes, torso, and extremities. It is present at rest and during voluntary muscle contraction. Van Bogaert and coworkers described oculomasticatory myorhythmia in 1963, and Masucci and coworkers provided the first detailed description of extremity myorhythmia in 1982.

Pathogenesis/Pathophysiology

Virtually all patients have pathology in the brainstem or cerebellum, produced by a long list of diseases including stroke, demyelinating disease, Whipple disease, celiac disease, Hashimoto encephalopathy, paraneoplastic disease, Wernicke disease, olivopontocerebellar degeneration, viral encephalitis, and collagen vascular disease.

Clinical Features and Diagnostic Criteria

Myorhythmia may affect one body part or multiple body parts, unilaterally or bilaterally. Contiguous body parts are often affected. The 1–3 Hz oscillations appear to be time-locked or synchronous in some patients, but this apparent synchrony is not the rule and has rarely been documented electrophysiologically.

Myorhythmia typically begins months or years after a posterior fossa stroke. In this regard, myorhythmia is similar to palatal tremor and Holmes (rubral) tremor, which may be related disorders. The delayed onset of these conditions suggests that secondary neuroplastic changes enhance or produce rhythmic brainstem and bulbospinal activity.

Oculomasticatory myorhythmia and oculofacioskeletal myorhythmia are classic signs of Whipple disease affecting the central nervous system (CNS). There is a characteristic pendular convergent–divergent movement of the eyes that is synchronous with movements of the face.

The classic clinical triad of Whipple disease is the combination of gastrointestinal malabsorption, supranuclear gaze palsy, and oculomasticatory myorhythmia, but isolated CNS signs and symptoms may occur. Furthermore, Rajput and McHattie reported a patient with vertical gaze palsy and lower limb myorhythmia.

Differential Diagnosis

Damage to the Guillain–Mollaret triangle is present in most patients. Consequently, some patients have olivary hypertrophy and palatal tremor (also known as palatal myoclonus). Palatal tremor has a frequency of 1–3 Hz and could be considered a form of myorhythmia. However, palatal tremor persists during sleep and is nearly always associated with olivary hypertrophy. Myorhythmia stops in sleep and is frequently present in patients who do not have olivary hypertrophy.

Extremity myorhythmia and Holmes tremor may coexist. Both occur at rest and during voluntary muscle contraction. Holmes tremor has a higher frequency (2–5 Hz), but there is an overlap, and some experts regard extremity myorhythmia and Holmes tremor as the same condition. Therefore, the proper nosology of these conditions is unclear. Additional electrophysiologic studies and clinicopathological correlations are needed.

Management

There are no controlled trials for the treatment of myorhythmia. Primary treatment should address the underlying disease whenever possible. Symptomatic treatment with valproate has helped in some patients with Whipple disease. Whipple disease is treatable with trimethoprim–sulfamethoxazole or with ceftriaxone in patients allergic to sulfa.

Prognosis

Prognosis is generally poor but depends on the underlying etiology. Myorhythmia should alert clinicians to pathology in the brainstem or cerebellum. The most common etiology is stroke, but myorhythmia occasionally occurs in treatable progressive conditions such as Whipple disease, paraneoplastic disease, and other immunologic disorders.

Myriachit

M J Bakker and M A J Tijssen, University of Amsterdam, Amsterdam, The Netherlands

Glossary

Coprolalia – Pathological use of foul language.
Culture-specific syndrome – Forms of abnormal behavior restricted in distribution to defined racial or social groups, discrete areas of the world, or particular historical periods.
Echolalia – Pathological repetition of words just spoken.
Echopraxia – Pathological repetition of the acts of other people.
Koryak, Yukaghir, Chuckchee, Yakut, Samoyed – Tribal groups living in Siberia.
Tungus – Russian settlers in Siberia.

Definition and History

The term Myriachit (meriachen'e, meriachit', or emiriachen'e in Russian, sometimes translated also as myryachit, meriachit, etc.) is derived from the Siberian Tungus word meaning 'doing something stupid and useless because of sudden fear.' It is also known as 'arctic hysteria' or 'olonism.' However, 'arctic hysteria' originally refers to a broader category of far-northern psychological disturbances.

The reports on incidents of Myriachit tend to be folkloric in nature. William Hammond, a surgeon/neurologist, collected stories from American soldiers who had been stationed in Siberia, and he tried to describe the syndrome on the basis of the soldiers' recollections. Hammond wrote: ". . .To annoy him [the patient, a steward of the boat], some of the passengers imitated pigs grunting, or called out absurd names; others clapped their hands and shouted, jumped, or threw their hats on the deck suddenly, and the poor steward, suddenly startled, would echo them all precisely, and sometimes several consecutively." As Hammond did not see the cases himself, the article was severely criticized. Shirokogoroff and Jackson also described the syndrome in about the same period, the beginning of the twentieth century. Shirokogoroff wrote: "One day he [the subject] was sitting alone, with his small son, in the wigwam. A knife fell down in front of him (evidently, the knife had been in the hanging hunting belt). He seized it and thrust it into his son's body."

Clinically, Myriachit is a Siberian syndrome consisting of excessive startle reactions, matching behavior (echolalia, echopraxia), and forced obedience (involuntary, immediate obedience to commands). Compared to other culture-specific movement disorders like Latah (Indonesia/Malaysia) and Jumping Frenchmen of Maine (US/Canada), the reports concerning Myriachit in Siberia are the least extensive.

Epidemiology

There is no information on the prevalence of Myriachit other than it was described to be well known to the Russians. In one account half of the Yukaghir women of age 30 or 40 and older were described to suffer from a mild or more severe form of Myriachit.

Pathophysiology

See 'Jumping Frenchmen of Maine.' Specifically for Myriachit, the symptoms have been attributed to difficulties adjusting to the far-northern environment. Shirokogoroff did not regard Myriachit as a disease but as a normal phenomenon. He further states that it has a social function 'without the *Tungus* life would be impoverished.' He thought it should not be considered hysteria.

Clinical Features and Diagnostic Criteria

As the response of the patients were never recorded, there are no clear diagnostic criteria other than that the responses are stimulus-induced. Several clinical features will be discussed. The most prominent is the matching or copying behaviour. When provoked, the individual with Myriachit imitates the actions of others against his will. According to Hammond's article, Myriachit appeared to involve *echolalia* and *echopraxia* only (*coprolalia* is not reported as part of the syndrome, like it is for Latah patients in Indonesia/Malaysia). However, a famous historical report describes a group of soldiers who repeated both the commands and swearing of a colonel. Shirokogoroff stated that "during a parade of this regiment, the soldiers began to repeat the words of command. The colonel grew angry and swore volubly at the men; but the more he swore, the livelier was the chorus of the soldiers repeating his curses after him." This is an account of a group of persons becoming infected simultaneously, something which has not been described for Latah or the Jumping Frenchmen of Maine. Reports of group Myriachit led some authors to conclude that Myriachit can be endemic in groups trained to obey, like the soldiers described by Shirokogoroff. Another consequence of mass Myriachit descriptions was that the occurrence of Myriachit was linked to the consumption of a drug. One story describes 14 soldiers who became liable to fits of echolalia following the consumption of hemp oil given by a sufferer from Myriachit in a settlement in Novokievsky. However, other reports of mass affects do not mention substances. The subjects are mostly female inhabitants of far eastern Siberia, especially Yakutsk. The *Koryak*, *Yukaghir*, *Chuckchee*, and the *Tungus* could all be affected (in other reports *Yakut* and *Samoyed* are included), but the latter were more prone as they were less acclimatized to the Siberian circumstances. Similar to Latah, milder and more severe forms were described. The mild form consisted of an obscenity exclaimed after a sudden fright and the more severe form consisted of a hypnotic-like state in which the person would mimic sounds and actions and follow orders. Shirokogoroff noticed that "Myriachit is liable to diffusion, fashions, and variations, both individual and ethnical, and is rooted in the normal psychomental complex." The behavior was said to be common in areas 'where the winter was harsh.' Further, the pattern is described to become more acute during periods of famine.

Prognosis

Neural Networks

N L W Keijsers, Sint Maartenskliniek, Nijmegen, The Netherlands

Glossary

(Artificial) neural network – Mathematical models that use learning algorithms to store information.
Back propagation – A common method of teaching artificial neural networks how to perform a given task.
Multilayer perceptron – The most successful and used neural network.
Training – The process of teaching/learning the network by way of presenting the network with a training set composed of input patterns together with their corresponding desired output pattern.

Definition and History

Neural networks are mathematical models that use learning algorithms inspired by the brain to store information. Since neural networks are used in machines, they are collectively called an 'artificial neural network.' Nowadays, the term machine learning is often used in this field and is the scientific discipline that is concerned with the design and development of algorithms that allow computers to learn, based on data, such as from sensor data or databases. A major focus of machine-learning research is to automatically learn to recognize complex patterns and make intelligent decisions based on data. Hence, machine learning is closely related to fields such as statistics, data mining, pattern recognition, and artificial intelligence. Neural networks are a popular framework to perform machine learning, but there are many other machine-learning methods, such as logistic regression, and support vector machines.

Similar to the brain, neural networks are built up of many neurons with many connections between them. Neural networks have been used in many applications to model the unknown relations between various parameters based on large numbers of examples. Examples of successful applications of neural networks are classifications of handwritten digits, speech recognition, and the prediction of stock prices. Moreover, neural networks are more and more used in medical applications. Many different types of neural networks exist. Examples of various types of neural networks are Hopfield network, the multilayer perceptron, the Boltzmann machine, and the Kohonen network. The most commonly used and successful neural network is the multilayer perceptron and will be discussed in detail.

The first step toward artificial neural networks came in 1943, when Warren McCulloch, a neurophysiologist, and a young mathematician, Walter Pitts, wrote a paper on how neurons might work. They modeled a simple neural network with electrical circuits. In the 1950s, Rosenblatt's work resulted in a two-layer network, the perceptron, which was capable of learning certain classifications by adjusting connection weights but also had some limitations. In the early 1980s, researchers showed renewed interest in neural networks.

Multilayer Perceptron

A multilayer perceptron consists of a number of layers containing one or more neurons (see **Figure 1** for an example). The role of the input neurons (input layer) is to feed input patterns into the rest of the network. After this layer, there are one or more intermediate layers of units, which are called hidden layers. Subsequently, the hidden layers are followed by a final output layer where the results of the computation are read off. Each unit is connected to all units in the subsequent layer and each unit receives input from all units in the previous layer. Each connection has a certain weight, and this weight illustrates the influence of the unit to the response of the unit in the subsequent layer. The output of a multilayer perceptron depends on the input and on the strength of the connections of the units. When information is offered to a

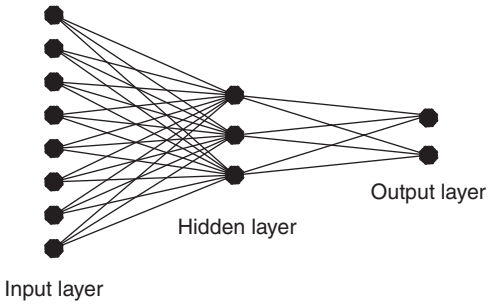

Figure 1 A multilayer perceptron with eight neurons in the input layer, three neurons in the hidden layer, and two neurons in the output layer.

multilayer perceptron by activating the neurons in the input layer, this information is processed layer by layer until finally the output layer is activated. Given enough hidden units and enough data, it has been shown that multilayer perceptrons can approximate virtually any function to any desired accuracy. In other words, multilayer perceptrons are universal approximators. However, these results are valid if and only if there is a sufficiently large number of training data in the series. If there are not enough data to 'train' the neural network, the network will not be able to learn the required input–output relationship accurately. Therefore, multilayer perceptrons are valuable tools to solve complex problems when sufficient data are available to train them.

In many respects, the learning process (training) of a neural network is rather similar to the way the brain learns to distinguish certain patterns from others. The learning process of a neural network proceeds by way of presenting the network with a training set composed of input patterns together with their corresponding desired output pattern. By presenting we mean that a certain pattern is fed into the input layer of the network. We start off with a network with random connections between the neurons, which gives a random output for a given input. We then train the network by presenting it with successive patterns drawn from an example set, which is typical of the problem we want the network to work on. For each of these patterns, we look at the output pattern the network gives us and compare it with the output we would ideally like to see. By comparing the output of the network with the target output for that pattern, we can measure the error the network is making. This error can then be used to alter the connection strengths between layers in order that the network's response to the same input pattern will be better the next time. In other words, the purpose of the training process is to minimize the error between the desired output and the neural network output by adjusting the weights between units of subsequent layers. The training of a network is commonly done by a procedure called backpropagation. Backpropagation modifies the strengths of the connections between a layer and the previous layer starting with the output layer based on the error between desired and actual output of the network. The network processes the records in the training data one at a time, using the weights and functions in the hidden layers, and then compares the resulting outputs against the desired outputs. Errors are then propagated back through the system, causing the system to adjust the weights for application to the next record to be processed. This process occurs over and over as the weights are continually tweaked. During the training of a network, the same set of data is processed many times as the connection weights are refined.

The architecture of a neural network plays a critical role in whether or not it can be trained to learn a particular set of data. The question of how many nodes and connections are ideal in a neural network cannot be answered easily. Clearly, the simpler the architecture, the simpler a function the neural network is computing. Too simple an architecture will result in a network that cannot learn to approximate a complex function. Too complex an architecture has been shown to result in a network losing its generalization capability. The generalization capability is the performance of a network to give a proper classification for new input pattern, which the network has not encountered before. Generalization is an important feature to maintain in order to avoid overfitting. Overfitting happens in case of a small training set, in which case the network cannot distinguish between information in the patterns and the noise. The consequence is that the network learns noise, rather than the general characteristics in the database. The generalization performance of a network can be evaluated by training the network with a part of the whole data set (e.g., 80% of the data, called the training set) and testing the trained network with the remaining data that was not used for training the network (e.g., 20% of the data, called the test set).

Ambulatory Assessment of Dyskinesia

An example of the benefit of neural networks in neurology is the ambulatory assessment of dyskinesia in patients with Parkinson's disease. Dyskinesias are a major problem in the long-term management of Parkinson's disease and add substantially to the patient's disability. Common methods to detect dyskinesia like clinical methods and self-reports have their limitations. Standard clinical detection and rating methods of dyskinesia can only be applied in a hospital setting under supervision of a trained clinical observer. These rating methods, provide only a momentary assessment of the clinical condition and cannot be applied for long-term measurements. Self-report of

the motor state in diaries has several limitations and can be troublesome, subjective or even unreliable. Therefore, patients will greatly benefit from quantitative objective assessment of their motor state in daily life.

New developments in micro-electronics have led to small and cheap miniature movement sensors such as accelerometers, which can be attached to the body and can measure human motion in daily life. These accelerometers appeared to be useful to assess dyskinesia in Parkinson's disease patients when the patients were instructed to abstain from voluntary movements. However, assessing dyskinesia when voluntary movements were present appeared to be problematic indicating that it is difficult to distinguish voluntary movements from dyskinesia in daily life. A more sophisticated approach using sensors on multiple body segments and neural networks resulted in a successful assessment of dyskinesia in daily life. The neural network received parameters of the accelerometer signals of multiple body segments as input pattern and the severity of dyskinesia rated by a neurologist was used as output. After training the neural network, the neural network could correctly classify the severity of dsykinesia for new patients. This study showed that movement parameters of multiple segments and their nonlinear relationships are important to assess dyskinesia in dialy life.

Neuroacanthocytosis Syndromes

R H Walker, James J. Peters VA Medical Center, Bronx, NY, USA; Mount Sinai School of Medicine, NYC, NY, USA

Glossary

Acanthocytes – Contracted erythrocytes with thorny protrusions.

Chorea-acanthocytosis – An autosomal recessive neurodegenerative disease characterized by involuntary movements (chorea) and acanthocytosis.

Huntington disease-like 2 – An autosomal dominantly-inherited disorder due to expansion of trinucleotide repeats in the gene coding for the protein junctophilin 3.

McLeod syndrome – An X-linked recessive neurodegenerative disease characterized by involuntary movements (chorea) and acanthocytosis, in which there is reduced expression of XK and Kell antigens on erythrocytes.

Neuroacanthocytosis – A term for the group of neurological conditions in which there are abnormalities of red blood cell membranes resulting in thorny protrusions.

Definition

The neuroacanthocytosis (NA) syndromes are those in which there are abnormalities of red blood cell (RBC) membranes, resulting in thorny protrusions, in addition to neurological symptoms (**Figure 1**). The term has been used for inherited disorders of lipoproteins such as abetalipoproteinemia and hypobetalipoproteinemia, which result in deficiency of vitamin E due to malabsorption, with the neurological consequences of degeneration of the posterior columns of the spinal cord and peripheral neuropathy. However, the term NA is more generally used at present, and is used in this article to refer to the syndromes in which the basal ganglia are affected and patients typically develop movement disorders and psychiatric symptoms.

The two core NA syndromes are autosomal recessive chorea-acanthocytosis (ChAc) and X-linked McLeod syndrome. These syndromes are similar in many aspects, and distinguishable from other choreatic disorders by the presence of specific other neurological and nonneurological features. There are two conditions in which acanthocytes are found in a minority of patients: Huntington's disease-like 2 (HDL2) and pantothenate kinase-associated

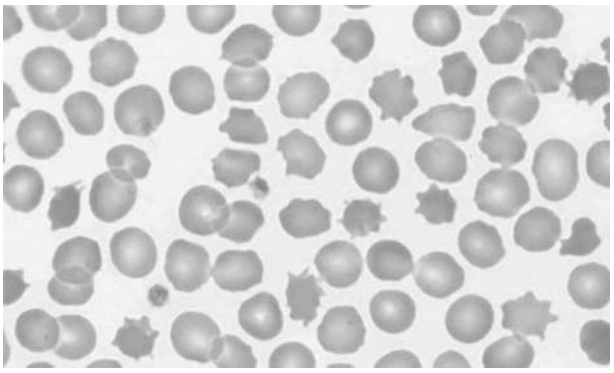

Figure 1 Acanthocytosis on peripheral blood smear. Courtesy of Dr. Hans H. Jung. Reprinted from Danek and Walker, Neuroacanthocytosis. *Current Opinion in Neurology* 18(4): 386–392. Lippincott Williams & Wilkins, Philadelphia, PA, with permission from Lippincott Williams & Wilkins.

neurodegeneration (PKAN). A condition initially known as hypoprebetalipoproteinemia, acanthocytosis, retinal pigmentation, and pallidal degeneration (HARPP) syndrome was subsequently identified as being allelic with PKAN.

A small number of single families with other neurologic syndromes and acanthocytosis have been reported. These include a familial syndrome due to a mitochondrial mutation and a patient with a paroxysmal exertional syndrome. A family with paroxysmal exertional dyskinesia, recently found to be due to mutation of the glucose transporter, GLUT1, was initially reported to have acanthocytosis; however, on electron microscopy, these were found to be echinocytes. This RBC membrane abnormality was likely due to electrolyte abnormalities from the cation leak caused by the transporter mutation.

The presence of acanthocytosis is not invariably present, even in the two core syndromes, and is not required to make the diagnosis. The basis for this abnormality of RBC membrane structure in most of these syndromes is not well-understood.

Pathogenesis

All NA syndromes are monogenic. The functions of the genes responsible for ChAc and McLeod syndrome are not yet understood, nor is it known how their dysfunction leads to neurodegeneration or acanthocytosis. The significance of the abnormality of RBC membranes and its relationship to neurodegeneration, predominantly affecting the basal ganglia, remain obscure.

The exception to this is PKAN, where absence, or reduced functioning, of pantothenate kinase results in reduced coenzyme A. Vulnerable brain areas may be those with the highest energy demands. Impaired lipid synthesis due to coenzyme A deficiency is likely to be the cause of acanthocytosis; however, it is not known why this is seen only in ~10% of patients.

Neurodegeneration, in cases which have come to autopsy, is found predominantly in the basal ganglia. Neuropathological findings consist of neuronal loss and gliosis of these regions, but no inclusion bodies of any nature have been detected.

Epidemiology

These disorders are very rare. The most common and widely-recognized of these syndromes is PKAN, which has been estimated to occur at a rate of 1–3 per 1 000 000.

Both ChAc and McLeod syndrome are exceedingly rare, and identified cases number in the hundreds worldwide. Both have been reported in most ethnic populations. ChAc has a higher incidence in Japan, apparently due to a founder effect.

HDL2 has been reported to date only in families of African ancestry, with the exception of one patient from the Middle East.

Clinical Features and Diagnostic Criteria

As is typical of neurodegenerative disorders involving the basal ganglia, this group of disorders may present with a variety of movement disorders and psychiatric features. In particular, ChAc, McLeod syndrome, and HDL2 may present in young adulthood initially with psychiatric findings. It is not uncommon for the development of the movement disorder and cognitive impairment to be attributed to neuroleptic administration, thus masking and delaying diagnosis.

Childhood onset of generalized chorea and dystonia, with additional features of pigmentary retinal degeneration, suggests PKAN. Dystonic tongue protrusion can be seen both in this disorder and ChAc, but in ChAc it is specifically induced by eating.

The neurological features of ChAc typically develop in the 20s–30s, but may present in adolescence with obsessive–compulsive spectrum symptoms, including tic disorders. Severe, self-mutilating lip- and tongue-biting is typical of ChAc.

McLeod syndrome develops in middle-aged men, and also may present with psychiatric or cognitive deterioration. Hepatosplenomegaly, seizures, peripheral sensorimotor neuropathy, and areflexia suggest either McLeod syndrome or ChAc. Cardiomyopathy is found only in McLeod syndrome.

Patients with HDL2 typically have a family history indicative of autosomal dominant inheritance, with a clinical phenotype also strongly suggestive of HD. Similar

to Huntington's disease (HD), the age of onset is inversely related to the size of the trinucleotide repeat expansion.

Diagnosis of McLeod syndrome and ChAc is made by detection of the absence of their protein marker in peripheral blood. Diagnosis of both these, and PKAN and HDL2, is confirmed by the detection of mutations in the respective genes.

Differential Diagnosis

The differential diagnosis of each of these diseases depends upon the presentation, and may include the possible etiologies of chorea, dystonia, parkinsonism, psychopathology, peripheral neuropathy, myopathy, and tics. The family history, additional clinical features, and laboratory and neuroimaging findings are often informative.

Diagnostic Work-up

Work-up of any patient with a movement disorder should include evaluation of liver enzymes, and if these enzymes are elevated, Wilson's disease should be excluded, which at present is the only treatable neurodegenerative disorder. Once Wilson's disease has been excluded, elevation of liver enzymes suggests ChAc or McLeod syndrome, as does elevation of creatine kinase, which is often increased many times the upper limit of normal.

Sensitivity for acanthocytosis on peripheral blood smear can be increased by incubating the RBCs with an equal volume of normal saline containing 10 IU ml^{-1} heparin for 30 min on a shaker. Electron microscopy of glutaraldehyde-fixed RBCs is also confirmatory. However, the presence of acanthocytes in the NA syndromes is not constant, for reasons which are not well understood, and their absence does not preclude the diagnosis.

Neuroimaging in ChAc, McLeod syndrome, and HDL2 is often reported as being consistent with HD, with bilateral atrophy of the caudate nuclei. In PKAN, iron deposition in the globus pallidus gives the 'eye-of-the-tiger' appearance.

Management

Management of all these neurodegenerative conditions is at present purely symptomatic. Dopamine-depleting and -blocking agents may be useful in the treatment of chorea; however, the involuntary movements may not impair function as much as other aspects of the disease such as psychopathology or peripheral neuromuscular abnormalities. Psychiatric and cognitive symptoms should be treated appropriately.

Results of deep brain stimulation (DBS) have been variable, and the optimal site and stimulation parameters remain to be determined; however, 40 Hz stimulation of the globus pallidus pars interna may be beneficial in ChAc. The largest experience with DBS is in patients with PKAN in which a number of positive responses to high-frequency pallidal stimulation have been reported.

Seizures in ChAc and McLeod syndrome usually respond to standard anticonvulsants, although lamotrigine and carbamazepine have been reported to worsen the involuntary movements.

A multidisciplinary approach with the involvement of paramedical therapists is essential for long-term care. Evaluation by a speech therapist is invaluable to minimize problems due to dysphagia and nutritional compromise. Physical and occupational therapists should be involved to assist difficulties like gait, balance, and activities of daily living.

Prognosis

These disorders are in general slowly progressive over several decades. Sudden death may be due to seizure, or possibly autonomic dysfunction, or there may be gradually progressive, generalized debility, as seen in Huntington's or Parkinson's diseases, with patients succumbing to aspiration pneumonia or to other systemic infection.

Neuroferritinopathy

M B Hartig, Technische Universität München, Munich, Germany

Glossary

Autosomal dominant – Mendelian pattern of inheritance associated with a risk of up to 50% of inheritance from affected persons to children.
Disinhibition – Impaired ability of patients to deal with their immediate impulsive response to a situation.
Ferritin – Protein, of which the light chain is encoded by the FTL gene, is responsible for iron detoxification and iron storage.
Ferritin inclusion bodies – Neuropathological finding of neuroferritinopathy mainly located in the nucleus and cytoplasma of glia and neurons.
Frameshift mutation – Sequence insertion or deletion causing a shift of the translational reading frame.
Neurodegeneration with brain iron accumulation (NBIA) – Group of disorders characterized by deposition of iron in the brain.

Definition and History

Neuroferritinopathy (adult-onset basal ganglia disease, hereditary ferritinopathy (HF), MIM 606159) is a rare autosomal dominant disorder belonging to a group of hereditary neurodegenerative disorders named neurodegeneration with brain iron accumulation (NBIA). Disorders of this group share deposition of iron in the brain as a common feature. It was not until 2001 that the genetic cause of neuroferritinopathy was identified. The causal mutation in the *FTL* gene was detected in a family that was originally believed to be affected by Huntington's disease, a common misdiagnosis of patients with neuroferritinopathy.

The different mutations in this gene had already been attributed to another disorder named hyperferritinemia–cataract syndrome.

Pathogenesis/Pathophysiology

The *FTL* gene is located on the chromosome 19q13.3 and encodes the light chain of ferritin. The mammalian ferritins are expressed in most cells. They are composed of 24 polypeptide subunits with variable proportions of the light (FTL) and the heavy (FTH1) chains. The protein structure is a dodecahedron, a 12-sided hollow ball. The function of ferritin includes iron detoxification and iron storage of up to 4500 iron atoms per ferritin. Iron plays a role in many physiological processes, for instance, in neuronal development, myelination, and synthesis of neurotransmitters. Its toxicity is believed to be based on the generation of reactive oxygen species (ROS) causing lipid peroxidation, DNA strand breaks, and protein modifications.

The first mutation described in the *FTL* gene was an insertional mutation of an additional adenine at positions 460 to 461 causing a frameshift. Reports of six other mutations in the *FTL* gene associated with neuroferritinopathy followed (**Table 1**). All but one mutation are frameshift mutations located in exon 4 leading to elongation of the 175 amino acids long ferritin protein. According to protein modeling, the terminal part of FTL is predicted to form the pores through which the iron molecules must pass when entering the ferritin complex. Uncontroled release of iron could be the underlying pathomechanism of the *FTL* mutations.

Postmortem neuropathological findings in patients with neuroferritinopathy are ferritin nuclear and cytoplasmic inclusion bodies and iron accumulation in glia and neurons throughout the CNS.

Epidemiology/Risk Factors

Neuroferritinopathy is a very rare disorder with about 50 cases reported worldwide until now. Both males and females are equally affected. The majority of patients carry the c.460dupA mutation, which probably represents a founder mutation. All other mutations have been reported in single families.

Clinical Features and Diagnostic Criteria

Diagnostic criteria of neuroferritinopathy include (1) clinical phenotype and progression, (2) family history consistent with autosomal dominant inheritance, (3) inappropriate low serum ferritin, and (4) evidence for iron deposits in the basal ganglia detected by magnetic resonance imaging (MRI).

Clinical Findings

The variability of age of onset and clinical manifestations represents a major problem when diagnosing neuroferritinopathy. The age of onset may vary from 13 to 63 years

Table 1 Clinical findings and mutation status in patients with neuroferritinopathy

MS, missense mutation; FS, frameshift mutation.

with a mean onset of about 40 years. The most frequently reported presenting symptoms are focal onset chorea (50%), focal dystonia (43%), and Parkinsonism (7.5%). Less common presenting symptoms include blepharospasm, writer's cramp, and ballistic movements. These symptoms usually progress slowly with ambulation, remaining possibly for up to two decades after disease onset. Some of the patients carrying mutations other than the common c.460dupA mutation were manifested with different symptoms such as hypotonia, tremor, and ataxia, and sometimes these patients showed faster disease progression. The distribution of symptoms is often asymmetric. During the course of disease, nearly all patients develop dystonia and chorea. Additional features patients may suffer from include oromandibular dyskinesia, dysphagia, and a typical speech characterized by a dysarthrophonia and action-specific dystonia. Cognitive impairment is a frequent finding (44% in the first decade of disease progression), but when present, tends to be mild in the form of minor defects of verbal fluency. Only rare cases of frontal/subcortical dementia have been reported. Disinhibition and emotional liability are a frequent finding even in the early stages of disease. Detection of more mutations could further broaden the clinical spectrum of neuroferritinopathy.

Clinical Chemistry

Detection of very low levels of ferritin supports the diagnosis neuroferritinopathy. It is usually combined with normal haemoglobin and serum iron levels. This clinical feature is seen in the majority of affected males and postmenopausal women but only in a quarter of premenopausal females. Other routinely analyzed blood parameters have not been shown to be altered specifically. Muscle biopsy reveals deficiency in the mitochondrial respiratory chain complex in some patients.

Neuroimaging

MRI of patients with neuroferritinopathy is characterized by the evidence of iron deposition in the brain and tissue destruction.

T2 sequence*

About half of the patients have a widespread hypointensity in the cerebral cortex and the basal ganglia (globus pallidus, putamen, caudate nuclei, thalamus, substantia nigra, dentate nuclei). In the remaining patients a confluent area of hyperintensity (cavitation) is found in the

globus pallidus and the putamen surrounded by a rim of hypointensity. In addition, a hypointensity of substantia nigra and dentate nuclei is detected. Rarely, the 'eye of the tiger' sign is seen as in patients with pantothenate kinase-associated neurodegeneration (PKAN) patients.

FSE (fast spin echo) scans

In about half of the patients FSE scans reveal small areas of hyperintensity within pallida, putamen, and caudates combined with hypointensity of substantia nigra and dentates. Remaining patients show confluent hyperintensity (probable cavitation) of pallida and putamen in addition to hypointensity of substantia nigra and dentate nuclei.

Differential Diagnosis

Other progressive neurological diseases with onset in adulthood need to be considered in the differential diagnosis (**Table 2**), especially disorders manifesting with symptoms like dystonia and chorea. Pantothenate kinase-associated neurodegeneration with brain iron accumulation (PKAN) and aceruloplasminemia are further disorder characterized by iron depositions in the brain.

Diagnostic Work-up/Tests

In patients with an adult-onset progressive neurodegenerative disease combined with evidence for an autosomal dominant pattern of inheritance or an inappropriately low serum ferritin, MR T2* imaging should be performed. In the case of evidence for iron deposition in the basal ganglia, diagnosis of neuroferritinopathy should be confirmed by molecular genetic testing. The *FTL* gene is the only gene described for neuroferritinopathy. Sequence analysis identifies mutations in the *FTL* gene in about 80% of affected individuals, in simplex cases the detection rate decreases.

Management

Guidelines for therapy are issued by Chinnery et al. based on their clinical data.

Treatment

No effective treatment exists so far. Therapies under investigation include iron chelation, phlebotomy and coenzyme Q10.

Symptomatic treatments exist in the form of levodopa, tetrabenzine, benzhexol, diazepam, clonazepam, and deanol in standard doses. Botulinum toxin is used to relieve the distress of dystonia. Supportive therapies such as physiotherapy and dietary measures are recommended.

Genetic Counseling

Neuroferritinopathy is inherited in an autosomal dominant manner. Each child of an individual with neuroferritinopathy has a chance of 50% to inherit the *FTL* mutation. Penetrance is age dependent and probably close to 100% at old age. Exact data on the age dependency of the penetrance are not available.

Prognosis

The course of disease is progressive albeit slowly in most cases. It may eventually lead to significant restrictions in form of aphonia, dysphagia, severe motor disability, and cognitive impairment.

Table 2 Differential diagnosis of neuroferritinopathy

Disorder	*Gene*	*MI*	*Difference to neuroferritinopathy*
Huntington's disease	HD	AD	More severe cognitive decline, normal ferritin
Huntington-like disease 2	JPH3	AD	More severe cognitive decline, normal ferritin
Idiopathic torsion dystonia	DYT1	AD	Age of onset is earlier in most cases, normal ferritin
Spinocerebellar Ataxia 17	SCA17	AD	Ataxia is the predominant feature, normal ferritin
AD dopa-responsive dystonia	GCH1	AD	Responsiveness to L-dopa, normal ferritin
Nieman-Pick disease type C	NPC1, NPC2	AD	Abnormal eye movements, normal ferritin
X-linked (McLeod's) neuroacanthocytosis	XK	XR	Elevated CK, compensated haemolysis, seizures, normal ferritin
Recessive choreoacanthocytosis	VPS13A	AR	Elevated CK, seizures, sensory axonopathy, normal ferritin
Pantothenate kinase-associated neurodegeneration (PKAN)	PANK2	AR	Spasticity in most patients, normal ferritin
Aceruloplasminemia	CP	AR	Not confined to neurological symptoms (diabetes mellitus, retinal degeneration) reduced serum copper, reduced serum iron and reduced plasma ceruloplasmin ferroxidase activity, increased serum ferritin

MI, Mode of inheritance; AD, autosomal dominant; XR, X-linked recessive; AR, autosomal recessive; CK, creatine phosphokinase.

Neurofibrillary Tangles

H Braak and K Del Tredici, University of Ulm, Ulm, Germany

Glossary

Bielschowsky silver stain – A histological silver technique developed by the neuropathologist Max Bielschowsky (*c.*1900), with which it was possible, for the first time, to visualize light microscopically not only nerve cells but also the so-called 'senile plaques' and intraneuronal neurofibrillary tau protein deposits (tangles) that characterize Alzheimer's disease.

Cytoskeleton – A kind of scaffolding found within the cellular cytoplasm consisting of intermediate filaments, actin microfilaments, and microtubules, which lend the cell shape and facilitate intracellular transport.

Gallyas silver stain – A histological silver technique developed by the still active Hungarian neurochemist Ferenc Gallyas, which uses silver ions plus a reducing agent and stabilizer to visualize light microscopically, among other entities, the neurofibrillary lesions associated with Alzheimer's disease.

Microtubule-associated proteins – A family of proteins, including the protein tau (MAPT), that binds to the microtubules of the cytoskeleton.

Tauopathies – Neurodegenerative diseases of the human brain involving aggregations of the protein tau and including Alzheimer's disease, argyrophilic grains disease, corticobasal degeneration, Pick's disease, progressive supranuclear palsy, and frontotemporal dementias (FTD).

Definition and History

A major criterion – and one that is mandatory for the neuropathological confirmation of the clinical diagnosis of Alzheimer's disease (AD) – is assessment of intraneuronal protein inclusions that appear as neurofibrillary tangles (NFTs) and neuropil threads (NTs) in vulnerable types of nerve cells. NFTs were detected and first described by Alois Alzheimer, who employed Max Bielschowsky's silver impregnation. These neurofibrillary lesions result from the pathological aggregation of the misfolded and abnormally phosphorylated protein tau. In healthy individuals, normal tau stabilizes the microtubules of the neuronal cytoskeleton. Among their diverse functions, microtubules facilitate the transport of substances between nerve cell compartments. Aggregated tau filaments cannot be degraded by host neurons and gradually accumulate within the cytoplasm.

Select Projection Neurons Especially Prone to the Neurofibrillary Pathology

NFTs and NTs develop in only a few of the many neuronal types within the human nervous system. Most of the vulnerable cells are projection neurons with a long and thin axon. By contrast, short-axoned cells generally are resistant. Exceptions include chandelier cells, which can develop a soluble material that contains abnormally

phosphorylated tau, but these rapidly disappear before NFTs/NTs can form; large cholinergic interneurons in the striatum can develop globose NFTs early in AD.

Susceptible projection cells not only have a long axon but also one that is unmyelinated or poorly myelinated. In addition, vulnerable cells contain lipofuscin or neuromelanin. Heavily myelinated projection neurons resist the pathological process as do those lacking pigment granules. On the other hand, cells with a long, sparsely myelinated axon and containing large amounts of pigment are not necessarily prone to become involved.

Pretangle Phase

Specific antibodies (e.g., AT8) that react with abnormally phosphorylated tau permit visualization of the very earliest pathogenic stage (pretangle phase) that marks the onset of the neurodegenerative process. Abnormally phosphorylated tau forfeits its binding capacity on the microtubules. It is still soluble and nonargyrophilic in cytosol, filling both the cell body and its cellular processes – an aspect closely resembling a Golgi impregnation (**Figure 1(a)**). The axon is homogeneously immunoreactive and can be followed for a considerable distance in the tissue, including its terminal ramifications (**Figure 2**). Initially, the cellular processes display no deviations from their normal shapes. It is unknown how long the cells remain in this 'pretangle' phase, but it is the forerunner of the argyrophilic NFT/NT stages that follow. Theoretically, the potential for reversing the intraneuronal disease process is at its peak during this phase.

NFT Formation

After the pretangle phase, the abnormal tau protein inclusions undergo crosslinkage (aggregation). The axon is no longer AT8-immunoreactive: distal dendritic segments appear twisted and dilated with shortened appendages, and dendrites become partially detached from their stems (**Figure 1(b)**). Traces of silver-stained fibrillary material occur near lipofuscin or neuromelanin granules (**Figure 1(c)**), and eventually the central portions of larger NFTs become concentrated around pigment deposits. It is even possible that pigment granules serve as initiation sites and support oxidative crosslinking reactions. Slender NTs appear in altered dendrites, and, thereafter, a NFT is visible within the cell body. NFTs are argyrophilic, insoluble, cannot be degraded by the host neurons, and occupy large portions of the cytoplasm (**Figure 1(d)**). In some neuronal types, such NFTs extend into the proximal dendrites (flame-shaped NFTs), whereas globose NFTs remain confined to the cell body. NFTs do not extend into the axon hillock or initial axonal segment. The earliest pretangles and NFTs/NTs denote the beginning of a process which, unless interrupted by death, inevitably progresses to clinically manifest AD (**Figure 1**).

Survival and Death of Tangle-Bearing Neurons

Projection neurons are remarkably sturdy and can survive for decades despite the presence of marked tau protein alterations. Because cell death does not occur immediately, the question arises whether NFTs/NTs are harmful to host nerve cells or whether, instead, the aggregation process represents an attempt to eliminate nonbiodegradable but otherwise benign material. Available evidence indicates that an absence of neuronal loss does not mean that the functional capabilities of involved neurons remain intact; the axonal and dendritic changes take years and are accompanied by a gradual decrease in basophilia. Moreover, microtubule destabilization and impaired axonal transport probably result in deficient protein metabolism, synaptic dysfunction, and impaired signaling by retrograde neurotrophic factors. In other words, functional decline may contribute to neuronal death, but we do not yet understand the exact circumstances of all of the biological mechanisms that are involved at each step along the way to cell loss. Tangle-bearing neurons display mechanisms of dying that most probably differ from apoptosis or necrosis. Neither blebbing, nor chromatin condensations, nor macrophagic activity are observable.

Ghost Tangles

After cell death extraneuronal lesions are visible in the tissue as so-called 'ghost' or 'tombstone' tangles. At this point, the fibrillary material shows markedly reduced immunoreactivity. Ghost tangles have a less tightly twisted, much less argyrophilic aspect than NFTs (**Figure 1(e)**) and are surrounded by local astrocytes. To the extent that ghost tangles are subject to so little change (e.g., disintegration or degradation) for many years, it is highly questionable whether they ever disappear from the tissue entirely. Just how the enormous amount of abnormal material in NTs is processed or metabolized following the deaths of NT-bearing neuronal processes is also unclear.

Evolution and Staging of the Pathological Process

The AD-related pathological process evolves slowly and nearly symmetrically throughout specific cortical areas and subcortical nuclei (**Figure 2**). Beginning in

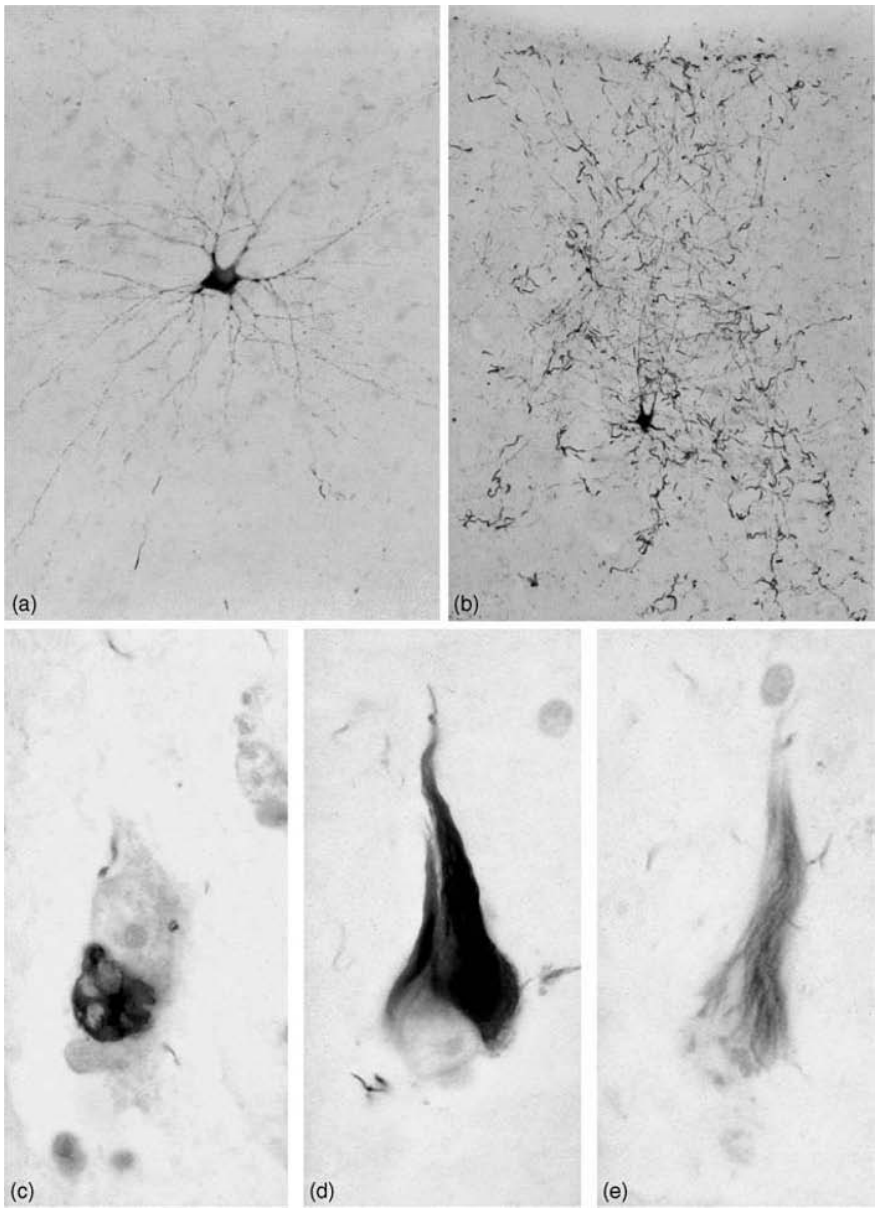

Figure 1 Formation of intraneuronal pretangles, tangles, and ghost tangles. (a) Initial hyperphosphorylation of tau defines the pretangle phase. Soluble tau fills the entire neuron. (b) In a second step, crosslinkage of this abnormal material occurs and distal dendritic segments become twisted (AT8 immunoreactions for abnormally phosphorylated tau protein in 100 μm polyethylene glycol-embedded tissue sections). (c) The now fibrillary material becomes argyrophilic, insoluble, and is nonbiodegradable (inert). Central portions of the NFT are concentrated around lipofuscin granules. (d) The material fills large portions of the soma and may extend into proximal dendrites. (e) After deterioration of the host cell, the NFT remains visible as an extraneuronal ghost tangle (Gallyas silver stain for neurofibrillary changes of the Alzheimer type plus aldehyde fuchsin–Darrow red staining for basophilic material and lipofuscin granules).

predisposed subcortical and cortical induction sites, it then progresses into other portions of the cerebral cortex and specific sets of subcortical nuclei according to a predictable topographic sequence with little interpatient variation. The distribution pattern of the neurofibrillary lesions has provided the conceptual basis for distinguishing six neuropathological stages. These comprise clinically 'silent' or preclinical cases in transentorhinal stages I and II, cases of incipient AD or mild cognitive impairment in limbic stages III and IV, and cases with fully developed AD in neocortical stages V and VI. Staging procedures are imperfect constructs because the lesions develop continually as part of a larger biological process rather than in artificially defined steps.

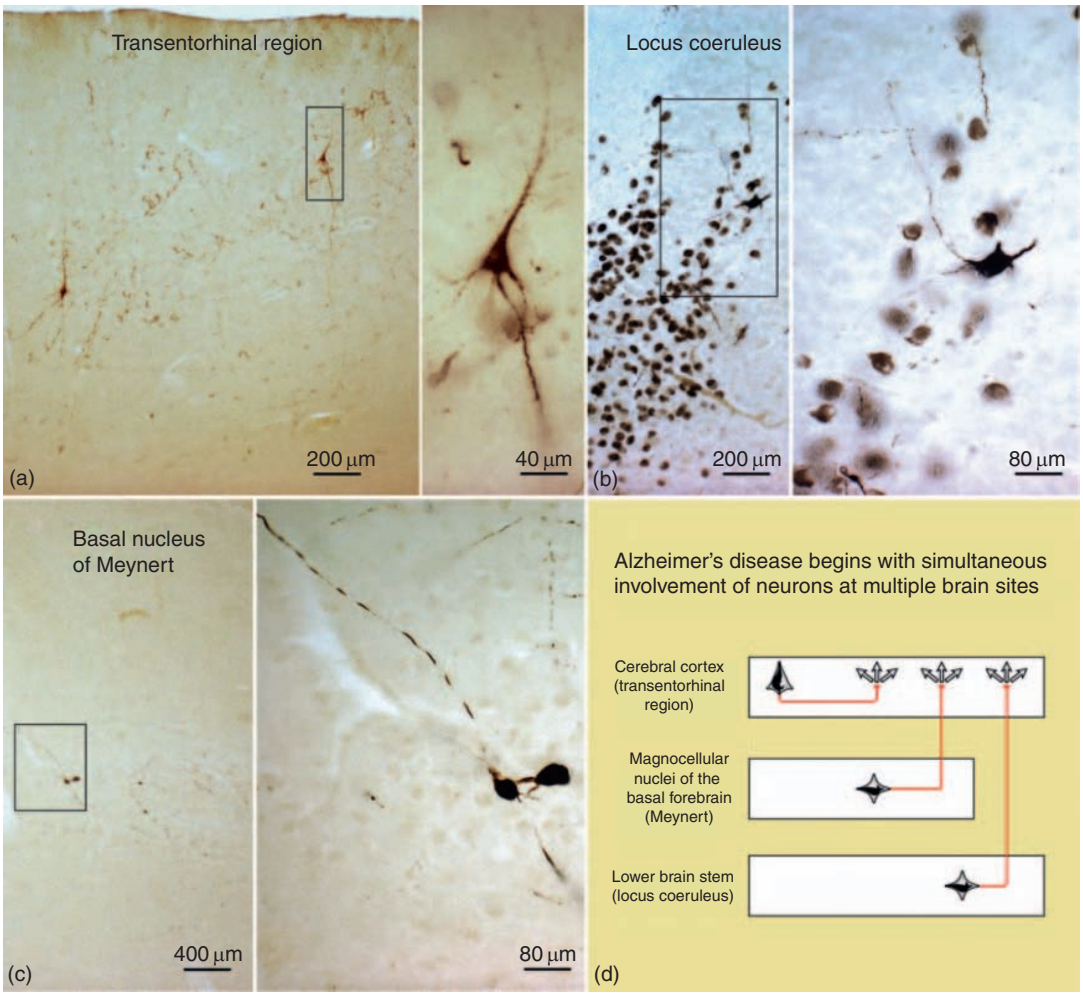

Figure 2 Pretangles displaying the earliest cytoskeletal abnormalities appear at multiple brain sites simultaneously. (a–c) 32-year-old male 'control' case, that is, brain tissue still free of NFT-bearing nerve cells. Framed areas appear at higher magnification to the right of each of the overviews. (a) Overview and detail of pretangle neurons in the transentorhinal region, the only cortical site where pretangles were seen in this case. (b) Solitary pretangle neuron in the noradrenergic locus coeruleus of the lower brainstem. (c) Pretangle-bearing neuron in the cholinergic nucleus of Meynert of the basal forebrain. These were the only two locations where pretangle pathology occurred in subcortical nuclei. (d) Although the possibly earliest predilection sites for pretangles are located at a considerable distance from each other, they share one feature in common, namely, all send projections to layer I of the cerebral cortex (arrows) (AT8 immunoreactions for abnormally phosphorylated tau protein in 100 μm polyethylene glycol-embedded tissue sections).

Prevalence of Alzheimer-Type Neurofibrillary Changes

The relationship between age and the NFT/NT-associated changes has been studied by staging large numbers of nonselected autopsy brains. **Figure 3** shows the percentage of such cases for each of the six NFT stages by age group. Data acquired in this manner indicates that NFTs and NTs are not associated with normal aging, although the lesions become increasingly prevalent with age and occur in a very large proportion of the aging population. Whereas human aging is a continuum of biological processes and adjustments in independent living skills, which transpire throughout a lifetime, and not a disease process, NFTs/NTs are not benign and not every aged individual develops them. A small number of cases display the lesions at an unexpectedly young age, that is, at a point in life when other age-related findings, such as accumulation of lipofuscin granules, neuronal atrophy, and cerebrovascular pathology, are not routinely present. Thus, advanced age is not a prerequisite for the lesions and AD is not an age-dependent but, rather, an age-related disorder because the arithmetic means of stages for NFTs/NTs increase with age (**Figure 3**).

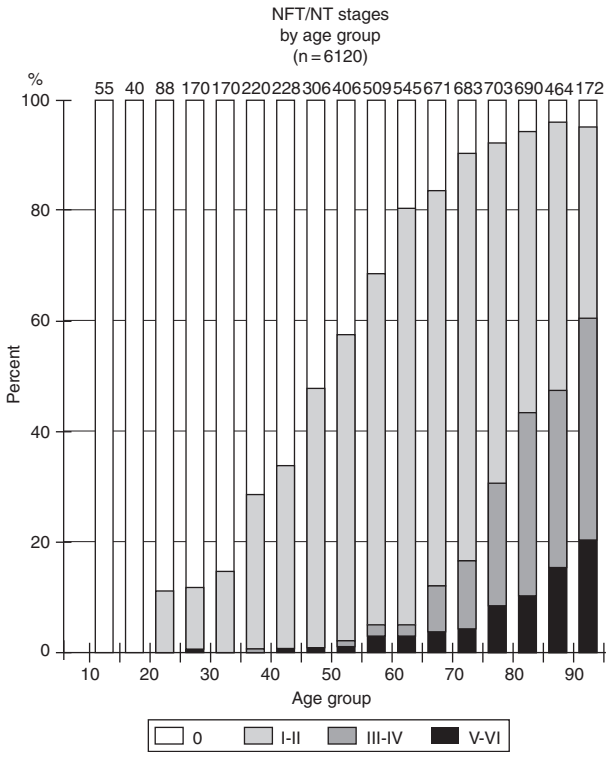

Figure 3 Schematic diagram showing the breakdown by age groups and percent for 6120 nonselected autopsy cases according to neurofibrillary stages: 0 (white), I and II (light gray), III and IV (gray), and V and VI (black). Neurofibrillary degeneration occurs with greater prevalence at later decades. Considerable variability exists with regard to the age at which the first NFTs/NTs develop: Stage I and II lesions are present in some cases even before the age of 25, which implies that advanced age is not required for their development. The white columns represent individuals whose brains lack NFTs/NTs. A tiny minority of elderly persons, even at 90 years of age, refrain altogether from developing Alzheimer's disease-associated intraneuronal lesions.

Considerable differences exist with respect to the age at which the earliest NFTs/NTs are detectable. Stage I and II lesions are found in persons under the age of 25. Around the age of 50, one-half of the cases examined exhibit the lesions, and by the age of 80, fewer than 10% are still unaffected. The age distributions from stages I–VI show that early stages occur preferentially in younger age categories, whereas more advanced stages increase in frequency with advancing age. The presence of even a few elderly subjects without NFTs and NTs is important because it demonstrates that even the very old can be resistant to the disease process.

Neurogenic Muscle Weakness, Ataxia, and Retinitis Pigmentosa (NARP)

M Hirano, Columbia University Medical Center, New York, NY, USA

Glossary

Adenosine triphosphate (ATP) – ATP is the common bioenergetic currency of the cell.
ATP synthase – Complex V of the mitochondrial pathway that generates ATP by oxidative phosphorylation.
ATP6 – ATP synthase subunit 6, which is encoded in mitochondrial DNA.
Cybrids – Cytoplasmic hybrid cells usually generated by fusing cytoplasm from patient cells harboring a mitochondrial (mtDNA) mutation with cells lacking mtDNA (rho-zero cells).
Heteroplasmy – A mixture of different forms of multicopy DNA molecules (e.g., mtDNA).
Homoplasmy – A uniform population of multicopy DNA molecules.
Leigh syndrome – A severe encephalopathy that typically manifests in infancy with psychomotor regression and lesions of brainstem, basal ganglia, or both.
Maternal inheritance – Vertical transmission of DNA from mother to progeny.
Mitochondrial DNA (mtDNA) – A small (16 569 bp) circular DNA molecule within mitochondria and encoding 37 genes.
NARP – Neuropathy, ataxia, and retinitis pigmentosa.
Respiratory chain – A set of four multisubunit enzymes (complexes I–IV) embedded in the mitochondrial inner membrane that transfer reducing equivalents (electrons) to generate a transmembrane proton gradient that is used to drive ATP synthesis through ATP synthase.

Definition and History

In 1990, Holt, Harding, and colleagues described four maternally related members of a family with neurogenic muscle weakness, sensory neuropathy, ataxia, retinitis pigmentosa, and encephalopathy due to a novel mitochondrial DNA (mtDNA) point mutation (m.8993T → G) in the ATP synthase 6 gene (ATP6). The syndrome was later called neuropathy, ataxia, and retinitis pigmentosa (NARP). Additional point mutations in the ATP6 gene have been identified in patients with the NARP phenotype. Subsequently, Tatuch and colleagues and Santorelli and colleagues reported that in some families with NARP, maternally related infants presented with Leigh syndrome, a severe devastating encephalopathy characterized by psychomotor regression with symptoms and signs of brainstem disease, basal ganglia dysfunction, or both.

Pathogenesis and Pathophysiology

NARP has been associated with four mutations at two sites in the ATP6 gene: m.8993T → G (p.156L → R), m.8993T → C (p.156L → P), m.9176T → G (p.217L → R), and m.9176T → C (p.217L → P). Curiously, at each mutation site, conserved leucines are converted to either an arginine or proline. Generally patients with the T → G (leucine to arginine) mutations are more severely affected than individuals with the T → C (leucine to proline) mutations. Heteroplasmic mutation burden correlates with severity of the phenotypes; patients with 70–90% mutation generally develop NARP while individuals with >90% mutation typically have Leigh syndrome. Individuals with <60% mutation load often do not show any neurological or retinal abnormalities.

The ATP6 mutations clearly impair oxidative phosphorylation – synthesis of ATP in the inner mitochondrial membrane; however, the molecular pathomechanism has not been fully defined. Reports indicate that the mutations may affect ATP synthase (complex V) assembly, coupling between proton transport and ATP synthesis, or both. Cell culture studies indicate that both m.8993T → G and m.8993T → C mutations cause energy deprivation and overproduction of reactive oxygen species (ROS), but the m.8993T → G mutation mainly impairs ATP synthesis while the milder m.8993T → C mutation generates higher levels of ROS.

Epidemiology/Risk Factors

NARP is a rare disorder with a prevalence rate that is probably <1:100 000. The major risk factor is presence of a NARP ATP6 mutation in the maternal lineage.

Clinical Features and Diagnostic Criteria

As the acronym implies, NARP is defined clinically by neuropathy, ataxia, and retinitis pigmentosa with onset

typically in childhood. The neuropathy manifests as proximal neurogenic weakness with stocking-glove sensory loss due to axonopathy. Encephalopathy is often prominent and can manifest as learning disability, mental retardation, dementia, and seizures. Other clinical features include short stature, sensorineural hearing loss, chronic progressive external ophthalmoplegia, cardiac conduction block, diabetes mellitus, and anxiety disorder. One patient had obstructive sleep apnea. Visual symptoms, particularly night blindness or reduced peripheral vision, may be the only manifestation and is primarily due to abnormal cone structure. On the other hand, retinitis pigmentosa may be absent in patients with other clinical features of NARP.

In families with NARP, some individuals may develop Leigh syndrome that typically begins during infancy often in association with a viral febrile illness.

Differential Diagnosis

The differential diagnosis of NARP includes other mitochondrial disorders such as Kearns–Sayre syndrome, myoclonus epilepsy with ragged-red fibers (MERRF), coenzyme Q10 deficiencies, mtDNA depletion syndrome, and multiple mtDNA deletion disorders. For NARP patients presenting with peripheral neuropathy, Charcot Marie Tooth syndrome is a differential diagnosis while for individuals with ataxia or retinitis pigmentosa, other genetic disorders may be considered.

Diagnostic Work-up/Tests

The diagnosis of NARP can be molecularly confirmed by identification of one of the known ATP6 gene mutations in blood, buccal mucosa, urine, or tissue. Additional diagnostic evaluation of patients with NARP should include: developmental assessment, complete neurological, ophthalmological, and cardiological evaluations; metabolic assessment (blood lactate and pyruvate); brain MRI; and, if seizures are suspected, electroencephalogram. Cerebrospinal fluid (CSF) lactate can be assessed by lumbar puncture or magnetic resonance spectroscopy, but is not essential. Unlike mitochondrial diseases due to mtDNA transfer RNA gene or deletion mutations or mtDNA depletion, muscle biopsies of patients with NARP do not show morphological alterations of mitochondria (e.g., ragged-red fibers or cytochrome *c* oxidase deficient fibers); therefore, muscle biopsies are not useful for the diagnosis of NARP.

Management

There are no specific treatments for ATP6 mutations. Nevertheless, supportive therapies are important, including management of seizures with anticonvulsants (such as avoiding valproic acid and barbiturates if possible), treatment of dystonia, and standard therapies for cardiomyopathy and diabetes mellitus if present. Coenzyme Q10 (50–200 mg tid) and L-carnitine (300 mg sid) have been used to improve mitochondrial function. Because ATP6 mutations, particularly m.8993T → C, may increase ROS production, antioxidants (e.g., vitamin C, α-lipoic acid, and idebenone) may be beneficial, but have not been proven to be efficacious through placebo-controlled clinical trials.

Prenatal diagnosis (PND) has been performed by measuring levels of the m.8993T → G mutation in chorionic villus or amniocyte samples. Steffan and colleagues reported that maternal mutation loads <75% in blood had no predictive value for fetal status except for women with no detectable mutation whose infants were mutation free. Based on three reports, in 10/20 PND, mutant loads were <30% and the children were healthy at ages 2–7 years while in 7/15 PND, mutation loads were ≥65% and pregnancies were terminated and tissues from six terminations showed high mutation levels in the PND samples and in all tissues of the fetuses.

Dichloroacetate (DCA) reduces lactate levels by activating the pyruvate dehydrogenase complex, and anecdotal reports indicate that in Leigh syndrome patients with the m.8993T → G mutation, during periods of acute deterioration, DCA can acutely lower lactate and may produce short-term clinical improvements.

Prognosis

The prognosis of patients with NARP is variable and depends, in part, on the particular mutation and mutation load. In general, patients with the m.8993T → G mutation are more severely affected than individuals with similar levels of the m.8993T → C mutation.

Neuroimaging, Parkinson's Disease

Y Mizuno, Juntendo University School of Medicine, Tokyo, Japan

Parkinson's Disease

Parkinson's disease (PD) is a common neurodegenerative disorder characterized by the loss of dopaminergic neurons in the substantia nigra and dopaminergic terminals in the striatum, particularly in the posterior putamen. Usually, Lewy bodies are present in the remaining neurons, although Lewy bodies do not develop in some familial forms of PD. Striatal neurons are not affected, including postsynaptic dopamine receptors. In recent years, many structures other than the substantia nigra are known to be involved in PD, some areas are involved only late in the disease and some very early. Regions affected include the olfactory bulb, postganglionic sympathetic fibers to the heart, vagal nerve, and the dorsal motor nucleus of the vagal nucleus, raphe nucleus, locus coeruleus, pedunculopontine nucleus, ventral tegmental area, the basal nucleus of Meynert, the amygdaloid complex, and the cerebral cortex. Changes in these structures are not yet easy to demonstrate by conventional neuroimaging except for the cardiac postganglionic sympathetic terminals. For the diagnostic purpose, neuroimaging is mainly focused on the demonstration of the loss of dopaminergic neurons in the nigrostriatal system.

Structural Computerized Tomography

Structural computerized tomography (CT) is normal unless the patient has other comorbidities or complications. Mild age-related cortical atrophy and/or ventricular dilatation may be seen in old patients.

Structural Magnetic Resonance Imaging

Structural magnetic resonance imaging (MRI) using routine 1.5 T MRI is normal unless the patient has some complications. Mild age-related cortical atrophy and/or ventricular dilatation may be seen in old patients (**Figure 1**). There have been attempts to identify quantitative differences between the PD patients and healthy controls using high-resolution 1.5 T MRI such as measuring the distance between the substantia nigra pars reticulate (SNR) and the red nucleus. SNR can be identified as a T2-low signal intensity area in the ventral part of the midbrain. Although the distance is shorter in PD, likely due to the loss of neurons in the substantia nigra pars compacta, there is an overlap between the age-matched controls and PD patients. This overlap limits this technique for application in daily clinical settings. Another attempt focused on measuring the volume of the substantia nigra by inversion-recovery pulse sequences of MRI. In this case, PD patients loose a lateral-to-medial gradient of signal in the substantia nigra. This technique remains investigational. Another strategy has been the examination of possible early structural changes of the olfactory nerves in PD by diffusion weighted imaging (DWI). Diffusion weighted images can detect the water diffusivity in the brain. In the nerve fibers, water molecules tend to move along the long axis of the nerve fibers and the movement perpendicular to the axis is limited. If there are degenerative changes in the nerve fibers, loss of neurons, or gliosis, water diffusivity is thought to increase in those areas and be detectable by DWI techniques. Water diffusivity in the olfactory nerves has been

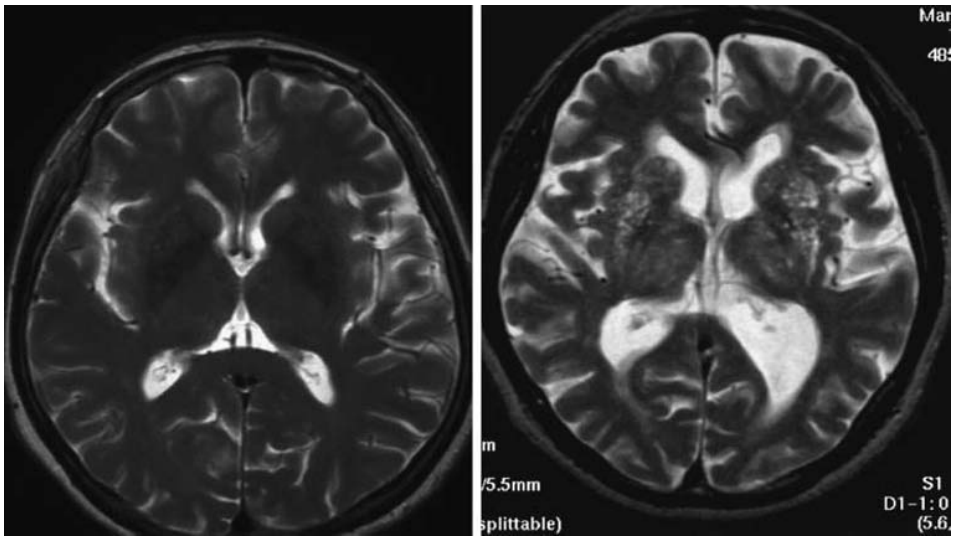

Figure 1 Left: 64-year-old man with PD. MRI is normal and cardiac MIBG uptake is markedly decreased. Right: 61-year-old woman with MSAp. The left putamen shows patchy T2-high signal lesions and the right putamen shows atrophic change, a T2-high signal lesion along the rim of the outer putamen and T2-low signal change within the putamen. Cardiac MIBG uptake is normal. In this patient, the left side of the body showed more prominent symptoms.

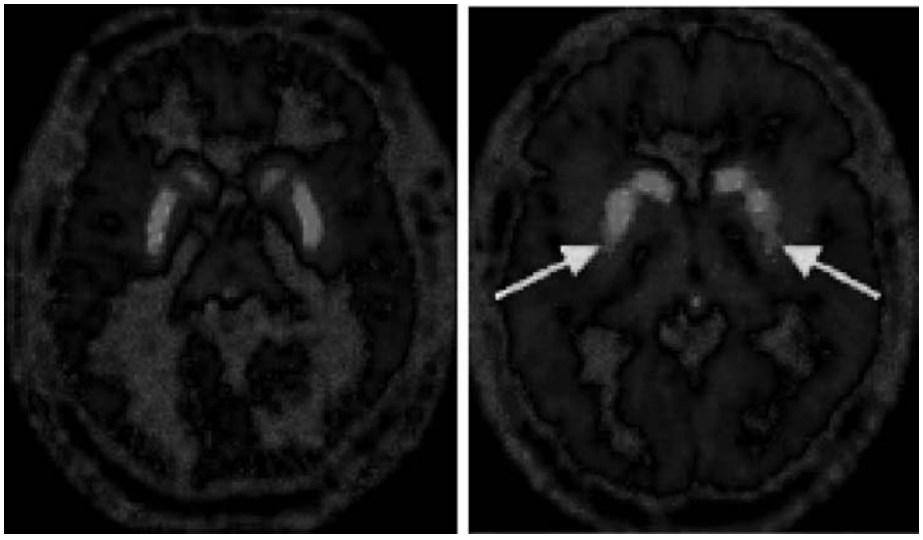

Figure 2 Right: normal, Left: a PD patient with right-sided hemiparkinsonism. 18Fluorodopa PET shows bilateral loss of uptake in the posterior part of the putamen, more on the left. demonstrated to be increased in patients with very mild PD, indicating the early involvement of this structure. These observations are in line with neurodegeneration observed histologically in the early stage of the disease in PD.

Positron Emission Tomography

Positron emission tomography (PET) utilizes radiolabeled ligands that emit positrons, which are detected by a gamma-camera, and the intensity of each voxel is calculated and reconstructed just as CT scan. Depending on the ligands utilized, various functions of the brain can be measured.

Dopaminergic tracers

Three kinds of tracers are being used to study the functional state of the nigrostriatal dopaminergic neurons. ^{18}F-dopa PET measures dopa decarboxylase activity in the striatum. Tropane-based tracers (^{11}C-CFT, ^{18}F-CFT, ^{11}CRTI-32) measure plasma membrane dopamine transporters (DATs) in the striatum. ^{11}C-dihydrotetrabenazine (DHTBZ) PET measures vesicle monoamine transporter density in dopaminergic terminals.

^{18}F-dopa uptake shows decreased activity in the caudal putamen in PD (**Figure 2**). Usually, 50% decrease of the uptake is present when the patient starts to show

parkinsonian symptoms. Presynaptic plasma membrane tracers bind not only to the DATs but also to serotonin and/or noradrenalin transporters. Presynaptic DAT image and vesicular monoamine transporter image tend to show lower uptake compared to ^{18}F-dopa image due to compensatory upregulation of dopa decarboxylase.

These PET scans cannot differentiate PD from multiple system atrophy (MSA) or progressive supranuclear palsy (PSP). Uptake of these dopaminergic markers is diminished in the striatum in both MSA and PSP. But PET scan is useful in the differential diagnosis of PD and essential tremor (ET). In ET, uptake of dopaminergic tracers remains normal. There is a good correlation between the severity of bradykinesia in PD and the degree of loss of uptake of dopaminergic tracers in PD, but not between the severity of tremor and the loss of dopaminergic markers. Some additional mechanisms appear to be involved in the pathogenesis of tremor.

Dopamine receptors

Postsynaptic dopamine receptors in the striatal neurons remain normal in PD. D2 dopamine receptor density is visualized by spiperone based PET and ^{11}C-racropride. D1 dopamine receptor density is visualized by ^{11}C-SCH23390. Spiperone based PET is normal in PD; ^{11}C-racropride PET may show some increases in putaminal D2 site availability; usually this is interpreted as upregulation of D2 receptor density due to denervation from dopaminergic terminals. D1 binding may show some decrease in the striatal binding. Chronic L-dopa treatment does not decrease D2 binding.

Serotonergic tracers

The raphe neurons are located in the central tegmentum of the midbrain and the upper pons. They are serotonergic neurons projecting to wide areas of the cerebral cortex and the striatum. In PD, raphe neurons are also involved but to a lesser degree compared to the substantia nigra. Loss of serotonin appears to be a cause of depression in PD, but also losses of dopamine and noradrenalin are implicated in the pathogenesis of depression in PD. Raphe serotonergic $5HT_{1A}$ autoreceptors in the presynaptic serotonergic neurons can be visualized by ^{11}C-WAY100635 PET, and one study showed loss of uptake in the raphe region. This may be due to loss of presynaptic $5HT_{1A}$ receptors on the dendritic processes of raphe serotonergic neurons. What is interesting is that there appears to be a correlation between the severity of rest tremor and loss of the $5HT_{1A}$ binding in the midbrain. Cortical uptake is not affected.

Cerebral blood flow and oxygen metabolism

Regional cerebral blood flow (rCBF) can be measured by $[^{15}O]H_2O$. In hemiparkinsonism, rCBF may show slight increase in the basal ganglia contralateral to the affected side. In bilateral patients, generalized decreases in rCBF may be seen unaccompanied by comparable changes in the regional cerebral metabolic ratio for oxygen ($rCMRO_2$). These changes are not pronounced, and its significance awaits further studies.

Glucose metabolism

Glucose metabolism, measured by ^{18}F-2-fluoro-2-deoxyglucose (^{18}FDG), is increased in the striatum, thalamus, and brain stem and decreased in the lateral premotor cortex and the supplementary motor cortex in PD. Demented PD patients show generalized impaired cortical glucose utilization, which is most prominent in the posterior cingulated cortex, lateral parietal, lateral temporal, and lateral frontal association cortex.

Single Photon Emission Computerized Tomography

Single photon emission computerized tomography (SPECT) utilizes isotopes which emit single photon, which can be detected by gamma cameras. The intensity of each voxel is calculated and reconstructed just as CT scan. SPECT is less sensitive compared to PET, but it is more widely available for clinical practice.

Dopaminergic tracers

Tropane-based SPECT tracers (^{123}I-β-CIT, ^{123}I-FP-CIT, ^{123}I-atropane, ^{99m}Tc-TRODAT-1) measure presynaptic DAT availability. Imaging using these tracers shows significant decrease in the uptake in the posterior striatum as in the case of PET (**Figure 3**). But they do not differentiate PD from MSA and PSP. This is a good marker of nigrostriatal dopaminergic involvement. There is a good correlation between the clinical severity as measured by UPDRS and loss of ^{125}I-β-CIT uptake in the striatum.

Dopamine receptors

D2 dopamine receptor density can be measured by ^{123}I-IBZM SPECT; uptake of ^{123}I-IBZN SPECT is normal in PD.

Functional MRI

Functional MRI in PD is mainly investigational. The patient is asked to perform a task and MRI is taken before and after the task. Functional MRI is based on the increase in blood flow when certain areas were used during the task. Increase in blood flow results in increased oxygen utilization and decreased deoxyhemoglobin concentration. Deoxyhemoglobin is paramagnetic and acts as an endogenous contrast agent. As the neuroimaging signal is weak, fMRI tests are usually performed on groups of patients and group averages or sums are reported, rather than data from individual patients.

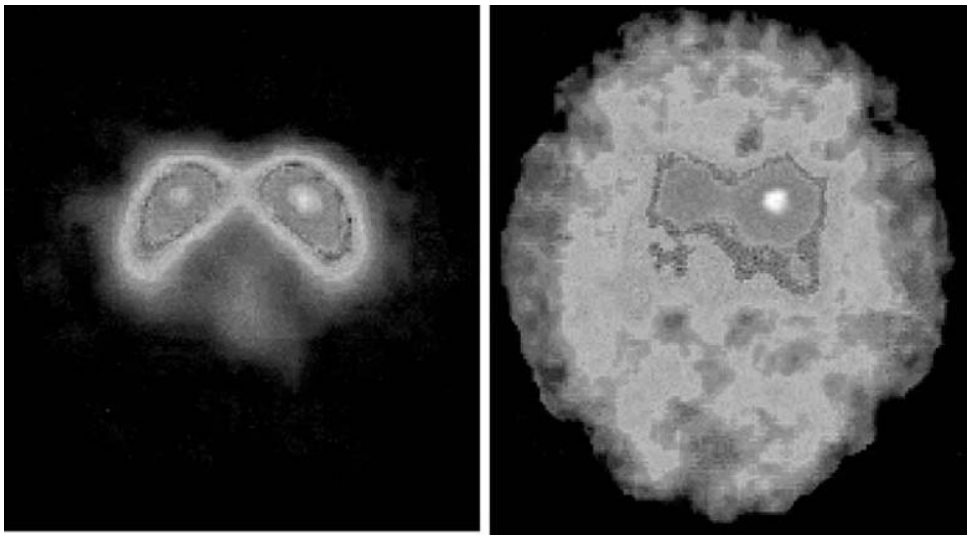

Figure 3 123I-b-CIT SPECT. Left: normal control (71-year-old woman). Right: 66-year-old man with PD. Courtesy of Drs. A. Varrone, J. P. Seibyl, et al. β-CIT uptake is diminished in an asymmetric way in the posterior putamen more on the right side.

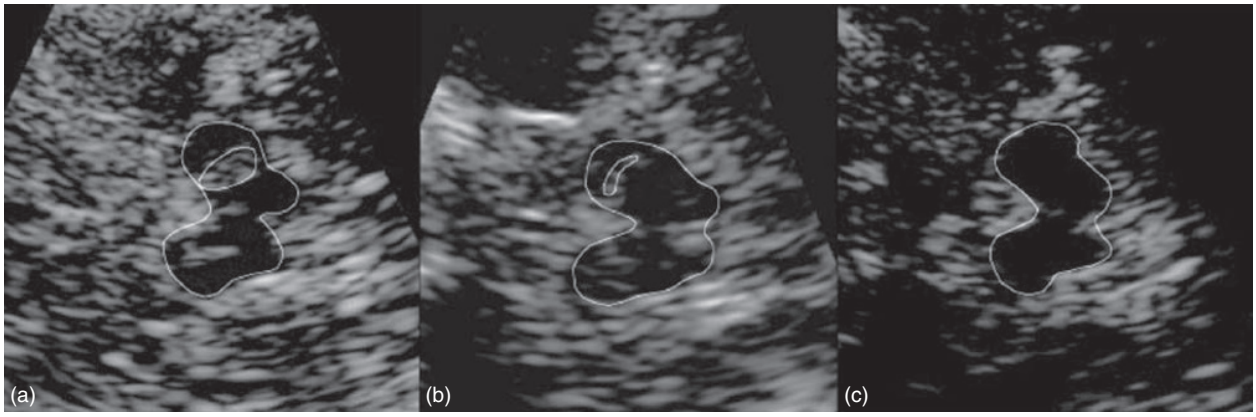

Figure 4 (a) A patient with Parkinson's disease. (b) A control subject. (c) A patient with RLS. The PD patient shows hyperechogenicity in the substantia nigra, and the patient with RLS shows hypoechogenicity. With the courtesy of Drs. W. Schmidauer, Poewe, et al. Reproduced from Schmidauer C, Sojer M, Seppi K, et al. (2005) Transcranial ultrasound shows nigral hypoechogenicity in RLS. *Annals of Neurology* 58: 630–634, with permission from Wiley Interscience © 2005.

PD patients performing a task with one hand show bilateral hypoactivation of the supplementary motor area, anterior cingulated cortex, and dorsolateral prefrontal cortex as well as the contralateral putamen. This pattern correlates well with the model of basal ganglia function in PD with regard to the motor functions.

Transcranial Ultrasound

Transcranial ultrasound is a relatively new technique to visualize the substantia nigra. The ultrasound beam is introduced from a small temporal bone window. In some patients, this temporal bone window is too small or absent and does not allow this examination. But when possible, this is a simple and useful test for daily practice. In PD, hyperechogenicity of the nigral regions is seen in majority of the tested patients. The area of SN echogenicity is larger, contralateral to the side with more severe symptoms, and therefore, transcranial ultrasound can detect asymmetry of involvement. In MSA and PSP, usually transcranial ultrasound remains normal. Hyperechogenicity is believed to be a result of iron accumulation in the substantia nigra. In patients with iron deficiencies, specifically restless leg syndrome (RLS), the substantia nigra shows hypoechogenicity (**Figure 4**).

Cardiac Metaiodobenzylguanidine SPECT

Cardiac ^{123}I-MIBG (metaiodobenzylguanidine) SPECT or scintigraphy visualizes noradrenalin transporters. Noradrenergic transporters are located on plasma membranes and synaptic vesicles of nerve terminals of the

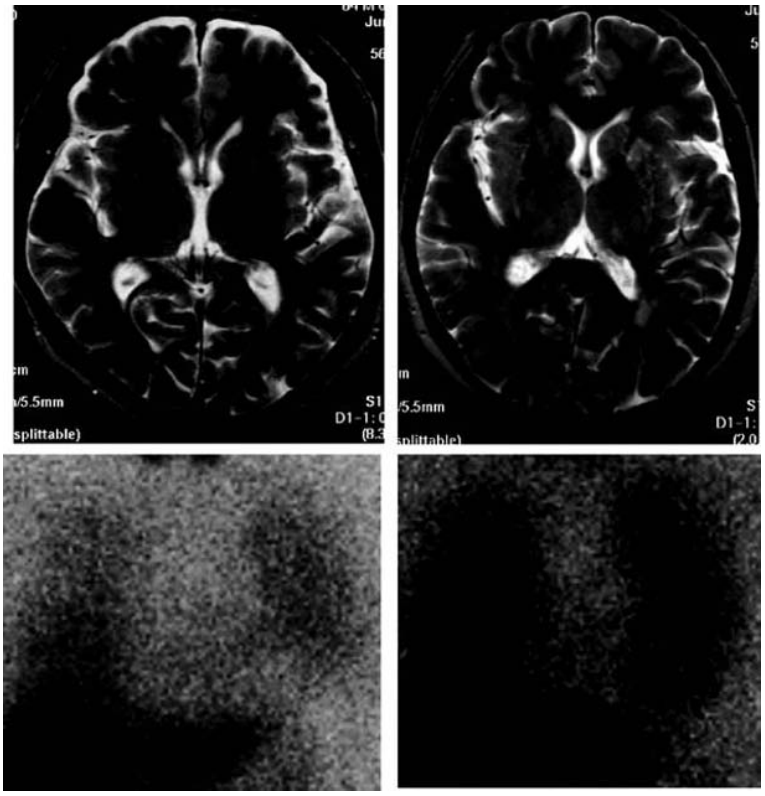

Figure 5 Left: 64-year-old man with PD. MRI is normal and cardiac MIBG uptake is markedly decreased. Right: 61-year-old woman with MSAp. The left putamen shows patchy T2-high signal lesions and the right putamen shows atrophic change, a T2-high signal lesion along the rim of the outer putamen and T2-low signal change within putamen. Cardiac MIBG uptake is normal. In this patient, the left side of the body showed more prominent symptoms.

postganglionic sympathetic fibers. In PD, postganglionic sympathetic neurons degenerate from the early stage of the disease and uptake of ^{123}I-MIBG is markedly reduced. MIBG uptake is also reduced in dementia with Lewy bodies (DLB). Thus, there is a good correlation between the presence of Lewy bodies in the brain and loss of MIBG uptake in the cardiac muscles. In MSA, the preganglionic sympathetic nerve fibers degenerate first; therefore, MIBG uptake is normal in the early stage (**Figure 5**), but in the advanced stage, postganglionic fibers are also involved and cardiac MIBG scintigram may show reduced uptake. In tauopathies such as PSP or Alzheimer's disease, and in ET, MIBG uptake remains normal. Thus, MIBG scintigraphy is a useful diagnostic tool for the differential diagnosis of parkinsonism and dementia (**Figure 6**). The reason why the postganglionic sympathetic fibers to the heart undergo degeneration from the early stage of the disease is not known. As cardiac muscles are under the high oxygen atmosphere, oxidative stress may be higher compared to the other organs, but the exact cause is not known. Aggregation of α-synuclein within the axons of the cardiac sympathetic nerve fibers was reported as the probable pathogenetic mechanism for their degeneration. Decrease in cardiac MIBG uptake is a good disease biomarker for the diagnosis of synucleinopathies, which include PD, Parkinson's disease with dementia (PDD), DLB, and primary autonomic failure associated with Lewy body formation. However, it is not a good marker for the evaluation of the disease progression, as the uptake decreases markedly from the early stage of the disease.

Differential Diagnosis of PD from MSA, PSP, and Corticobasal Degeneration (CBD)

Magnetic Resonance Imaging

Patients with MSA often show MRI evidence of atrophy of the pontocerebellar system and the putamen. In typical cases, cerebellar sulci are enlarged indicating cerebellar atrophy and atrophy of the pontine base with 'hot cross ban' sign, which is a cross form-T2-high signal intensity lesion in the pons spreading horizontally in the boundary of the pontine base and the pontine tegmentum, and vertically in the midline. Putaminal atrophy may appear as a decreased lens-form prominence along the lateral border of the putamen; the border looks more straight

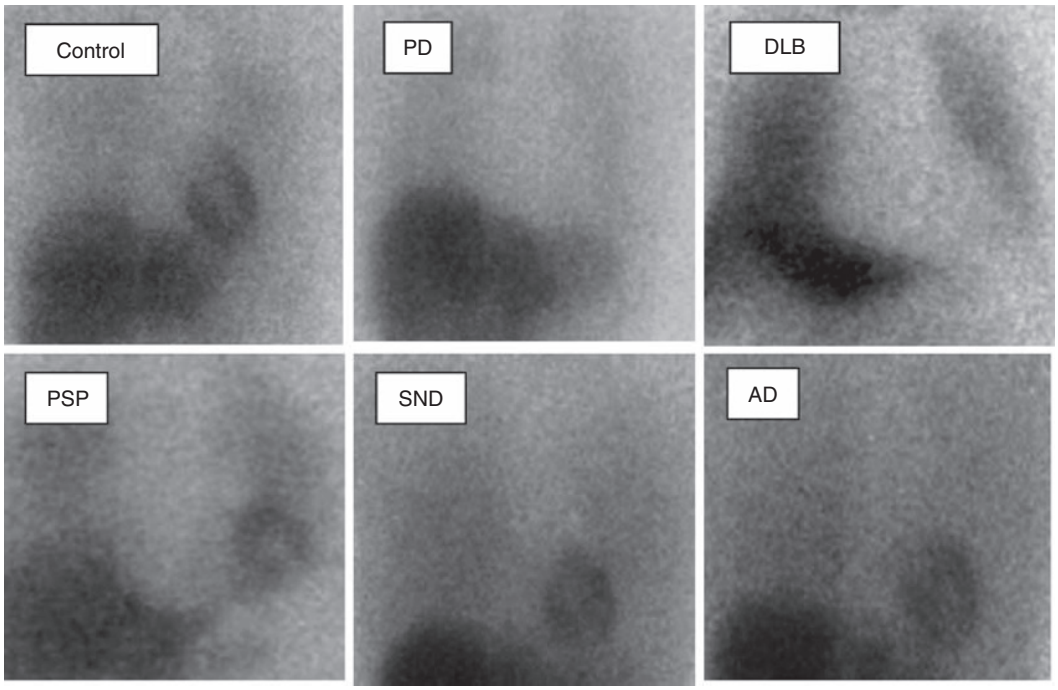

Figure 6 Cardiac MIBG uptake is markedly reduced in PD and DLB but in other conditions, it remains normal. Delayed images.

than curved. In addition, T2-low signal intensity change appears within the putamen, often with a T2-high signal linear intensity lesion along the lateral margin of the putamen. At times, T2-high signal lesions appear within the putaminal region in a patchy manner. Usually some asymmetry in these changes is seen with more prominent atrophic changes contralateral to the more affected side. The high-signal intensity change is believed to represent neuronal loss and gliosis, and the low signal intensity change represents accumulation of iron. These typical changes may not be apparent in early stage MSA patients; in such case, diffusion weighted MRI imaging is useful. If there is neuronal loss, gliosis, or degenerative changes in axons, the mobility of water molecules increases and this can be measured as the increase of 'apparent diffusion coefficient.' With this method, it is possible to differentiate MSA from PD and PSP from PD; however, differential diagnosis between MSA and PSP is impossible, as PSP and MSA show similar results.

In PSP, structural MRI may show atrophic changes in the tegmentum of the midbrain, atrophy of the base of the third ventricle in the sagittal section (humming bird sign), and the dilatation of the third ventricle. However, these changes are not clear in many cases of clinical PSP patients. In CBD, asymmetric cortical atrophy is frequently seen. Suprasylvian sensory-motor areas are involved most frequently and this atrophy, if it is on the dominant hemisphere, appears to be a cause of limb-kinetic apraxia, ideomotor apraxia, or motor neglect, which are frequently seen in CBD.

PET/SPECT

^{18}F-Fluorodopa uptake by PET cannot discriminate PD from MSA or PSP, as nigrostriatal neurons are degenerating in all of these conditions. β-CIT SPECT also cannot discriminate these conditions. Measurement of D2 dopamine receptor density in the striatum by ^{123}I-iodobenzamide and SPECT is normal in PD, but it may show low binding in MSA and PSP. However, D2 dopamine receptor density measurement by raclopride and PET cannot discriminate these three conditions.

Cardiac MIBG SPECT

Cardiac MIBG SPECT is very useful to diagnose, if the uptake is reduced. Approximately 10% of patients who fulfill clinical criteria of PD, however, show normal MIBG uptake. In MSA, PSP, and CBD, MIBG uptake usually remains normal.

Neuroleptic-induced Nonhuman Primate Models of EPS and TD

G S Linn, The Nathan S Kline Institute for Psychiatric Research, Orangeburg, NY, USA

Glossary

Acute dystonia – Involuntary sustained muscle contractions.
Atypical antipsychotic – Second-generation antipsychotics such as clozapine, olanzapine, and amisulpride that differ from first-generation antipsychotics in that they interact with serotonin as well as dopamine receptors or display some partial dopamine agonism.
Dyskinesia – Involuntary muscle movements such as a tic or chorea.
Neuroleptic – Term applied to first-generation or typical antipsychotics such as haloperidol, chlorpromazine, and fluphenazine, due to their observed effect of slowing movement when originally given in high doses.
Tardive dyskinesia – Dyskinesias that arise as a late side effect of long-term treatment with dopamine receptor blocking agents such as antipsychotics or upon treatment termination.

Since their introduction in the 1950s, neuroleptic drugs have become the primary agents for treating acute and chronic psychosis. However, most neuroleptics (also called typical antipsychotics) have been associated with a wide range of neurological side effects. Among the most troubling are extrapyramidal side effects (EPS) that may occur in up to 75% of patients. Although some of the newer second-generation antipsychotics (often called atypical antipsychotics) appear to have a lower risk of inducing EPS, most have been associated with at least some cases of EPS, with youths possibly having more prevalent and severe side effects than adults. Extrapyramidal side effects consist of a diverse range of symptoms, including acute dystonia, akathisia, and Parkinsonism, and may be an indicator of a predisposition to develop tardive dyskinesia (TD). TD is an involuntary dyskinetic disorder that occurs in some individuals as a late complication of prolonged neuroleptic treatment or upon treatment termination. The most common orofacial symptoms of TD include tongue protrusions and chewing motions and grimacing. TD can persist for several months to years after treatment termination and may be irreversible in some individuals.

Although substantial research has been devoted to understanding the basic mechanisms underlying the effects of neuroleptic medications and the pathophysiologic processes responsible for EPS and TD, a cohesive explanation remains to be found. Over the last four decades, several nonhuman primate models have been developed to study different hypotheses about mechanisms of EPS and for predicting the potential of new antipsychotics to induce EPS and TD.

Early Studies with Nonhuman Primates

Early studies with nonhuman primates in the late 1960s and early 1970s established that treatment with neuroleptic medications would induce movement disorders that were similar to those observed in the clinic. In 1976, the first demonstration of the development of two distinct dyskinetic syndromes in monkeys following chronic daily oral administration of haloperidol to capuchin monkeys (*Cebus apella*) was reported. One syndrome contained elements similar to acute dystonia and Parkinsonism and the other closely corresponded to TD. Although not all neuroleptic-treated monkeys developed symptoms, once acute dystonic and dyskinetic effects were established in a monkey the animal became neuroleptic sensitized and symptoms could be elicited by a single injection of the neuroleptic, even after a drug-free period of several or more years.

Nonhuman Primate Models of EPS and TD

Two nonhuman primate models of neuroleptic-induced movement disorders emerged from these early studies. These models can be categorized as homologous and correlational models. In a homologous model, a disease state is produced whose symptoms, causes, biological basis, and response to treatments are similar to those seen in humans. In a correlational model, the factors between the model and the clinical syndrome do not need to be similar, but the results of the model need to be highly predictive of the clinical situation. Induction of TD by long-term treatment with neuroleptic medications in nonhuman primates meets all the criteria of a homologous animal model. Identical symptoms occur in both humans and monkeys over a similar time-course. Initially, acute dystonias and Parkinsonism are seen. TD develops after prolonged treatment or upon discontinuation of treatment. The same antipsychotic medications induce these symptoms in humans and monkeys and, in both, acute dystonias but not TDs can be attenuated by the same medications (anticholinergics). Finally, there is individual vulnerability as not all monkeys or humans exposed to chronic neuroleptic treatment develop TD. The limitations of this monkey model of TD are the time and expense to treat a large number of monkeys for up to several years to get a large enough subgroup of animals with TD symptoms.

The nonhuman primate correlational model is derived from the correlation between the ability of drugs to induce acute EPS in neuroleptic-sensitized monkeys and the future likelihood of specific antipsychotic drugs to cause EPS and TD in the clinic. This model is used to predict the potential liability of new antipsychotics to induce acute EPS or TD in humans. An advantage of the correlational model is the lower cost and shorter time of conducting acute studies that have high predictive power for chronic treatment outcomes. A limitation is that this type of model typically does not inform about underlying mechanisms of TD.

Although neuroleptic-induced AD and TD have been demonstrated in both New World (Superfamily: *Ceboidea*) and Old World (Superfamily: *Cercopithecoidea*) monkeys, New World monkeys, and particularly capuchin monkeys (*C. apella*), appear to be much more prone to developing EPS and TD. Consequently, *C. apella* became the primate species most frequently used for studies of EPS and TD. Recent sequencing of the D_3 dopamine receptor (DRD3) gene in *C. apella* monkeys revealed that they carry the monomorphic glycine 9 DRD3 genotype. This version of the single nucleotide polymorphism has been associated with TD in humans. Although the prevalence of this genotype in other monkey species is yet to be determined, another New World monkey, the common marmoset (*Callithrix jacchus*) also may be particularly susceptible to neuroleptic-induced EPS and TD.

Homologous Model Studies

The homologous monkey model has been used to test potential treatments for TD and investigate potential new antipsychotic agents. Also, several studies investigating the effects of repeated or intermittent treatment regimens on induction of acute or TDs and Parkinsonism have supported suggestions that intermittent treatment schedules with typical antipsychotics may increase the incidence and severity of EPS and TD. A series of studies with specific dopamine receptor agents led one group to suggest that D_1 hyperfunction may be involved in the pathophysiology of oral dyskinesia and that in TD a relative D_1 hyperfunction (compared to D_2 function) may facilitate or modulate the syndrome.

Other studies with this model have led to the hypothesis that chronic neuroleptic treatment upregulates glutamatergic neurons from the subthalamic nucleus terminating in the globus pallidus and substantia nigra. Chronic upregulation has excitotoxic effects on the inhibitory GABA pathways from the globus pallidus and substantia nigra to the thalamus, giving rise to disinhibition of thalamocortical ventral anterior and ventral efferents. This results in a hyperkinetic state that underlies the choreic elements of

TD and suggests a glutamate hypothesis for neuroleptic-induced TD. Determination of mRNA for different glutamate receptor subunits in basal ganglia of neuroleptic-treated *Cebus* monkeys with TD symptoms revealed fewer NR1 expressing neurons and lower NR1 signal intensity in caudate, putamen, and globus pallidus, supporting the theory of altered glutamatergic neurotransmission in neuroleptic-induced TD.

Correlational Model or Studies with Neuroleptic-Sensitized Monkeys

Neuroleptic-sensitized animals can be used as a model for several different research strategies. One approach is to induce EPS with a typical antipsychotic and then test novel antipsychotics to evaluate their influence on these disorders as new treatments. Another strategy is to evaluate response to agents that either target specific receptors (e.g., D_1, D_2, serotonin (5-HT)) or combinations of receptors. Different methods of administration, such as oral or by injection, can also be compared. Finally, one can give acute treatments with a wide dose range of several agents to compare the range of behavioral effects (see **Table 1** for a representative list and scores of behavioral measures used). This last strategy is probably the most widely used nonhuman primate preclinical method for evaluating new antipsychotic agents. It remains as the most predictive animal model of EPS for several reasons: the acute dystonic reactions in sensitized *Cebus* monkeys are identical to acute EPS in humans; the reactions in sensitized monkeys to existing antipsychotic drugs are elicited proportional to their propensity to induce EPS in the clinic; the acute dystonias can be controlled by the same agents that control EPS in humans (anticholinergics); clozapine does not induce EPS in the clinic and does not induce acute dystonia in sensitized *Cebus* monkeys.
