Linn GS (2004) Neuroleptic-induced acute dystonia and tardive dyskinesia in primates. In: LeDoux M (ed.) *Animal Models of Movement Disorders*, pp 725–733. Burlington: Elsevier.

Casey and colleagues used this comparative strategy in neuroleptic-sensitized *Cebus* monkeys to estimate EPS and TD liability across a range of typical and atypical antipsychotics with varying ratios of D_2 and 5-HT_2 receptor antagonism. All clinically effective antipsychotic medications have some D_2 receptor affinity. Yet, all the typical neuroleptics that block D_2 receptors have the capacity to cause EPS and TD. Antipsychotics with high 5-HT_2 to D_2 antagonism ratios, such as clozapine and olanzapine, are hypothesized to have a low EPS liability at effective antipsychotic doses. (Alternatively, EPS liability may be related to D_2 dissociation constants or high D_2 receptor occupancy.) Neuroleptic-sensitized monkeys were exposed to a range of doses of each agent (remoxipride, sulpiride, haloperidol, fluphenazine, clopenthixol, melperone, sertindole, risperidone, clozapine, quetiapine, ritanserin) and observed for signs of acute dystonia or Parkinsonism. For each compound, the researchers then predicted a dystonia-inducing threshold dose range for humans by multiplying the threshold dose for monkeys by a conversion factor. The conversion factor was derived by dividing the haloperidol-induced threshold dose for monkeys into the accepted EPS-producing dose range for haloperidol in humans. Results (shown in **Table 2**; compounds are arranged in order of high D_2/low 5-HT_2 to low D_2/high 5-HT_2 occupancy) indicated that, with the exception of clozapine, all the compounds tested had the potential to produce EPS in *Cebus* monkeys and, by extension, in humans. The separation between effective dose–response ranges for antipsychotic and EPS effects, which predicted low EPS liabilities for effective doses of sertindole, quetiapine, lower doses of risperidone and olanzapine, has been supported by clinical studies. Their finding of low EPS liability for antipsychotics with high 5-HT_2/D_2 receptor affinity ratios, such as clozapine, quetiapine, and olanzapine is compatible with the hypothesis that 5-HT_2 / D_2 antagonism ratios may underlie the favorable EPS profiles of atypical antipsychotics.

Neuroleptic-sensitized *C. apella* monkeys have also been used to study the antipsychotic properties and EPS liability of a muscarinic M1/M4 receptor agonist. Antipsychotic effect was evaluated by attenuation of D-amphetamine-induced motoric unrest and stereotypies. Results indicate

Table 2 Neuroleptic-inducing dystonia dose thresholds in monkeys and patients

Drug[a]	*Dystonia-inducing threshold in monkeys (mg kg^{-1})*	*Conversion factor × 100*	*Clinical dose (mg day^{-1})*	*Estimated dystonia-inducing threshold in humans (mg day^{-1})*
Remoxipride	5.0	2–8	150–600	1000–4000
Sulpiride	10	2–8	800–2000	2000–8000
Haloperidol	0.025	2–8	5–20	5–20
Fluphenazine	0.025	2–8	5–20	5–20
Clopenthixol	0.1	2–8	30–60	20–80
Melperone	1.0	2–8	300–600	200–800

that the agents that target these receptors are potential antipsychotics with low EPS liability.

Combining Models to Test Antipsychotic Efficacy and EPS Liability: Prepulse Inhibition in Neuroleptic-Sensitized Monkeys

A limitation of most studies with neuroleptic-sensitized monkeys is that they cannot directly test for potential antipsychotic effect in the same animals in which EPS liability is evaluated. Several studies have used D-amphetamine-induced motoric unrest and stereotypies to model psychosis and then tested putative antipsychotics for efficacy in relieving symptoms and for inducing adverse effects in neuroleptic-sensitized monkeys. However, a criticism of this model is that dopaminergic agents, such as amphetamine, induce behaviors similar only to positive symptoms of schizophrenia, and so this model may not be able to distinguish atypical-like compounds that also improve negative or cognitive symptoms.

An alternative model for testing potential antipsychotics for treatment efficacy and EPS liability uses phencyclidine (PCP)-induced deficits in prepulse inhibition (PPI) in neuroleptic-sensitized *Cebus* monkeys. PPI of the acoustic startle reflex is a measure of sensorimotor gating that occurs across species and is deficient in severe neuropsychiatric disorders such as schizophrenia. Deficits in PPI correlate closely with cognitive dysfunction in schizophrenia patients. PCP, a potent drug of abuse that induces positive, negative, and cognitive schizophrenia-like symptoms by blocking neurotransmission at *N*-methyl-D-aspartate-type glutamate receptors, disrupts PPI in monkeys. In one study, the atypical antipsychotic clozapine reversed PCP-induced PPI deficits in monkeys whereas the typical antipsychotic haloperidol did not significantly attenuate PCP-induced PPI deficits even at doses that significantly attenuated effects of a dopaminergic agent (apomorphine). This suggests that PCP-induced PPI deficits in neuroleptic-sensitized monkeys can be a valuable preclinical model for evaluating the EPS liability at effective treatment doses in putative atypical antipsychotics.

In summary, neuroleptic-induced nonhuman primate models of EPS and TD have been effective tools for investigating the underlying mechanisms of EPS or TD and for predicting EPS liability in new antipsychotic agents. Newer antipsychotic medications need to be developed that treat positive, negative, and cognitive symptoms of schizophrenia and are devoid of neurological side effects. Combined models will allow the study of antipsychotic treatment efficacy and EPS liability in the same subjects. Until alternative models of equivalent effectiveness can be developed, nonhuman primate models of EPs and TD will continue to serve an important preclinical research function.

Glossary

Agonist – A molecule that binds to a receptor and stimulates the signaling processes associated with the receptor.
Agranulocytosis – A potentially serious condition characterized by an absence of white blood cells exposing an individual to infection risk.
Antagonist – A molecule that binds to a receptor and neutralizes the periodic signaling processes associated with the receptor without affecting the constitutive activity of the receptor.
Atypical – A reference to the characteristic of a neuroleptic to attenuate psychosis without producing motor side effects.
Delusions – False, fixed irrational beliefs out of keeping with the person's educational, cultural, and social background.
Extrapyramidal symptoms – A group of side effects to neuroleptics consisting of, but not limited to, dystonia, parkinsonism, akathisia, and tardive dyskinesia.
First generation antipsychotics (FGAs) – The initial group of antipsychotic drugs based on the original pharmacological mechanism; also referred to as typical or conventional antipsychotics.
Hallucinations – Perceptions in any sensory modality occurring in the absence of an external stimulus.
Inverse agonist – A molecule that binds to a receptor and inhibits the signaling processes associated with the receptor if signaling is constitutively active.
Mesolimbic pathway – The dopamine pathway from the ventral tegmental area of the midbrain to the nucleus accumbens or ventral striatum involved in antipsychotic treatment response among other functions.
Metabolic syndrome – A collection of symptoms including obesity, hypertension, glucose intolerance, and dyslipidemia, which increase the risk of coronary artery disease and stroke, caused by the weight gain associated with second generation antipsychotics.
Neuroleptics – The class of psychotropic medications efficacious as antipsychotics.
Nigrostriatal pathway – The dopamine pathway from substantia nigra to the dorsal striatum affected in Parkinson's disease.
Partial agonist – A molecule that binds to a receptor and stimulates the signaling processes associated with the receptor to a lesser degree than a full agonist.
Phenothiazines – One of the major antipsychotic families that includes the agent chlorpromazine.
Second generation antipsychotics (SGAs) – A more recent group of antipsychotic drugs based on a transition to a different pharmacological mechanism; also referred to as atypical or novel antipsychotics, they are purported to carry less risk of neurological adverse effects.

Definition and History

Neuroleptics comprise a large, diverse group of medications known for their ability to attenuate hallucinations and delusions, the core symptoms of psychosis. The term

Table 1 Neuroleptics listed by class and generation

First generation
Phenothiazines
Acetophenazine
Butaperazine
Carphenazine
Chlorproethazine
Chlorpromazine[a]
Cyamemazine
Dixyrazine
Fluphenazine[b]
Mesoridazine[c]
Methotrimeprazine
Perazine
Pericyazine
Perphenazine
Piperacetazine
Pipotiazine[d]
Prochlorperazine
Promazine
Propericiazine
Sulforidazine
Thiopropazate
Thioproperazine
Trifluoperazine[e]
Triflupromazine
Nonphenothiazines
Benperidol
Bromperidol
Chlorprothixene
Clocapramine
Clopenthixol
Clothiapine
Droperidol[f]
Fluanisone
Flupenthixol[b,g]
Fluspirilene
Haloperidol[b,h]
Loxapine[i]
Melperone
Molindone[j]
Moperone
Mosapramine
Nemonapride
Oxypertine
Penfluridol
Pimozide[k]
Pipamperone
Sulpiride
Sultopride
Thiothixene
Tiapride
Timiperone
Trifluperidol
Zuclopenthixol[l]
Second generation
Amisulpride
Asenapine
Bifeprunox
Clozapine[m]
Iloperidone
Mazapertine
Olanzapine[n]
Paliperidone
Perospirone
Quetiapine[o]
Risperidone[b, p]
Sertindole
Ziprasidone[q]
Zotepine
Aripiprazole[r]

[a]Example of aliphatic phenothiazine.
[b]Oral and depot (long-acting intramuscular) formulations.
[c]Example of piperidine phenothiazine.
[d]Depot formulation only.
[e]Example of piperazine phenothiazine.
[f]Parenteral form only.
[g]Example of thioxanthene.
[h]Example of butyrophenone.
[i]Example of dibenzoxazepine.
[j]Example of dihydroindolone.
[k]Example of diphenylbutylpiperidine.
[l]Oral and short-acting and long-acting depot formulations.
[m]Example of dibenzodiazepine.
[n]Example of thienobenzodiazepine.
[o]Example of dibenzothiazepine.
[p]Example of benzisoxazole.
[q]Example of benzothiazolylpiperazine.
[r]Example of dihydrocarbostyril, aripiprazole is considered to be the next generation of antipsychotics due to its novel partial dopamine agonist pharmacology.

neuroleptic is Greek meaning 'to take hold of the nerves.' This refers to the absence of movement induced in experimental animals by early antipsychotics that was akin to the loss of dopamine neurons in Parkinson's disease. Historically, the therapeutic efficacy of these agents was believed to correlate with their capacity to produce psychomotor slowing and a calm emotional indifference. This led to their anachronistic classification as major tranquilizers. Most neuroleptics are antipsychotic agents although metoclopramide is one example of a drug in the neuroleptic class used primarily as an antiemetic. There are currently close to seventy antipsychotics from over a dozen chemical families prescribed around the world. These are listed in **Table 1**. The most clinically useful categorization divides them into two groups: (1) the conventional, typical, or first generation antipsychotics (FGAs) that are more likely to cause motor side effects, and (2) the novel, atypical, or second generation antipsychotics (SGAs) that are less prone to do so.

Neuroleptics trace their origin to the manufacturing of dyes in England in the nineteenth century. In 1856, Perkin devised mauve, which led to Caro's development of methylene blue, a phenothiazine derivative. Ehrlich, a German bacteriologist credited with discovering the biotherapeutic effects of these dyes, recognized in 1891 that methylene blue could treat symptoms of malaria.

However, quinine proved more effective for this purpose. In World War II, with access to quinine limited, unsuccessful attempts were made by Gilman and others to manipulate the phenothiazine ring to produce alternative antimalarial compounds.

Serendipitously, French scientists chose to evaluate the phenothiazines for their antihistaminergic effects. Laborit, an anesthesiologist, found that promethazine's long duration of action could potentiate the effects of other anesthetics, allowing for lower dosages. In 1950, chlorpromazine demonstrated the same quality as well as calming and antiemetic properties in animals. The following year, Laborit and Huguenard noted that chlorpromazine quieted patients preoperatively without inducing coma, and they supplied it to two groups of Parisian psychiatrists led by Hamon and Delay. The first patient, a 57 year old laborer admitted to the Val de Grace Hospital for erratic, grandiose, and assaultive behavior, responded dramatically. Chlorpromazine was released in 1952 with open-label studies and a 1960 controlled trial in the United States confirming its efficacy. It replaced reserpine, a plant derivative that had been used as an antihypertensive in the late 1940s and subsequently as an antipsychotic due to its tranquilizing properties.

The magnitude of the discovery of chlorpromazine's antipsychotic therapeutic benefit cannot be understated. Worldwide inpatient populations decreased significantly. Theories of mental illness were powerfully influenced and treatments transformed from restrictive to compassionate. The locus of care changed from asylum to community. The risks of more invasive biological therapies were avoided, and the physical and mental wellbeing of countless ill patients was improved.

In the 1960s, when reserpine was found to deplete biogenic amines such as dopamine, norepinephrine, and serotonin, the dopamine hypothesis of schizophrenia and the monoamine hypothesis of depression emerged. Although overly simplistic, these theories remain the cornerstones of our pathophysiologic understanding of these psychiatric disorders. Carlsson and Linquist supported the dopamine hypothesis further by attributing to dopamine antagonism – the ability of nonreserpine neuroleptics to reduce amphetamine-induced psychomotor agitation in animals and to cause extrapyramidal symptoms in humans.

The psychopharmacological revolution continued with the proliferation of phenothiazine-related compounds, although chlorpromazine remained the most prescribed antipsychotic through the 1960s and 1970s. They eventually became known as low-potency neuroleptics because they required high doses for antipsychotic efficacy. Soon high-potency agents, which at small doses reduced stimulant-related hyperkinetic behavior in rodents, were synthesized. However, these new compounds were found to dramatically increase the incidence of extrapyramidal symptoms to as many as one in three patients in 1958, the year haloperidol was introduced. The following year, Sigwald reported the first case of antipsychotic-induced tardive dyskinesia.

The motor side effects of high-potency antipsychotics drove scientists, in particular German and Swiss psychiatrists, to search for atypical compounds. Clozapine, the antipsychotic least susceptible to motor complications, was synthesized in 1959 but could not be used until the late 1970s or marketed until the late 1980s due to its infrequent but life-threatening risk of agranulocytosis. In 1990, clozapine was finally released to the United States market and, shortly thereafter, its limited liability for extrapyramidal symptoms and tardive dyskinesia and its efficacy in treatment-refractory patients were uncovered. Riding on the coat tails of clozapine's success, risperidone was approved and marketed using its claim of atypical features in 1994, then olanzapine in 1996, quetiapine and sertindole in 1997, and ziprasidone, aripiprazole, and others more recently. The significant morbidity due to the metabolic syndrome of obesity, hypertension, dyslipidemia, and glucose intolerance from these agents, and their overstated therapeutic benefits continue to motivate the search for more suitable compounds.

Pharmacology

Pharmacokinetics

To maximize absorption, orally administered neuroleptics are given with food. Age, gender, drug interactions affecting protein binding or cytochrome P450 activity, hepatic or renal impairment, and caffeine and nicotine consumption affect plasma concentrations.

The half-life of the various neuroleptics ranges although most are given once daily. Peak levels are established within 4 h if given orally. In acute settings, intramuscular delivery is preferable. Bioavailability can also be augmented with short-acting (2–3 days) and long-acting (2–4 weeks) depot intramuscular formulations. Parenteral administration of certain agents is appropriate for acute monitored medical settings.

Pharmacodynamics

Chlorpromazine was marketed outside the United States as Largactil, a name reflecting its large number of actions in the central nervous system. In general, neuroleptics claim a vast array of neurotransmitter receptor affinities. Those that are quantifiable are listed in **Table 2**. Each medication is characterized by unique pharmacodynamics and receptor affinities, particularly in the dopamine, serotonin, and acetylcholine systems.

Table 2 Receptor systems affected by neuroleptics and their postulated effects

Dopamine D_1 blockade: antipsychotic
Dopamine D_2 blockade: antipsychotic; parkinsonism and motor side effects; hyperprolactinemia
Dopamine D_3 blockade: antipsychotic
Dopamine D_4 blockade: antipsychotic
Dopamine partial agonism: antipsychotic; attenuation of motor side effects and hyperprolactinemia
Dopamine reuptake inhibition: antidepressant; antiparkinsonian; psychomotor acceleration
Histamine$_1$ blockade: antiemetic; sedation; hypotension; weight gain; potentiation of other CNS drugs
Muscarinic M_1 blockade: attentuation of parkinsonism, dystonia, and akathisia; dry mucous membranes; blurred vision; constipation; urinary retention and incontinence; sinus tachycardia; ECG changes; memory disturbances; sexual dysfunction; potentiation of other anticholinergics
Norepinephrine reuptake inhibition: antidepressant
α_1 Norepinephrine blockade – postural hypotension, dizziness, reflex tachycardia, sedation, hypersalivation, urinary incontinence; potentiates other alpha blockers
α_2 Norepinephrine blockade – sexual dysfunction; may antagonize antihypertensives and increase cholinergic activity
Serotonin (5-HT$_1$) blockade (A, D): antidepressant; anxiolytic; inhibition of impulsivity
Serotonin (5-HT$_2$) blockade (A, C): antidepressant; anxiolytic; attenuation of motor side effects; hypotension sedation; weight gain; sexual dysfunction
Serotonin (5-HT$_{3,6,7}$) blockade: undefined
Serotonin reuptake inhibition: antidepressant

As early experimenters surmised, a reduction in postsynaptic dopamine activity by D_2 receptor binding predicts the efficacy of antipsychotics. All compounds share this mechanism. PET studies in schizophrenia confirm an increased release of dopamine and increased baseline D_2 receptor occupancy in the striatum of psychotic individuals. When an antipsychotic reaches 48% D_2 receptor occupancy, dopamine activity begins to normalize. D_2 blockade in the mesolimbic pathway, specifically the ventral striatum, correlates with antipsychotic efficacy, whereas blockade in the dorsal striatum, leading to low endogenous dopamine activity and consequently increased acetylcholine, is associated with extrapyramidal symptoms. D_2 blockade in the tuberoinfundibular pathway causes hyperprolactinemia as dopamine inhibits prolactin release. An antipsychotic effect is also postulated to occur by modulation of D_1, D_3, and D_4 receptor activity. Serotonergic blockade produces anxiolytic and mood-enhancing effects and antihistaminergic activity sedation. Other receptor affinities result in untoward effects. The search for pharmacodynamic factors that explain atypicality, the mitigated risk of motor complications with certain antipsychotics, has resulted in a number of possibilities described below.

Variability in D_2 blockade

The magnitude of D_2 blockade does not differentiate the agents that are more or less likely to cause motor side effects. Studies of D_2 striatal receptor occupancy leave little margin for error suggesting that a therapeutic antipsychotic effect occurs between 60 and 70% occupancy and extrapyramidal symptoms between 74 and 82%. At higher doses, the SGAs begin to resemble FGAs. It was therefore considered that at certain doses, the SGAs might fall within the therapeutic window of ~70% occupancy, but studies tend to show similar peak occupancy levels as conventional agents and, in fact, occupancy measurements of newer atypical agents are reported to reach as high as 90%. An alternative explanation is that minimal motor side effects may be attributable to neuroanatomical selectivity of D_2 receptor blockade. SGAs have lower striatal:cortical D_2-binding ratios compared to FGAs and greater preference for A_{10} mesolimbic dopamine neurons over A_9 nigrostriatal neurons. This is complicated by a drug's capacity to penetrate the blood–brain barrier that also determines its variable effects in various dopamine pathways.

A range in D_2 receptor affinity can also distinguish FGAs from SGAs. Physiological dopamine transmission occurs in phasic bursts in response to task requirements or stress-induced demands. Medications that block these receptors more permanently have a greater impact on these functions. Some SGAs have been found to have lower affinities for the D_2 receptor with quetiapine and clozapine having particularly fast dissociation rates. Following recognition of the receptor and alteration of the associated signaling system, these compounds quickly detach. In vitro studies of the dissociation coefficient, K_d, predict motor side effects clinically. The rapid psychiatric relapses seen when patients discontinue these compounds may also relate to an accelerated physiological displacement of these drugs by endogenous dopamine. While rapid dissociation is a characteristic of some SGAs, others have slower dissociation coefficients. It is possible that D_2 receptor affinity is affected by binding at other receptors.

Serotonin–dopamine blockade

Serotonin modulates presynaptic dopamine release from axon terminals to varying degrees depending on the pathway involved. In the nigrostriatal and tuberoinfundibular pathways, dopamine may be released by 5-HT$_{2A}$

antagonism, a common SGA characteristic, thus limiting motor side effects and hyperprolactinemia. Alternatively, when 5-HT_{2A} antagonism occurs in the mesocortical and mesolimbic pathways, the efficacy of the therapeutic dopamine blockade may be complemented. However, serotonin antagonism is not the critical defining feature of atypicality. Some conventional neuroleptics that commonly produce motor side effects are also serotonin antagonists. Some SGAs that produce few motor side effects have minimal serotonin blockade. The likelihood of avoiding neurological complications does not correlate with the 5-HT_{2A}/D_2 binding affinity ratios for some SGAs. At higher doses, even SGAs with serotonin blockade become increasingly liable to produce extrapyramidal symptoms. Finally, PET studies confirm that even in the presence of serotonergic blockade, there is high striatal D_2 blockade.

Dopamine partial agonism

In 1993, haloperidol was shown to stimulate the release of prolactin in vivo in the absence of dopamine. Previously thought to act as an antagonist at the dopamine receptor by neutralizing periodic receptor activity, this demonstrated that its mode of action was actually that of an inverse agonist, inhibiting all signaling activity. A number of in vitro tests confirmed this as the mechanism of many neuroleptics of both generations. Partial agonists at the D_2 and D_3 receptors inhibit excessive dopamine activity by ensuring high occupancy but low efficacy. This low-level stimulation of postsynaptic receptors also prevents the dopamine tone of the synapse from declining excessively. The end result is moderate antipsychotic efficacy with minimal motor side effects and hyperprolactinemia. However, this mechanism of action is claimed only by the most recent antipsychotics, and therefore cannot fully explain the atypical effects of SGAs.

Other explanations of atypicality

It is unlikely that one hypothesis explains atypical antipsychotic activity. High intrinsic muscarinic and histaminergic blockade are also considered protective against motor side effects. Other theories put forth include: a discrepancy between the effects of FGAs and SGAs on different signaling pathways such as G proteins; modulation of ligand-gated ion channels by atypical antipsychotics; and neuronal and glial cell proliferation as an intrinsic mechanism of some antipsychotics but not others.

Indications

Psychiatric

The primary indications for the use of antipsychotic agents are psychiatric. FGAs and SGAs are the standards of care in schizophrenia, mood disorders especially bipolar affective disorder and unipolar depression with psychotic features. They are also effective in attenuating the psychosis accompanying schizoaffective disorder, delusional disorder, dementia, substance abuse, neurological conditions such as epilepsy, and organic brain syndromes such as acute intermittent porphyria. Certain agents are approved for refractory generalized anxiety disorder. Low-dose SGAs improve the behavioral disturbances associated with autism and pervasive developmental disorders. Off label uses include: aggression, hostility, and impulsivity in neuropsychiatric illness such as traumatic brain injury; refractory OCD, depression, and posttraumatic stress disorder (PTSD); trichotillomania; assaultive and self-mutilatory behavior; personality disorders; insomnia; substance use disorders; anorexia nervosa; and disruptive behavior disorders and comorbid attention deficit/hyperactivity disorder in children.

Neurological

Migraine headaches

Included in the many off-label strategies for the abortive treatment of acute migraine are antipsychotics from either the first or second generation.

Movement disorders

Chronic tic disorders respond favorably to neuroleptic treatment. Pimozide and haloperidol are approved medications in Tourette's syndrome, but many other FGAs and SGAs are commonly used. Antipsychotics, particularly clozapine, are also prescribed off label to suppress ballismus, essential tremor, akinetic disorders, chorea, blepharospasm, Meige syndrome, and tardive dyskinesia.

Psychosis, tremor, and dyskinesias in Parkinson's disease

Few pharmacological options exist for patients with Parkinson's disease functionally compromised by hallucinations or delusions. First generation antipsychotics, risperidone, olanzapine, and aripiprazole have all been reported to worsen parkinsonism. The effects of ziprasidone remain unclear. Quetiapine is favored for its ease of use despite complaints of sedation and postural hypotension. In open label and prospective studies in the Parkinson's population, it is modestly effective as an antipsychotic at an average dose of 50 mg day^{-1}. Controlled studies, however, do not demonstrate this effect. In fact, clozapine is the only agent successful in treating psychosis in Parkinson's disease in double-blind controlled trials. Despite this evidence as well as reports of improvement in tremor and dyskinesias, clozapine, even at a low dose of 25–37.5 mg day^{-1}, introduces the risk of agranulocytosis although no deaths have been reported in this population. As a result, weekly monitoring of complete blood count with differential for 6–12

months is required then monthly monitoring if no abnormalities are detected. Patients also struggle with the side effects of sedation and exacerbations in drooling and postural dizziness.

Psychosis and chorea in Huntington's disease

Conventional agents have for some time been part of the pharmacological armamentarium for suppressing choreiform movements in early Huntington's disease. Once gait disturbance and postural instability are marked, the parkinsonism and other motor side effects which often accompany long-standing antipsychotic use can put patients at increased risk of falls. SGAs may be useful at this stage. For patients who also suffer from psychosis, usually presenting as delusions, clinical experience supports the use of FGAs early in the course of disease and SGAs, specifically quetiapine and clozapine, at later stages.

Dementia

Antipsychotic agents are given off-label for the behavioral and psychological symptoms of dementia. Treatments are exclusively short-term due to a black box warning by the FDA following the discovery of higher mortality and stroke risk associated with chronic use of antipsychotics in the elderly. Visual hallucinations in dementia with Lewy bodies are treated with quetiapine or clozapine when cholinesterase inhibitors are ineffective or contraindicated.

Other Uses

Antipsychotics are also prescribed to reduce nausea and vomiting, to relieve intractable hiccups or pruritus especially when associated with neurodermatitis, and to serve as adjunctive anaesthesia or tetanus therapy.

Contraindications

From the available data, no conclusions can be drawn about the risk/benefit profile of the majority of antipsychotics in breast-feeding or pregnancy, with the exception of clozapine, which can be potentially life threatening in the infant, and olanzapine, which poses an increased risk of motor side effects in breast-fed babies. While they are not clearly teratogenic as a class, antipsychotics should be avoided in pregnancy, particularly in the first trimester. Moderate to high doses in the last trimester produce extrapyramidal symptoms and temperature regulation difficulties in the newborn.

Caution should be exercised in patients with extensive heart, lung, liver, and kidney disease, glaucoma, prostatic enlargement, or a QTc interval > 450 ms.

Side Effects

While each antipsychotic has a unique side effect profile, overall tolerability does not seem to differ between FGAs and SGAs. More patients discontinue treatment with the FGAs due to extrapyramidal symptoms and the requirement for anticholinergic agents. Greater weight gain is observed with the SGAs. **Table 3** lists reported adverse effects of antipsychotics. Further discussion of some psychiatric, neurological, and endocrine complications follows.

Psychiatric

Sedation, particularly in children and adolescents, is the most common psychiatric side effect of neuroleptics. Although it often attenuates over time, sedation impairs cognition and decreases function even when the agent is prescribed at bedtime. De novo depression and panic attacks, the provocation of mania, and the exacerbation of aggression, agitation, and insomnia are all linked to antipsychotic use. Cognitive impairment occurs with agents with anticholinergic properties, although as a class antipsychotics are less likely than the illnesses they treat to cause cognitive dysfunction. Discontinuation symptoms such as restlessness, insomnia, nausea, vomiting, tachycardia, diaphoresis, akathisia, extrapyramidal symptoms, and florid psychosis have long been described with sudden cessation of treatment. These phenomena are mediated by rebound from blockade of multiple receptors and can be difficult to distinguish from relapse. Longer tapers or the addition of anticonvulsants and benzodiazepines while tapering are prophylactic.

Neurological

Although attempts to avoid extrapyramidal symptoms are extensive, these side effects are habitually missed on clinical examination. While FGAs pose a higher risk, SGAs are still associated. Baseline assessment for movement disorders prior to antipsychotic initiation with repeat examination twice yearly is minimum standard of care.

Acute dystonia

Attributed to strong D_2 blockade, acute and painful prolonged spasms are commonly localized to the neck although involvement of the tongue, trunk, and limbs is also reported. Oculogyric crises, opisthotonus, and laryngospasm are fortunately rare. Usually occurring in the first week of treatment, with drug initiation or escalation, dystonia is treated with parenteral benztropine, diphenhydramine, or lorazepam, but may recur necessitating an antipsychotic dose reduction or daily oral anticholinergics. Risk factors include male gender, African–American

[d]Malignant arrhythmias rare; avoid doses of pimozide > 20 mg, thioridazine > 800 mg, and higher doses of ziprasidone.
[e]Monitoring of bone loss recommended in female patients with hyperprolactinemia.

ethnicity, young age, treatment naïveté, thyroid and parathyroid irregularities, and recent cocaine use.

Parkinsonism

Correlating with nigrostriatal dopamine reduction, antipsychotic-induced parkinsonism emerges in a typical although more symmetrical fashion after several weeks of treatment. Risk factors include older age, female gender, comorbid neurological disorders, and high doses of FGAs. The differential diagnosis includes negative symptoms of schizophrenia, depression, and idiopathic Parkinson's disease. Parkinsonism is expected to resolve after drug tapering and discontinuation, but may take up to 6 months. In those cases that persist longer with parkinsonian signs, the diagnosis of Parkinson's disease, unveiled by neuroleptic exposure, is likely.

Akathisia

In up to 20% of patients started on neuroleptics, a dose-related subjective sense of unease, restlessness, and dysphoria develops in the first few weeks. The clinician observes repetitive movements of the lower limbs, pacing, and rocking. Psychomotor agitation, anxiety, drug seeking, and withdrawal may confound the recognition of akathisia. Associated with the elderly, women, mood and anxiety disorders, concurrent treatment with selective serotonin reuptake inhibitors (SSRIs), excess caffeine intake, and low iron, akathisia may attenuate with

β-blockers or benzodiazepines but tends to persist for at least the first several months of treatment and is a common contributor to noncompliance, insomnia, violence, and suicide. Akathisia can also be a part of a tardive syndrome, starting after months of therapy (see later text).

Tardive dyskinesia

Although an upregulation or supersensitivity of postsynaptic D_2 receptors has been proposed, the exact mechanism of tardive dyskinesia is poorly understood. After several months or years of treatment in younger adults, or weeks in the elderly, often when an antipsychotic is tapered or discontinued, patients begin to display orofacial choreoathetosis, chewing or jaw clenching, protruding the tongue, grimacing, frowning, pursing, smacking, or puckering the lips, and blinking. Involvement of the limbs, trunk, neck, and diaphragm, with grunting, are seen. Movements are difficult to suppress and potentially embarrassing, although there is often a lack of awareness. Worsened by stress and the use of anticholinergics, tardive dyskinesia is absent in sleep. The differential diagnosis includes dyskinesias that can occur spontaneously in neuroleptic-naïve patients, Huntington's, and Tourette's. The movements persist in 75% of patients after 5 years and worsen with ongoing treatment, limiting adherence to medications, quality of life, and health status. Risk factors include previous extrapyramidal symptoms, diabetes, older age, mood disorders, cognitive impairment, and female gender in some reports. Concomitant lithium therapy may be protective. There is little rigorous data on exact incidence and prevalence. Conservative estimates suggest a rate of 5–8% per year for FGAs and 1–3% in SGAs in adults, and 5–30% per year in those over 45 years old depending on the agent used and population sampled. Children experience tardive dyskinesia at a rate of 0.4%, but they are often exposed to lower doses for shorter durations. Treatment efficacy is lacking and options include switching to clozapine, reintroducing the causative agent, and slowly tapering it, or starting tetrabenazine. Vitamin E or B_6, clonazepam, clonidine, and anticonvulsants are minimally effective. Deep brain stimulation remains experimental.

Other tardive phenomena

Delayed onset dystonias associated with prolonged use of FGAs and SGAs require distinction from Wilson's disease and idiopathic dystonia. Treatment with anticholinergics, clozapine, tetrabenazine, or BoTox is modestly effective. Tardive dyskinesia may coexist. Tardive parkinsonism, akathisia, ballismus, Tourette's, vomiting, and hypothalamic syndrome (sense of cold accompanied by polydipsia) are rare.

Other movement disorders

Rabbit syndrome or a rhythmic, fine, perioral tremor occurs in association with neuroleptics. Female gender, age, and previous brain injury predispose. This facial tremor is thought to be a manifestation of drug-induced parkinsonism. Movements tend to respond to a reduction in therapy, cessation of antipsychotics, or introduction of anticholinergics. Less commonly, Pisa syndrome or persistent lateral flexion of the trunk to one side may begin after months of treatment. The predisposed demographic and treatment are similar to rabbit syndrome. Exacerbation of tic disorders, de novo cataplexy, and myoclonus are also reported.

Other neurological complications

Generalized tonic–clonic seizures occur with an incidence rate as high as 10% in children and 4% in adults, especially with polypharmacy. Headaches are infrequent with most agents. Stroke and TIA are three times more common in demented elderly patients on antipsychotics compared to placebo.

Neuroleptic malignant syndrome

An emergent condition characterized by varying combinations of hyperthermia, diaphoresis, muscle rigidity, elevated serum creatinine kinase, altered level of consciousness, labile blood pressure, tachycardia, and hypersalivation, NMS is associated with a 25% mortality rate. A precipitous decrease in dopamine levels in the striatum and hypothalamus is responsible. Not only occurring with FGAs and SGAs when rapidly increased or initiated, but also with metoclopramide and withdrawal of dopamine replacement therapy, it must be differentiated from heat stroke, catatonia, serotonin syndrome, delirium tremens, toxidromes, and thyrotoxicosis. Risk factors include male gender, young age, associated brain injury or illness, mood disorder, and dehydration. Treatment consists of rehydration, preventing myoglobinuria and renal failure, and cooling. Dantrolene up to 10 mg kg^{-1} or until rectal temperature normalizes, bromocriptine, reinstatement of levodopa, and steroid pulse therapy are all useful.

Endocrine

Metabolic syndrome

Weight gain due to some FGAs and most SGAs is a serious cause of morbidity and a leading contributor to medication nonadherence. On average, one-half of patients taking neuroleptics gain 20% of their body weight increasing their probability of developing the metabolic syndrome, which involves hypertension, dyslipidemia, glucose intolerance, and subsequent coronary artery and cerebrovascular disease. Risk factors include females, children, adolescents, and patients experiencing their initial episode of schizophrenia, although this may be due to SGAs being first-line agents in these populations. Compounds with greater histaminergic, serotonergic, and alpha blockade are often implicated. Strict monitoring of

weight, diet, exercise, blood pressure, lipids, and glucose levels is encouraged. Strategies for pharmacological intervention are not yet well elucidated.

Interactions

Pharmacodynamic

The increasingly common practice of combining antipsychotics magnifies the risks of excessive D_2 antagonism with associated neurological complications and NMS, and serotonin and anticholinergic toxicity. Antipsychotics produce additive: hypotension with antihypertensives and monoamine oxidase inhibitors; motor side effects with SSRIs, cholinesterase inhibitors, lithium, and metoclopramide; hyperprolactinemia with some oral contraceptive pills; and sedation with benzodiazepines.

Pharmacokinetic

The most likely etiology for any drug interaction with antipsychotics derives from the inhibition or induction of hepatic cytochrome P450 1A2, 2D6, and 3A4 subtypes. Tegretol is a potent inducer of 1A2 and 3A4 lowering FGAs and SGAs to undetectable levels. Smoking induces 1A2, so altered smoking status, including abstinence in hospital, affects antipsychotic levels. Various genetic polymorphisms of the 2D6 enzyme, although present in a minority of individuals, lead to increases or decreases in activity, necessitating dose changes. Many antipsychotics are 2D6 inhibitors, so cautious use of other 2D6 substrates is necessary. Side effects to medications may be additive like the combined lowering of seizure threshold by lithium and clozapine. Interactions such as cardiotoxic levels of pimozide due to impaired clearance by clarithromycin, and decreases in the INR due to induction in warfarin metabolism by quetiapine, are of adequate frequency and severity to demand careful consideration prior to introducing neuroleptics.

Dosing

Principles

Antipsychotic prescribing involves: an estimate of the drug's starting dosage and potency based on its D_2 affinity with 2–10 mg day^{-1} of haloperidol equivalence; individualized dosing based on symptom severity, comorbidity, age, potential drug interactions including nicotine and caffeine intake, side effect profile, dosing schedule, and personal and family history of prior response to a particular compound; choice of appropriate route of administration based on the acuity of the setting, the duration of treatment, and the expectation of compliance; lowering doses for chronic maintenance therapy; gradual titration over at least 2–4 weeks with increases of every five half-lives; and adjusting the dose based on response and not drug level.

Switching

After several weeks, if lack of response is attributable to medication choice, switching antipsychotics is advised. Symptoms, side effects, and quality of life measures improve with a change from FGAs to SGAs. Olanzapine and clozapine are considerations for improved efficacy. Switches from one SGA to another or to the FGAs can optimize triglyceride levels and weight. Switching strategies should consider the relevant pharmacology of the involved agents and the risks of rebound and additive effects.

Neuronal Ceroid Lipofuscinosis

J D Cooper, Institute of Psychiatry, King's College London, London, UK

Glossary

Autosomal recessive – Genetic mutations can be passed on from one generation to the next by different patterns of Mendelian inheritance. In autosomal recessive disorders (like Batten disease), an individual needs to have two mutated copies of the disease-causing gene to be affected. Their parents are both carriers who have one mutated copy of this gene, but are themselves asymptomatic. Each time they reproduce, they have a 25% chance of having an affected child, 50% chance of producing another carrier, and 25% chance of having a completely unaffected child.

Cross-correction – Many of the therapeutic strategies used to combat LSDs depend upon this simple principle, so that an enzyme produced by a cellular subpopulation can be used to treat neighboring deficient cells. Much of the lysosomal enzymes normally made by a cell are secreted into the extracellular space, but will be recaptured and delivered back to the lysosome via binding to mannose-6-phosphate receptors that are present at the plasma membrane of all cells. In LSDs, the missing enzyme is typically delivered by direct enzyme replacement, gene transfer, or the transplant of stemcells. This delivered enzyme is then taken up by deficient cells to 'cross-correct' their functional defect.

Genetically engineered mutant mice – If the disease-causing gene has been identified, it is now relatively routine, to generate a mouse model of this disorder via genetic manipulation. Homologous recombination is used to replace the gene of interest with a construct in which this gene has been altered in some way. This may be to completely disrupt a gene so that no protein is made – a 'knockout' mouse. Alternatively, in a 'knockin' mouse, a particular disease-causing mutation can be introduced into the gene to recreate the human disease. More complicated targeting constructs, allow genes to be switched on or off, either globally or more usually in a particular cell type or tissue.

Lysosomal storage disorder – Lysosomes are acidic organelles that contain over 50 hydrolytic enzymes that degrade a wide variety of substrates. In addition to this classical role as the cell's 'waste-disposal unit,' lysosomes form an important part of the machinery for antigen presentation and are in a key position to influence both endocytosis and exocytosis, and intracellular trafficking. Lysosomal storage disorders (LSDs) are monogenic inherited disorders, each caused by a mutation in a single gene. This may encode one of the lysosomal enzymes, or one of the many lysosomal membrane proteins that regulate the environment within the lysosome. Many LSDs have prominent neurologic and neurodegenerative components, and these are uniformly fatal.

Definition and History

The neuronal ceroid lipofuscinoses (NCLs or Batten disease) is the collective name for a group of at least 10 fatal inherited lysosomal storage disorders, which affect mostly children and young adults. These are profoundly disabling, and progressive neurodegenerative disorders that have a devastating impact upon affected individuals and their families. Common features include visual failure, seizures of increasing severity, and relentless declines in motor and cognitive abilities, invariably ending in premature death as there are no effective therapies available. Although varying widely in their age of onset and rate of progression, all forms of NCL display pronounced accumulation of autofluorescent material within the lysosome due to its dysfunction.

Despite being first described by the Norwegian physician Otto Christian Stengel in 1826, the NCLs are more widely known as Batten disease, after the British pediatrician Fredrick Batten, who reported juvenile onset cases in 1903. Each form of NCL is caused by a defect in a single gene, and inherited almost exclusively in an autosomal recessive fashion. Dependent on which of these genes are mutated, the age of onset varies from congenital to adult onset forms. Although neuronal ceroid lipofuscinosis is usually abbreviated as NCL, rather confusingly these disease-causing genes are instead called 'ceroid lipofuscinosis neuronal' (CLN) and designated by gene symbols *CLN1–10* (see **Table 1**). Initially four forms of NCL were described, including infantile (INCL, caused by mutations in *CLN1*), late infantile (LINCL, caused by mutations in *CLN2*), juvenile (JNCL, caused by mutations in *CLN3*), and adult onset forms. However, it is now apparent that many other forms exist, with an ever-increasing number of variant forms (caused by mutations in *CLN5–9*) and a congenital form (caused by mutations in *CLN10*) recently identified. Regardless of the gene defect present, all forms of NCL are commonly referred to as Batten disease, using the prefix 'infantile,' 'late infantile,' and so on to distinguish between them, for example, infantile Batten disease or INCL, late infantile Batten disease or LINCL, and so on. Alternatively, these disorders are sometimes described by the name of the deficient gene, for example, *CLN1*, or palmitoyl protein thioesterase-1 deficiency in infantile NCL (see **Table 1** for details).

Pathogenesis/Pathophysiology

Although eight different disease-causing genes have now been identified, the mechanisms by which their mutation results in the profound effects of these disorders upon the brain remain poorly understood. This situation is further complicated by not knowing the normal function of many of these gene products, or how this is altered by mutation. The *CLN* genes fall into two broad categories encoding either soluble lysosomal enzymes (*CLN1*, *CLN2*, *CLN10*) or glycoproteins (*CLN5*), or a series of transmembrane proteins that are expressed in the lysosome (*CLN3*, *CLN7*) or elsewhere in the endosomal–lysosomal system (*CLN6*, *CLN8*). As discussed later, the nature of the gene product has a significant impact upon the possible therapeutic options available (see section Prognosis), but at present, all forms are incurable. There is a broad correlation between the type of gene products and disease severity, with earlier onset and faster progressing forms of NCL caused by mutations in the genes that encode lysosomal enzymes (*CLN10*, *CLN1*, and *CLN2*). In these forms, there is some evidence for genotype–phenotype correlations, with mutations that leave a higher residual enzyme activity resulting in a markedly later and slower disease progression. However, in the remaining forms of NCL, the situation is not as clear as with many different mutations and heterogeneous presentations evident.

Although little detailed information is available about disease mechanisms, the advent of genetically accurate animal models of NCL has greatly advanced the understanding of the events that happen in each form of the disorder. The vast majority of these models are genetically engineered ('knockout' or 'knockin') or naturally occurring

Table 1 List of genes mutated in each form of NCL, with a description of the type of gene product, its nature, and main intracellular location

Form of NCL	*Gene symbol*	*Gene product*	*Nature and main intracellular location of gene product*
Infantile (INCL)	*CLN1/PPT1*	Palmitoyl protein thioesterase-1	Lysosomal enzyme
Late infantile (LINCL)	*CLN2/TPP-1*	Tripeptidyl peptidase-1	Lysosome enzyme
Juvenile (JNCL)	*CLN3*	CLN3	Endosomal/lysosomal transmembrane protein
Adult	*CLN4*	Gene not identified	Unknown
Variant LINCL	*CLN5*	CLN5	Lysosomal glycoprotein
	CLN6	CLN6	Endoplasmic Reticulum transmembrane protein
	CLN7/MFSD8	CLN7/MFSD8	Lysosomal transmembrane protein
	CLN8	CLN8	Endoplasmic reticulum transmembrane protein
	CLN9	Gene not identified	Unknown
Congenital	*CLN10/CTSD*	Cathepsin D	Lysosome enzyme

mutant mice, but several large animal models (most notably sheep and dogs) also exist, and have particular advantages for modeling human disease. Models in more simple species, including yeast, *Drosophila* (fruit-fly), and zebrafish are also being used to address disease mechanisms and to discover the functional pathways in which the CLN genes normally operate.

Analysis of these models has provided a detailed series of landmarks of CNS disease progression. These data have informed the timing and targeting of therapeutic approaches in preclinical studies, and identified events that are specific to each form of NCL that may be amenable to therapeutic intervention. Examples include blockade of excitotoxicity and immunomodulation strategies to target the autoimmune response in JNCL. Broad themes in pathogenesis have also emerged from these studies. Unexpectedly, neuron loss is not global, but displays remarkable selectivity, especially in the early stages of the disease with the thalamus and populations of inhibitory interneurons particularly affected. However, there is no direct relationship between this selective neuron loss and the widespread build-up of storage material, which appears to be a by-product of the disease process. Instead, localized neuron–glial interactions appear more important in pathogenesis with the distribution of early glial activation accurately predicting the sites of subsequent neuron loss, which occurs many months later. This glial activation is already evident prenatally, and it will be important to determine whether these astrocyte and microglial responses are neuroprotective or contribute directly to neuron loss. The selectivity of effects upon the NCL brain extends to a cellular level, and the synapse is emerging as an important early pathological target. Although reaching a common pathological endpoint, it is clear that the precise sequence of events, their timing, and the place they occur differs markedly between forms of NCL. Indeed, this distinct pathological profile of each disorder challenges the notion that these disorders should be grouped together.

Epidemiology/Risk Factors

The NCLs have been described collectively as the most common inherited neurodegenerative disorder of childhood. Estimates of prevalence have been reported as high as 1 in 12 500 live births, but are more likely to be in the region of 1 in 20 000 or 30 000. The incidence of some forms is much higher in certain populations, most notably in Finland for INCL/*CLN1* and *CLN5*. However, as diagnosis and genetic testing has become more efficient, it is now apparent that each of these disorders has a far wider geographical distribution. With the exception of some rarer types of adult onset NCL, all forms display a classic autosomal recessive pattern of inheritance. Once identified within a family, the issue of carrier testing of siblings and prenatal diagnosis becomes important, and appropriate genetic counseling support is advised.

Clinical Features and Diagnostic Criteria

Although sharing a broadly similar clinical presentation, the age at which the symptoms are first detected and the rapidity of disease progression differ greatly between forms. This age of onset, combined with the symptoms that occur first, may provide the first important clue to which disease form is present. However, this situation is complicated by the wide clinical spectrum of disease for each form, and the influence of different mutations in a particular gene, with widely heterogeneous presentation, even among affected siblings. The early development of all NCL children is thought to be largely normal with no overt signs of the disease.

INCL children typically begin to lose fine motor skills late in their first year, and subsequently display clumsiness, irritability, loss of speech and vision, and sleep disturbances. Visual failure progresses rapidly to blindness, and a variety of seizure types (myoclonic, clonic, tonic, or hypomotor features) become more evident together with a loss of all cognitive and voluntary motor skills by 3 years. Affected children often persist in this highly dependent state for a number of years, before dying between 8 and 13 years of age.

The first symptoms in LINCL children usually appear between 2 and 4 years of age as declining motor ability with clumsiness and ataxia, together with speech deterioration. Motor function and speech decline rapidly in parallel from 3 years onwards, with children completely dependent by 5 years. Seizures usually appear by 3 years as partial, generalized tonic–clonic, secondarily generalized, or sometimes absence seizures. These should be distinguished from the myoclonus that presents a major problem for these children, frequently disturbing their sleep. A gradual decline in vision occurs from 4 years, with blindness usually evident from 7 years, although this may be delayed. The loss of swallowing ability and associated problems often requires fitting a gastrostomy tube, and these children will typically die in the mid-teenage years.

The first presentation of JNCL is usually visual failure between 4 and 7 years of age, often leading to blindness 2–4 years later, and accompanied by learning difficulties in the early school years. Generalized tonic–clonic seizures typically develop ~10 years and worsen progressively, often with complex partial seizures present. Predominantly extrapyramidal motor signs, including rigidity, hypokinesia, stooped posture, shuffling gait, and impaired balance also present from 10 years onwards, accompanied by increasing speech difficulties and leading to a complete loss

of independent mobility. A great range of disturbing psychiatric symptoms is evident in these individuals with anxiety, aggressive and depressive behaviors, sleep disturbances, and a variety of hallucinations. An early onset of puberty in girls, and progressive cardiac involvement are also reported with premature death typically occurring in the mid-to-late twenties.

The features of variant forms of late infantile NCL (*CLN5*, *CLN6*, *CLN7*, and *CLN8*) are variously described as resembling later onset forms of *CLN2* deficiency, or earlier onset forms of *CLN3*. With a wide range of mutations and presentations possible, it may be difficult to distinguish between these disorders. With improved tools for obtaining an accurate molecular diagnosis, it is now apparent that these variant forms are not as geographically restricted as once thought, and should not be excluded from differential diagnosis.

Diagnostic Work-up/Tests

With the advent of widely available enzymatic and genetic testing protocols, it should now be relatively straightforward to produce a definitive diagnosis of the major forms of the Batten disease, without relying as heavily on previously used electron microscopic analysis of skin or rectal biopsies. These depend upon the expert detection and ability to distinguish between the form-specific appearances of accumulated storage material, although light microscopy screening for the presence of vacuolated lymphocytes specific to JNCL in blood smears is still informative. Enzymatic testing for deficiencies in *CLN1* and *CLN2* is now comparatively standard, and can be performed on blood or saliva samples. This testing should be considered in all potential NCL cases as a higher level of residual activity may result in a later onset and slower progression. Identifying the presence of two mutated copies of a *CLN* gene provides a definitive diagnosis, and can also be performed using blood samples, although cheek swabs are now increasingly used. Sequencing through an entire gene may prove prohibitively costly and/or time-consuming, but routine tests for the most common mutations (e.g., the 1.02 kb or 'big' deletion in *CLN3*) are now available. However, if these prove negative, a more detailed mutational analysis may be required, and is important for subsequent carrier or prenatal testing. Some families with a known history of NCL have also opted for preimplantation diagnosis following *in vitro* fertilization procedures. See websites provided under Relevant Websites for details of diagnostic protocols and testing laboratories.

Management

With no effective therapy existing for any form of NCL, treatments are supportive and aimed at minimizing the distressing and disabling symptoms of these disorders. The rapidity of disease progression in INCL and LINCL leaves less scope for these approaches than in the more slowly progressing JNCL, in which many psychiatric and extrapyramidal motor symptoms need to be addressed. The management of seizure activity is difficult and usually requires a complex series of medications that need to be regularly monitored and modified as the disease progresses. In contrast, approaches that minimize pharmacological intervention and focus on supporting the quality of life are more often used in parts of Europe. With progressively declining visual and cognitive performance, supportive educational approaches are increasingly employed, especially in JNCL. With disease progression, problems of mobility increase, and occupational and physical therapy become particularly important. The difficulty in arranging suitable support for children who are rapidly declining cannot be underestimated, and careful advance planning and dialog between different agencies is beneficial. Copious mucous secretions and reduced ability to swallow often prove particularly distressing, with regular suction frequently required. The question of whether to have a gastrostomy is an emotive one for many families, but offers significant nutritional and practical benefits. For all similar logistical issues, Batten disease charities offer a wealth of invaluable expert advice and support, especially for newly diagnosed families.

Prognosis

The therapeutic outlook for individuals diagnosed with any form of NCL is currently uniformly bleak. However, concerted preclinical research in animal models is ongoing to test and refine a variety of therapeutic strategies, although it is realistically going to be some time before any of these reach the clinic.

Theoretically, more options are available for forms of NCL due to a defect in a soluble lysosomal enzyme (*CLN1*/INCL, *CLN2*/LINCL), since delivered enzyme can be bound to surface receptors to cross-correct deficient cells. This could be achieved by enzyme replacement (delivery of recombinant enzyme) or gene transfer approaches (providing a functional copy of the missing gene via viral or nonviral vectors). These approaches have shown promise in mouse models, especially of LINCL, if given early in disease progression, but many technical issues remain before these strategies can be transferred to a clinical setting. A phase I trial of AAV2 mediated gene transfer for LINCL has been undertaken at Cornell University, but it is likely that newer generations of vectors that are much more successful in mice will be required to improve the clinical efficacy. An alternate approach to deliver the missing enzyme is to use intracerebral grafts of neural stemcells. Following preclinical tests in INCL mice, a Phase I trial

of this strategy has been performed in INCL and LINCL at Oregon Health Sciences University (sponsored by Stemcells Inc.), but it is too early to know its outcome. Despite this activity, it must be stressed that these highly experimental approaches are still in their early stages, and it may take many years before they reach the clinic.

The therapeutic options for NCL types caused by mutations in transmembrane proteins (*CLN3*/JNCL and variant forms *CLN6*, *CLN7*, *CLN8*) are much more limited. This is because these proteins cannot be released from cells to cross-correct deficient neurons within the brain. Moreover, strategies that overexpress these proteins widely are likely to prove harmful to neuron survival. Until the precise function of these transmembrane proteins is revealed and more specific mechanistic based therapies become available, the current strategy is to investigate the consequences of mutations in these genes, and see if blocking these effects provides any therapeutic benefit to mouse models. In JNCL mice, this approach has been used by blocking AMPA-mediated excitotoxicity and by using immunosuppression to target the autoimmune response specific to this form of NCL. Although providing partial benefit in mice, these novel treatment forms are yet to reach clinical trials. In readiness, a Batten Disease Diagnostic and Clinical Research Center has been established at the University of Rochester and the Unified Batten Disease Rating Scale devised for assessing disease progression.

A variety of other approaches have been suggested as treatments for different forms of NCL. These include dietary supplements, fish oils, antioxidants, and the analgesic flupirtine, with many of these given regularly to children. However, there is no evidence that any of these approaches provide any benefit.

Neuroprotection in Movement Disorders

T Voss and B Ravina, University of Rochester, Rochester, NY, USA

Glossary

Clinical Trials – Research studies that administer an intervention to human participants. May or may not be randomized or use a placebo or a control group.

Disease-modifying therapies – Treatments that change the time course of the disease or delay the development of later complications or disability. This does not necessarily equal neuroprotection.

Neuroprotection – The ability to delay or prevent neuronal death, which will lead to slowing of disease progression.

Parkinson Plus Disorders – Degenerative disorders that manifest with symptoms similar to Parkinson disease. Including multisystem atrophy, progressive supranuclear palsy, and corticobasal degeneration, these disorders are typically less responsive to current therapies and carry a worse prognosis.

Definition and History

Neuroprotection is typically defined as the ability to delay or prevent neuronal death and dysfunction, which should translate into delayed disease onset or slowed disease progression in human disease. In movement disorders, the search for neuroprotective therapies concentrates within neurodegenerative movement disorders, primarily Parkinson disease (PD) but also Huntington disease (HD) and parkinsonian syndromes such as multisystem atrophy (MSA), progressive supranuclear palsy (PSP), and corticobasal degeneration. Despite the clinical differences, neuroprotective strategies to date have been remarkably similar, focusing on improving antioxidant activity and stabilizing mitochondrial function.

Unfortunately, the search for a neuroprotective therapy has proved difficult. This difficulty stems from several issues: understanding of disease pathophysiology, proper selection of potential therapeutics, appropriate selection of outcome measures, and the type of clinical trial design. Additionally, the definition of neuroprotection requires that researchers demonstrate improved neuronal survival or function. This task is feasible in preclinical models but difficult to prove in humans. Recognition of these problems has led to the development of innovate trial designs and a reconsideration of which outcomes should be used in efficacy trials.

Neuroprotection and Parkinson Disease

Since 1989, 15 published trials have examined putative neuroprotective effects in PD and at least four trials are ongoing (**Table 1**). These trials have generally enrolled participants with early PD on minimal or no treatment. Potential agents have included dopaminergic compounds (selegiline, pergolide, levodopa, rasagiline); antioxidants and mitochondrial enhancers (tocopherol, coenzyme q10, creatine); antiapoptotic compounds and trophic factors (lazabemide, riluzole, TCH-346, GPI-1485, CEP-1347); and antiinflammatory compounds (minocycline). Despite positive results of several trials, no trial has been accepted as providing sufficient evidence of neuroprotection to warrant regulatory approval for this indication. There are several potential reasons for this that span both preclinical work and clinical trials: inadequate disease models, errors in selection of agents or dosages, inability to document activity against the proposed biological target in humans, confounding of symptomatic with disease-modifying effects, or using the wrong outcome or study design. Although all of these reasons are important, this chapter concentrates on issues in clinical development.

Outcome Selection

Appropriate outcome selection is a recurring question in clinical trials of PD. In the absence of an accepted biomarker for disease progression in PD, trials must rely on clinical rating scales or assessments of disability. Although these outcomes are designed to measure clinically important aspects of PD, they are susceptible to several influences. The Unified Parkinson's Disease Rating Scale, for example, is the most widely used scale in PD. It is clinically relevant, reliable, and reproducible. It is weighted heavily, however, toward the motor aspect of PD. This leads to two issues in measuring disease-modifying effects: first, the motor symptoms of PD are highly responsive to dopaminergic therapy, making it difficult to use the scale

Table 1 Published clinical trials of neuroprotection in Parkinson disease

Clinical trial	*Agents used*	*Total sample size*	*Primary outcome examined*
Tetrud & Langston (1989)	Selegiline	54	Time to disability requiring levodopa therapy
DATATOP (1993)	Selegiline, tocopherol (vitamin E)	800	Time to disability requiring levodopa therapy
SINDEPAR (1995)	Selegiline	101	Change in UPDRS
ROADS (1996)	Lazabemide	321	Time to disability requiring levodopa therapy
Swedish Selegiline (1998)	Selegiline	157	Time to disability requiring levodopa therapy
Norwegian-Danish (1999)	Selegiline	163	Change in UPDRS
QE2 (2002)	Coenzyme Q10	80	Change in UPDRS
Jankovic & Hunter (2002)	Riluzole	20	Change in UPDRS
TEMPO (2004)	Rasagiline	404	Change in UPDRS
ELLDOPA (2004)	Levodopa	361	Change in UPDRS
U.K. Low-dose Pergolide (2005)	Pergolide	106	Time to disability requiring levodopa therapy
NET-PD futility (2006)	Minocycline, creatine	200	Change in UPDRS
TCH-346 (2006)	TCH346	301	Time to disability requiring dopaminergic therapy
NET-PD futility (2007)	GPI-1485, coenzyme Q10	213	Change in UPDRS
PRECEPT	CEP-1347	806	Time to disability requiring dopaminergic therapy

in individuals already on treatment. Second, the UPRDS is less sensitive at measuring nonmotor aspects of PD, which take on increasing importance as the disease progresses and are typically unresponsive to current therapies. Assessment of disability sufficient to require dopaminergic therapy is another commonly used outcome in clinical trials. Again, while relevant and meaningful to providers and patients, this outcome can be affected by depression, type of employment, family environment and resources, and several other factors not captured by either the assessment or the UPDRS.

All rating scales can only measure clinically observable effects. They are unable to determine what caused those changes – for example, UPDRS motor scores may improve, but whether this is due to a symptomatic effect, a neuroprotective effect, or a nonmotor effect is unknown. For example, UPDRS motor scores and assessment of disability are affected by nonmotor effects such as depression, making causal interpretation impossible. In addition, rating scales are impacted by inevitable variation in the administration, scoring, and interpretation of these scales. This problem can be minimized but not eliminated by standardized training and certification.

Given the complex pathophysiology and clinical presentation in PD, some researchers have suggested using a global statistical test instead of separate scales. In this analysis, multiple correlated outcome measures are combined into a single measure of effectiveness. When all outcome measures respond to treatment in the same direction, the power of this test is enhanced over traditional methods. This makes it especially useful for an intervention that would be expected to affect global function, but less ideal for an intervention designed to impact a single aspect of PD.

Functional outcomes include assessments of quality of life or assessments of functional transitions such as loss of independent walking or loss of independent living. These measures suffer the same flaw, in that they cannot address the underlying biological processes of PD, but offer intuitively meaningful outcomes that are relevant to clinicians and patients alike. Combined with potential biomarkers of disease activity, these outcomes may become increasingly useful in measuring a disease-modifying effect.

Biomarkers as Outcomes

The difficulty in interpreting current rating scale outcomes, when combined with the slow progression of PD, have spurred the search for biomarkers that could reliably measure disease progression and ideally also represent a biological target for early stage trial designs. Several potential markers have been identified, but unfortunately, none are yet ready to serve as an interim endpoint in clinical trials. α-Synuclein remains an appealing candidate because it is the main component of Lewy bodies, the pathologic inclusion in PD, and because mutations in α-synuclein genes lead to familial forms of PD. Although it has been used to distinguish individuals with PD from unaffected controls, its correlation with disease activity or progression is not known, nor is it known whether changes in α-synuclein levels predictably correlate with changes in clinical disease manifestation. Other candidate biomarkers include smell testing, changes in gene expression, metabolomics, and proteomics. These biomarkers are also being considered as potential tools to identify early PD and to distinguish PD from other conditions such as vascular parkinsonism, MSA, or PSP.

Neuroimaging has been extensively studied for use as a potential biomarker in PD. Radiotracer imaging of the nigrostriatal dopaminergic system has been evaluated in three large pharmacologic clinical trials: ELLDOPA, CALM-PD, and REAL-PET. In all instances, the group that did better on the primary clinical outcome performed worse on the neuroimaging outcomes. This contradiction between clinical and imaging outcomes needs to be solved before dopamine-based radiotracer imaging can be used as a marker for underlying disease progression, and also emphasizes the challenges in demonstrating an actual neuroprotective effect in humans. In addition, measurements of the dopamine system may not account for important nondopaminergic aspects of the disease. Other tracers or different forms of neuroimaging will likely be needed to better capture additional aspects of the underlying pathologic processes in PD.

Clinical Trial Design

Currently, clinical trials in PD suffer from the successful development of dopaminergic therapy for PD. Because of the powerful symptomatic effects of these medications, it is difficult to measure disease progression clinically. For this reason, clinical trial populations for potential disease-modifying treatments are generally early, treatment-naïve PD. New trial designs are emerging to attempt to detect disease-modifying effects, even in the presence of symptomatic treatment. The delayed-start design has been proposed as a method for detecting such effects. In this design, all patients eventually receive active therapy. However, one group is randomized to placebo first, and their exposure to active therapy is delayed, typically by 6–12 months. If the therapy under investigation is purely symptomatic, then the delayed group should catch up to the early-treatment group. If the intervention modifies the disease, however, then the delayed group should continue to lag behind the early group. This design is promising and has been used in two recent clinical trials of rasagiline, the TEMPO and ADAGIO trials.

The delayed start design is not without potential flaws. One concern is the potential for differential dropout

between the early and delayed treatment arms, especially during the initial placebo phase. This endangers the benefits of randomization by making the groups inequivalent. Also, the method for analyzing missing data in a delayed start design may affect the results. For example, dropout may occur for different reasons in the two different groups. When the last observation is carried forward for these dropouts, the data may be biased to either reduce or enhance the treatment effect, depending on the reasons for dropout. This concern may be addressed by performing a sensitivity analysis, in which multiple methods for dealing with missing data are compared. This can provide an assessment of the robustness of the observed treatment effect.

The futility trial is an early-stage clinical trial design that attempts to identify ineffective therapies within a relatively short timeframe while minimizing cost and patient exposure to less promising therapies. A futility trial saves cost and time by using a single active treatment arm and comparing their response to historical controls. These trials may be unblinded or may use a small placebo group to preserve blinding and minimize placebo effect. Futility trials save cost because using historical controls minimizes sample size while preserving power. Also, because they use one-sided statistical tests to prove a treatment is ineffective, they increase power for a defined sample size. Because they are not designed to prove efficacy, futility trials can be completed more quickly, allowing promising therapies to move forward rapidly.

The limitations of the futility design are inherent in its purpose. First, it is not a comparative efficacy trial and should not be judged as such. They are an early-stage screening design that works best when the hypothesized treatment effect is modest, because large treatment effects can be measured efficiently within a traditional efficacy design and do not require a futility design. This design requires that the historical control response be constant and well-defined. Changes in this rate will increase the chance for error, and may lead to either rejecting an effective treatment or falsely proceeding with an ineffective treatment. If the outcome measures are susceptible to changes in ancillary care or changes in practice style, this variability will damage a futility trial and obscure its interpretation.

Emerging Interventions in PD

As trial design and outcome selection continue to evolve, potential interventions continue to emerge for Parkinson disease. The ADAGIO study, recently completed, should provide additional evidence about whether rasagiline represents a disease-modifying intervention for PD. Creatine and coenzyme Q10 are both in definitive comparative efficacy trials, while inosine is being examined in an early-stage trial and should be enrolling participants in 2009.

Neuroprotection and Huntington Disease

Two of the most promising experimental interventions in HD are high dose coenzyme Q10 (CoQ_{10}) and high dose creatine monohydrate. An initial NIH-funded study of 600 mg per day of CoQ_{10} in manifest HD showed a nonsignificant trend toward improvement on the Total Functional Capacity scale. A subsequent study in transgenic R6/2 HD mice showed a dose-dependent increase in therapeutic benefit at higher doses of CoQ_{10}. High-dose CoQ_{10} significantly improved both the behavioral and neuropathological phenotype of R6/2 mice, delaying the development of weight loss, motor deficits, grip strength, gross brain atrophy, striatal neuron atrophy, and huntingtin aggregates in R6/2 mice. Based on this combination of animal and clinical data, a second clinical trial was developed. This NIH-funded study is studying up to 2400 mg per day of CoQ_{10} and is currently enrolling subjects with manifest HD.

Based on the interest in mitochondrial function and data in transgenic models of HD, there have been several small clinical trials of creatine in HD at a variety of dosages. A recent clinical trial has studied up to 40 g per day of creatine monohydrate in manifest HD (S. Hersch, personal communication). While the sample size was small (<20), this open label study showed that creatine was safe and well tolerated for over one year and led to dose-dependent increases in plasma and brain creatine levels and dose-dependent suppression of serum 8-hydroxydeoxyguanosine (8-OHdG), a marker of oxidative DNA injury. These findings led to an NIH-supported comparative efficacy study of creatine monohydrate in HD. This flexible dose study will allow subjects to take up to 40 g per day of creatine and is expected to begin recruitment in early 2009.

These studies illustrate two important points for future clinical trials. First, dose-ranging studies are critical in both preclinical and early clinical work. Underdosing, especially for dietary supplements, may partially explain why prior clinical trials in neurodegenerative diseases have failed. Dose ranging can evaluate short-term safety, examine the relationship between dosage and exposure, and possibly assess biological activity on potential markers such as 8-OHdG. These studies provide additional information that then allows for more rational dose selection in comparative efficacy trials. Second, functional outcomes and parallel group designs provide clearly interpretable information about disease. Unlike PD, there is little interest in the distinction between short-term symptomatic effects and long-term effects on disease progression in HD. Rather, agents have been selected because of their potential to ameliorate the underlying pathophysiology of HD and the definitive trials are designed to demonstrate benefit on functional outcomes. This straightforward

approach may also be useful in PD given the many unmet therapeutic needs and the lack of biomarkers to measure disease progression.

Neuroprotection in MSA and PSP

Neuroprotective trials in MSA and PSP are hampered by their relative rarity and the difficulty in separating them from PD. The potential for misdiagnosis is maximal early in the course of disease, when disease-modifying therapies would be most useful. Still, multicenter study groups have formed to organize clinical research for both conditions, leading to a growing pool of potential trial participants. In MSA, no efficacy trials are currently registered, but lithium, valproate, and CoQ_{10} are all under investigation for PSP.

Summary

Neuroprotection is a difficult but important goal in the treatment of neurodegenerative movement disorders. Despite early setbacks, continuing advancement in preclinical works, improvements in study design and outcome measurement, and the development of possible biomarkers all offer continued hope for the development of disease-modifying therapies for these fatal diseases.

Nicotine

E Cubo, Complejo Hospitalario Burgos, Burgos, Spain

Glossary

Dopamine – Dopamine is mainly a neurotransmitter occurring in a wide variety of animals, including both vertebrates and invertebrates. In the brain, it works as a neurotransmitter, activating the five types of dopamine receptors – D1, D2, D3, D4, and D5, and their variants. Dopamine is produced in several areas of the brain, including the substantia nigra and the ventral tegmental area.

Neuroprotection – Mechanisms within the nervous system that protect neurons from apoptosis or degeneration.

Neurotoxins – A neurotoxin is a toxin that acts specifically on neurons, usually by interacting with membrane proteins such as ion channels.

Nigrostriatal pathway – The pathway that connects the substantia nigra to the striatum. It is one of the four major dopamine pathways in the brain and is particularly involved in movement, forming part of a system called the basal ganglia motor loop.
Receptor – A protein molecule, embedded in either the plasma membrane or cytoplasm of a cell, to which a mobile signaling molecule may attach. A molecule which binds to a receptor is called a 'ligand,' and may be a neurotransmitter, a hormone, a pharmaceutical drug, or a toxin, and when such binding occurs, the receptor undergoes a conformational change which ordinarily initiates a cellular response.

Nicotine

Nicotine is an alkaloid found in the nightshade family of plants (Solanaceae) predominantly in tobacco, and in lower quantities in tomato, potato, eggplant, and green pepper. Nicotine can also be found, along with cocaine, in the leaves of the coca plant. Nicotine constitutes ~0.6–3.0% of dry weight of tobacco, with biosynthesis taking place in the roots and accumulation in the leaves. It functions as an antiherbivore chemical, being a potent neurotoxin with particular specificity to insects. As nicotine enters the body, it is distributed quickly and can cross the blood–brain barrier. Nicotine is metabolized in the liver by cytochrome P450 enzymes (mostly CYP2A6, and also by CYP2B6). A major metabolite is cotinine.

The neurochemical systems involving the neurotransmitter acetylcholine are divided into muscarinic and nicotinic, the latter receptors responding to nicotine and its derivatives. Nicotine interacts with multiple nicotinic receptor (nAChR) subtypes in the peripheral and central nervous system, as well as in skeletal muscle. In small concentrations, it activates these receptors. Toxic symptoms from nicotine can occur in children with doses as low as 1 mg and in adults with doses as low as 2–5 mg. The lethal dose of nicotine in adults is from 0.5 to 1.0 mg kg^{-1} or a total dose of 30–60 mg. Symptoms of nicotine poisoning include: central nervous system signs ranging from dizziness, to tremor to lethargy and coma; sympathetic or parasympathetic autonomic signs such as hypertension or hypotension, cardiac arrhythmias, salivation, and diaphoresis; and neuromuscular effects including neuromuscular excitability followed by weakness and even rhabdomyolysis.

The nAChRs are members of the large family of ligand-gated ion channels and are constituted by the assembly of five subunits arranged pseudosymmetrically around the central axis that forms a cation-selective ion pore. They are widely distributed in both the nervous system and nonneuronal tissues and can be activated by endogenous agonists such as acetylcholine or exogenous ligands such as nicotine. Neuronal nAChRs may play a role in neurodegenerative disorders. Smoking may have a protective effect against Parkinson's disease (PD) and multiple system atrophy. Both retrospective and prospective epidemiologic studies have consistently demonstrated an inverse association between cigarette smoking and PD, leading to theories that smoking in general and low-dose, chronic nicotine exposure in particular might be neuroprotective. Within twin pairs, the risk of PD is inversely correlated with the dose of cigarette smoking. This effect is most pronounced in monozygotic twins. Cigarette smoke contains many different chemicals, but nicotine seems to be the strongest candidate as the agent responsible for neuroprotection against PD for several reasons. First, nicotine is known to protect against the degenerative effects of toxic insults in different experimental systems. Second, nicotine pretreatment consistently reduces the detrimental effects of excitotoxin exposure in cultured cells, including neurotoxin-induced degeneration of nigral dopamine-containing neurons. In rats and mice, nicotine can protect against parkinsonism-inducing neurotoxins, like 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and methamphetamine, probably by increasing the level of neurotrophic factors. Nicotine has also shown to stimulate the release of dopamine in the striatum of animals and to preserve nigral neurons and striatal dopamine levels in laboratory animals with lesioned nigrostriatal pathways. As a result, nicotine seems to stimulate brain dopaminergic systems, provides some potentially symptomatic benefits in PD, and may have neuroprotective actions. However, the dose of nicotine that is employed appears to be critical since low doses and not high seem to be protective. As a result, despite the evidence that nicotine is neuroprotective, it is clear that nicotine can be toxic under some circumstances. The balance between nicotine neuroprotection and toxicity depends on dose, developmental stage, and regimen of administration.

There is a well-established loss of nAChRs in postmortem brains from patients with Alzheimer's disease, PD, and a range of other disorders. Nicotine and subtype selective nAChR ligands provide neuroprotection in in vitro cell culture systems and in in vivo studies in animal models of such disorders. Most studies agree that nicotine is protective against glutamate and β-amyloid toxicity in various culture systems. This effect appears to be mediated by α7 subtype nAChRs since the protection is blocked by α-bungarotoxin and is mimicked by α7 selective agonists. In vivo studies indicate that α7 receptors play a critical role in protection from cholinergic lesions and enhancing cognitive function. The exact subtype involved in the neuroprotective effects seen in animal models of PD is not clear, but in general, broad spectrum nAChR agonists appear to provide protection, while α4β2

receptors appear to mediate symptomatic improvements. Recently, α6 subunits have been associated with both potential symptomatic and neuroprotective effects of nicotinic agonists in MPTP-pretreated primates. These observations suggest that development of nAChR agonists or antagonists targeted to α6β2-containing nAChRs may represent a particularly relevant target for PD therapeutics. On the other hand, brain expression of cytochromes P450 2B6, 2D6, and 2E1 is higher in smokers, and is induced by nicotine in animals. These enzymes can metabolize many of the neurotoxins associated with PD. Since smoking is considered as protective against PD, it has been hypothesized that nicotine-induced elevations of brain CYPs in smokers may contribute to neuroprotection against PD.

Smoking has also been associated with a lower risk of incident essential tremor. Likewise, nicotine alone (delivered by gum, or transdermal patch, or in combination with neuroleptics) may improve tics and improve attention-related behaviors. Finally, nicotine may have neuroprotective effects in an experimental model of Huntington's disease and has been reported to reduce hemiballism–hemichorea and akathisia.

Against this backdrop, it is essential to emphasize that nicotine exposure in the form of cigarette smoking is not recommended by physicians. The danger of smoking-related medical disorders, including nausea, vomiting, tachycardia, and with long term use, lung cancer, outweigh arguments of benefit. To this end, significant pharmacological research efforts are currently directed towards developing drugs that can activate central nicotinic receptors outside of cigarettes and specifically to develop agents that are not associated with systemic side effects.

Niemann–Pick Type C

B R Barton, Rush University Medical Center, Chicago, IL, USA

Glossary

Filipin – A polyene antibiotic that binds to unesterified cholesterol, used to identify abnormal cholesterol accumulation patterns in NPC.

Glycosphingolipids – A subtype of glycolipids involved in cell membrane structure, modulation of membrane protein function, and cell recognition, which accumulate in central nervous system tissues in NPC. Gangliosides are a subtype of glycosphingolipids.

Niemann–Pick disease (NP) – A heterogeneous group of neurovisceral lipid storage disorders with different underlying biochemical defects and clinical presentations.
Niemann–Pick Type C (NPC) – A subtype of Niemann–Pick disease related to accumulation of lipids in the cells of multiple tissues.
Polymorphous cytoplasmic bodies – Characteristic cellular inclusions detected in NPC-affected cells by electron microscopy.

Definition and History

Niemann–Pick disease (NP) is a heterogeneous group of neurovisceral lipid storage disorders with a wide spectrum of clinical presentations. The first case was described by Albert Niemann in 1914, with further pathological characterization of the disease by Ludwick Pick in the 1920s. In 1958, Crocker and Farber reviewed 18 patients with a wide range of clinical features, unified by findings of increased tissue sphingomyelin and 'Niemann–Pick cells' (foamy macrophages). Four subtypes were delineated by Crocker in 1961 (A, B, C, and D); Type C was defined as a chronic neuropathic form, which in the 1980s was found to be associated with defects in cholesterol storage.

Pathogenesis/Pathophysiology

While NP Types A and B are associated with primary mutations in the structural gene for acid sphingomyelinase (ASM), resulting in accumulation of sphingomyelin in cells, NP Type C (NPC) is characterized by impaired cholesterol transport from lysosomes, with only milder, secondary deficiency decrease in ASM activity. The hallmark biochemical finding in NPC is intracellular accumulations of several types of lipids in the endosomes and lysosomes of multiple tissues, with unesterified cholesterol predominating in nonneuronal organs and glycosphingolipids being more prevalent in the central nervous system.

NPC is inherited in an autosomal recessive manner, affecting males and females equally. Approximately 90% of patients have mutations in the *NPC1* gene (mapped to 18q11), while 4% have mutations in the *NPC2/HE1* gene (mapped to 14q24.3). The exact functions of the abnormal protein products remain unclear, but are postulated to be involved in the intracellular trafficking or transport of cholesterol and glycolipids.

Epidemiology

NPC is a pan-ethnic disease, with prevalence estimated at ~1:150 000 in Western Europe, but higher frequency has been noted in some isolated populations. Prevalence is likely underestimated because of underrecognition of atypical phenotypes.

Clinical Features and Diagnostic Criteria

Clinical manifestations vary widely depending on the age of presentation, which ranges from the perinatal period to the sixth decade of life, with a large variety of psychiatric, neurological, pulmonary, hepatic, or splenic signs. Neurologic progression is independent from other systemic involvement. Cases have been categorized based on age of onset and predominant symptoms:

Perinatal: Symptoms may be variable and nonspecific, with liver disease (cholestasis, hepatosplenomegaly, ascites) as the most frequent sign. A minority of cases develop rapid liver failure without neurologic symptoms or pulmonary failure secondary to infiltration of lungs with foam cells.

Infantile: Isolated hepatosplenomegaly, though not always present, may be the only sign until 12–18 months, when hypotonia, developmental delay or regression, pyramidal signs, and ataxia may develop.

Childhood/adolescent: The most common manifestation, accounting for 60–70% of cases. Ataxic gait is common with presentation at age of 3–5, while cognitive decline and decreased fine motor control are more commonly seen with onset between 6 and 12 years. Frequent signs include ataxia, dystonia, dysarthria, choreoathetoid movements, intellectual impairment, and vertical supranuclear gaze palsy (VSGP). One-third may develop seizures, and gelastic cataplexy occurs in 10–20%. Dystonia typically develops distally, spreading proximally to become generalized. Later complications include spasticity, pyramidal signs, psychosis, and severe dysphagia. Visceromegaly is less common than in earlier presentations.

Adult: Late presentations are rare, with prominent psychiatric or cognitive disturbance possibly overshadowing other signs of the disease, mimicking schizophrenia, depression, or bipolar disease. Clinical signs are similar to earlier phenotypes, including ataxia (76%), VSGP (75%), dysarthria (63%), or cognitive decline (61%); movement disorders occur in 58%, including dystonia (40%), chorea (19%), or parkinsonism (10%). Progression is slower, with less frequent occurrence of seizures, cataplexy, or visceromegaly. Rare cases have presented with isolated splenomegaly or spontaneous splenic rupture.

Differential Diagnosis

The differential diagnosis is broad and varies by age of onset and phenotype. In younger patients, other storage diseases (Gaucher's disease, other forms of NP) or inborn errors of metabolism, Wilson's disease, mitochondrial

disorders, dopa-responsive or primary dystonia, encephalitis, or other dementing illnesses should be considered. Adult presentations may mimic primary psychiatric disease, multiple sclerosis, or neurodegenerative disorders such as Alzheimer's disease, frontotemporal dementia, or progressive supranuclear palsy.

Diagnostic Work up/Tests

Diagnosis of NPC may be confirmed by biochemical or genetic testing, which has superseded the need for tissue biopsies:

Biochemical testing: Diagnosis of NPC can be confirmed by the demonstration of abnormal intracellular cholesterol homeostasis. In majority of cases, affected cells show the classic results of markedly reduced or absent cholesterol esterification after loading cultured fibroblasts (obtained by skin biopsy) with exogenous low density lipoprotein (LDL)-type cholesterol. In addition, staining of fibroblasts with filipin shows a punctate, perinuclear pattern of fluorescence, highlighting the accumulation of unesterified cholesterol (**Figure 1**). In 15% of affected individuals, more commonly in adult cases, there may be a 'variant' biochemical phenotype, with less distinctive staining patterns or intermediate cholesterol esterification abnormalities. Normal ASM activity in leukocytes excludes other forms of NP.

Genetic testing: Molecular genetic testing is mainly used to confirm the diagnosis of NPC in cases with equivocal findings on biochemical testing. Given the size of the *NPC1* gene, the large number of known mutations, and high frequency of polymorphisms, interpretation of DNA changes may be difficult.

Histology: Microscopic examination of spleen, liver, or bone marrow may demonstrate the presence of lipid-laden macrophages (foam cells), with sea-blue histiocytes in the bone marrow of advanced cases. Brain tissue examination demonstrates minimal cholesterol deposition and marked accumulation of multiple glycolipids in gray matter, with numerous, widespread degenerative changes in cortical and subcortical neurons, manifest earliest in the cerebellum and brainstem. Purkinje cells are most vulnerable to NPC pathology, accounting for the high incidence of ataxia seen clinically. Chronic cases may display neurofibrillary tangle pathology remarkably similar in quality and distribution to Alzheimer's disease, in addition to accumulation of amyloid precursor protein. Polymorphous cytoplasmic bodies may be seen with electron microscopy of brain, conjunctival, rectal, or skin tissues, and are more pathognomonic for NPC than light microscopic findings.

Neuroimaging: Imaging findings are nonspecific, and may be normal in early stages, with only late development of prominent cerebellar, callosal, and cerebral atrophy or periatrial white matter abnormalities.

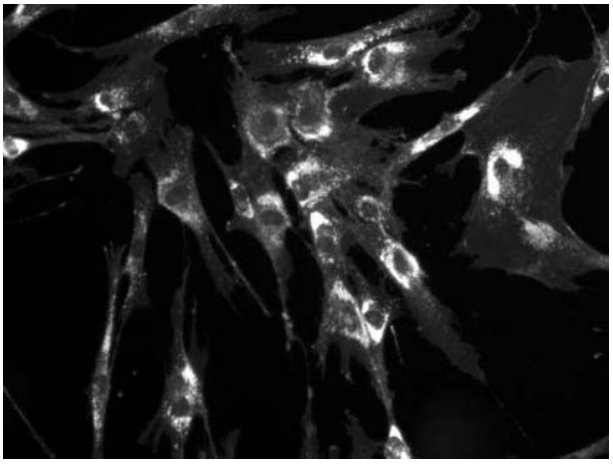

Figure 1 Filipin-stained cultured skin fibroblasts in the classic form of NPC show increased perinuclear fluorescence, reflecting abnormal accumulation patterns of unesterified cholesterol.

Management

There is no specific treatment for NPC, although several treatment approaches are being investigated. As demonstrated in a randomized controlled trial, Miglustat is the only agent to show improvement or stabilization of markers of neurologic progression in some patients. Miglustat is an inhibitor of ganglioside synthesis currently used to treat Gaucher's disease, and crosses the blood–brain barrier to reduce the biosynthesis of glycosphingolipids, resulting not only in the reduction of pathological substrates in the brain but possibly the normalization of lipid trafficking abnormalities. Neither strategies to reduce somatic or hepatic lipid overload, including low-cholesterol diets and various combinations of cholesterol lowering agents, nor hepatic or bone marrow transplantation have altered the course of neurodegeneration.

Symptomatic treatment is indicated for the management of dystonia, spasticity, seizures, or sleep disorders. Cataplexy has responded to clomipramine or modafanil. Secondary complications may be prevented by monitoring swallowing, gastrointestinal, and respiratory function for avoidance of aspiration, malnutrition, or severe constipation. Physical, occupational, and speech therapy may assist in functional adaptation and prevent complications of immobility. Genetic counseling is indicated for family planning and guidance of testing for other family members.

Prognosis

The rate of disease progression is variable, depending on age of presentation. Neonatal disease may cause death within months, while patients presenting in childhood

usually die before the age of 5. Childhood/adolescent forms typically die in teenage years from aspiration pneumonia, but have been reported to survive to the fourth decade. Adult onset forms may have prolonged courses, potentially over 2–3 decades.

Nitric Oxide

C Rajakumar and N Rajakumar, The University of Western Ontario, London, ON, Canada

Glossary

Apoptosis – A process of programmed cell death where cells die in a controlled and regulated manner.
Cyclic GMP (cGMP) – A second messenger similar to cyclic AMP. Nitric oxide activates guanylate cyclase to produce cGMP from GTP.
NMDA receptor – An ionotropic receptor for glutamate, critical for learning and synaptic plasticity by means of allowing the influx of calcium ions.
Nitric oxide – A gaseous molecule that participates in several physiological and pathological processes in neurons and other mammalian cells.
***S*-nitrosylation** – A process of modification of cysteine residues in proteins by nitric oxide.

Definition

Nitric oxide (NO) is a gaseous molecule with autocrine and paracrine effects on many cell types. NO is synthesized from the amino acid L-arginine by NO synthase (NOS) and is involved in a myriad of cellular functions, including muscle relaxation, neuronal signaling, and immune function. NO synthesis is dependent on the availability of cofactors such as tetrahydrobiopterin (BH4), heme, flavin adenine dinucleotide (FAD), and reduced nicotinamide–adenine dinucleotide phosphate (NADPH). The rate limiting enzyme, NOS, exists in three different isoforms: neuronal NOS (nNOS), endothelial NOS (eNOS), and inducible NOS (iNOS). nNOS and eNOS are Ca^{2+}/calmodulin-dependent, constitutively active enzymes, whereas the activity of iNOS is independent of Ca^{2+}. The human nNOS gene is located on chromosome 12, iNOS on chromosome 17, and eNOS on chromosome 7. nNOS has been localized to discrete populations of central neurons and in peripheral autonomic nerves; eNOS is abundant in endothelial cells, including cerebral blood vessels, while iNOS can be induced in macrophages, astrocytes, and microglia following injury or inflammation. In the brain, nNOS labeling coexists with NADPH-diaphorase staining, and purified nNOS shows NADPH-diaphorase activity.

NO may diffuse readily across plasma membranes up to 200 μM in vivo in normal brain tissue. Under physiological conditions, NO may affect neuronal function by at least two independent mechanisms: (1) NO activates soluble guanylyl cyclase and increases intracellular levels of cyclic guanine monophosphate (cGMP) that in turn modulates neurotransmitter release, receptor efficacy, signaling, and synaptic plasticity and (2) NO *S*-nitrosylates a variety of

proteins, including NMDA receptor subunits, catalytic subunits of caspases, α-tubulin, and sodium pump ATPase, thereby affecting intracellular signaling. In addition, by modulating the release of neurotransmitters, NO affects neurotransmission indirectly. NO increases the release of dopamine and serotonin in the rat medial preoptic area, and noradrenaline and glutamate in the hippocampus, while suppressing GABA release in the hippocampus. At physiological concentrations, NO is neuroprotective, although higher levels may be neurotoxic.

nNOS-containing neurons are abundant in motor areas of the brain, including the frontal cortex, basal ganglia, pontine tegmentum, midbrain dopaminergic centers, and the cerebellum. NO participates in physiological activities in these centers, including altering neurotransmitter release, modulating the efficacy of receptor function and signaling, and synaptic plasticity. NO also regulates long-term depression in striatal neurons, an effect critical for learning and motor control of basal ganglia.

nNOS-containing neurons are distributed throughout the cerebral cortex and in the subcortical white matter. In rat sensorimotor cortex, they are aspiny interneurons, which coexpress GABA and are distributed primarily in layers II and III. NADPH-diaphorase or nNOS activity is seen in ~2% of striatal neurons and is localized to a subpopulation of GABAergic interneurons containing somatostatin and neuropeptide Y in all mammals. NADPH-diaphorase-containing striatal neurons in rats receive glutamatergic projections from the cerebral cortex, GABAergic fibers from the globus pallidus external segment, dopaminergic projections from the substantia nigra pars compacta, and innervate striatal projection neurons. Burst firing of nigral dopaminergic neurons activates striatal nNOS neurons via D_5 dopamine receptors, leading to the synthesis of NO that increases the levels of cGMP in striatal projection neurons, facilitating long-term depression at corticostriatal synapses. nNOS is physically attached to the postsynaptic density protein 95 (PSD95) which is part of the NMDA receptor complex. Consequently, NMDA activity in the striatum causes nNOS-mediated NO synthesis and a subsequent increase in cGMP levels. In cholinergic neurons, this leads to NMDA-induced acetylcholine release in the striatum.

Pharmacological blockade of nNOS suppresses spontaneous locomotion and exploratory activity in rats. Coadministration of nNOS inhibitors reduces the hyperlocomotion produced by the NMDA antagonists or dopamine agonists. However, no abnormalities have been observed in the voluntary motor activity or basal ganglia function in mice following targeted deletion of nNOS. Interestingly, these mice showed deficits in balance and coordination only in the dark, while their visual acuity appeared normal. In addition, the male $nNOS^{-/-}$ mice are hyperaggressive and show increased sexual behavior. It is worth noting that in these mice, NADPH-diaphorase activity is only partially reduced in the cerebral cortex and the striatum, while the cerebellum and amygdala showed a complete loss of activity.

Increased concentrations of NO affect mitochondrial function, facilitate apoptotic signaling, and promote oxidation, nitration, and excessive *S*-nitrosylation of proteins, leading to interference with their function and clearance, and thereby causing neurotoxicity. nNOS is physically coupled to NMDA receptors and excessive NMDA activity leads to increased production of NO, augmenting the excitotoxicity. Increased concentrations of NO inhibit cytochrome C oxidase (COX), leading to disruption of mitochondrial membrane integrity and depletion of cellular energy, allowing the diffusion of superoxide ions from mitochondria. Apart from this, superoxide ions are also produced as a by-product of dopamine metabolism. Superoxide ions avidly bind to NO to form peroxynitrite, which is degraded into hydroxyl and reactive oxygen radicals. These free radicals, along with peroxynitrite, cause serious damage to proteins, lipids, and DNA, forcing cells to undergo apoptosis. NO and these radicals themselves and the process of DNA damage activate poly-ADP-ribose-polymerase (PARP) to cause further depletion of energy, thereby driving cells toward apoptosis. PARP also facilitates translocation of apoptosis-inducing factor (AIF) from the mitochondria to the nucleus to cause further DNA damage (**Figure 1**).

Excessive levels of NO also lead to nitration of molecules causing impairment of cellular functions. High levels of nitrotyrosine have been seen in the brains of patients with Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis, and Alzheimer's disease. Apart from nitration, NO-mediated *S*-nitrosylation of reactive cysteine residues of proteins interferes with their function and clearance. NO-mediated *S*-nitrosylation of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) facilitates the formation and nuclear translocation of mutant Huntingtin-GAPDH-Siah 1 complex in the neurodegenerative process of striatal neurons in Huntington's disease. Similarly, NO *S*-nitrosylates parkin. Parkin is a ubiquitin ligase involved in protein degradation via the ubiquitin–proteosome system, and mutations of parkin are the most common cause of familial, early-onset parkinsonism.

In conclusion, NO is produced in the brain by neurons, astrocytes, microglia, and endothelial cells, and participates in a number of physiological functions such as learning and plasticity, as well as several degenerative processes. NO mediates its effects by increasing the concentration of cGMP, and causing oxidation, nitration, and *S*-nitrosylation of cellular proteins. At high concentrations, NO affects mitochondrial permeability, impairs cellular energy production, alters protein structure, trafficking, function and degradation, causes DNA damage, and induces the apoptotic-signaling

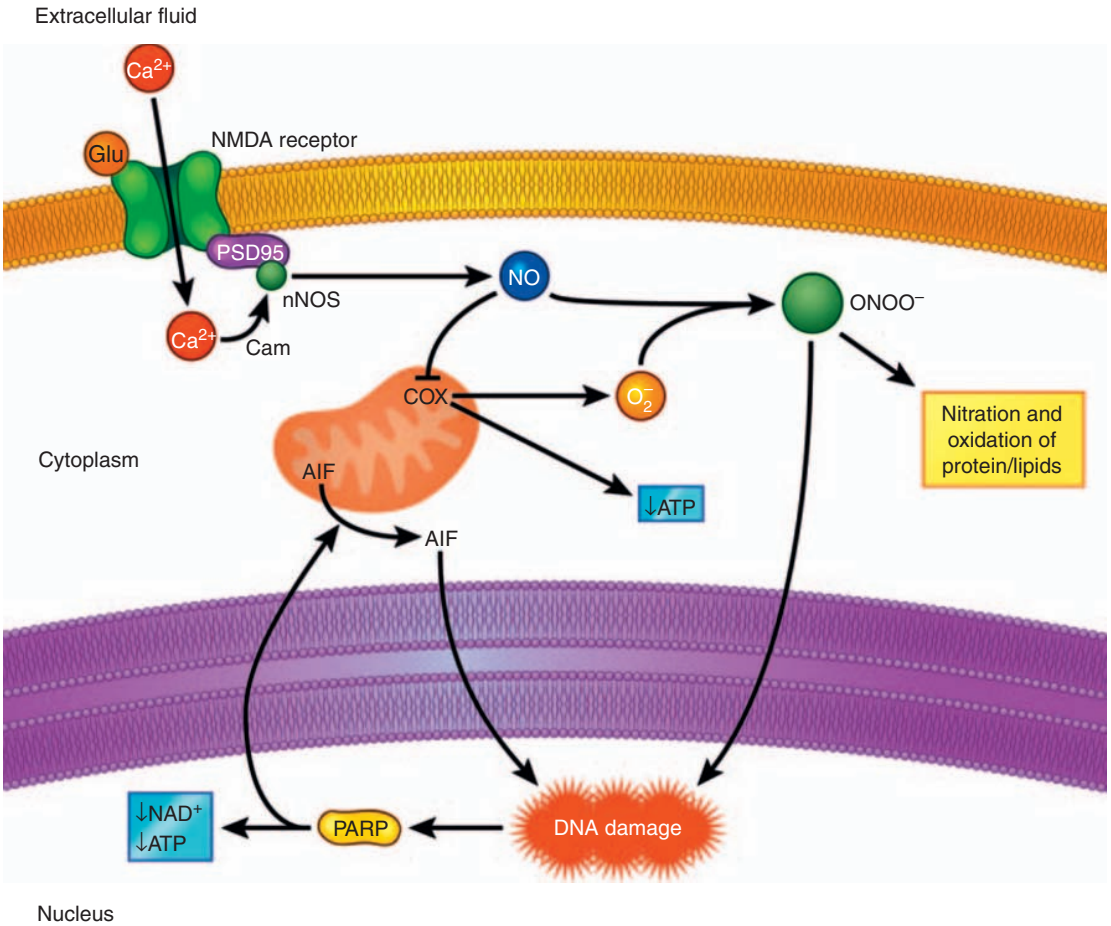

Figure 1 Glutamate binding to NMDA receptors results in Ca^{2+} influx leading to a local increase in Ca^{2+} concentration and the consequent formation of the calcium–calmodulin complex that activates nNOS at the postsynaptic density. Activated nNOS produces NO that rapidly defuses and blocks COX, leading to a reduction in ATP and compromised mitochondrial permeability, allowing diffusion of superoxide ions (O_2^-) from mitochondria. Superoxide ions bind to NO and form peroxynitrite ($ONOO^-$). Peroxynitrite diffuses freely and cause nitration and oxidation of proteins and lipids, and DNA damage. DNA damage activates PARP. Activated PARP depletes energy production by depleting the levels of NAD^+, as well as facilitating the translocation of AIF from the mitochondria to the nucleus to cause further DNA damage leading to apoptosis.

cascade. NO signaling is emerging as a potential therapeutic target in neurological disorders such as Parkinson's and Huntington's disease.

Normal Pressure Hydrocephalus

G Rosseau, CINN Medical Group, Chicago, IL, USA

Glossary

Class 1 evidence – Data derived from prospective, randomized, controlled clinical trials;
Class 2 evidence – Prospective data collection with retrospective analysis of clearly reliable data;
Class 3 evidence – Studies based on retrospective analysis, such as chart reviews, clinical series, data bases or registries, case reports, and expert opinion.
Evidence-based medicine – The conscientious, explicit, and judicious use of current best published scientific evidence in making decisions regarding patient care strategies. The quality of the scientific evidence is grouped into three classes, as follows:
Guideline – A particular strategy or range of management strategies that reflect a *moderate* degree of clinical certainty.
Guidelines for clinical practice – Evidence-based medical treatments are based on a systematic analysis of all available scientific literature on a topic, and are divided into three categories, defined as follows:
Hydrocephalus – Pathologic condition characterized by abnormally elevated cerebrospinal fluid pressure.
Idiopathic normal pressure hydrocephalus (iNPH) – Clinical syndrome characterized by gait ataxia, dementia, and urinary incontinence with evidence of ventriculomegaly on an imaging study and favorable response to reduction in cerebrospinal fluid pressure.
Lumbar drainage trial – Inpatient diagnostic test for iNPH in which a sterile, flexible catheter is placed in the lumbar spine for several days and serial assessment of gait, cognition, and continence are assessed; generally used to predict probability of favorable response to cerebrospinal fluid shunting procedure.
Options – Remaining strategies for patient management for which there is *unclear* clinical certainty.
Standard – Accepted principles of management that reflect a *high* degree of clinical certainty.
Ventriculomegaly – Imaging evidence of abnormally large ventricular size; usually refers to CT or MR images.

Definition and History

Hydrocephalus has been recognized as a cause of brain dysfunction and movement disorders for several centuries. (**Figure 1**) The first use of the term 'normal pressure hydrocephalus (NPH)' appeared in 1964 in a thesis by the Columbian neurosurgeon Salomon Hakim '*Some Observations on CSF Pressure: Hydrocephalic Syndrome in Adults With 'Normal' CSF Pressure.*' The concept was more fully developed in an article that appeared the next year in the *New England Journal of Medicine*. This article described a newly recognized syndrome in aging adult patients who were discovered to have ventriculomegaly *without* increased intracranial pressure after presenting to medical attention with gait difficulty, cognitive disturbance, and urinary incontinence. Subsequent work described improvement in the symptoms of patients with the 'classical triad' of gait ataxia, dementia, and incontinence with lowering of cerebrospinal fluid (CSF) pressure.

At the current time, the most common definition of idiopathic normal pressure hydrocephalus (iNPH) is a progressive disorder, without identifiable cause, that results in reported and observed gait ataxia, cognitive loss, and/or urinary incontinence, accompanied by imaging evidence of ventriculomegaly.

Pathogenesis/Pathophysiology

The initial description of NPH as 'symptomatic occult hydrocephalus with "normal" CSF pressure' included one patient with idiopathic and two patients with posttraumatic hydrocephalus. This, as well as the recognition that patients with subarachnoid hemorrhage, stroke, and meningitis could also develop ventriculomegaly without elevated pressure on the lumbar puncture (LP) led to controversies regarding the nomenclature, diagnosis, and treatment of the condition.

The gait disturbance in iNPH appears to be a disturbance of the phased activation of muscle groups, as would be observed in dysfunction of subcortical motor control, rather than a primary pyramidal tract imbalance. Dysfunction of the subcortical dopaminergic pathways may also contribute to the gait disturbance.

In regard to dementia, the locus of dysfunction in iNPH is not known, but the frontostriatal system and periventricular projection fibers have been implicated. In addition to cognitive disturbances, psychiatric features with behavioral disturbances ranging from aggressiveness

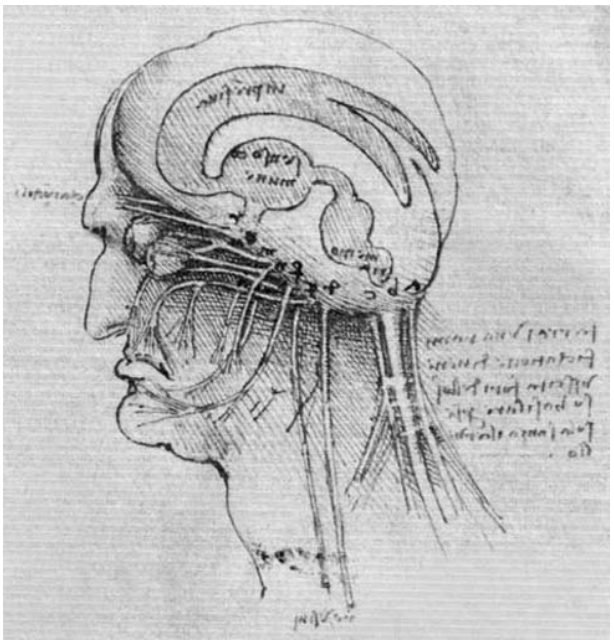

Figure 1 Leonardo da Vinci (1452–1519): Anatomic study of the ventricular system.

and impaired impulse control to depression and hallucinations have been reported, but their association with iNPH is poorly understood.

There are no generally accepted neuropathological criteria for postmortem diagnosis of iNPH. While potentially causative abnormalities, such as arachnoid fibrosis, have been reported in postmortem brain autopsies of some patients who carried the diagnosis of INPH, this has not been studied in a systemic manner, and therefore, cannot verify a clinical diagnosis of iNPH.

Epidemiology/Risk Factors

There is an ongoing need for standardized diagnostic criteria that will permit study of the incidence and prevalence of iNPH. These results may differ among the community-independent, community-assisted, and institutionalized populations. Details of age, gender, comorbidities, and risk factors need to be collected and analyzed to determine the extent of the problem, and to plan diagnostic and treatment services for a growing elderly population in North America.

Clinical Features and Diagnostic Criteria

Clinicians of multiple medical specialties may be the initial evaluator of a patient with suspected iNPH, including internal and family medicine, neurology, neurosurgery, gerontology, urology, and psychiatry. It is, therefore, important that the presenting symptoms and signs, and initial noninvasive diagnostic evaluation be widely understood. As cognitive disturbance is a hallmark of the condition, a knowledgeable informant who can describe the change in the patient's condition over a period of several years is very helpful.

Clinical Diagnosis

All three components of the classic triad of gait, cognitive, and sphincteric disturbance need not be present to establish the diagnosis of iNPH. Medical students have coined the mnemonic 'wobbly, weird, and wet' to help themselves, as well as patients and families, keep in mind the three clinical components of this condition. The initial clinical manifestation and order of appearance of symptoms is variable. The most common and earliest abnormality is usually gait ataxia. Signs and symptoms in iNPH are bilateral, unless accompanied by an identifiable comorbidity, such as stroke or lumbar degenerative spine disease, that accounts for a lateralizing feature. Dementia does not occur in all patients, and its speed of progression and severity are variable. Urinary urgency and incontinence in iNPH are difficult to distinguish from other causes of such urologic dysfunction, and may be secondary to the gait disturbance, which may prevent the patient from attending to an urge to void in a timely manner.

Gait

The gait disturbance in iNPH is often likened to walking on a boat: wide-based, side-to-side, bent forward, and with feet 'glued' to the deck. It is described as 'magnetic' and with a characteristic manner of turning that requires several steps, and is referred to as 'en bloc' or clocklike, rather than the easy pivot of a healthy turn. Videotape or computer analysis reveals reduced speed, decreased step height, and stiffness resulting from reduced counter rotation of the shoulders and pelvis during walking.

Dementia

Impaired speed and accuracy of gross and fine motor functions, decreased attention and apathy, impaired executive function, and personality/behavior changes are all observed. Often, these features of the clinical presentation are best described by family and friends. Neuropsychologic testing and mini-mental status testing (MMSE), as well as functional scales of wellness, are useful in establishing the degree of disability and assessing response to treatment.

The cognitive disturbance in iNPH includes slowed reaction time and recall, inattention, apathy, and decreased executive functions. Decreased volume and output of speech are common, but true aphasia is rare.

Imaging

Ventriculomegaly is most often a qualitative and subjective finding in clinical radiologic practice. Quantification of ventricular enlargement on CT or MR images is defined as an Evan's index of 0.3 or greater, reflecting an increased ratio of diameter of the biventricular size compared to the cranial size.

MRI provides additional anatomic detail, and may demonstrate periventricular halo on standard T-1 weighted images. Fluid-attenuated inversion recovery (FLAIR) sequences may best depict the degree of leukoaraiosis associated with iNPH. Both static and dynamic MR imaging may demonstrate the flow void associated with aqueductal stenosis. None of these studies are pathognomonic for iNPH.

The role of functional imaging techniques is under evaluation. This includes investigations such as single-photon emission computed tomography (SPECT) and positron emission tomography (PET). The routine use of these studies and/or the use of older investigations, such as nuclear cisternography, is not recommended.

Differential Diagnosis

Variations in the clinical presentation complicate the accurate diagnosis of iNPH and the frequency of comorbidities further complicates both the diagnosis and treatment of the condition. The vast majority of patients with iNPH will have comorbidities, which include cerebrovascular disease and neurodegenerative disorders, which both mimic features of iNPH and may coexist with iNPH in a single patient. In addition, several other causes of ventricular enlargement may also be observed in this population, including compensated childhood hydrocephalus, and the syndrome of long-standing overt ventriculomegaly in adults, both of which normally may be distinguished by enlarged head circumference and/or erosion of the sella turcica. In cerebral atrophy, passive enlargement of the ventricular walls by loss of brain volume produces 'hydrocephalus ex vacuo.' Secondary hydrocephalus is readily distinguished by its precipitating event, such as trauma, spontaneous subarachnoid hemorrhage, and/or meningitis. Aqueductal stenosis produces characteristic imaging abnormalities, with enlarged lateral and third ventricles and normal fourth ventricular size.

Hypertension, lumbar stenosis, peripheral neuropathy, and vestibular dysfunction may accompany or complicate the diagnosis of iNPH. In men, prostatism should be investigated as a common cause of urinary urgency and/or incontinence.

In general, patients in whom ventriculomegaly is associated with cerebrovascular disease, neurodegenerative disorders, and cerebral atrophy will not respond favorably to a lumbar drainage trial or CSF shunting procedures (**Table 1**).

Table 1 Conditions to consider in the differential diagnosis of iNPH

Neurodegenerative disorders
Alzheimer's disease
Parkinson's disease
Vascular dementia
Cerebrovascular disease
Stroke

Spinal stenosis
Wernicke's encephalopathy
Carcinomatous meningitis
Spinal cord tumor

Diagnostic Work-Up/Tests

A number of invasive and noninvasive tests have been used to establish the diagnosis of iNPH. In clinical practice, the diagnosis is most often suggested by clinical correlation of symptoms, physical exam, and imaging. The most reliable technique at present for selecting patients who would benefit from surgery appears to be a two-step process. In step 1, patients are selected for an inpatient trial of lumbar drainage based on an appropriate clinical history of one, two, or three components of the classical triad, correlative physical exam, and imaging study demonstrating ventriculomegaly. In step 2, patients undergo a 3-day inpatient lumbar drainage trial, with serial measurement of response of gait, cognition, and

continence to the lowered CSF pressure. Prolonged lumbar drainage of 300 ml or greater is associated with a sensitivity of 50–100%, and a positive predictive value of 80–100% in estimating favorable response to surgical treatment. Therefore, surgery is most readily offered to those patients who undergo prolonged lumbar drainage in whom improvement is documented on standardized gait scales and/or videotaped gait analysis.

In patients with iNPH, CSF opening pressure averages slightly higher than in normal subjects, but the range of pressures in iNPH overlaps the range of pressures observed in normal subjects.

A high volume LP, usually defined as removal of 40–50 ml of CSF, has been used in the outpatient setting as a diagnostic test, with symptoms assessed during the first 24 h after the procedure. Its low sensitivity, estimated at 26–61%, eliminates its utility as an exclusionary test. A positive response to a high volume LP is, nevertheless, a more reliable indicator of positive response to shunting than the clinical exam alone.

Measurement of CSF outflow resistance via an infusion test with lumbar catheter in place has a higher sensitivity at 57–100%. The positive predictive values for both the high volume LP and infusion test have been estimated to be 75–92%.

Some authors have suggested that the most reliable test for the diagnosis of iNPH is response to surgical placement of a ventriculoperitoneal shunt. Prolonged positive response to shunting has been estimated to occur less than 30% of the time when shunt placement is used as both diagnosis and treatment for iNPH. It seems preferable, therefore, to use other diagnostic criteria, including the invasive inpatient testing of a lumbar drainage trial, in order to allow more accurate patient selection prior to surgery.

Surgical Management

Surgical diversion of CSF is recommended in patients with iNPH in whom the benefits of surgical treatment outweigh the potential risks. There is little data on the degree or duration of improvement that may be expected with surgical treatment; degree of improvement with 3 days of lumbar drainage appears to be the best available estimate. Comorbidities such as functional status, cerebrovascular and cardiac status, and immune competency should be considered. The natural history of untreated iNPH has not been studied well.

The most common shunt configurations performed are ventriculoperitoneal and ventriculoatrial shunts. The ventriculoperitoneal shunt has the advantage of not requiring access to the vascular system, thus obviating the risk of the rare complication of shunt nephrosis caused by long-standing subclinical shunt infections. The ventriculoatrial shunt has the advantage of not being subject to dysfunction due to intraabdominal adhesions or pressures. Lumboperitoneal shunts are seldom used due to the difficulty in assessing their function, and lack of suitable configurations for valve placement. Endoscopic third ventriculostomy has been reported with some success, but needs confirmation, due to theoretical concerns that the intracranial pressures in iNPH may not be sufficient to maintain patency of the ventriculostomy.

Valve selection is a controversial and highly debated topic among neurosurgeons. Multiple valve types are available, including mechanisms based on differential pressure, gravity compensation, and flow limitation. The value of externally programmable valves has not definitively been established.

Complications include immediate and delayed adverse procedure-related effects. The risk of intracerebral hematoma along the ventricular catheter track may be as high as 3%. Delayed morbity includes infection (3–6%), seizures (3–11%), subdural hematomas or effusions (2–17%), and other complications of overdrainage and underdraingage of CSF. The risk that patients may require operative shunt revision in the first 5 years after surgery may be as high as 21%.

Prognosis

Patients whose symptoms of gait disturbance, dementia, and/or urinary incontinence have been of 2 years or less in duration tend to be more responsive to surgical treatment than patients with more advanced or longstanding manifestations of the clinical triad of iNPH. Thus, early diagnosis and intervention is recommended for optimal outcomes.

Summary

NPH is increasingly recognized as a treatable cause of gait disturbance, cognitive decline, and urinary incontinence in the aging population. The impact of treatment on both improved quality of life and decreased need for institutional care is potentially substantial, and will only increase as the population ages. This article provides a state of the art review of the presentation, diagnosis, surgical treatment, and clinical management of iNPH. In particular, new clinical guidelines and recently developed programmable valve technology that make the diagnosis more sure and the treatment safer are detailed.

NR4A Subfamily

W Le, Baylor College of Medicine, Houston, TX, USA
S Chen, Shanghai Jiao Tong University, Shanghai, China

NR4A Subfamily

The NR4A subfamily includes three members, notably NUR77 (NGFI-B/TR3/NAK-1/N10/ST59/T1S1/NR4A1), NURR1 (NR4A2/NOT/TINUR/RNR-1/HZF-3), and NOR-1 (MI-NOR/TEC/CHN/NOR-2/NR4A3). Since the ligands for these transcription factors have not yet been found, they are member of 'orphan' nuclear receptor superfamily of transcription factors. NR4A subfamily consists of a central DNA-binding domain (DBD), a C-terminal ligand-binding domain (LBD), and a N-terminal transactivation domain. These family members have been shown to play an important neuroendocrine regulatory role at all levels of the hypothalamic/pituitary/adrenal axis, and they participate in cell proliferation, growth, differentiation, and apoptosis. In addition, these transcription factors are immediate-early genes (IEG) whose expression and activity are regulated in cell-specific manner by a variety of extracellular mitogenic, apoptotic, and differentiation stimuli with a rapid and transient manner. Protein kinase A, protein kinase C, calcium–calcineurin, nuclear factor kappa B (NF-κb), and mitogen-activated pathway kinases (MAPK) are upstream signal of NR4A members. These signals can activate the expression of cyclic adenosine monophosphate responsive element-binding protein, activator protein 1, and myocyte enhancer

factor 2 (MEF-2), which leads to an upregulation of expression of NR4A through interaction with NR4A promoters.

The members of the NR4A subfamily are well conserved in the DBD (~91–95% homology) and the C-terminal LBD (~60% homology), but are divergent in the N-terminal domain (~30% homology).

Nurr1

NURR1 was mapped to human chromosome 2q22–q23 in 1994. The DNA sequence of *Nurr1*, especially in the CyS2–CyS2, overlaps with that of *NURR77 and NOR-1. Nurr1* is expressed predominantly in the central nervous system (CNS), especially in substantia nigra (SN), ventral tegmental area (VTA), limbic area, olfactory bulb, hippocampus, temporal cortex, subiculum, cerebellum, posterior hypothalamus, and habenuclear nuclei. *Nurr1* plays a critical role in the development of dopamine (DA) neurons. Nur77 and NOR-1 are highly expressed in vascular smooth muscle cells (SMCs) and atherosclerotic lesion macrophages or foam cells. Nur77 and NOR-1 are involved in vascular response to injury through inhibiting the process of inflammation includes the formation of macrophage form cell in vascular-endothelia.

Structure of *Nurr1* Gene

Nurr1 gene embraces eight exons and seven introns; the total length of the gene is 9.822 kb (**Figure 1(a)**). The open reading frame of *Nurr1* gene contains 1794 bases that encode for 598 amino acids. The initiation site of translation is in the third exon, and the termination of translation is at the upstream region of the eighth exon. There is a 3′-untranslated region (UTR) that contains ATTTA repetitive sequence at the downstream region of the eighth exon, and the total length is ~0.3 kb. UTR is important for the stabilization of mRNA transcription. This feature of *Nurr1* gene as an immediate early gene facilitates rapid transcription in response to stimulation by any of the several factors involved in the regulation of the gene expression. Promoter and transcription regulatory element (cAMP-response element, CRE, CArG-like element, SP-1 element) of *Nurr1* is located at the upstream region of transcription initiation site. CRE plays an important role in the signal transduction mediated by cAMP. The sequence of CArG-like element, CC (A/T) 7GG, takes part in the transcription regulation, which is known to participate in delayed early response. The sequence of human *NURR1* gene is highly conserved compared with the *Nurr1* gene of mice. Many transcription regulators can regulate the expression of *Nurr1* gene through interaction with CRE. Parathyroid hormone (PTH) can

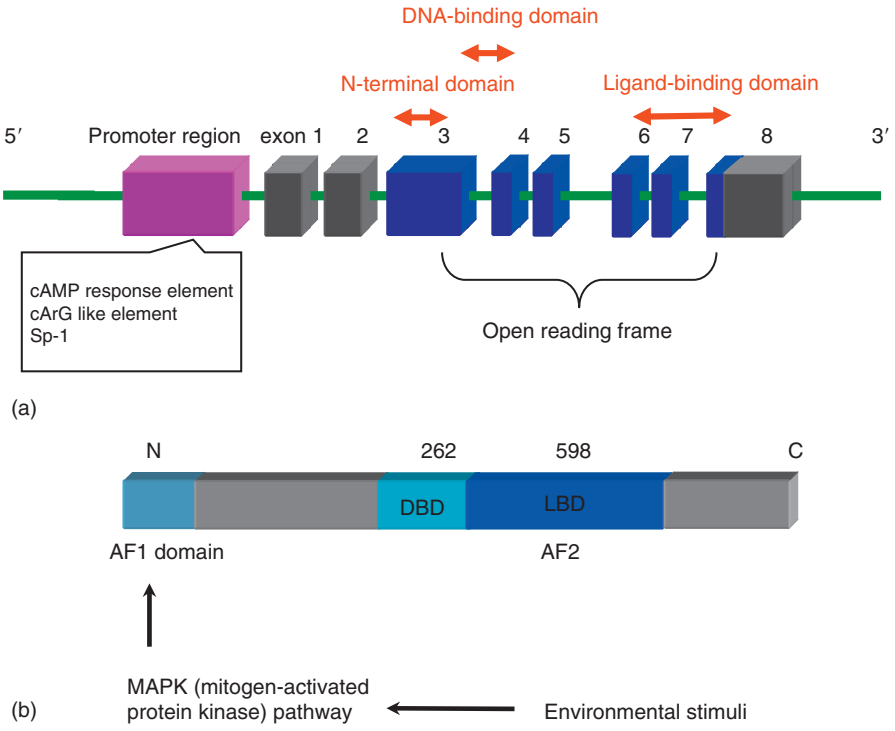

Figure 1 The structure of *Nurr1* gene and protein. (a) *Nurr1* gene includes eight exons. The open reading frame initiates in the third exon and terminates at the upstream region of the eighth exon that encode for 598 amino acids. Promotor region contains three elements: CRE, cArG, and SP-1. Four mutation sites located in exon 1 and 3 have been identified with PD. (b) Nurr1 contains DBD (DNA-binding domain) and ligand-binding domain (LBD) AF1 domain is in N terminal region that can be activated by MAPK pathway due to the environmental stimuli.

induce expression of *Nurr1* in bone cells. This process is mediated primarily through the cAMP/PKA pathway.

Structure of Nurr1 Protein

Nurr1 includes three major parts: LBD, DBD in the central region of Nurr1, and variable region (**Figure 1(b)**). Nurr1 LBD, similar to the LBD of holo retinoic acid receptor γ (RARγ), adopts a canonical protein fold resembling that of agonist-bound and transcriptional active LBDs in nuclear receptor. The structure of Nurr1 has two distinctive features. The first feature is that Nurr1 LBD has no cavity that is normally occupied by ligands because of the tight packing chains from several bulky hydrophobic residues. The second feature is that Nurr1 LBD lacks the binding site for coactivators. DBD of Nurr1 is well-conserved (over 90% homology) and consists of two zinc-fingers which can bind to nerve growth factor inducible-β-binding response element; NGFI-B response element (NBRE: AAAGGTCA) of DNA as monomers or to the palindromic Nur-responsive element (NurRE: TGATATTTX6AAAGTCCA) as homodimers, which participates in the process of transcription that includes the activation of expression of tyrosine hydroxylase (TH) and dopamine transporter (DAT). In addition, Nurr1 can also form heterodimers with retinoid X receptor (RXR) and binding to RXR response element. Nurr1 contains an amino-terminal activation function 1 (AF1) domain and a carboxy-terminal activation function 2 (AF2) domain, both of which are important for transcriptional activity. N-terminal region (AF1) of Nurr1 is highly conserved, which can be activated by mitogen-activated protein kinase (MAPK) pathway as a consequence of several environmental stimuli.

Isoforms of Nurr1

Because of multiplicity of cleavage and splicing, there are at least six isoforms of Nurr1 (Nurr1a, Nurr1b, Nurr1c, TINUR, Nurr2, Nurr2c) that have been reported. Nurr1a lacks the carboxy-terminus (most of LBD and entire AF2 domain) produced by an alternative splicing in exon 7, which exhibits less transcription activity than Nurr1. The LBD of Nurr1b lacks 18 amino acids, but the carboxy-terminus is intact. The function of Nurr1b is not known yet. An alternative splicing in exon 3, truncating the AF1 domain, produce transcriptional inducible nuclear receptor (TINUR), which is known to be dominant negative. Nurr2 is produced by alternative splicing of exon 3 and exon 7, truncating of Nurr1a and TINUR. Both Nurr2 and Nurr2c have no intrinsic activity, but bind to Nurr-response DNA sequence such as NBRE. A novel splicing variant of Nurr1, named Nurr1c, has been identified in non-neuronal tissues including lymphocytes, liver, muscle, and kidney, which has 25 amino acids deletion in the C-terminal region of exon 5. This splicing variant shows a significant reduction of luciferase activity in vitro as compared to Nurr1.

Nurr1 Distribution in CNS

Nurr1 is distributed widely in cell nucleus in CNS, especially in DA neurons. The proportion of neurons that expressed Nurr1 is 96% in SN, 95% in VTA, 91% in liner nucleus raphe, 85% in olfactory bulb, and 61% in cortex. Neurons of paraventricular area and nucleus of hypothalamus only modestly express Nurr1 and TH, whereas the noradrenaline neurons in the brainstem do not express Nurr1. Thus, the expression of Nurr1 is confined to periglomerular cells of the olfactory bulb, and DA neurons to mesencephalon. The level of Nurr1 expression is different in the different stages of development. While it is highest in the embryonic stage than other stages, its expression remains high in DA neurons throughout life.

Function of Nurr1 in Central Nerves System

Nurr1 is first expressed at E10.5 in the mouse, just before Pitx-3 and TH (E11.5). Nurr1 is essential for differentiation of the mesencephalic DA precursor cells as well as maintains the function of the DA neurons. Numerous lines of evidence demonstrates that dysfunction of Nurr1 is related with degeneration of DA neurons. Nurr1 can regulate several gene expressions, including TH, L-aromatic amino acid decarboxylase (AADC), DAT, and vesicular monoamine transporter (VMAT-2). These genes are essential for synthesis, transport, and secretion of DA. Furthermore, Nurr1 can directly transactivate the osteocalcin gene and regulate adrenal aldosterone production. There is an emerging body of evidence suggesting a 'cross-talk' between Nurr1 and several other transcriptional factors and neurotrophic growth factors in different development and maturation stages of mensencephalic DA neurons. Lmx1b is a member of the LIM hemodomain family that is essential for the development of DA neurons. Pitx-3 is the bicoid-related homeodomain-containing transcription factor that is only expressed in mesencephalic DA neurons. Lmx1b–Pitx-3 pathway is critical for specific location of DA neurons in SN. Although the expression of these two factors is independent of Nurr1, Nurr1 may have a role in the maintenance of Lmx1b and Pitx-3 in the late stages of DA neuron development. Nurr1 may be associated with several neurotrophic factors such as glial-derived neurotrophic factor (GDNF) and fibroblast growth factor (FGF), which is important in the process of neuronal growth and differentiation. Nurr1 is essential for the expression of GDNF receptor Ret in mesencephalic DA neurons. Furthermore, in Nurr1-overexpression neuronal stem cells,

FGF-20 significantly promotes neuronal stem cells into TH-positive neurons, indicating a 'cross-interaction' between Nurr1 and neurotrophic factors. Nurr1 also interacts with Wnts, a family of glycoproteins that regulates cell proliferation and differentiation. Another factor with which Nurr1 interacts is p57kip2, a kinase inhibitor of the CIP/KIP family, whose expression in postmitotic differentiating midbrain DA neurons partly depends on Nurr1. Nurr1 can also interact with the *GRIK5* gene, which codes for kainate receptor (KA2), a subunit of the glutamate receptor. Nurr1 is able to protect dopaminergic neurons by suppressing inflammatory gene expression in astrocytes and microglia. Nurr1 exerts anti-inflammatory effects by recruiting CoREST co-repressor complex to clear NF-κB-p65. Other downstream genes and interacting protiens of Nurr1 include SUMO (small ubiquitin-like modifier)-E3 ubiquitin-protein isopeptide ligase (PIASγ), Neurophilin 1, vasoactive intestinal peptide (VIP), P53, and Nurr1 interacting protein (NuIP).

Nurr1 and Parkinson's Disease (PD) and Related Disorders

Following evidence suggests that NURR1 may be associated with PD and several other neurodegenerative disorders: (1) PD patients have declined NURR1-ir in DA neurons which contains α-synuclein inclusions in SN. (2) Quantitatively measuring the level of NURR1 mRNA in human peripheral blood lymphocytes has revealed a significant decrease in individuals with PD and parkinsonian syndromes. These results suggest that *NURR1* might be useful biomarker for early diagnosis of PD and related disease. (3) Abnormalities in *NURR1* gene might be a risk factor for both familial PD and sporadic PD. Genetic analyses in 201 individuals with PD identified two variants in NURR1 (−291T del and −245 T → G), which mapping to in 5′ untranslated region of the first exon and affect one allele in apparently autosomal dominant form of familial PD but not in sporadic cases. Recently, two novel variants at exon 3 of *NURR1* gene were identified in two nonfamilial PD patients. First, a heterozygous C→G transversion at exon 3 (−253) changes the amino acid serine to cysteine, and the second is a −223C → T sequence. Both of these mutations affect phosphorylation procedure in transcription of the gene encoding TH. Furthermore, one of the single nucleotide polymorphisms (SNP) is in the BseRI restriction site resulting in a homozygous7048G7049 in intron 6 (NI6P), which shows a significantly higher frequency in familial and sporadic PD and diffuse Lewy body disease. (4) NURR1 is also reported in association with other diseases such as schizophrenia and depression. Two different missense mutations in the third exon of NURR1 have been found in two schizophrenic patients, and another missense mutation in the same exon has been found in manic-depressive patients. (5) Long-time uptake of cocaine may lead to markedly decreased level of NURR1 expression within the DA neurons. NURR1 is known to regulate transcription of the gene encoding the cocaine-sensitive DAT, which is markedly reduced in the DA neurons of NURR1-deficient cocaine abusers, suggesting that NURR1 plays a critical role in controlling human DAT gene expression and adaptation to repeated exposure to cocaine.

Nur77 and *NOR-1*

Nur77 and NOR-1 are also early response genes. The activators of these transcriptional factors include 6-mercaptopurine (6-MP, a metabolite of the immunosuppressive drug azathioprine), prostaglandin A2 (PGA2), and certain 1, 1-Bis (3V-indolyl)-1-(psubstituted phenyl)-methanes as well as benzimidazole derivatives, which can bind to LBDs of these transcriptional proteins. Rapid and transient response to these activators as well as several unknown environmental stimuli is hallmark of Nur77 and NOR-1. The process of regulation of Nur77 and NOR-1 is through protein kinase A, protein kinase C, calcium–calcineurin, NF-κb, and mitogen-activated kinases (MAPK) pathways. Furthermore, Nur77 can also form heterodimers with RXR to bind DR5 motifs that mediate retinoid responses process, which could down-regulate and affect the activity of mitochondrial proteins such as Bcl-2 family and Cyt C, like Nurr1 protein, which indirectly participate in the process of mitochondrial-mediated cellular survival and apoptosis. In addition, Nur77 and NOR-1 can be phosphorylated by protein kinase B/Akt on the site of serine-350, which could suppress its activity of DNA-binding domain. These findings indicate a cross relationship between Nur77 and NOR-1 with function of cellular apoptosis, growth, differentiation, and survival.

NR4A Family and Atherosclerosis and Vein-Graft Disease

NR4A family members, Nur77 and NOR-1, are expressed in SMCs and macrophages, which can be regulated by several environmental stimuli and signals relevant to atherogenesis. Nur77 and NOR-1 can bind to NF-κb, which leads to the suppression of inflammatory gene expression. Atherosclerosis may result from the proliferation of SMC and macrophage as well as other factors responsible to the athero-injury such as stretch response leading to the reduction of $p27^{Kip1}$, calponin, and SMα-actin. This process can be inhibited by over-expression of Nur77 and NOR-1. Nur77 and NOR-1 can also suppress the expression of other inflammatory cytokines, including interleukin-1β (IL-1β), IL-6, chemokines IL-8, monocyte chemoattractant-1, macrophage

inflammatory protein-1a, and macrophage inflammatory protein-1b. Therefore, Nur77 and NOR-1 may promote a quiescent SMC phenotype and inhibit the formation of macrophage foam cell, and prevent cardiovascular sclerosis.

Glossary

Grasp reflex – Flexion clenching of the fingers or toes on stimulation of the palm or sole.
Neurotrophic factors – A generic term for any of a family of substances with roles in maintenance and survival of neurons.
Prepotent response – A response that is or has been previously associated with reinforcement.
Striatum – Include putamen and caudate nucleus.

Definition and History

The maturation of frontal and prefrontal cortex proceeds by construction and acquisition of novel behavioral functions and by inhibition of some reflexive or automatic reactions. Conversely, dysfunction of frontal and/or prefrontal cortex is related to impairment of the acquired neuronal function associated with a loss of inhibition of these neonatal reflexes. For example, the role of frontal cortex in aiding attention appears to depend on the inhibitory functions of frontal cortex. Thus, damaged frontal cortex fails to inhibit the tendency to be drawn towards any compelling or interesting stimulus, and to sharpen the signal-to-noise ratio. The absence of such inhibition results in difficulties for the subject to concentrate on a specific task. Similarly, inhibition of the grasp reflex depending on the maturation of the supplementary motor area or inhibition of the prepotent response tendencies depending on the maturation of the dorsolateral region of prefrontal cortex is also impaired when frontal cortex is injured. These latter reflexes have been carefully studied in both human and monkey infants by Diamond et al. They used a specifically designed task to assess the dorsolateral prefrontal function called the object retrieval detour task (ORDT). The ORDT was designed to evaluate the ability to inhibit the natural tendency to reach straight for what the subject wants when an object is seen through one of the closed sides of a transparent box. For example, an infant must inhibit the impuls to reach directly for the object, and instead detour around to the open side of the box. Between 6 and 12 months, human infants show a clear developmental progression in their ability to retrieve an object from inside a clear, open box whereas infant monkeys show similar developmental progression between 1.5 and 4 months after birth. Adult monkeys with a lesion of the dorsolateral prefrontal cortex show the same error on this task as do infants, whereas lesions located in the parietal cortex or hippocampus of adult monkeys do not induce any impairment in the ORDT.

Is the ORDT Task Capable of Detecting a Frontal-Type Cognitive Deficit Generated by Subcortical Neuronal Dysfunction?

Subcortical frontal cognitive deficits are observed in Parkinson's disease (PD), Wilson's disease, Progressive supranuclear palsy, and Huntington disease (HD). They can be clinically differentiated from deficits in other neurodegenerative diseases that primarily affect the cerebral cortex such as Alzheimer's disease, Creutzfeldt–Jakob, or Pick's disease. Qualitative cognitive performance analyses in diseases associated with subcortical dementia point not so much to altered cognitive programming, but rather to disruptions in initiation, planning, and use of these cognitive programs. Thus, cortical and subcortical dementias differ from each other by the disruption of these functions used to regulate cognitive behavior and by a relative preservation of instrumental 'activities' including memory and language.

It comes as no surprise that in late stage PD and HD patients, a frontal-type cognitive deficit is prevalent, as the head of the caudate nucleus receives fibers arising

from the dorsolateral prefrontal cortex and from the orbito-frontal cortex. Indeed, cardinal features of late stage PD and HD dementia include difficulties in retrieving memories, slowed information processing, cognitive inflexibility, perseverative behavior as well as a severe impairment in the ability to elaborate set-shifting strategies. The hypothesis that a primary striatal lesion could be associated with such a frontal-type syndrome has been reinforced by observations in patients presenting with uni- or bilateral infarcts in the caudate nucleus, who exhibit cognitive alterations very similar to those observed in HD.

All these observations therefore suggest that the dementia observed in PD and HD is of a frontal type, associated with subcortical damage and very similar to that observed in patients with lesions of the dorsolateral prefrontal cortex. Thus ORDT appears to be an appropriate cognitive task to detect such a frontal deficit in animal models of HD and PD.

Replication of a Subcortical Frontal-Type Cognitive Deficit in Nonhuman Primate

One possible way to develop such a primate model based on progressive bilateral caudate nucleus degeneration is to systemically administrate daily doses of a mitochondrial toxin, 3-nitropropionic acid (3NP), an irreversible inhibitor of succinate dehydrogenase.

The ORDT task was initially used in 3NP-treated primates to detect the earliest manifestation of frontal cognitive impairment during the initiation of 3NP intoxication. In primates, the ORDT is capable of assessing the ability to retrieve an object (in the present case, a piece of fruit) from inside a transparent box only open on one side (**Figure 1**(**a**)). The level of difficulty can be modified by the experimenter by varying the location of the box, the location of the reward in the box, and finally the orientation of the open side of the box in relation to the subject (**Figure 1**). Each ORDT test session consisted of 15 trials corresponding to different configurations related to either the position of the reward in the box or the position of the box on the tray facing the animals (**Figure 1**). The reward was visible to the animal only after raising an opaque screen placed between it and the box. Subjects were then allowed a 60-s time period to retrieve the reward, after which the screen was put back in place and the box set up for the next trial. The animals' responses were video recorded and measures of performance included: number of 'success' responses (retrieval of the reward on the first attempt of the trial), number of 'correct' responses (retrieval of the reward within the 60-s time period, whatever the strategy used by the animal to retrieve the piece of fruit). This 'correct' response represents the ability for the animal to perform the task. Finally, 'barrier hits' responses (hitting the closed transparent side of the box instead of making a detour) and 'motor problems' responses (reaching the open side of the box but failing to retrieve the reward) were quantified.

Following 4 weeks of systemic injection of a mitochondrial toxin 3NP, 4 consecutive ORDT test sessions were performed on a weekly basis in three baboons intoxicated with 3NP and their performances compared to those of 10 control animals. Compared to intact animals, 3NP-treated animals were significantly less successful in obtaining the

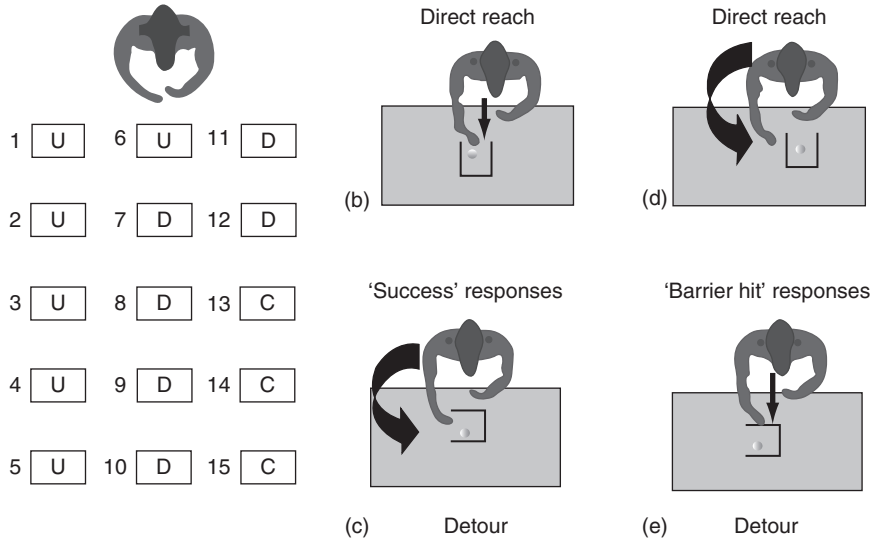

Figure 1 The ORDT: experimental set-up and principles. In the ORDT the ability of monkeys to retrieve an object from inside a transparent box only open on one side can be assessed. (a) A total of 15 different configurations are randomly presented to the animals. Measures of performance include: (b and c) number of 'success' responses (retrieval of the reward on the first reach of the trial), (d and e) 'barrier hits' responses (hitting the closed transparent side of the box instead of making a detour). Examples of easy trials (direct reach possible, b and d) and difficult trials (i.e., when a detour around the transparent side of the box is required, c and e) are illustrated.

reward on the first reach and were making more barrier hits as soon as 6 weeks after the initiation of 3NP treatment, indicating that they were impaired in their ability to respond using the appropriate strategy. Importantly, 3NP-intoxicated animals were not impaired in motor problems or correct responses indicating that they were as able as the controls to get the rewards. Postmortem neuropathological examination of 3NP-treated animals presenting cognitive deficit showed histological abnormalities restricted to the striatum. The lesion always began in the most lateral part of the putamen, encompassing later the dorsolateral aspect of the body of the caudate nucleus. No other histological lesion was observed in the brain, particularly in the frontal, parietal cortex, and the hippocampus.

Using the same ORDT task, similar frontal cognitive deficits have been documented in other nonhuman primate species with caudate lesions (such as *Macaques fascicularis* or *Cebus appella*) following repetitive daily doses of 3NP. In another study, impairment on the ORDT task was also observed in primate animals with severe striatal dopamine depletion following MPTP administration, suggesting that neuronal dysfunction without striatal cell loss could also induce a frontal-type cognitive deficit.

Further experiments in macaques with either striatal allografts in the caudate nucleus to reconstruct the interrupted frontostriatal circuitry, or neurotrophic factors such as CNTF to protect striatal neurons from degeneration showed a progressive restoration of frontal cognitive deficits using the ORDT task. These latter experimental findings reinforce the crucial role of subcortical structures in frontal-type cognitive deficits observed in neurological diseases with predominance of subcortical pathologies.

Obsessive-Compulsive Disorder

G S Chasson and S Wilhelm, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

Glossary

Cognitive-behavioral therapy – A form of psychotherapy that helps a patient to identify and address maladaptive patterns of thoughts, feelings, and behaviors.

Compulsions – Overt or covert rituals, escape strategies, and avoidance behaviors that serve to decrease the distress associated with an obsession.

Exposure and response prevention – A form of cognitive-behavioral therapy in which a patient with OCD participates in repeated sessions of prolonged contact with fear-inducing stimuli while simultaneously preventing compulsions.

Habituation – The natural reduction of a physiological fear response over repeated sessions of prolonged contact with fear-inducing stimuli.

Obsessions – Intrusive thoughts, impulses, or images that elicit distress and are inconsistent with one's beliefs, values, or self-image.

OC-spectrum – A hypothesized family of psychiatric disorders which are similar to OCD.

Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) – An etiological theory of OCD in which streptococci infections purportedly elicit an autoimmune attack of the basal ganglia.
Yale-Brown obsessive compulsive scale (Y-BOCS) – A clinician-rated instrument that assesses the nature and severity of OCD.

History and Definition

Obsessive–compulsive disorder (OCD) has been described consistently since the seventeenth century and initially, was conceptualized from a religious perspective. Obsessions and compulsions were considered products of the devil and thus, required religious intervention (e.g., exorcism). Scientific understanding of OCD did not start until the nineteenth century, when early characterizations of the disorder suggested that individuals with OCD could not resist the obsessions but had insight into the unreasonable nature of their symptoms. Further theoretical understanding of the disorder developed from early case studies, such as several accounts by Sigmund Freud (e.g., *Rat Man*), who formulated a psychodynamic theory of OCD that has evolved and persisted to date in many professional circles.

The twentieth century saw great strides in the understanding of psychopathology as a result of behavioral research, leading to theoretical advances in understanding the development and maintenance of phobias from a classical and operant conditioning perspective. In the early part of the century, O.H. Mowrer introduced a model of phobia maintenance in which certain behaviors are rewarded because they result in escape from feared stimuli and decrease or preclude a fear response. This model of phobia maintenance naturally was extended to the understanding of OCD; that is, compulsions serve to decrease the distress elicited by obsessions, thus, negatively reinforcing the compulsions and increasing their frequency. Other important strides in the understanding of OCD occurred later on in the twentieth century when biological, cognitive, and neuropsychological models of psychopathology emerged.

Currently, the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV) provides a commonly used taxonomic definition of OCD. Defining OCD using a taxonomic approach has elicited several lines of research on how best to carve OCD phenomena at their joints. One growing area of research examines the heterogeneity of OCD in an attempt to split the condition further by defining discrete OCD subtypes or dimensions. A second line of research aims to lump OCD with similar conditions into an OC-spectrum.

More traditional subtype research has attempted to define OCD subtypes based on categorical differences, such as the presence or absence of comorbid tics. Most of the latest research, however, has focused on exploring symptom dimensions in an effort to define specific OCD subtypes. While the evidence regarding the number and type of dimensions is still inconclusive, preliminary data suggest that four symptom themes appear consistently across studies. One of the themes relates to fears and rituals that involve checking for or avoiding contamination. The second consistent OCD dimension concerns symmetry, a distressing sense of imperfection, and an impulse to straighten or arrange. The third reliable dimension is defined by hoarding symptoms, which is characterized by fears of needing to save items and rituals of collecting seemingly valueless items. The fourth less consistent dimension of OCD concerns a variety of checking compulsions and harm, sexual, or religious intrusive thoughts or images.

While many investigations have attempted to split OCD phenomena into subtypes or dimensions, other lines of research have attempted to lump them with other similar conditions into an *OC-spectrum*. The spectrum has many potential overlapping DSM-IV conditions, including somatoform disorders (e.g., body dysmorphic disorder, hypochondriasis), impulse control disorders (e.g., trichotillomania), eating disorders (e.g., anorexia nervosa), tic disorders (e.g., Tourette's disorder), personality disorders (e.g., obsessive–compulsive personality disorder), dissociative disorders (e.g., depersonalization disorder), paraphilias (e.g., fetishism), and pervasive developmental disorders (e.g., Asperger's disorder). Typically, these disorders have been lumped together because of similarities in a variety of domains, including symptom overlap, demographics, etiology, course, and treatment response. There is currently debate in the scientific community regarding the status of an OC-spectrum and the specific disorders that comprise this category.

One disorder within the OC-spectrum, Tourette syndrome, is a movement disorder characterized by multiple motor tics and one or more vocal tics. OCD and Tourettes can be challenging to differentiate, especially when a tic-related OCD subtype is also considered. However, evidence suggests some differentiating characteristics. Compared to the individuals with tic-free OCD, those with Tourettes or tic-related OCD are more likely to report specific types of obsessive–compulsive symptoms, such as touching or tapping rituals, hoarding, symmetry compulsions, and self-injurious behaviors. In contrast, those with tic-free OCD report more physiological anxiety and OCD-related cognitions associated with the stereotyped movements. That is, those with Tourettes typically report an urge that immediately precedes and elicits a tic, but those

with OCD typically indicate that compulsions are triggered by anxiety stemming from an obsession.

Etiology and Clinical Correlates

With the exception of genetic factors, cognitive, neuroanatomical, and neuropsychological factors might best be considered clinical correlates of OCD until further research is conducted. With respect to genetics, family studies over many decades have suggested strong familial patterns of OCD symptoms. In addition, twin studies of the concordance rates of OCD in monozygotic and dizygotic twins have provided estimates of the influence of genes on the phenotypic expression of the disorder. The differential concordance rates suggest a range of 27–65% for the influence of genes, with pediatric samples demonstrating a higher range. Research findings from segregation analyses, candidate gene studies, and genetic linkage studies are mixed, but there is some evidence that has implicated specific inheritance patterns for OCD symptoms, particular genes involved in the serotonergic and dopaminergic pathways in the brain, and a location on chromosome 9p that is associated with a glutamate transporter.

While evidence concerning the pathophysiology of OCD remains inconclusive, research has implicated several brain regions. In particular, research in this area has suggested impairment in the corticostriatal–thalamic circuit. This brain circuit includes the orbitofrontal cortex, caudate nucleus, anterior cingulate cortex, and thalamus. This circuit has many hypothesized functions, including the integration of sensory information, voluntary bodily movements, modulation of social behavior, and higher-level cognitive skills that include planning and inhibition of responses. Other brain regions have been implicated in OCD pathophysiology (e.g., corpus callosum), but these two models have received the most attention in the research literature.

Similar to the neuroanatomical research, the neuropsychological research on OCD remains inconclusive. Reviews of the research suggest that those with OCD predominately engage in inefficient approaches to organize information, possibly as a result of focusing mainly on irrelevant details rather than global and contextual features. This organizational strategy may have a negative impact on overall executive functioning, thus accounting for other noted neuropsychological dysfunctions in OCD, including deficits in set shifting and planning abilities. There seems to be less evidence for impairment in attention span, verbal fluency, and aspects of verbal memory.

While a discussion of all of the cognitive models of OCD is outside the scope of this article, it is worth noting the recent work of *The Obsessive Compulsive Cognitions Working Group*, which consists of the world's experts on the cognitive processes of OCD. The research from this group has provided strong evidence for three cognitive dimensions of OCD. The first dimension, labeled *Responsibility/Threat Estimation*, reflects a tendency to overestimate personal responsibility and worry excessively about harm to self or others. A second cognitive dimension, called *Perfectionism/Certainty*, suggests a tendency to maintain rigid and unreasonable standards, as well as demonstrate excessive need for certainty. The final cognitive dimension is called *Importance/Control of Thoughts*, which measures one's overvaluation of thoughts and need for controlling obsessions.

Other epidemiological data suggest a range of risk factors and clinical correlates. Older adolescents appear at-risk for developing OCD, but an inverse relationship may exist between adult age and OCD onset. Growing evidence also indicates an increased risk in females during the postpartum period. Another clinical concomitant includes psychiatric comorbidity, such as other anxiety disorder diagnoses, major depressive disorder, and substance dependence. In addition, the results are mixed with respect to the relationship between OCD and several other factors: IQ, race and ethnicity, and socioeconomic status. Some reliable evidence suggests a direct relationship between the size of a household and the risk for OCD symptoms, implying the possibility of an infection causing OCD. One possible infection theory for OCD is called Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS).

The association of PANDAS and OCD has received growing attention in the research community. According to the theory, antibodies produced by the body to fight *Streptococci* infections purportedly attack the host as a result of the similarity in antigens between streptococci and the basal ganglia. At this time, however, the evidence remains inconclusive. While some case studies and cross-sectional data support a link between strep infections and OCD (as well as tic disorders), causal evidence is yet to be found. Similar lines of research have started to explore other infections, as well, including the role of mycoplasma pneumoniae and the Borna virus.

Epidemiology

Current epidemiological evidence suggests that OCD has a lifetime prevalence rate between 2 and 3% of the general population. Males and females develop the disorder in roughly equal proportions, but there may be gender differences in the age at onset. Males typically develop the disorder at a younger age (i.e., 13–15 years old for male modal onset), while females develop it later in life (i.e., 20–24 years old for female modal onset). While development of the disorder is usually gradual, acute onset is not uncommon. Most reports suggest that the course of OCD symptoms wax and wane over time, but some evidence indicates that 10% of patients with OCD experience a

deteriorating course. With respect to comorbidity, most evidence suggests that 50–75% of OCD sufferers meet criteria for at least one other psychiatric disorder, usually major depressive disorder, other anxiety disorders, or other conditions similar to OCD.

Assessment and Treatment

Diagnosing OCD can be complicated, especially considering the rate of comorbidity and phenomenological overlap with other disorders. The option for a *poor insight* specifier in the diagnosis of OCD can make the differential with psychotic disorders particularly challenging. A trained expert must determine if the obsession reaches delusional intensity, and whether or not the patient can test reality. Another difficult differential exists between OCD and generalized anxiety disorder, which is characterized by excessive worry about realistic issues. The distinction generally involves assessing the intensity and frequency of the thoughts, the realism of the fear content, and the degree to which the patient believes the fears are consistent with his or her beliefs, values, and self-image. While a distinction is sometimes difficult between OCD and autistic disorders, the latter class of disorders typically presents with a range of non-OCD signs and symptoms, as well as a specific and required developmental history. Often, it is difficult to distinguish OCD from other OC-spectrum disorders, but spectrum disorders typically present with a particular theme that usually takes precedence in diagnostic classification.

There are many tools for assessing various aspects of OCD, including diagnostic interviews, clinician-rated measures, and self-report measures. Diagnostic interviews generally consist of a standardized structured or semistructured interview to determine whether or not OCD diagnostic criteria are met. Clinician-rated instruments require a trained expert to judge information about a patient's OCD presentation. One clinician-rated instrument in particular has been considered the gold standard assessment of OCD severity: the Yale-Brown Obsessive–Compulsive Scale (Y-BOCS). The scale contains two parts, including a checklist to determine the current and past obsessions and compulsions, and also a clinician rating of the patient's OCD symptom severity. In addition, there are numerous self-report measures of OCD and its correlates. Some commonly used examples include a self-report Y-BOCS, the Obsessive–Compulsive Inventory-Revised, and the Padua Inventory, and its revised form. Many adjunctive measures evaluate OCD correlates, including cognitive constructs like perfectionism, biological correlates like physiological anxiety, and symptom-specific measures such as hoarding severity.

There are two first-line treatment options for those who suffer from OCD. One is exposure and response prevention (ERP), which is considered the gold standard psychological treatment model for OCD. ERP consists of two parts: (1) stepwise and prolonged exposure to a fear-inducing stimulus to facilitate a natural reduction of the physiological fear response over time (i.e., *habituation* or *extinction*) and (2) simultaneous and purposeful prevention of avoidance strategies, escape plans, or rituals that serve to decrease the fear response during a therapeutic exposure. This procedure is repeated until the stimulus elicits a minimal fear response, and then the model is applied to a different fear-inducing stimulus. Participating in roughly 10–20 ERP sessions is associated with symptom improvement in at least 85% of patients, with 55% reporting considerable improvement; however, these numbers are deceptive, because ~25% of patients refuse to participate in ERP and a roughly equal percentage of patients drop out of ERP once initiated. As a result of these high refusal and dropout rates, many lines of research have attempted to develop additional cognitive-behavioral therapy (CBT) approaches. Examples include cognitive therapy, which focuses on helping the patient directly address the distorted beliefs associated with OCD, and motivational interviewing techniques, which help facilitate the patient's willingness to engage in treatment.

For the other first-line treatment option for OCD, psychopharmacologists suggest the use of serotonin reuptake inhibitors (SRIs), in particular all of the selective SRIs, such as fluoxetine, paroxetine, and sertraline. They also reported evidence for clomipramine, a tricyclic antidepressant that affects serotonin reuptake. Evidence suggests that SRIs elicit a favorable response in 40–60% of OCD patients, but they are also associated with high rates of relapse following their discontinuation. While the selective SRIs appear more effective than tricyclic antidepressants (except clomipramine), no specific selective SRI is more or less effective than its counterparts. When patients do not respond to monotherapy, SRIs often are augmented with typical or atypical neuroleptics. While the evidence is mixed concerning any added benefit of combining psychological and psychopharmacological interventions (e.g., CBT plus an SRI), some experts recommend the use of this joint approach. One promising combination of psychopharmacology and psychotherapy concerns the use of D-cycloserine, a partial agonist that affects a specific type of glutamatergic receptor in the brain, to expedite the habituation process during ERP.

Nontraditional medical techniques also might benefit those with OCD. Evidence for neurosurgery suggests that anterior cingulotomy, anterior capsulotomy, subcaudate tractotomy, or limbic leucotomy might benefit patients who have failed multiple trials of medication and CBT. There is promising preliminary evidence concerning transcranial magnetic stimulation and deep brain stimulation, but further research is needed to clarify possible effects further. At this time, these nontraditional approaches are reserved as a last line of treatment.

Oculomasticatory Myorhythmia

S S Kapur, University of IL at Chicago, Chicago, USA

Glossary

Bruxism – The grinding of the teeth or clenching of the jaw, which may be involuntary (a form of focal dystonia).
Myorhythmia – A hyperkinetic involuntary movement disorder characterized by a tremor of irregular frequency (from 1 to 4 Hz).
Pendular vergence oscillations – Alternating convergent–divergent movements of the eyes that occur at about 1 Hz frequency.

Oculomasticatory myorhythmia (OMM) is characterized by involuntary movements that involve the eyes, the muscles of the face, the muscles of mastication, and the pharyngeal muscles. OMM was first described in 1986 by Schwartz et al. and has since been reported in multiple cases.

The ocular movements are described as convergent–divergent 1 Hz movements, which can be more precisely described as pendular vergence oscillations (PVOs). PVOs of OMM are mostly horizontal and may affect one eye more than the other. OMM is typically associated with supranuclear ophthalmoplegia.

Myorhythmia involves 1–2 Hz movements of the face characterized by contractions of the muscles of mastication as well as other muscles of the face or the pharynx (see **Figure 1**). These movements occur in synchrony with the PVOs and can persist during all sleep phases. There has been a case report of permanent bruxism severe enough to cause tooth abrasions.

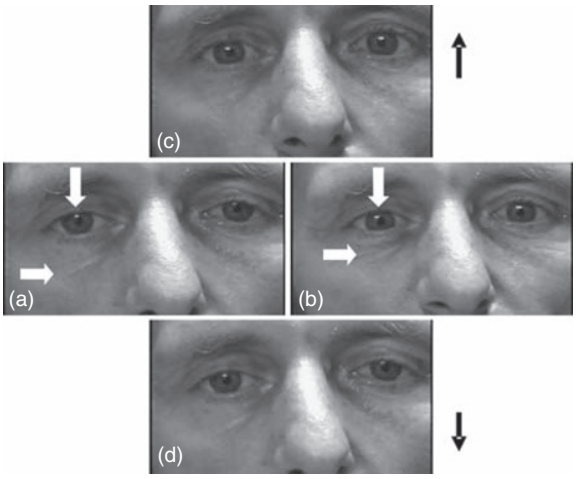

Figure 1 Episodes of divergent (a) and convergent (b) ocular oscillations can be appreciated in primary gaze (the corneal light is displaced laterally from a to b). Note the elevation of the inferior eyelid crease (horizontal arrow, a to b), indicating contraction of the levator labii muscles, synchronous with the convergent ocular movements. Attempts to upgaze (c) and downgaze (d) are ineffective.

OMM, along with the associated oculofacialskeletal myorhythmia (OFSM), which can also involve proximal and distal skeletal muscles, has been found in about 20% of reported cases of central nervous system (CNS) Whipple's disease. The specificity, on the other hand, is 100%, hence making this sign pathognomonic for CNS Whipple's disease.

OMM and OFSM can improve or remit entirely if a patient has been satisfactorily treated for Whipple's disease. Typical treatment is with an antibiotic drug such as trimethorim-sulfamethoxazole, penicillin, doxycycline, or ceftriaxone. With proper treatment, the disease can remit in up to 70% of patients. The relapse rate, however, can approach 40%.

Olivopontocerebellar Atrophy

J Berciano, University Hospital 'Marqués de Valdecilla', UC, IFIMAV and CIBERNED, Santander, Spain

Glossary

Essick cellbands – Groups of cells in the developing rhombencephalon that migrate in two bands, one of which eventually forms the inferior olivary nucleus and the arcuate nucleus, and the other the pontine nuclei.

Neuronal intranuclear inclusions – Intranuclear inclusion bodies in the neurons that have been reported in SCAs with expanded trinucleotide repeats and are composed of ataxins, ubiquitin, and proteins of the nuclear matrix and proteasomes.

Polyglutamine or polyQ – CAG repeat expansions cause expanded polygutamine stretches; imply that corresponding gene products (e.g., ataxins or atrophin) induce neurodegeneration by means of 'gain of toxic functions.'

Spinocerebellar atrophy – Degeneration of spinocerebellar tracts, posterior white columns and griseum pontis with preservation of inferior olivary nuclei and corticospinal tracts, often the pathological hallmark of inherited SCAs.

Definition, History, and Classification

The term OPCA (olivopontocerebellar atrophy) was introduced by Dejerine and Thomas in 1900 to designate the pathological presentation in a patient with sporadic

adult-onset progressive cerebellar ataxia. In 1891, however, Menzel had reported an autosomal dominant pedigree of OPCA who exhibited a complex clinical picture including progressive cerebellar ataxia, spasmodic dysphonia, lower limb rigidity, dysphagia, and dystonic neck posture.

The sporadic case described by Dejerine and Thomas ('Vais D.V.', Dejerine Laboratory, Paris, reviewed by Berciano) featured progressive ataxic gait, dysarthria, impassive face, hypertonia, hyperreflexia, and urinary incontinence beginning at the age of 53. Autopsy 2 years later showed an advanced degeneration of the basis pontis, inferior olives, middle cerebellar peduncles (MCP), and to a lesser degree inferior cerebellar peduncles. There was severe atrophy of Purkinje cells, more marked in the cerebellar hemispheres than in the vermis. Neither the basal ganglia nor substantia nigra are mentioned. According to the authors, OPCA would be a nonfamilial disease to be included among primary cerebellar degenerative disorders. While confirming the reported olivopontocerebellar lesions (**Figure 1**) and the absence of apparent lesions of the putamen, it was not possible to establish whether or not the substantia nigra had degenerated. This finding would have been of great interest because the patient may have had incipient parkinsonism; in fact, this clinicopathological study probably represents the first description of multiple system atrophy (MSA).

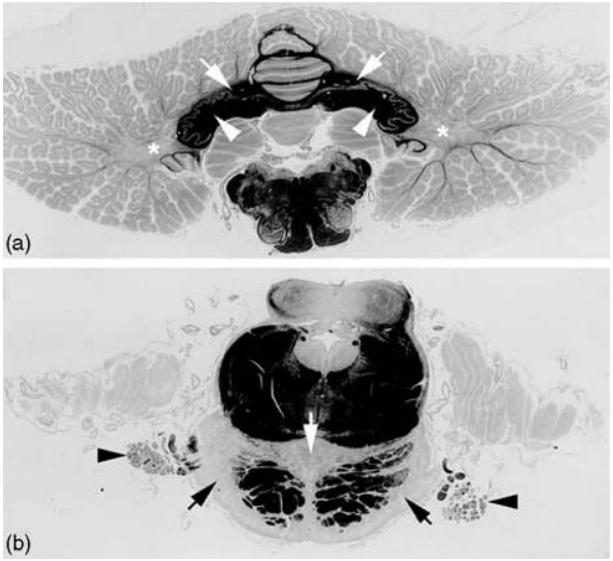

Figure 1 Olivo-ponto-cerebellar lesions in the case reported by Dejerine and Thomas. Both transverse sections are stained using the Weigert–Pal method. (a) This section through medulla and cerebellum shows demyelination of the olivo-cerebellar fibers and the cerebellar white matter (asterisks) with preservation of fibers surrounding (arrows) and exiting (arrowheads) the dentate nuclei. (b) This section through the upper half of the pons, at the emergence of trigeminal nerves (arrowheads), shows demyelination of pontocerebellar fibers (arrows); note that corticospinal and corticopontine fibers stand out due to complete disappearance of transverse pons fibers. Reproduced from Berciano J, et al. (2006) Olivopontocerebellar atrophy: Toward a better nosological definition. *Movement Disorders* 21: 1607–1613.

In 1954, Greenfield proposed a pathological classification of the ataxias, where OPCA was divided into two forms: sporadic (Dejerine–Thomas type) and familial (Menzel type).

For almost a century clinicopathological studies in hereditary ataxias contributed to a confused nosology as it ignored the fact that genetic heterogeneity affects not only the clinical picture but also the pathological features, making the classification difficult within reported families with inconsistent pathological findings. There was a pressing need to find a new classification, a task achieved by Harding culminating in a series of exceptional contributions to the field of hereditary ataxias. In 1983, she proposed to start from genetic and clinical features which are, certainly, the tools used by neurologists in clinical practice. Along these lines, she proposed a clinicogenetic classification (**Table 1**), which was soon universally accepted.

Table 1 Harding's clinicogenetic classification of the hereditary ataxias and paraplegias

I. Congenital disorders of unknown aetiology
II. Ataxic disorders with known metabolic of other cause
III. Ataxic disorders of unknown aetiology
  A. *Early onset cerebellar ataxia (usually before 20 years)*
    i. Friedreich's ataxia
    ii. Early-onset cerebellar ataxia with retained tendon reflexes
    iii. With hypogonadism ± deafness and/or dementia
    iv. With myoclonus (Ramsay Hunt syndrome, baltic myoclonus)
    v. With pigmentary retinal degeneration ± mental retardation and/or deafness
    vi. With optic atrophy ± mental retardation
    vii. With cataracts and mental retardation (Marinesco–Sjögren syndrome)
    viii. With childhood-onset deafness and mental retardation
    ix. With congenital deafness
    x. With extrapyramidal features
    xi. X-linked recessive spinocerebellar ataxia
  B. *Late-onset cerebellar ataxia (onset usually after 20 years)*
    i. Autosomal dominant cerebellar ataxia with optic atrophy/ophthalmoplegia/dementia/extrapyramidal features/amyotrophy (probably includes Azorean ataxia) (ADCA type I)
    ii. Autosomal dominant cerebellar ataxia with pigmentary retinal degeneration ± ophthalmoplegia and/or extrapyramidal features (ADCA type II)
    iii. 'Pure' autosomal dominant cerebellar ataxia of later-onset (over 50 years) (ADCA type III)
    iv. Autosomal dominant cerebellar with myoclonus and deafness (ADCA type IV)
    v. Periodic autosomal dominant ataxia
    vi. 'Idiopathic' late-onset cerebellar ataxia
IV. Hereditary spastic paraplegia
  A. 'Pure' spastic paraplegia
  B. Complicated forms of spastic paraplegia

In the last decade this clinicogenetic classification has been modified with the molecular genetic advances; in fact, hereditary ataxias and paraplegias now comprise around 80 *loci*, 29 of them belonging to autosomal dominant cerebellar ataxia (ADCA), and designated as SCA1 to SCA29 (from *spinocerebellar ataxia*, numbers indicating the chronological order of discovery of locus linkage). In 14 of these syndromes the underlying mutations are known. Seven SCA subtypes (SCA1, SCA2, SCA3, SCA6, SCA7, SCA17, and dentatorubral-pallidoluysian atrophy (DRPLA)) are caused by CAG trinucleotide expansions in the respective genes. OPCA might be the pathological hallmark in every subgroup of Harding's classification except for Friedreich's ataxia (FA), ADCA III, and 'pure' hereditary spastic paraplegia. According to neuroimaging studies (see below) or pathological findings, OPCA is the usual pathologic substrate of SCA1, SCA2, SCA7, SCA12, SCA13, and DRPLA; furthermore, mild OPCA may also occur in SCA3, though spinopontine atrophy is the most common pathological picture in this setting.

Pathogenesis

OPCA is a type of primary neuronal degeneration of the spinocerebellar systems, namely, a form of sporadic or hereditary neurodegenerative disorder. The recent molecular advances in the field of hereditary ataxias have demonstrated that degeneration of olivopontine and cerebellar systems may occur in a vast number of genetic defects, including SCAs caused by polyglutamine (or polyQ or CAG trinucleotide repeat) expansions.

Major insights into the molecular pathology of the trinucleotide repeat neurodegenerative diseases have been attained over the past decade. For OPCA associated with SCA caused by CAG repeat expansion in the coding region of a gene, the functions of the affected proteins (ataxin-1 for SCA1, ataxin-2 for SCA2, ataxin-3 for SCA3, ataxin-7 for SCA7, and atrophin for DRPLA) are still unknown. Expanded polyQ repeats can form insoluble aggregates that are the hallmark of all polyQ diseases. Neuronal intranuclear inclusions (NIIs) characteristically occur. It is generally held that polyQ disorders are due to a toxic gain of function of mutant expanded proteins, though haploinsufficiency remains a tenable possibility in which polyQ domains would alter proteasomal degradation in a malignant manner. The most intriguing possibility is transcriptional dysregulation. PolyQ sequences are relatively hydrophobic and can interact with each other in 'polar zipper' configurations. Many transcriptionally active proteins have polyQ domains, and the expanded sequences resulting from expanded CAG repeats may sequester transcriptionally active proteins and alter cellular functions. This does not necessarily imply that the NIIs are themselves pathogenic agents of neurodegeneration; in fact, NIIs may be epiphenomenal or even protective. The proposed pathogenic cascade of neurodegeneration probably includes protein misfolding, interference with DNA transcription and RNA processing, activation of apoptosis, and dysfunction of cytoplasmic elements. The molecular and cellular bases for the differential vulnerability of olivopontine and cerebellar neurons in SCA polyQ expansion disorders are poorly understood. It has been speculated that expanded polyQ-containing proteins differ in their affinity for different transcriptionally active proteins, and that the intersection of a given protein with an expanded polyQ domain and the repertoire of transcriptionally active proteins expressed by specific populations of neurons may determine regional effects. Animal models of SCA1, SCA2, SCA3, or SCA7 have not as yet reliably reproduced OPCA pathology. This is not the case of MSA, however, where combined mitochondrial inhibition and overexpression of oligodendroglial α-synuclein in a transgenic mouse generates a novel model of MSA demonstrating OPCA and striatonigral degeneration; furthermore, in MSA, degeneration of the olivopontocerebellar system significantly correlates with the frequency of glial (oligodendroglial) cytoplasmic inclusions (GCIs).

Epidemiology

OPCA is not explicitly considered in general epidemiological surveys on spinocerebellar syndromes. In my Community of Cantabria (Spain), the prevalence ratios of ADCA and idiopathic late-onset cerebellar ataxia (ILOCA) were 1.2 and 2.2 cases per 100 000, respectively. Some 60% of patients included in these groups had a cerebellar-plus syndrome and their CT or MRI scans revealed cerebellar and brainstem atrophy, allowing a presumptive diagnosis of OPCA. According to these estimations, prevalence ratio of OPCA is around 2 out of 100 000. In Japan, the prevalence of ILOCA has been established in 12 out of 100 000, with OPCA being the presumptive pathological hallmark in 65% of cases.

Clinical Features and Pathophysiology

In 1982, Berciano gathered together 117 cases of pathologically proven OPCA of which 63 were sporadic and 54 (43 pedigrees) were hereditary with an autosomal dominant transmission in 30 families, autosomal recessive in 7, and uncertain due to lack of information in 6. The mean ages of onset were 28.35 years (standard error of the mean (SEM)), $\pm$1.18 years; range, 2 months to 66 years) for familial OPCA and 49.22 ($\pm$1.64; 0–66) for sporadic OPCA, the difference being significant ($t = 6.43$; $p < 0.001$).

The predominant presentation was progressive gait and limb cerebellar ataxia and dysarthria, which was almost always accompanied by additional noncerebellar symptoms summarized in **Figure 2**.

The fundamental lesions, accounting for gait and limb ataxia and dysarthria, were those localized in the cerebellum and in structures derived from Essick cell-bands: the pontine, inferior olivary, arcuate, and pontobulbare nuclei. These fundamental lesions are accompanied by a variable involvement of other structures (**Figure 3**), which undoubtedly account for the additional noncerebellar symptoms and signs observed (**Figure 2**).

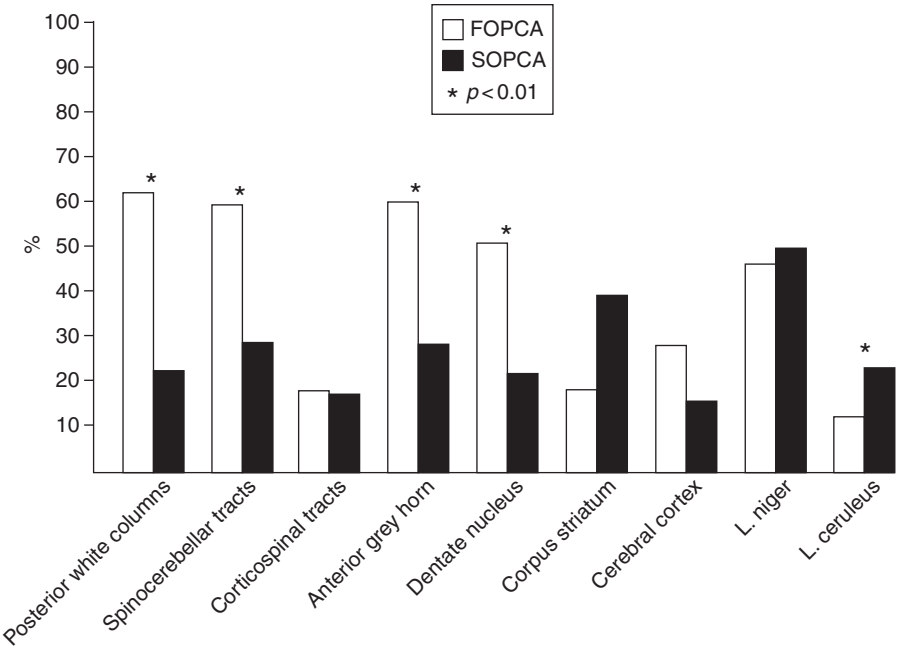

Figure 3 Histogram showing frequencies of the main associated lesions in familial OPCA (FOPCA) and sporadic OPCA (SOPCA). Reproduced from Berciano (2007) Olivopontocerebellar atrophy (OPCA). In: Gilman S (ed.) *Neurobiology of Disease*, pp. 95–104. London: Elsevier Academic Press.

Differential Diagnosis

OPCA may be part of the pathological hallmark of other disorders, namely, mitochondrial encephalomyopathy, hexosaminidase deficiency, adrenoleukodystrophy or sporadic spongiform encephalopathies among others described below. Familial OPCA has been misdiagnosed in some cases of familial prion disorders, either Gerstmann–Straussler–Scheinker syndrome or fatal familial insomnia.

Diagnostic Work-up

Brain CT scan or MRI studies are essential techniques in clinical practice for delineating brainstem and cerebellar atrophy characteristic of OPCA (**Figure 4**). The most sensitive feature differentiating between OPCA and cortical cerebellar atrophy (CCA) appears to be the diameter of the MCP. It is worth noting that besides OPCA, bilateral involvement of MCP may occur in many disorders including fragile X-associated tremor and ataxia syndrome, adrenoleukodystrophy, Wilson disease, and cerebrovascular, inflammatory, or neoplastic processes. Nevertheless, this neuroimaging finding combined with marked atrophy in the posterior fossa is characteristically seen in OPCA (**Figure 4**). In the first year after onset of cerebellar symptoms in OPCA patients, the CT scan may be normal; serial neuroimaging examination is then necessary for detecting infratentorial atrophy. Conversely, there may be brainstem atrophy without clinical correlate. Intermediate and T_2-weighted MR images may show cruciform hyperintensity ('hot-cross bun' sign) of the ventral part of the pons (**Figure 5**), accountable for by demyelination and gliosis of transverse fibers of the pons secondary to atrophy of nuclei pontis. The cruciform hyperintensity may extend

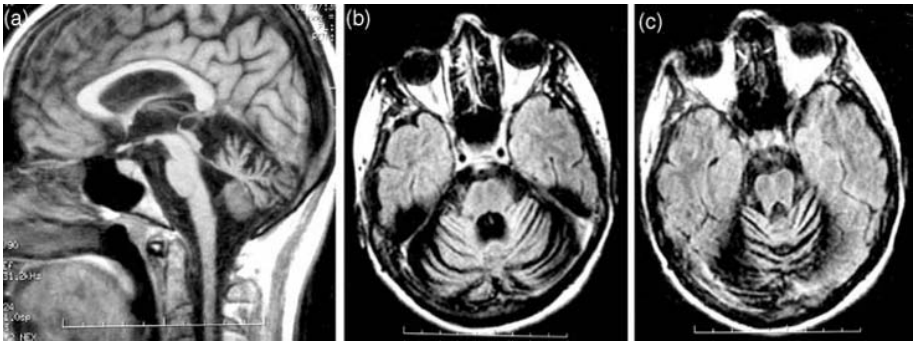

Figure 4 T_1-weighted MR imaging pictures from an SCA2 patient with cerebellar-plus syndrome. (a) Sagittal section showing extensive wasting of the brainstem and cerebellar vermis. (b) Axial section through mid-pons illustrating marked atrophy of the pons and cerebellar hemispheres with enlargement of the fourth ventricle. (c) This higher axial section shows atrophy of the pons and cerebellar vermis. Reproduced from Berciano (2007) Olivopontocerebellar atrophy (OPCA). In: Gilman S (ed.) *Neurobiology of Disease*, pp. 95–104. London: Elsevier Academic Press.

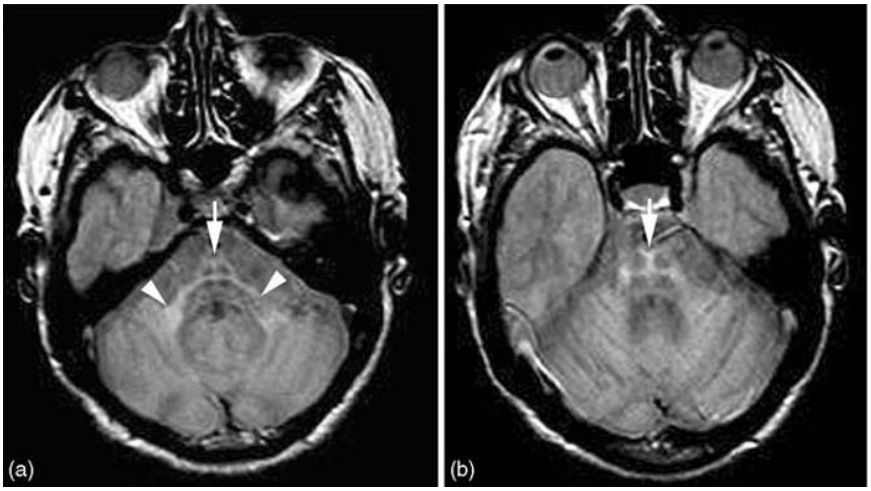

Figure 5 Axial proton-weighted density MRI pictures passing through lower (a) and mid pons (b) from a patient with probable MSA-C. Arrows indicate the presence of hyperintensity of pontocerebellar fibers conforming incipient (a) and fully developed (b) 'hot-cross bun' sign. Note also that signal hyperintensity involves middle peduncles extending to deep cerebellar white matter (a, arrowheads). Reproduced from Berciano et al. (2006) Olivopontocerebellar atrophy: Toward a better nosological definition. *Movement Disorders* 21: 1607–1613.

into MCP, a combination of lesions highly suggestive of OPCA, either sporadic or associated with any SCA.

Positron emission tomography (PET) scans of OPCA patients, as compared with those of normal control subjects, show a clear decrease of local cerebral metabolic rate for glucose (LCMRgluc) within the vermis, cerebellar hemispheres, and brainstem. The cross-validated sensitivity of absolute LCMRgluc as a predictor of OPCA was 82% with a corresponding specificity of 71%. A significant relationship was found between the degree of atrophy and the level of LCMRgluc in the cerebellum and brainstem. Nevertheless, there may be patients with minimal atrophy and substantially reduced LCMRgluc. PET study may therefore be especially useful as a diagnostic test in patients with presumptive clinical diagnosis of OPCA and normal CT or MRI.

Together with olivopontine and cerebellar systems, other neural systems (e.g., pyramidal tracts, spinal anterior horns or spinal posterior white columns) may degenerate, and there may be extracerebellar semiology (e.g., abnormal eye movement or sleep disorders; **Figure 2**). Electrophysiologic techniques are useful to investigate the extracerebellar semiology or the subclinical involvement of extraolivopontine neural systems.

Sporadic OPCA, MSA and ILOCA

The most complex nosologic problem is probably the relation among sporadic OPCA, MSA, and ILOCA. In fact, it has been proposed that MSA and sporadic OPCA are actually one and the same disease. We will briefly analyze the nosology of MSA and ILOCA in relation to OPCA.

MSA is defined as a sporadic neurodegenerative disease that causes a clinical syndrome of extrapyramidal, pyramidal, cerebellar, and autonomic features. The pathological hallmark of MSA is the presence of glial and neuronal inclusions showing pronounced α-synuclein immunoreactivity, on a highly variable topographic histopathological process. Lesions may vary from minimal, just involving the substantia nigra and locus ceruleus, to fully developed OPCA or striatonigral degeneration, with or without atrophy of the intermediolateral columns and Onuf's nucleus. GCIs have rarely been reported in OPCA associated with SCA1 or SCA2, but unlike MSA, they do not exhibit immunoreactivity for α-synuclein. As reviewed in a Consensus Conference, patients should be clinically classified as having MSA-P if parkinsonian features predominate, or MSA-C if cerebellar features predominate. The diagnosis of probable MSA requires a sporadic, progressive adult-disorder, including rigorously defined autonomic failure and poorly levodopa responsive parkinsonism or cerebellar ataxia. Starting from such diagnostic guidelines, a considerable number of classical sporadic OPCA descriptions could be reclassified as examples of MSA-C.

Harding introduced the eponym ILOCA to designate an ataxic disorder of unknown origin in three groups of patients with sporadic and progressive cerebellar ataxia, onset ranging between 30 and 74 years. The first group, with pure cerebellar ataxia, was composed of 12 patients who had greater truncal ataxia compared to limb ataxia and relatively late-onset (mean ± SD, 54.75 ± 10.0 years); Harding related this group to the Marie–Foix–Alajouanine type of CCA. The second group included six patients who had prominent upper limb tremors, both resting and during action (onset, 52.83 ± 9.89 years). The third group comprised 16 individuals with a cerebellar-plus presentation similar to patients previously reported as sporadic OPCA (onset, 45.22 ± 9.43 years). Radiological investigations were limited and neuropathological studies were lacking in Harding's series. Subsequent CT or MRI studies usually showed either cerebellar atrophy with an intact brainstem suggestive of CCA (in patients with pure cerebellar presentation) or combined cerebellar and brainstem atrophy suggestive of OPCA (in patients with cerebellar-plus syndrome). Therefore, in this second subgroup a working diagnosis of sporadic OPCA could be made, though in clinical practice a diagnosis of ILOCA with cerebellar-plus syndrome is preferred.

In Harding's and two further ILOCA series encompassing 35 patients with cerebellar-plus syndromes and extended follow-up, only three cases demonstrated parkinsonism or autonomic failure/urinary dysfunction as required for the diagnosis of probable MSA. Moreover, a substantial number of cases exhibited features not typically seen in MSA, such as dementia, chorea, generalized areflexia, or polyneuropathy. Conversely, in another ILOCA series, all 13 patients with additional extracerebellar symptoms showed parkinsonian features whereas urinary dysfunction was found in only five. Therefore, 16 out of 48 (33%) cases with cerebellar-plus syndrome from these four ILOCA series would fulfill criteria of MSA-C. This reinforces the criterion that not all sporadic OPCA patients (i.e., ILOCA patients with cerebellar-plus syndromes) necessarily have MSA. Intriguingly this percentage is comparable to a recently reported, longitudinal study of 51 sporadic OPCA cases, in which one-quarter of them evolved into MSA-C.

Treatment

Symptomatic treatment is only possible for a selection of clinical manifestations. Levodopa or other dopaminergic agents may provide some benefit for extrapyramidal rigidity or bradykinesia. Urinary disturbances due to detrusor hyperreflexia may be treated with a peripherally acting anticholinergic agent such as oxybutinin (5–10 mg at bedtime) or propatheline. In any case, treatment of either urinary or sexual disturbances should be carried out in close collaboration with an expert in neurourology.

Autonomic dysfunction including constipation, erectile dysfunction, sphincter disturbances, and syncope may require specific treatments. Although numerous reports have discussed the treatment of ataxia, most authors agree that results obtained with a variety of therapies are generally disappointing; in fact, none of the trials reported to date has produced results convincing enough to justify routine use of any drug in OPCA.

Psychosocial support and therapies are most important. Physical, occupational, and speech therapies may be essential to reduce patient's disability and to maintain longer independent functioning. Gait training and assistive devices may help prevent falls.

Opioid System

J Brotchie, Toronto Western Hospital, Toronto, ON, Canada

Glossary

Direct pathway – One of two major routes by which the striatum can influence basal ganglia outputs, from the internal globus pallidus (GPi) and substantia nigra pars reticulata (SNr). The 'direct' pathway is a monosynaptic GABAergic connection.

Indirect pathway – One of two major routes by which the striatum can influence basal ganglia outputs, from the internal globus pallidus (GPi) and substantia nigra pars reticulata (SNr). The 'indirect' pathway or network incorporates poly-synaptic connections through the intermediaries of the external globus pallidus (GPe) and the subthalamic nucleus.

Opiate – Opiate refers to a specific subset of opioids that have an alkaloid structure similar to morphine. Not to be confused with opioid. Endogenous opioids in the brain are not opiates.

Opioid – A substance, natural or synthetic, that produces an action mimicking morphine.

Pharmacology

In the early nineteenth century, the principle active component of opium, morphine, was isolated from the opium poppy, *Papaver somniferum.* The realization that the effects of opium could be mimicked by morphine formed the starting point of opioid pharmacology. However, it had taken until the 1950s to provide a body of evidence to support the existence of receptors to mediate these effects. It had not

been until the early 1970s that opioid receptors in the brain were demonstrated by the binding of high affinity ligands.

The effects of opioid peptides are classically mediated via three receptors, termed μ-, δ-, and κ-opioid receptors. A fourth receptor has been identified which, while not completely fitting classic criteria for opioid receptors, is clearly related. This opioid receptor-like receptor is activated by the peptide nociceptin/orphanin FQ (N/OFQ) and is termed the N/OFQ peptide (NOP) receptor. Opioid receptors fall into the family of G-protein coupled receptors (GPCRs) and have a prototypical seven transmembrane domain organization. Their signal transduction is typically through coupling to Gi and inhibition of adenylyl cyclase activity, thus reducing cAMP levels.

Opioid receptors can be stimulated by a variety of endogenous peptides produced from a range of large molecular weight precursors. Thus, pre-proenkephalin-A (PPE-A) is the precursor for the pentapepide enkephalins, leu- and met-enkephalin. Enkephalins are endogenous ligands for δ-opioid receptors. Pre-proenkephalin-B (PPE-B) is processed to a range of dynorphins of different molecular weights (e.g., dynorphin A and B), α-neoendorphin, β-neoendorphin, and leu-enkephalin. PPE-B-derived peptides are endogenous ligands for δ, μ, and κ subtypes of opioid receptors. Pre-opiomelanocortin (POMC) is a precursor for both opioid and nonopioid peptides and is processed differentially in different tissues. The principle opioid peptide produced from POMC is β-endorphin, an extended form of met-enkephalin that can stimulate μ- and δ-opioid receptors.

Endomorphin-1 and -2, the precursor(s) for which are unknown, activate μ-opioid receptors.

Opioids in the Basal Ganglia

Striatal output neurons employ opioid peptides as cotransmitters with GABA. The use of neuropeptide cotransmitters by neurons equivalent to striatal output neurons is highly conserved across a range of vertebrate species, from reptiles to man. However, in mammals, striatal opioid peptides are segregated with respect to the direct and indirect striatal output pathways. Thus, the indirect pathway projection neurons utilize enkephalins derived from the precursor PPE-A, while the direct pathway employs opioids derived from PPE-B. Opioid peptides are released from striatal output neurons, both from recurrent collaterals within the striatum, and from terminals in the targets of striatal output, for example, the globus pallidus and the substantia nigra.

δ-, μ-, and κ-Opioid receptors are found in high concentrations within the striatum, being localized on GABAergic neurons and on terminals of glutamatergic and dopaminergic afferents. Striatal μ-opioid receptors show a patchy distribution, being more concentrated in striosomes. μ-Receptors are localized presynaptically on dopamine terminals. Stimulation of striatal μ-receptors enhances dopamergic transmission. Striatal κ-opioid receptors localized presynaptically on dopaminergic and glutamatergic terminals, activation of κ-receptors can reduce the release of dopamine and glutamate.

The striatum also contains high levels of endomorphin-1 and -2 and the NOP receptor.

δ-, μ-, and κ-Opioid receptors and NOP receptors are also found in regions receiving input from the striatum. For instance, in the external globus pallidus, the terminals of the indirect pathway express δ-opioid receptors and release enkephalins. These enkephalins can thus act upon the terminals from which they are released and reduce GABA release. With respect to the direct pathway, release of peptides produced from PPE-B can have multiple effects. Thus, α-neoendorphin or dynorphins released from the terminals of the direct pathway in the internal globus pallidus or substantia nigra pars reticulata inhibit basal ganglia outputs, either by inhibiting output neurons directly, by μ-receptor activation, or by reducing glutamate transmission by subthalamic efferents, by κ-receptor activation.

Opioids and Parkinsonism – Mechanisms and Opportunities for Novel Therapies

Striatal opioid peptide function, especially that involving enkephalins, is intimately linked to dopaminergic transmission. Thus, PPE-A mRNA and enkephalin protein levels are elevated in the dopamine-depleted striatum in parkinsonism. Enkephalin via activation of δ-opioid receptors in the GPe reduces GABA release from the indirect pathway. Elevation of enkephalinergic transmission, after dopamine loss in Parkinson's disease, and a consequent reduction in GABA transmission by the indirect pathway, is considered as a compensatory mechanism, that is, an attempt to overcome the loss of functionality resulting from dopamine loss. Enhancement of this endogenous compensatory mechanism has been suggested as a means to alleviate parkinsonian symptoms. In animal models of Parkinson's disease, δ-opioid agonists have antiparkinsonian actions. To date, these actions have not been translated into a clinically available therapy.

In contrast to PPE-A/enkephalins, the levels of PPE-B and one of its major products, dynorphin, are reduced in neurons of the direct pathway in parkinsonism. Reduced stimulation of κ-opioid receptors in the striatum and GPi would enhance glutamate release in these regions. As enhanced glutamate transmission in these regions is a component of mechanism of parkinsonism, κ-opioid-replacement therapy may thus be useful in the treatment of parkinsonian symptoms. Some κ-opioid receptor agonists have been shown to increase locomotion in animal models of Parkinson's disease, but to date, no subtype-selective opioid agonists have been assessed for antiparkinsonian efficacy in Parkinson's patients.

NOP receptor activation reduces dopamine neurotransmission in the striatum. In animals, at least, selective NOP antagonists have antiparkinsonian actions and potentiate the antiparkinsonian actions of levodopa. Further research is required to define how and whether it is possible to combine NOP antagonists with levodopa therapy in a manner to alleviate parkinsonism without worsening motor complications in patients.

Opioids and Dyskinesia – Mechanisms and Opportunities for Novel Therapies

The long-term treatment of parkinsonism with levodopa is associated with the development of motor complications such as levodopa-induced dyskinesia. Such treatment, and dyskinesia, is also associated with an elevation, within the striatum, in the synthesis of both PPE-A and PPE-B and their opioid peptide products. In contrast, dopamine agonists that have less propensity than levodopa to induce dyskinesia do not elevate striatal opioid peptide synthesis. The correlation between elevation of opioid peptide levels and dyskinesia has been interpreted as suggestive of a potential role for opioids in the pathophysiology of levodopa-induced dyskinesia. In this case, opioid receptor antagonists could represent a useful therapeutic approach to dyskinesia. However, data from preclinical and clinical studies are confusing. Non-subtype selective opioid receptor antagonists such as naltrexone or naloxone can either have no effect, or reduce or increase levodopa-induced dyskinesia.

It now seems likely that subtype-selective agents will be required to obtain robust antidyskinetic therapies from an opioid antagonist approach. μ- and δ-Opioid receptor antagonists appear the most interesting candidates, although, to date, no subtype-selective opioid receptor antagonists are available for clinical study.

Opsoclonus-Myoclonus Syndrome

Brandon R Barton, Rush University Medical Center, Chicago, IL, USA

Glossary

Ataxia – Incoordination or unsteadiness in regulation of posture and limb movements, due to impaired function of the cerebellum or its connections.

Myoclonus – Sudden, brief, shock-like involuntary movements caused by contraction or inhibition of a muscle or groups of muscles.

Opsoclonus – A disorder of eye motility involving involuntary, chaotic, arrhythmic, large-amplitude, conjugate saccades.

Paraneoplastic disorders – A variety of syndromes affecting any part of the nervous system related to the remote effects of cancer, usually attributed to the action of antibodies formed against tumor antigens.

Definition and History

Opsoclonus–Myoclonus syndrome (OMS) is a rare movement disorder consisting of involuntary eye movements, myoclonus, ataxia, or behavioral disturbances. It may be idiopathic or occur in association with a broad number of underlying disorders. OMS was originally described by Orzechowski in 1913 and has since been known by many names, including Kinsbourne syndrome, dancing eye syndrome, dancing eyes–dancing feet syndrome, myoclonic encephalopathy of infants, infantile polymyoclonia, and opsoclonus–myoclonus–ataxia (OMA) syndrome.

Pathogenesis/Pathophysiology

The pathophysiology and pathological substrate of OMS are not well understood and may vary according to the underlying cause. Most lines of evidence suggest an immune mechanism, including: symptom occurrence in the postinfectious state, documented responses to immunosuppressive therapy, demonstration of B- and T-cell recruitment in cerebrospinal fluid (CSF), and intense lymphocytic infiltration of associated tumors. Autopsy findings have either been normal or demonstrated abnormalities such as brainstem, basilar meningeal, and cerebellar inflammatory infiltrates, Purkinje cell loss, or peridentate gliosis and demyelination. The abnormal eye movements have been suggested to result from impaired interactions between omnipause and burst neurons in the brainstem or disinhibition of cerebellar nuclei have been suggested to cause the abnormal eye movements. Myoclonus may originate from abnormalities in the subcortical–supraspinal pathways connecting the brainstem and cerebellum, as supported by electrophysiological observations.

Epidemiology

OMS is rare, affecting children more than adults, and has largely been described in small series or case reports. Prevalence is not reported.

Clinical Features and Diagnostic Criteria

OMS is usually gradual in onset over several days, but can occur abruptly. Some patients have a prodrome consisting of nausea, vomiting, vertigo, oscillopsia, and gait difficulties. A subset may present with subacute, mild ataxia weeks before developing other symptoms. Despite the limited descriptive terms used in the name of the syndrome, patients may display any combinations of the following clinical signs.

Involuntary Eye Movements

Opsoclonic eye movements are involuntary, chaotic, conjugate, continuous, arrhythmic, multidirectional, large-amplitude saccades, without intersaccadic intervals. Opsoclonus is more prominent with agitation or when attempting to change fixation, may be associated with eyelid flutter or blinking, and can persist during sleep and eyelid closure. Patients can experience visual blurring and oscillopsia. Alternatively, ocular flutter (horizontal bursts of conjugate saccades interrupting gaze fixation) may occur as the primary eye movement abnormality or become apparent after resolution of opsoclonus, possibly representing a subform of opsoclonus.

Myoclonus

Myoclonus occurs mainly with action, typically localized to the head, face, limbs, or trunk, and rarely involving the diaphragm, larynx, pharynx, or palate. The amplitude may vary from larger, violent jerks to very small amplitude, generalized, continuous movements resembling tremulousness (which is termed minipolymyoclonus). Myoclonus and/or ataxia often compromise the ability to stand, walk, or even sit upright.

Ataxia

Ataxia is mainly truncal with varying degrees of appendicular involvement, and can be difficult to ascertain in the presence of severe myoclonus. Some cases have had severe ataxia without myoclonus.

Encephalopathy

Many patients develop a diffuse encephalopathy, ranging from lethargy and confusion to coma. Neurobehavioral and affective disorders also occur, including irritability, anxiety, personality changes, hallucinations, or 'rage attacks.'

Other Symptoms

Children may also have hypotonia, malaise, or psychomotor retardation. Hearing loss, lid retraction, hemifacial spasm, blepharospasm, sleep disorders, vertigo, head tilt or nodding, dysarthria, or mutism rarely occur.

Differential Diagnosis

Many medical and neurological diseases have been associated with OMS and are here grouped under the general disease categories.

Paraneoplastic

Children

OMS is the most common paraneoplastic disorder of childhood, most associated with neural crest-derived tumors. Neuroblastoma is discovered in the chest or abdomen of 50% of pediatric cases, with the neurologic symptoms preceding tumor diagnosis in 50%. Only 2–3% of children with neuroblastoma have OMS. The average age of presentation is 18 months. Anti-Ri/ANNA-2 is the most commonly associated paraneoplastic antibody, and 5–10% may have anti-Hu antibodies.

Adults

Only 20% of adults with OMS have an underlying neoplasm, with older age at onset (>50) as compared to idiopathic cases. Adult paraneoplastic OMS is mostly due to breast, gynecological, and small-cell lung cancers when Anti-Ri or Anti-Hu antibodies are detected. Other rarely associated paraneoplastic antibodies include anti-Yo, anti-Ma2, and amphiphysin antibodies. However, many do not have detectible antibodies. Adult paraneoplastic OMS has also been reported with non-small cell lung cancer, non-Hodgkin's lymphoma, Hodgkin's disease, benign ovarian teratoma, malignant melanoma, neurofibrosarcoma, chondrosarcoma, esthioneuroblastoma, pharyngeal squamous cell carcinoma, or primary malignancies of most organs (pancreas, gallbladder, renal, gastric, ovarian, ovarian duct, uterus, bladder, thymus, or thyroid).

Autoimmune/Demyelinating

OMS has been associated with anti-glutamic acid decarboxylase (GAD), adrenocorticotropic hormone (ACTH), antimitochondrial, acetylcholine receptor, and celiac antibodies. Ocular flutter, myoclonus, and ataxia with positive anti-GQ1b antibodies have been reported. Patients with sarcoidosis, multiple sclerosis, Guillain–Barre syndrome, acute disseminated encephalomyelitis, and HIV-associated immune reconstitution inflammatory syndrome have rarely developed OMS.

Infectious/Parainfectious

As a more common cause in adults, OMS has occurred in conjunction with, or following, various infectious etiologies. Documented infectious agents include viral infections (rubella, mumps, lymphocytic choriomeningitis, varicella-zoster, cytomegalovirus, poliomyelitis, Epstein–Barr, parainfluenza, Hemophilus influenzae, Coxsackie B, human immunodeficiency virus, St. Louis encephalitis, human herpesvirus 6, and West Nile), neurosyphilis, Salmonella typhi, streptococcal infection, Lyme disease, mycoplasma pneumoniae, tuberculosis, psittacosis, and malaria. Whipple's disease may cause a clinical picture similar to OMS, and should be considered in the differential diagnosis.

Drug Toxicity

OMS has occurred as part of toxicity syndromes of numerous drugs, including tricyclic antidepressants, dopamine blocking agents (haloperidol, metoclopramide), recreational drugs (cocaine, phencyclidine, amphetamines), lithium, nicotine, isoniazid, and antiepileptic drugs (phenytoin, diazepam, carbamazepine). Several toxic exposures have caused OMS, including lead, mercury, strychnine, toluene, thallium, and bismuth salts, have caused OMS.

Idiopathic

Workup in up to 50% of cases may yield no identifiable etiology despite an exhaustive search, which more often is the case in younger (<40) adult patients. OMS may represent a transient phenomenon in otherwise normal infants.

Miscellaneous

OMS has been associated with focal intracranial tumors (lymphoma, glioma, pineal, posterior fossa cysts), stroke (thalamic or pontine hemorrhage, vertebrobasilar insufficiency), pregnancy, trauma, post-vaccination, post-infectious encephalitis, metabolic derangements (nonketotic hyperosmolar coma, multiple carboxylase deficiency), allogeneic stem cell transplant, and congenital malformations.

Diagnostic Work-up/Tests

Neoplastic Work-up

An aggressive search for associated neoplasms should be guided by age and individual risk factors, and may include high-resolution CT or MRI imaging of the neck, chest, abdomen, and pelvis. Discovery of suspicious masses may further direct neoplasm-specific workup. Meta-iodobenzylguanidine (MIBG) whole-body scintigraphy may sensitively detect neuroblastoma if other imaging is negative. Directed or broad screening for paraneoplastic antibodies should be considered, although the absence of detectable antibodies does not always rule out a paraneoplastic syndrome.

Brain Imaging

Imaging studies are usually normal, but may reveal evidence for focal brain lesions or other clues to the specific underlying etiology.

CSF analysis

CSF may be normal or show lymphocytic pleocytosis, oligoclonal bands, or elevated protein. Neuroblastoma results in reduced 5-HIAA and homovanillic acid in CSF in conjunction with elevated urine catecholamine levels.

Management

Management is not standardized, and the rarity of OMS has not permitted randomized treatment trials. Therapeutic strategies vary according to identified causative factors and are directed towards symptomatic treatment of the most disabling symptoms. For paraneoplastic disorders, treatment modalities specific to underlying tumor can include chemotherapy, radiotherapy, or surgery. Empiric immunomodulatory therapy is commonly employed, initially with high-dose steroids or ACTH. Resistant or relapsing cases may be treated with combinations of intravenous immunoglobulin (IVIG), plasmapheresis, cyclophosphamide, or azathioprine. Rituximab, an anti-CD20 antibody, has been used in resistant or relapsing cases and is being investigated in open-label trials. Some patients have benefited from the serotonin precursor 5-hydroxy-L-tryptophan, thyrotropin-releasing hormone, or protein A column immunoabsorption. Symptomatic treatment includes trazodone for sleep difficulty or rage attacks, mood-stabilizing medications, anti-myoclonic drugs (clonazepam, valproic acid, levitiracitam, piracetam), or monoamine depleting drugs. Oscillopsia may be treated with propranolol, clonazepam, thiamine, or baclofen.

Prognosis

The prognosis varies depending on the symptoms, promptness of treatment, the presence and type of neoplasm, and individual-specific factors. Children respond more robustly to immune therapy than adults, with partial or complete relief in 80% of patients after 1–4 weeks of treatment. Corticosteroids or IVIG appears to accelerate recovery in adults. Although most patients initially respond to initial therapy, many exhibit persistent neurologic problems such as persistence of movement disorders, sleep difficulty, learning disorders, mood disorders, or neuropsychiatric deficits. Patients may have clinical remissions of any subset of symptoms or waxing and waning of neurologic function, requiring repeat treatment or maintenance therapy. Idiopathic causes typically have a more benign course, although older patients may have residual gait ataxia. Paraneoplastic OMS may have partial or complete remission if the underlying malignancy is treated; if the malignancy remains untreated, outcome is poor regardless of therapy.

Oral Dyskinesia

P Blanchet, Universite de Montreal, Montreal, QC, Canada

Glossary

Oral dyskinesia – Abnormal, involuntary, aimless, repetitive movements affecting the tongue, lips, and jaw.
Oral stereotypies – Repetitive, aimless, patterned movements of the tongue, lips, and jaw.
Oromandibular dystonia – Sustained muscle contractions resulting in twisting repetitive movements and abnormal postures, producing lip retraction and grimacing, tongue rolling and thrusting, jaw closure with trismus, jaw opening or lateral deviation, and jaw jerks, sometimes generating teeth grinding noise (wakeful bruxism) and tremor.
Tardive dyskinesia – Term encompassing a variety of abnormal, involuntary movements following chronic exposure to dopamine receptor-blocking agents (e.g., antipsychotic drugs, antiemetic agents such as metoclopramide), commonly involving the lower facial musculature to justify the label 'orobuccolinguomasticatory syndrome'.

Definition

Oral dyskinesia consists of abnormal, involuntary, aimless, repetitive movements affecting the tongue, lips, and jaw. These movements produce lip pursing, pouting, retracting, smacking, sucking, and licking, tongue writhing and thrusting, and chewing. Compared with extraoral hyperkinetic movement disorders, oral dyskinesia more often results from exposure to an offensive medication or a peripheral condition. Thus, oral dyskinesia should be considered drug induced until proved otherwise, allowing a proper inquiry into the patient drug history to take place. Clinical examination should first proceed without any foreign object in mouth, and should not be restricted to the oral cavity since extraoral findings may point to a specific diagnosis.

Differential Diagnosis

The various forms of oral dyskinesia are classified according to the predominant phenomenology of the manifestations as stereotyped (if patterned and predictable), choreiform, and dystonic in nature. Oromandibular dystonia is recognizable by sustained lip retraction and grimacing, tongue rolling and thrusting, jaw closure with trismus, jaw opening or lateral deviation, and jaw jerks, sometimes generating teeth grinding noise (bruxism). Sensory signals ('geste antagoniste') provided by holding something in the mouth (seed, gum, straw), or a local light touch, may reduce these spasms. A rare form of myorhythmic movements of the jaw and eyeballs may be seen as a distinctive feature of systemic Whipple disease. Oral dyskinesia must be distinguished from motor tics (more sudden, irregularly occurring, and suppressible, sometimes preceded by an urge) and the 'rabbit syndrome' (vertical labial or orofacial resting tremor of the parkinsonian type).

Oral dyskinesia occurs in a variety of brain conditions (**Table 1**), including mental retardation, Rett syndrome, and neurodegenerative conditions such as Huntington's disease. Reported estimates of the incidence of orofacial dyskinesia in antipsychotic-free patients with Alzheimer disease have varied between 10% and 40%. The issue of the occurrence of 'spontaneous' (or unmedicated) oral dyskinesia in normal aging remains blurred, since complete drug history and other dyskinesigenic conditions (e.g., orodental and cognitive status) are often incompletely documented. Lip smacking and chewing may be seen in never-medicated patients with chronic schizophrenia, with prevalence estimates averaging 12%. Other neurological disorders associated with oral dyskinesia include chronic hepatic encephalopathy, infectious or paraneoplastic encephalitis, and subcortical infarcts. Severe lingual dystonia, uncommon in primary dystonias, suggests the presence of a secondary or heredodegenerative cause, such as neuroacanthocytosis, pantothenate kinase-associated neurodegeneration, Lesch–Nyhan syndrome, postanoxic encephalopathy, and drug-induced ('tardive') dystonia. A wide range of medications crossing the blood–brain barrier also causes various types of orofacial dyskinesia, particularly the first-generation antipsychotic drugs (potent dopamine D2 receptor antagonists) and antiparkinsonian medications (chiefly levodopa). Certain drug addictions (amphetamines, cocaine, alcohol) may trigger orofacial dyskinesia.

Oral dyskinesia may also occur in association with certain orodental conditions. Edentulism is a neglected source of stereotyped oral dyskinesia. Orodyskinesia has been documented in 16% of edentulous subjects. The smacking and pursing of the lips, lateral deviation and protrusion of the tongue, and lateral deviation and protrusion of the jaw,

Table 1 Causes of oral dyskinesia

Subtype	*Cause*
Stereotypies	'Spontaneous' (detailed characterization lacking)
Chorea	Stress
Dystonia	Anxious clenching habit
Myorhythmia	Idiopathic
	oromandibular dystonia
	Meige syndrome (with blepharospasm)
	Non-DYT1 primary generalized dystonia
	Task-specific dystonia (e.g., speaking, embouchure instrument playing)
	Episodic focal lingual dystonic spasms
	Drug induced
	antipsychotic drugs (conventional > > atypical)
	antiemetic agents (metoclopramide, prochlorperazine)
	antidepressants

	Whipple (oculomasticatory myorhythmia)
	Paraneoplastic (anti-Ma2, anti-*N*-methyl-D-aspartate receptor (NMDAR)
	Tumors
	Metabolic conditions
	Lesch-Nyhan syndrome (with self-mutilation)
	Gaucher disease
	chronic acquired hepatocerebral degeneration
	Peripherally induced
	grossly incorrect occlusion
	edentulous dyskinesia
	denture-related dyskinesia (ill fitting)
	posttraumatic
	dental procedure-related dystonia

have been observed. The movements are generally mild in intensity, but a significant fraction of subjects still feel distressed by the condition. These individuals are more likely to wear inadequate or no dentures at all than edentulous subjects without dyskinesia. In those with unstable dentures and oral discomfort, the label 'denture-related dyskinesia' may be justified. The prevalence of this complication is undetermined. Edentulous orodyskinesia may be distinguished from oral tardive dyskinesia (TD) on the basis of excessive aimless movements always restricted to the oral region, never dystonic in nature, and the absence of tongue writhing or thrusting at rest. In rare case reports, peripherally induced dystonia-like activity has followed a routine dental procedure, facial or orodental trauma, or ill-fitting denture or bridge insertion. No direct relation has been found between the severity of the injury and the development of dystonia. Several of these patients have had the onset of their manifestations within 1 week of the procedure. Spreading to other muscle groups, fixed jaw-deviating spasms, and pain have been noted. A coincidence or unmasking effect of a latent movement disorder by the dental procedure cannot be ruled out, as well as a psychogenic disorder.

Pathophysiology

The pathophysiologic mechanisms underlying oral dyskinesia remain unclear. Most forms of oral dyskinesia are of cerebral origin. Transient chemical disruption of inhibitory signaling in the lentiform nucleus of conscious monkeys produced orofacial dyskinesia, and deep brain stimulation of the external globus pallidus caused controlateral chorea in humans. The impact of many offensive medications on dopamine and acetylcholine neurotransmission suggests that these transmitters are implicated in the induction process and expression of oral dyskinesia. The antidyskinetic benefit afforded by the VMAT2 ligand tetrabenazine, a central monoamine depleter, supports this hypothesis. In animal models, the enhancement of striatal dopamine D1 receptor-mediated responses and the striatal activation of the Ras-extracellular signal-regulated kinase 1/2 mitogen-activated protein kinase signaling pathway have been correlated with levodopa-induced dyskinesia. Whether these molecular changes constitute a common neural substrate

for drug-induced dyskinesias and potential targets for future therapy remains undetermined.

The possible contribution of orodental factors such as edentulism should not be ignored, since they not only can generate oral dyskinesia amenable to correction, but also can worsen orofacial TD ratings. In edentulous orodyskinesia proprioceptive defects, due to loss in nerve endings and periodontal ligaments resulting from tooth extractions, have been suggested as a mechanism. However, no change in perioral pain sensory threshold has been documented in edentulous orodyskinesia cases relative to controls. Clinical findings support the view that edentulous orodyskinesia often takes place in a context of inadequate occlusion and overclosed vertical dimension (biomechanical factors associated with denture instability, and reduced facial support). On the other hand, long-standing oral dyskinesias can lead to premature wear and instability of the dentures, damaging gingival and bone structures, causing atrophy and additional prosthetic problems.

Management

The management of involuntary orolingual movements remains difficult. Since the diagnosis essentially relies on clinical assessment, recognition and proper therapy are not always straightforward. The emphasis of management strategies for drug-induced oral dyskinesia should focus on prevention. Early detection of vermicular tongue movements should be immediately reported to the treating physician, and the offensive drug withdrawn if possible. For disabled cases, palliative antidyskinetic treatment with tetrabenazine may be offered, but this is not an option in levodopa-induced dyskinesia. The benzodiazepine clonazepam can be used alone or in combination, but causes dose-dependent somnolence and carries a risk of dependence and tachyphylaxis over time. In dystonic cases, young subjects in particular, benefit may be obtained with an anticholinergic drug (e.g., trihexyphenydil). These oral treatments should in general not be discontinued abruptly to avoid a dystonic storm or a withdrawal syndrome. Intramuscular botulinum toxin administration is an excellent option in orofacial dyskinesia. The genioglossus muscle may be injected in severe tongue protrusion dystonia, but this approach has been rarely described. Severe refractory cases may respond to bilateral deep brain stimulation of the internal globus pallidus.

The potential complications (**Table 2**) caused by oral dyskinesia must be evaluated and treated diligently. In case reports, the insertion of dentures offering proper fit and adjustment of the occlusion has quickly relieved oral movements in edentulous orodyskinesia. Occlusal treatment has also ameliorated oral TD, as well as oral dyskinesia displayed by Down syndrome subjects with orofacial dysmorphology. Since denture retention may be troublesome in the presence of oral dyskinesia, an osteoimplanted mandibular prosthesis has been proposed, but only few isolated cases have been reported. In jaw-closing dystonia responsive to a sensory trick, a simple bite-raising soft device fitting between the molars to prevent jaw closure by a few mm can improve function. This should be introduced early to prevent tooth wear and temporomandibular joint dysfunction.

Table 2 Potential complications resulting from oral dyskinesia

Complications
Tooth wear
Tooth and denture damage
Accelerated bone loss in edentulous patients
Oral pain
Temporomandibular joint degeneration
Mandibular luxation
Friction/biting injuries (tongue, cheek bites)
Speech impairment
Dysphagia
Drooling
Chewing difficulties
Inadequate food intake and weight loss
Breathing difficulties
Displacement/impaired retention of removable dental prostheses
Social embarrassment (unemployment, isolation, depression)

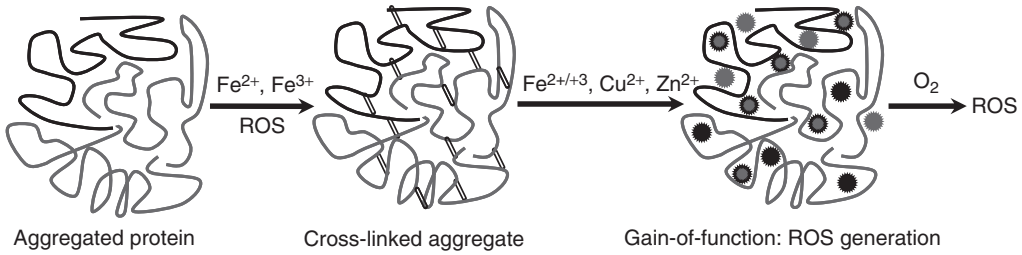
Oxidative Stress and Movement Disorders

I G Gazaryan and R R Ratan, Burke Medical Research Institute, Weill Medical College of Cornell University, NY, USA

Glossary

Complex I deficiency – The mitochondria generate ATP via chemical coupling of a gradient of protons to ATP synthesis. A gradient of protons (between the outer mitochondrial membrane and the inner mitochondrial membrane) is generated by the transport of electrons from Complex I to IV. Abnormalities of complex I in PD lead to a buildup of electrons (which are passed on to oxygen to generate superoxide) and a decreased proton gradient leading to decreased ATP.
Free radical – Stable molecules contain two paired electrons of opposite spin in one or more of their outer most orbitals. Radicals contain an unpaired electron in their outer most orbitals. They are called 'free,' because they are stable enough for independent existence. Radicals move around the cell, looking for electrons to steal from cellular constituents such as lipid, protein, or DNA and thereby leave the target irreversibly altered.
Glutathione – An endogenous tripeptide, γ-glutamyl-cysteinyl-glycine, that is present in brain and peripheral tissues in concentrations approaching millimolar. It is a versatile antioxidant that along with enzymes such as glutathione peroxidase and glutathione reductase protects neurons. Of note, glutathione is one of the earliest known changes in Parkinson's disease – its levels are decreased.
Oxidative stress – Operationally defined as an imbalance between oxidants (free radicals) and antioxidants in the cell in favor of oxidants and above a threshold that leads to damage or death of a cell.
Superoxide dismutase – Superoxide is produced as a result of an addition of one electron to oxygen. Superoxide is produced as a consequence of many reactions, particularly as a byproduct of oxygen utilization in the mitochondria to generate ATP. Superoxide is thus a free radical that is produced as a consequence of normal metabolism. Mitochondrial dysfunction in PD leads to increase superoxide production.

Prototypic neurodegenerative movement disorders include Parkinson's disease (PD) and Huntington's disease (HD). Both the disorders are linked to inherited mutations resulting in accumulation of the damaged proteins or their wrongly processed variants. However, sporadic neurodegenerative conditions are also associated with accumulations of misfolded proteins and their aggregates resulting in the endoplasmic reticulum (ER) stress. The ER has a quality-control function with these proteins; only correctly folded proteins are excreted from the ER, while unfolded or misfolded proteins are degraded via ER-associated protein degradation, which is mediated by the ubiquitin–proteasome system. The accumulation of unfolded or misfolded proteins in the ER is one of the major causes of ER dysfunction. Downstream of these events, metal-catalyzed oxidation leading to oxidative stress has been implicated as a common final pathway of injury (**Scheme 1**). Despite the rarity of the familial forms of PD and HD, the identification of the genes and their defects has fueled our understanding of the pathogenic mechanisms,



Scheme 1 Widely accepted hypothetic gain-of-function transformation of cross-linked aggregates of misfolded proteins. Confirmed for AD, PD, ALS, and supposed for HD.

which include ubiquitin–proteasome system malfunction, oxidative stress, and mitochondrial dysfunction.

Oxidative stress can be operationally defined as an imbalance of cellular oxidants and antioxidants in favor of oxidants. However, cellular oxidants and the injuries they perpetrate are not an undifferentiated whole. Rather distinct oxidants act in distinct cell types and subcellular locations to trigger a continuum of responses from adaptation to apoptosis to necrosis. Here, we provide a 30 000 foot view of oxidative injury in the nervous system, as it relates to movement disorders and from this hope to build a conceptual framework for understanding how changes in redox balance can mediate dysfunction in the CNS.

Oxidative Stress: Inescapable Component of Mitochondrial Respiration

Mitochondria as a Major Source of Superoxide under Normal Conditions

Neurodegeneration is directly modified by cell aging. Some theories invoke the mitochondria as the major site of generation of deleterious free radicals that promote aging. The chemistry of reactive species that could result in oxidative damage under normal physiological conditions is the same for any cell. The major species in cells is superoxide radical produced as a byproduct of the mitochondrial respiration, in particular by Complex I and III of the respiratory chain. Complex III breaks 2e reducing equivalent into two single-electron reducing equivalents inside the membrane (Q-cycle), and the resulting quinone radical reacts with oxygen, giving rise to superoxide radical. This side reaction is known as 'mitochondrial leakage' and comprises up to 3–4% of the total oxygen consumption. If in a lifetime, we consume nearly 60 000 L of oxygen per kg weight, it means that we produce ~2000 L superoxide per kg weight. What happens to the released superoxide and how does cell handle the consequent 'oxidative' load?

Antioxidant/Antiaging Mechanisms: Superoxide Scavenging

In both cytosol and mitochondria, superoxide is scavenged and converted into hydrogen peroxide and oxygen by superoxide dismutase (SOD), although the nature of SOD in mitochondria and cytosol is different (MnSOD and CuZnSOD). The formed hydrogen peroxide is further decomposed into water with the help of catalase or reduced by the glutathione peroxidase/glutathione system. Very recent studies show that thioredoxin reductase/thioredoxin system is also capable of reducing hydrogen peroxide to water.

There are a number of theoretical reasons why the nervous system in general and neurons in particular are under the biggest load of oxidative stress under basal conditions. Neurons have a very high metabolic rate in order to meet the demands of electrical signaling. Specifically, our brain uses 20% of the total oxygen consumed, although brain is only 2% of the body weight. An expected corollary of high oxygen utilization is 10-fold higher level of radical production. Paradoxically, despite higher radical production, catalase is absent in brain mitochondria. This is not the case for heart mitochondria.

Given the higher level of radical production and the absence of catalase in brain mitochondria, what are the mechanisms at play inside neuronal mitochondria to neutralize the formed hydrogen peroxide and to keep oxidative damage to tolerable levels? In addition to glutathione peroxidase, the only other known system that neutralizes hydrogen peroxide is that of thioredoxin and peroxiredoxin. Reduced thioredoxin provides peroxiredoxin with reducing equivalents to reduce hydrogen peroxide to water. Oxidized thioredoxin is reduced back by mitochondrial thioredoxin reductase, selenocysteine flavo-dithiol oxidoreductase. Why mitochondrial catalase is absent in neurons is not well understood, but could be related to signaling functions of peroxide in neurons that are not necessary in other tissues. The absence of catalase from neuronal mitochondria places the burden of neutralizing hydrogen peroxide generated in mitochondria squarely on the shoulders of the thiol-based detoxification systems, particularly glutathione, thioredoxin, and periredoxin. A causal role for mitochondrial peroxide in aging was supported by the generation of transgenic mice that overexpress catalase in the nucleus, the peroxisome, and the mitochondria. Significant extension of lifespan was seen only in animals in which catalase was overexpressed in the mitochondria. The extension of lifespan was associated

with improvement in cardiac function, decreased development of cataracts, and diminished mitochondrial DNA mutations. It is unclear to what extent the increased lifespan reflected improvements in brain function.

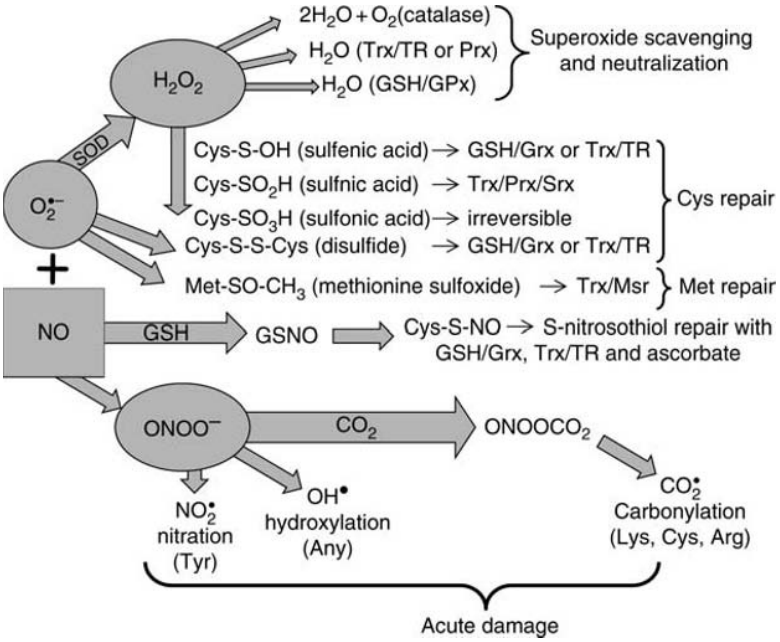
Antioxidant/Antiaging Mechanisms: Repair of Oxidized Residues

Unscavenged radicals are thermodynamically driven to oxidize cellular constituents including protein cysteines and methionines. These critical amino acid residues can be reduced back only with the help of specialized enzyme systems (**Scheme 2**). Cysteines are reduced back with glutaredoxin-glutathione system, and methionines are reduced back with methionine sulfoxide reductase (MSR) system. The MSR system includes two enzymes, only one of which belongs to the same enzyme class as glutathione reductase and thioredoxin reductase.

The glutaredoxin-glutathione enzyme system has beneficial effects on the functional activity of a number of proteins, including the thiol-containing mitochondrial Complex I, the inhibition of which was caused by administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin that produces PD-like symptoms in primates, including humans. Interestingly, glutathione depletion is an early feature of PD and appears to be disease specific. The depletion of glutathione may explain defects in Complex I function found in sporadic forms of PD.

MSR, another important enzyme in repair of proteins, is proposed to play a central role in neurodegeneration and aging. Genetically engineered organisms overexpressing the enzyme live longer. On the contrary, the reduced or suppressed activity of the enzyme results in shortened life span, hippocampal degeneration, and increased sensitivity to oxidative stress. The enzyme can repair oxidized methionines and restore the function of many important proteins, for example, calmodulin. MSRs act on oxidized calmodulin and repair all the eight methionine sulfoxide residues initially present in the inactive protein.

As mentioned earlier, neuronal mitochondria protect themselves against hydrogen peroxide formed inside the matrix solely with the thiol-dependent enzyme systems. Moreover, repair systems also largely depend on reduced thiols (see above). In many cases, the catalytically important enzyme thiols were shown to be protected against oxidative damage by glutathionylation. Glutathionylation is a posttranslational, reversible redox modification of proteins by thiol/disulfide exchange. Indeed, glutathione used to be a dominant theme in brain neurodegeneration, and it was only recently that the significance of thioredoxin-based systems has been fully appreciated. Measurements of NAD(P)H-dependent thiol reducing activity in



Scheme 2 ROS/RNS generation and neutralization reactions & systems: Upper level: Superoxide scavenging reactions catalyzed by superoxide dismutase (SOD), catalase, thioredoxin reductase (TR), peroxiredoxin (Prx), and glutathione peroxidase (GPx) and mediated by thioredoxin (Trx) and glutathione (GSH). Center: Oxidation states of cysteine and methionine and their repair; glutathione repairs most of the oxidative modifications by glutathionylation followed by its removal with glutaredoxin (Grx) system; methionine is repaired with methionine sulfoxide reductase (Msr)/Trx system; sulfonic acid modification is irreversible, while sulfinic acid can be repaired with the use of a recently characterized ATP- and Mg2+-dependent enzyme, sulfiredoxin (Srx), which is capable of reducing the sulfinic form of peroxiredoxin. Lower level: peroxynitrite-generated radicals cause largely non-repairable damage to proteins, DNA and lipids.

brain mitochondria show that glutathione reductase and thioredoxin reductase are equally important. Thiol-dependent systems of hydrogen peroxide neutralization and subsequent repair by themselves are targets for oxidative modification, and this obviously creates a threshold of oxidative damage that can be handled by neuronal mitochondria. Once reached, it results in mitochondria failure and the subsequent cell death by either apoptotic or necrotic pathways.

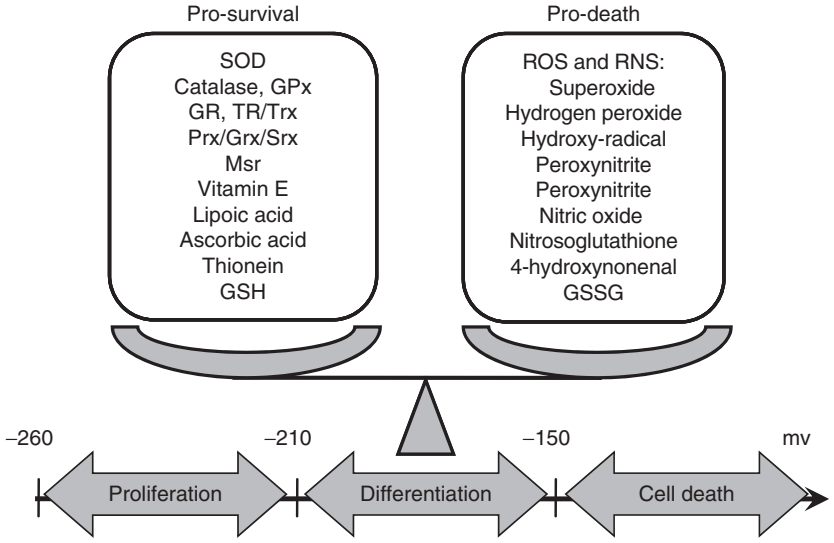
Oxidative Stress and Aging

Chronic Oxidative Stress and Ischemia

The delicate balance existing under normal conditions between oxidant production and antioxidant defensive mechanisms (**Scheme 3**) can be either slowly shifted with aging or disturbed at once upon acute injury. The 'slow acting' factor is a progressive mitochondrial malfunction, which originates mainly from the damage of the mitochondrial DNA: the superoxide released by mitochondria is directed both 'in' and 'out' of the mitochondrial inner membrane, and therefore, is capable of damaging mitochondrial DNA, matrix proteins, inner membrane proteins, and lipids. The progressive 'oxidation' eventually results in mitochondrial inability to utilize oxygen efficiently and makes them less competitive with respect to other intracellular processes consuming oxygen, particularly those controlling the ratio between aerobic and anaerobic respiration. Aging cells are more and more dependent on mitochondrial respiration, and consequently are less prepared for the increased risk of ischemia. Paradoxically, ischemia results in the increased production of ROS and excessive damage upon reperfusion. The master regulator of the hypoxic adaptation, hypoxia-inducible factor (HIF), has been recently shown to activate one of the key antioxidant proteins in mitochondria, metallothionein-3. HIF is a widespread transcription factor activating a battery of genes including those involved in glucose uptake and metabolism, extracellular pH control, angiogenesis, erythropoiesis, and mitogenesis, acting to enhance the cell survival ability. More and more new genes are found to be regulated by HIF. Tyrosine kinase receptor B (TrkB) for Brain-derived neurotrophic factor (BDNF) is also a HIF target implicating HIF in the regulation of neurotrophin signaling. The most exciting finding was the upregulation of tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of dopamine, by HIF. However, the link between hypoxia and mitochondrial biogenesis activator PGC-1α as well as the mechanism of hypoxic upregulation of mitochondrial uncoupling protein-3 is still controversial.

The predominant O_2-dependent regulation of HIF-1α is mediated by posttranslational mechanisms, among which hydroxylation of Pro564 (HIF-1α is the major regulator and is catalyzed by nonheme iron αKG-dependent dioxygenases known as the HIF prolyl hydroxylases (HIF prolyl hydrodxylases isozymes 1–3). Deficiency or inhibition of PHD1 induces hypoxia tolerance in skeletal muscle by reprogramming basal metabolism through activation of HIF-2α – > Pparα – > Pdk4 (pyruvate dehydrogenase kinase isozyme-4, restricts entry of glycolytic intermediates into TCA cycle), although no direct link between HIF-2α and Pparα has been established.

PHD3 only recently gained full attention because of two major findings. First, PHD3 was shown to accumulate



Scheme 3 Delicate balance between pro-death and pro-survival factors determines the cell fate *in vivo*. For the cultured nerve cells, the depletion of intracellular redox potential (shown as that for GSSG/GSH couple) below a certain level determines whether the cells will differentiate or die.

with age in different tissues. Age-associated changes in PHD3 expression inversely correlate with the expression of HIF-target gene macrophage migration inhibitory factor (MIF), which was described to be involved in cellular HIF-mediated antiaging effects. In a recent study, evidence was provided that HIF-1 plays a critical role in delaying the onset of senescence in rodent cells via transcriptional activation of MIF and thereby inhibition of the p53-mediated pathway. It is worth mentioning here again that PHD3 in mice has a mitochondria-targeting leader sequence and that PHD3 seems to be most flexible PHD isoform regarding stimuli-induced change in expression.

Second, PHD3 was found to form subcellular aggregates. The most intriguing finding was that PHD3 inhibition prevented it from forming aggregates. The PHD3 aggregates were dependent on microtubular integrity and contained components of the 26S proteasome, chaperones, and ubiquitin, thus demonstrating features that are characteristic of aggresome-like structures. Forced expression of the active PHD3 induced the aggregation of proteasomal components and activated apoptosis under normoxia. The apoptosis was seen in cells prone to PHD3 aggregation and the PHD3 aggregation preceded apoptosis. The data demonstrate the cellular oxygen sensor PHD3 as a regulator of protein aggregation in response to varying oxygen availability. Given the fact that PHD3 expression is upregulated with aging, it may actually contribute to the reduced cell tolerance to hypoxia-reoxygenation and other pathological scenarios of oxidative stress.

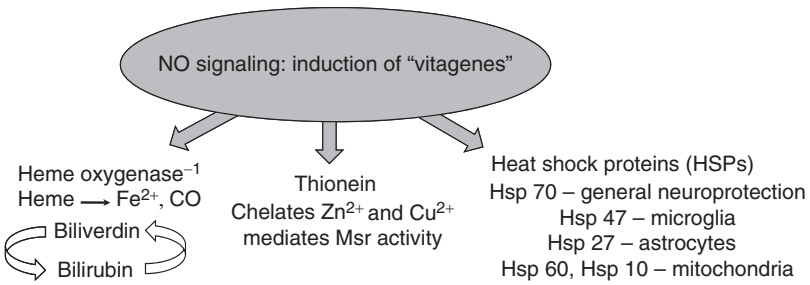
Acute Oxidative Stress

The neurotoxins (rotenone, MPTP) and neurotoxic animal models of PD renewed interest in possible environmental causes of PD. The most common form of neurodegeneration occurs after an acute injury. The causes of neuronal injury are many and include trauma, DNA damage from radiation, chemotherapeutic agents, exposure to environmental neurotoxins, and others. Acute neuronal damage involves a complex combination of processes including excitotoxicity, inflammation, necrosis, and apoptosis. The adaptive response to tissue damage includes the activation of transcription factors such as nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) and others to switch on the inflammation response to limit damage and promote repair.

Excitotoxicity

Excitotoxicity is a particularly important event that initiates acute neurodegeneration. Accumulation of glutamate within the synaptic cleft leads to Ca^{2+} influx via hyperactivation of *N*-methyl-D-aspartate receptors, voltage-gated Ca^{2+} channels, and nonspecific cation conductances. The latter non-specific cation channels are represented by the recently discovered transient receptor potential (melastatin) (TRPM) ion channels, among which TRPM7 and TRPM2, shown to be permeable for Ca^{2+} and inhibited by gadolinium, appear to play a critical role in anoxic cell death.

Excess Ca^{2+} via ionotropic glutamate receptors results in the initiation of neurotoxic signaling cascade by activating calmodulin and neuronal NO synthase (nNOS). Current opinion holds that the intracellular redox state is the critical factor determining whether in brain cells NO is toxic or protective (**Scheme 4**). NO is known to signal the induction of heme-oxygenase-1, which is considered as a prosurvival enzyme. It degrades heme yielding ferrous iron, CO, and biliverdin, which cycles between the oxidized and reduced form, bilirubin. The latter exhibits strong antioxidant properties. Biliverdin reductase is present in brain in large functional excess, suggesting that such redox cycling amplifies antioxidant effects of heme-oxygenase expression. On the other hand, NO also reacts with glutathione, generating nitrosoglutathione, which is able to modify and thus inactivate protein thiols. However, the most dangerous species, peroxynitrite, is generated via the direct interaction of superoxide radical and NO, a comparatively stable and harmless molecule. Peroxynitrite is extremely reactive and capable of nitrating tyrosine residues in proteins (**Scheme 2**). A downstream effect of peroxynitrite production is the activation of TRPM channels. Molecular deletion of TRPM2 or TRPM7 channels renders neurons resistant to hypoxia/aglycemia. Whether



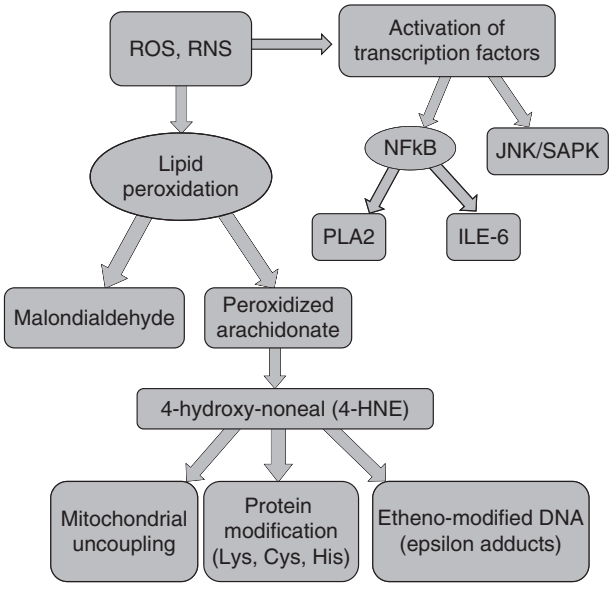
Scheme 4 Pro-survival role of NO: induction of synthesis of (a) heme oxygenase, which provides cells an antioxidant bilirubin/biliverdin/biliverdin reductase system; (b) thioneins, which chelate metal ions and in addition can mediate/enhance methionine sulfoxide reduction by Msr and Trx; and (c) heat shock proteins.

peroxynitrite induces activation of TRPM channels via nitration of its critical components or some upstream modulatory protein is unclear. Protein nitration has been shown to take place in brain injuries and some but not all neurodegenerative diseases.

Superoxide and especially peroxynitrite-induced modification of the metallothionein thiols results in the release of zinc. Neurodegenerative diseases are characterized by a mobilization of intracellular zinc. The latter was shown to mediate NO-induced neuronal death by directly affecting mitochondrial respiration through inhibiting Complex III. In addition, it has recently been shown that zinc is capable of entering mitochondria and directly inactivating lipoamide dehydrogenase, the terminal enzyme of major multienzyme energy-producing complexes, as well as glutathione reductase and thioredoxin reductase. The inactivation is irreversible, and only the newly synthesized proteins transported into mitochondria may compensate for the damage (**Scheme 5**). Thus, acute oxidative damage resulting in massive release of intracellular zinc will cause the mitochondrial failure and cell death.

Inflammation

Oxidative stress can directly or indirectly initiate an inflammatory cascade. Collective evidence from many recent studies suggests that increased phospholipase A2 activity plays a central role in acute inflammatory responses in the brain as well as in oxidative damage associated with AD, PD, and multiple sclerosis. PLA2 contributes to the pathogenesis of neuroinflammation by attacking neural membrane phospholipids to yield arachidonic acid and lysophospholipids. These are subsequently metabolized to a variety of proinflammatory lipid mediators such as prostaglandins, leukotrienes, thromboxanes, and platelet activating factor. Arachidonic acid metabolism is also one of the major sources of oxidative damage (**Scheme 6**). Arachidonic acid undergoes catalytic oxidation by cyclooxygenases 1 and 2, and in addition, can react with superoxide or peroxynitrite to generate one of the most potent modifying agents, 4-hydroxy-2-nonenal (HNE). The latter can modify lysine, cysteine, histidine residues in proteins and can bind to free amino acids and deoxyguanosine. Immunostaining for HNE-modified proteins shows that such modification is characteristic of acute oxidative stress, occurring during brain and spinal cord injury.

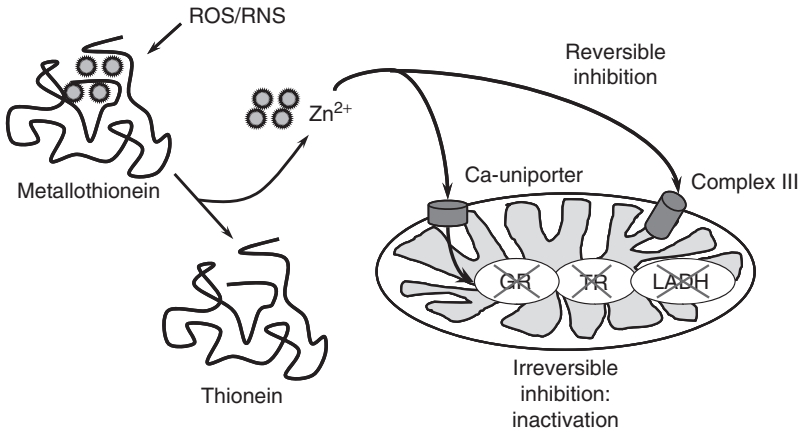


Scheme 5 4-hydroxy-nonenal: the most damaging product of lipid peroxidation. Phospholipase A2 (PLA2) inhibitors were shown to be neuroprotective.

Inflammation is characterized by the increased deposition of iron. Iron, especially in the ferrous or unbound form, is able to catalyze the formation of free radicals and could be a cause of neuronal injury. Depletion of antioxidants in the brain and rise in iron-dependent oxidative stress and monoamine oxidase B (MAO B) activity are key characteristics of aging that contribute to the onset of neurodegenerative disorders. MAO B is a mitochondrial flavin-dependent enzyme that catalyzes oxidative deamination of neurotransmitters and exogenous arylalkylamines. MPTP, an impurity in synthetic heroin, being activated by MAO B, gives a widely used chemically induced model of PD.

1-methyl-4-phenylpyridinium (MPP^+), the toxic product of MPTP conversion, increases superoxide formation by suppressing activity of NADH dehyrogenase (Complex I) and increasing leak of electrons to oxygen. Superoxide is then available to attack Fe/S cluster proteins such as aconitase. Destabilization of cytosolic as well as mitochondrial aconitase results in an increase in iron regulatory protein-1 (IRP-1), an RNA-binding protein that signals cellular iron deficiency. This leads to the paradoxical and maladaptive increase in iron in the cell. The mechanisms underlying iron cellular toxicity are only beginning to emerge. A representative trend in neuroprotective drug development is to combine an iron chelator and a MAO inhibitor in the same compound. Iron chelators have recently been shown to have the ability to induce adaptive gene expression via the stabilization of factors such as HIF-1. HIF is a heterodimeric transcriptional complex that mediates the induction of more than 70 genes involved in hypoxic compensation including vascular endothelial growth factor (VEGF) and Epo.

Activated neutrophils and macrophages generate widespread secondary damage at the traumatic site by releasing cytokines and free radicals. They produce inducible NO synthase and NAD(P)H oxidase (Phox) generating nonmitochondrial superoxide, both the enzymes cooperate to generate peroxynitrite and thus, expose cells to further oxidative damage. In addition to peroxynitrite, leukocytes possess myeloperoxidase, which generates hypochlorite



Scheme 6 Zn-induced damage to mitochondrial enzymes of energy production and antioxidant defense.

from hydrogen peroxide and chloride anion. Hypochlorite is a strong oxidizing agent capable of chlorinating protein residues and oxidizing membrane lipids. In all cases of rodent neurodegeneration, medications reducing inflammatory responses were shown to exhibit beneficial effects on the disease progression.

Apoptosis

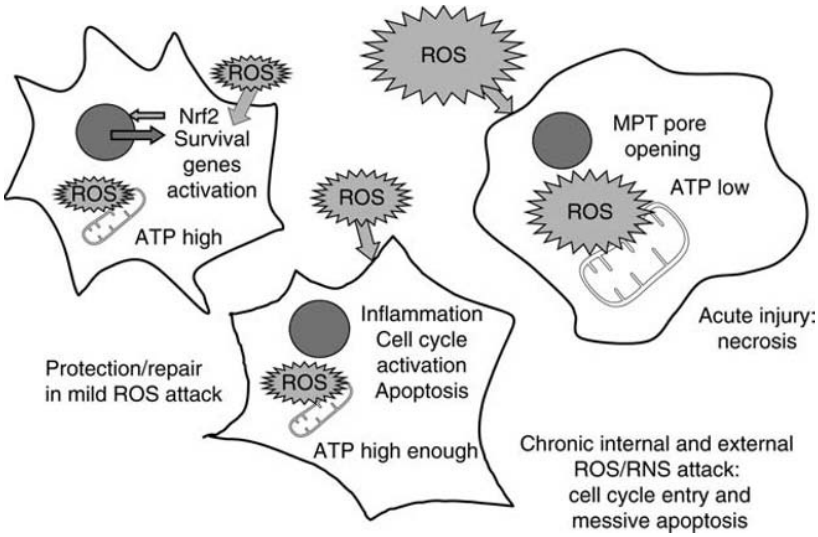
The discovery that oxidative stress can trigger a program of cell death in neurons with features of apoptosis was significant in several aspects. First, it showed that oxidative stress does not always result in random and disordered cell damage. Second, it demonstrated the possibility of free radical triggering an endogenous program of cell suicide.

Oxidative stress has been shown to activate a host of downstream signaling pathways leading to apoptosis. In some schemes, c-Jun N-terminal kinases (JNKs) signaling pathway resulting in Bax translocation, cytochrome c release, and apoptosis. In other schemes, Erk activation or PARP activation leads to translocation of apoptosis inducing factor and caspase-independent cell death. Oxidative stress has been implicated in the activation of cell cycle resulting in cell death, although two studies in which oxidative stress has been induced by downregulating antioxidant defenses failed to demonstrate a protective effect of cell cycle inhibitors.

The superoxide released by mitochondria is directed both 'in' and 'out' of the mitochondrial inner membrane and, therefore, is capable of damaging mitochondrial DNA, matrix proteins, inner membrane proteins, and lipids, and cytosolic proteins and nuclear DNA. With respect to DNA damage, more than 1000 DNA damaging events occur in each mammalian cell every day from replication errors and cellular metabolism. To cope with the deleterious consequences of DNA lesions, cells are equipped with efficient defense mechanisms to remove DNA damage by DNA repair pathways, control cell cycle progression, and eliminate damaged cells via apoptosis. The complicated network of DNA repair mechanisms includes base excision repair, transcription-coupled repair, global genome repair, mismatch repair, homologous recombination, and nonhomologous end-joining damage. Evolution has overlaid the core cell cycle machinery with a series of surveillance pathways termed cell cycle checkpoints. Checkpoints in proliferating cells tightly control progress through the cell cycle; cells may be arrested at any of the checkpoints and either DNA will be repaired or cells will die by apoptosis. It appears that apoptosis induced by oxidative damage may be promoted by multiple pathways, both cell cycle dependent and independent. The determining factor for the pathway(s) induced is an area of active exploration (**Scheme 7**).

Nature of Aggregated Deposits in Neurodegenerative Diseases

PD is a common neurodegenerative disorder affecting 1% of the population over the age of 65. Clinically, PD generally presents with bradykinesia, resting tremor, muscular rigidity, and postural instability. PD is a heterogeneous disease, and the majority of the cases appear to have sporadic origins. The disease is characterized by the loss of dopaminergic neurons in the substantia nigra pars compacta, as well as the presence of Lewy body inclusion in these cells. At least 20% of Parkinson's cases are familial. Ten different genetic loci have been linked with familial PD, and the genes responsible for PD at these loci include α-synuclein and dardarin/LRRK2 associated with dominantly inherited PD, and parkin, DJ-1, and PINK1 causing recessively inherited PD. α-synuclein readily aggregates and is a major fibrillar component of Lewy bodies. Aggregation of α-synuclein is enhanced with tissue transglutaminase: Lewy bodies in PD patients are positively immunostained with antibodies recognizing isodipeptide bonds, a marker of tissue transglutaminase cross-linking. Phosphorylation also promoted



Scheme 7 Cell fate depends on the level of oxidative stress.

α-synuclein aggregation. Culture cells overexpressing α-synuclein generate reactive oxygen species. One mechanism by which aggregated synuclein leads to ROS generation in PD is via trapping trace metals into the aggregates. These metals can then easily accept electrons from reducing substances such as superoxide or glutathione and transfer them to oxygen to form superoxide radical.

Two types of disruptions of the DJ-1 gene have been identified in PD patients. One is a deletion of several of its exons, which abolishes the production of the DJ-1 protein. The other disruption is a single point mutation giving rise to the L166P mutant at the protein level, which destroys DJ-1 dimeric structure. The monomer apparently loses its antioxidant properties and redistributes from cytosol to the mitochondria and nucleus.

DJ-1 inactivation promotes α-synuclein aggregation state in a cellular model of oxidative stress.

Polyglutamine diseases, the CAG trinucleotide repeat/polyglutamine diseases, are characterized by the occurrence of protein aggregates within neurons. The most well-characterized among 10-known diseases of this origin are HD, dentatorubral and pallidoluysian atrophy (DRPLA), spinal and bulbar muscular atrophy, and multiple forms of spinocerebellar ataxia. Each disease is caused by a distinct gene product with expanded polyglutamine repeats.

HD: The hallmarks of this genetic disorder are a progressive chorea combined with dementia. Historically, the lurching madness was mistaken for possession by witchcraft (some of the Salem witches burnt in 1693 may have actually had HD). It is caused by a single, dominant gene, that is, only one copy is sufficient to cause the disease unlike most genetic disorders which are recessive, that is, two 'bad' copies are needed to cause the disease. The average onset is from 35 to 40 years. Huntingtin is a large (350 kDa) protein of unknown function; once the polyglutamine tail crosses the threshold of 38 residues, the mutant begins to form aggregates. The latter precipitate in cytosol and also form nuclear inclusions. The mechanisms by which huntingtin aggregates launch the disease are still disputable. It is supposed to be a gain of function event. It is documented that mutant huntingtin can interfere with gene expression that is associated with adaptation to oxidative stress or mitochondrial dysfunction. Thus mutant huntingtin may be directly toxic to mitochondria and this toxicity may be sustained by mutant huntingtin's suppression of compensatory gene expression. While defects in energy metabolism are widely documented in human HD and associated animal models, the only evidence for oxidative stress is oxidative DNA damage.

DJ-1 in Focus: Linking Antioxidant Defense, HIF Prolyl Hydroxylase, and ER Stress

DJ-1 antioxidant activity is still a mystery. DJ-1 contains an active cysteine 106 (see **Fig. 1**) which redox cycling is indispensable of DJ-1 functioning. The adjacent His 126 and Glu 18 residues may form a putative active site (see **Fig. 1**).

Cytoprotective binding of DJ-1 to apoptosis signal-regulating kinase-1 (ASK1) depends on the central redox-sensitive Cys-106 and may be modulated by peripheral cysteine residues. ASK1 is a member of the mitogen-activated protein kinase family, which activates c-Jun N-terminal kinase and p38 in response to a diverse array of stresses such as oxidative stress, ER stress, and calcium influx. In the past decade, various regulatory mechanisms of ASK1 have been elucidated, including its

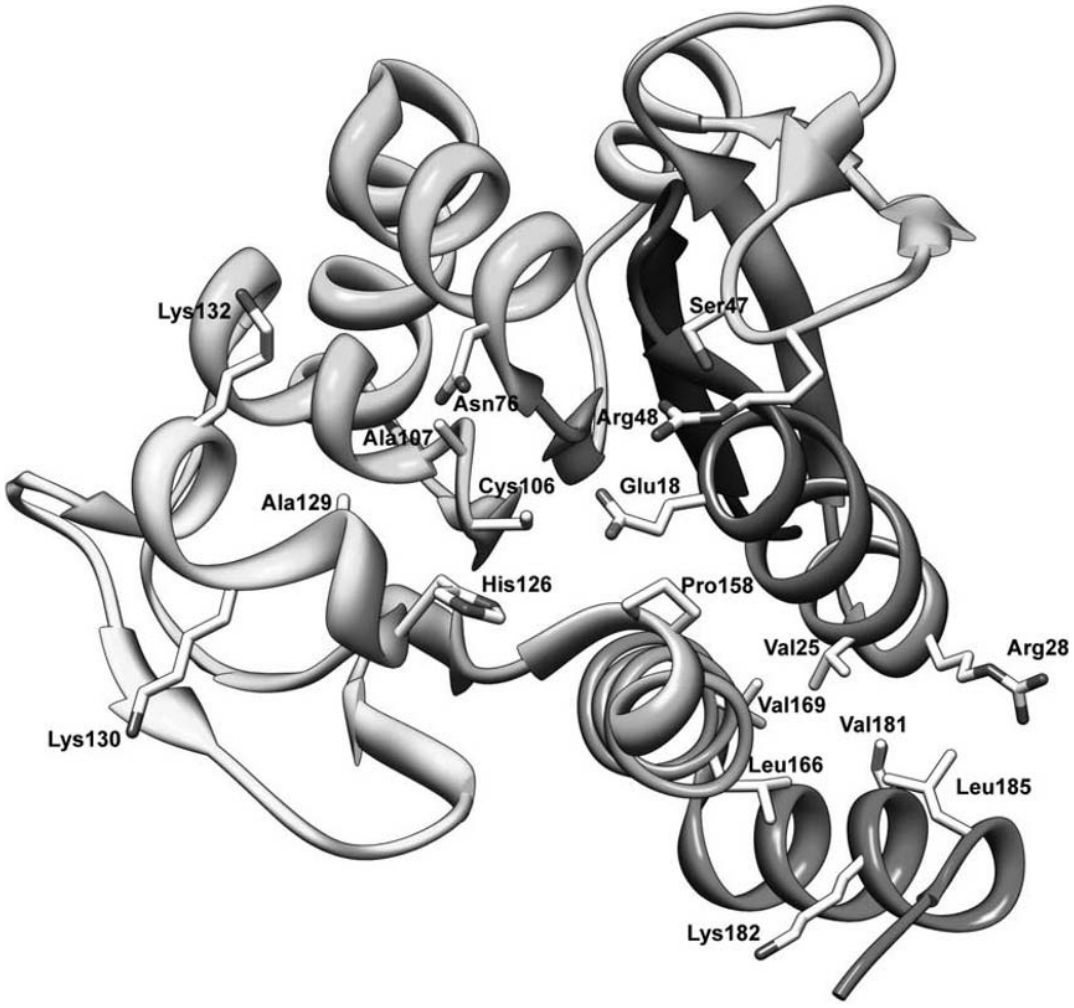


Figure 1 Redox active cyseine 106 and neighborous His126 and Glu18 residues may form a putative active site in DJ-1.

oxidative stress-dependent activation. Recently, it has emerged that ASK family proteins play key roles in cancer, cardiovascular diseases, and neurodegenerative diseases.

DJ-1 is required for the activity of Nrf2 (nuclear factor erythroid 2-related factor), a master regulator of response to oxidative stress. Nrf2 is a member of the cap'n' collar family of basic leucine zipper transcription factors that regulate the expression of many antioxidant pathway genes. Nrf2 is maintained at basal levels in cells by binding to its inhibitor protein, Keap1. Keap1 is a BTB (Broad complex, Tramtrack, Bric-a-Brac) domain-containing protein that targets Nrf2 for ubiquitination by Cul3, leading to its constitutive degradation. Upon exposure to oxidative stress, xenobiotics, or electrophilic compounds, Nrf2 protein is stabilized and translocates to the nucleus. There, it forms heterodimers with other transcription regulators, such as small Maf proteins, and induces the expression of antioxidant genes. Nrf2 drives the expression of detoxification enzymes, such as NAD(P)H quinone oxidoreductase-1, heme oxygenase-1, thioredoxin reductase, and other enzymes that generate antioxidant molecules, such as glutathione. DJ-1 is indispensable for Nrf2 stabilization by affecting Nrf2 association with Keap1, an inhibitor protein that promotes the ubiquitination and degradation of Nrf2.

Finally, DJ-1 was identified as the regulatory subunit of a 400-kDa RNA-binding protein complex and its presence inhibits the binding of RNA by the complex. It is worth emphasizing that the large subunit of RNA polymerase II, Rpb1, has been very recently shown to behave as a substrate for hydroxylation (P1465) by HIF prolyl hydrodxylase-1 (PHD1), in response to low-grade oxidative stress.

Neuroprotection Strategies: Problems and Perspectives

By the time the patient is diagnosed as having a neurological illness, extensive neuronal damage has usually

already occurred. Consequently, there is a great need for the discovery of biomarkers that would allow earlier diagnosis and intervention. Common features among neurodegenerative diseases, that is, genetic mutations, protein misfolding and aggregation, mitochondrial dysfunction, and apoptosis have implications for disease prevention and development of effective therapies. Despite common final pathways, it is unlikely that a single drug or targeting a single mechanism will be sufficient to halt neurodegenerative processes.

Chronic neurodegeneration is age-related, and thus, delay in biological aging will decrease the occurrence of age-related diseases with resulting prolongation of a healthy life span. Available evidence suggests that to delay aging one has to maintain healthy mitochondria and reduce oxidative stress. One of the proposed approaches is to maintain or recover the activity of the so-called vitagenes. The positive effect of heme-oxygenase is linked to the production of bilirubin and biliverdin (already mentioned), which administration after the first few weeks of life in the doses slightly above normal levels resulted in cytoprotective effects.

Another approach to activating vitagenes is administration of nutritional antioxidants. Curcumin, the most prevalent nutritional and medicinal compounds used by Indian populations, has the potential to inhibit lipid peroxidation, and efficiently neutralize reactive oxygen and nitrogen species. It has been recently shown that curcumin inhibits NF-κB activation and induces heme-oxygenase-1. Caffeic acid phenethyl ester, an active component of propolis, has been shown to induce hemeoxygenase-1 in astroglial cells. Gene induction in both the cases occurs through the antioxidant response element (ARE), and this led to the conclusion that the increased expression of genes regulated by the ARE may provide CNS with protection against oxidative stress. Indeed numerous studies have supported a role for ARE activators in the prophylaxis against acute and chronic neurodegenerative conditions.

Antiinflammatory and antiapoptotic treatments will have also shown benefit for many forms of neurodegeneration, although it is also becoming clear that the parts of the inflammatory response must be maintained to facilitate repair.

A recent development in chelators involves the design and synthesis of multifunctional drugs that have the ability to bind iron, inhibit a particular enzyme, and exhibit antioxidant properties (free radical scavengers). Metal, and in particular, iron chelation therapy has been proposed as a way of reducing the level of redox active metals in neurodegenerative diseases. The green tea catechin, EGCG, which is known for its iron-chelating and antioxidant properties, the antibiotic iron chelator clioquinol, and intracerebroventricularly injected desferal (DFO) are potent neuroprotective agents. Obviously, iron chelation targets not only unbound iron and that in the aggregated deposits, but also, more significantly, iron-dioxygenases such as HIF prolyl hydroxylase. The latter is emerging target for neuroprotection although HIF may be not the only substrate of this enzyme. More than 70 genes of putative nonheme iron oxygenases have been identified in the human genome, but only a number of them have the physiological functions ascribed. An assumption on the uniqueness of an inhibitory action of a particular drug selected among others may be wrong, if only one enzyme candidate has been tested. The best example is probably EGCG, which targets HIF prolyl hydroxylase, MAO B, and MICAL, a flavin monooxygenase implicated into axonal guidance and highly homologous to MAO B. The recently discovered M30 as an antioxidant/chelator/MAO inhibitor was also shown to stimulate neurite outgrowth and thus may actually target MICAL as well.

Conclusion

Therapies targeted at reducing oxidative damage in the nervous system must achieve several goals in order to be effective. First, they must interdict pathological oxidant interactions without affecting physiological signaling by radicals. Over the past two decades, peroxide and nitric oxide were shown to play the role of messengers in the nervous system. Antioxidants that inadvertently abrogate these signaling functions would not be desirable. Second, antioxidants or alternatively effective repair strategies must be augmented in distinct cell types and subcellular compartments. Oxidative and nitrosative stress are not an undifferentiated whole and are mediated by distinct species produced in distinct cellular compartments and distinct cell types. The great challenge has been to divine a multimodal strategy that inhibits a cassette of targets without the expected toxicity that arises as the specificity of the therapy decreases. We propose that understanding endogenous homeostatic pathways for protecting against oxidative and nitrosative stress is the way forward. These homeostatic pathways involve the activation of preexisting proteins as well as de novo gene expression. Small molecules that activate homeostatic responses to oxidant stress are expected to reap large therapeutic benefits. Evidence that such an approach is effective and safe continues to emerge from preclinical studies. The ultimate proof will be the demonstration of neuroprotection in a human clinical trial. Such success will also provide long overdue evidence supporting a role for oxidative damage in human neurological disease.

P

Painful Limbs Moving Extremities (PLME)

S Papapetropoulos, Biogen Idec, Cambridge, MA, USA

Historical Note and Typical Variant

The syndrome 'painful legs and moving toes' (PLMT) was initially described by Spillane et al., when in 1971 they described six patients manifesting spontaneous causalgic pain in at least one lower limb and involuntary foot and toe movements. The movements and pain typically affected one side, subsequently spreading to the contralateral side. Resolution on one side in case of bilateral localization of the symptom onset was possible, whereas reduction of pain in some cases or increase in others occurred following voluntary inhibition of movements. Moreover, an increase in the amplitude of the movements was linked to exacerbation of pain and the severity of pain tended to correlate with the amplitude of movements. Since the periodic involuntary movements may affect both the upper and lower limbs, the term painful limbs/moving extremities (PLME) has been subsequently suggested for this movement disorder.

Pathogenesis of PLME

Despite that a rather simplistic approach to the pathophysiologic mechanism underlying PLME involves hyperexcitability of peripheral nerve fibers, several studies have suggested that central region may be the source of the complex patterns of muscle activities. However, the level of central involvement is currently under debate. In any case, it should be mentioned that most of the proposed pathogenetic mechanisms have been proposed based on studies of single cases or small case series.

As previously mentioned, peripheral nervous system (PNS) damage, including peripheral nerve, plexus, or spinal root lesions, can induce PLME. Lesions in the PNS may rarely evoke semirhythmic or rhythmic involuntary movements of the limbs without pain, which is one of the cardinal symptoms of PLME. Peripheral nerve lesions are able to influence the normal interrelation between the afferent information and the motor system. Alterations in afferent sensory information with subsequent reorganization of segmental or suprasegmental efferent motor activity and more specifically, structural damage of somatosensory pathways caused by injury of A delta and C fibers may be responsible for the genesis of involuntary movements.

Kinesiologic electromyography (EMG) pointed toward a common central oscillator for finger movements in PLME affecting both sides. In the latter study, somatosensory-evoked potential testing showed a marked attenuation of N20 potential recorded from the left somatosensory cortex, while paired transcortical magnetic stimulation of the left motor cortex suggested failure of cortical facilitation, thereby suggesting that the central oscillator responsible for finger movements is located above the level of the spinal cord.

Likewise, a central mechanism has been proposed by a similar case study, involving sensory-evoked potentials, back-averaging, cerebral MRI, and functional MRI. Nevertheless, cortical involvement was rather improbable due to the different levels of afferent and efferent pathways involved. Moreover, the functional MRI findings strongly argued against a cortical origin, as a reduction of activity in the motor cortex region of interest upon tactile stimulation compared with rest condition was not present. The authors proposed that the inhibitory effect of the sensory stimulus on both pain and movement could be viewed as a gating mechanism, tactile information acting on neuronal networks at a spinal cord level, inhibiting the transmission of pain to upper centers and acting on interneurons implicated in the genesis of the involuntary movement. On the other hand, the movement generator was localized below the spinal cord: a finding in keeping with previously published data suggesting that separate oscillators in the segmental interneuron pool of different spinal areas may drive individual movements in PLME.

Whether the level of dysfunction that produces alteration of the motor behavior is the spinal interneuron or

other supraspinal centers remains to be clarified. However, the coexistence of peripheral and central nervous system disorders increase the likelihood of abnormal sensory motor integration. The phenotypic variability and numerous associations of PLME point toward a complex etiology, involving purely central or a combination of peripheral and central cause at different levels (spinal and/or supraspinal).

Peripheral trauma remains the most accepted predisposing factor for the development of PLME. The development of dystonia secondary to peripheral trauma ('peripheral dystonia') supports this view and may well explain the potential cooccurrence of PLME with focal limb dystonia.

Clinical Characteristics of Syndrome

Characteristics of Pain

Pain and involuntary movements can occur simultaneously. However, although the reverse sequence may occur, pain usually precedes the involuntary movements and is rarely distributed to a specific peripheral or segmental dermatomal pattern. Ectopic and/or ephaptic excitation in damaged peripheral nerves may generate abnormal impulse transmission in peripheral sensory and sympathetic nerves, which afterward leads to a reorganization of the central processing of sensory information. This reorganization could be responsible for the spread of pain over areas that are not limited to a specific dermatomal distribution.

Pain is diffuse, burning, crushing, aching, or throbbing in character, varying in severity between patients from a constant discomfort to an intractable condition. Position does not influence pain, which could spread from one limb to the other, while its severity may increase with activity.

Cooccurrence of PLME with alterations of cutaneous sensation, such as hyperpathia and allodynia, is not uncommon and this fact supports the view of an analogy between PLME and complex regional pain syndrome type 2.

Characteristics of Finger Movements

Movements are spontaneous and purposeless, consisting of complex sequences of slow (1–2 Hz) involuntary, writhing, and wriggling movements of flexion–extension and/or abduction–adduction of at least one finger or toe flexion, extension, abduction, and adduction. Movements cannot be reproduced by unaffected persons or on unaffected sides in unilateral cases. The movements of each toe are independent of those of the others, in a pattern that is intermittent or continuous in the awake state and usually disappears at sleep. Voluntary inhibitory effort may temporarily suppress movements, while they may increase after mechanical stimulation or after consumption of a caffeine-containing drink.

Clinical Phenotypes of PLMT

PLME can also be identified as a syndrome with additional variants, that is, unilateral or involving only arms, only legs, or both arms and legs. Sole affectation of the upper limbs is rarely described. Painless arms/moving fingers (PAMF) is a rare variant of the PLME syndrome characterized by slow involuntary movements of the fingers without pain. To our knowledge, literature contains very few PAMF cases. PAMF cases are usually bilateral and are associated with PNS injuries or coexisting peripheral and central nervous system involvement.

Associations of PLME

Despite that several cases are idiopathic, associations with PLME can occur with central and/or PNS conditions. PLME has been suggested to be induced following entrapment neuropathy, that is, carpal tunnel syndrome, following viral central nervous system infections, due to deficiency in circulating adenosine levels, following ischemic stroke and Wilson's disease. Moreover, other conditions that have been previously linked to PLME include spinal cord or cauda equina injury, posterior nerve roots, lumbar and sacral radiculopathy, peripheral neuropathies, hypertrophic mononeuritis, alcoholic neuropathy, and traumatic lesions involving soft tissue and bone in the foot. PLME has been also reported to occur as a side effect of treatment with neuroleptics, anticholinergics, vincristine, cytarabine, and metronidazole.

More recently, PLME has also been reported in Hashimoto's disease. Basal ganglia abnormalities and central lesions have been topographically associated with PLME. In any case, peripheral tissue, nerve root, or dorsal column damage secondary to herpes zoster or HIV infection and trauma are the most common precipitant factors of PLME, thus pointing toward an overlap between PNS damage and movement disorder in the context of PLMT.

Diagnostic Tests

Despite that several methods, including clinical examination, laboratory, neurophysiological, and neuroimaging studies, are currently used to diagnose PLME, none of the tests is sensitive enough for or specific to this syndrome, mainly because they lack continuity. In the majority of cases, clinical examination, nerve conduction studies (NCS), EEG pattern, and cerebrospinal fluid assay reveal no abnormalities, excepting cases with PLMT and peripheral or entrapment neuropathies, where clinical examination and NCS are abnormal.

Concerning the neuroimaging studies, spine MRI, or computed tomography (CT) are mostly used to rule out PLME syndrome secondary to common vertebral abnormalities, such as stenosis and disc degeneration. In fact, neuroimaging reveals only mild findings in these cases, whereas myelography usually shows minor and nonspecific changes. Unlike that, literature contains very few reports of cases in which irritation of neuronal tissue was shown on nerve biopsy, it is widely accepted that nerve biopsies in the context of PLME are usually normal.

It has been previously reported that EMG studies may reveal abnormalities. However, it should be mentioned that they lack continuity. Schoenen et al. described two distinct EMG patterns that have been related to different causes, including a pattern of short, erratic, low-amplitude discharges in foot and leg muscles, and a complex alternating pattern of long-duration high-amplitude bursts in antagonistic muscles. In the first pattern, the physiopathologic mechanism was suggested to act in the periphery, while in the second pattern the resultant cause was of central origin, implying a more general disturbance of sensorimotor control in the context of an overlap of both peripheral and central cause. On the other hand, others support that the movements are generated by long-duration bursts of activity, comprising normal motor units and normal recruitment patterns.

Finally, taking into consideration that symptoms of PLMT may worsen during periods of psychologic stress, the implication of the sympathetic nervous system in generating PLME has been also previously suggested. Therefore, the activation of sympathetic nervous system through the Valsava or cold pressor tests may have a diagnostic role. However, since others have reported opposite results, further study is warranted before definite conclusions about the potential involvement of sympathetic nervous system in the syndrome of PLMT can be drawn.

Differential Diagnosis of PMLE

There are several conditions that have to be ruled out before a firm diagnosis of PLME is to be made. Restless leg syndrome (RLS) is one of these conditions. However, in RLS, pain and movements are related to the sleep–wake cycle and are relieved by lower limbs movement or walking. Additionally, the spontaneous toe movements in PLMT are different from the voluntary fidgeting movements that diminish the distress of RLS.

The characteristics of PLME may resemble those of segmental myoclonus and epilepsia partialis continua. The main difference of PLME and spinal segmental myoclonus is the lack of pain in the context of the second entity. On the other hand, as opposed to PLME, EEG changes are present in epilepsia partialis continua, whereas loss of reciprocal innervation is seen in epilepsia partialis continua and not in PLME syndrome.

On the basis of the association with traumatic events and the presence of Sudeck's atrophy, there have been previously suggested similarities between PLMT and reflex sympathetic dystrophy. However, common vasomotor or trophic changes occurring with reflex sympathetic dystrophy or its kindred causalgia are lacking in the context of PLMT. Additionally, there are also reports describing causalgia and involuntary limb movements (spasms of amputation stumps or 'jumpy stumps') after the occurrence of a severe trauma to the affected limb. Finally, there might occur a link between posttraumatic dystonia and PLME syndrome and therefore posttraumatic dystonia has as well to be excluded.

Treatment Options in PLME

To date, there is no effective prophylactic treatment against PLME and treatment is merely symptomatic. The armamentarium of pharmacological agents commonly used for the symptomatic treatment of PLME include oral medications such as baclofen, clonazepam,carbamazepine, tricyclic antidepressants, β-blockers, and corticosteroids. However, disappointingly, there are a few reports of success and only modest symptomatic relief was observed after the administration of such treatment schedules. In some patients with PLMT, the pain can be severe and unbearable, failing even high doses of opioids.

Additionally, in the 1980s, Progabide, a γ-aminobutyric acid (GABA) receptor agonist has been previously used with some measure of success. More recently, Gabapentin, a novel anticonvulsant having an effect on voltage-dependent Ca^{2+} channel currents at postsynaptic dorsal horn neurons, has been proposed as being able to be effective against PLMT syndrome through peripheral or central nervous system effect, modulating an abnormal sensory processing in the spinal cord.

The use of botulinum toxin type A injections has been previously reported as being able to provide benefit in a single case of the PAMF variant of PLMT. Treatment with Botulinum toxin type has been reported to result in both pain relief and the improvement of involuntary movements due to reduction of muscle spindle discharge leading to a decreased activity of gamma loop and central sensitization; antisympathetic, antiglutamergic, and antiinflammatory effects; and the inhibition of local pain neurotransmitters.

Among nonpharmacological approaches, the use of lumbar neural blocks has been commonly reported in PLME, providing transient relief in about 50% of patients. Repeated or continuous lumbar epidural block provided some degree of symptomatic benefit to PLMT patients. However, symptoms recurred subsequently after treatment. In any case, lumbar epidural block may be considered as the

treatment of choice if pain is due to the involvement of posterior nerve roots and peripheral nerves.

Literature contains a case report of successful use of epidural spinal cord stimulation against the symptoms of PLME. Epidural spinal cord stimulation is a useful treatment for a variety of painful conditions, including neuropathic pain, pain in peripheral vascular diseases, complex regional pain syndrome, failed back surgery, and angina pectoris. Finally, in a single report, unilateral painful hand and moving fingers significantly improved (movement and pain) following tactile stimulation with a glove.

Paired Pulse TMS

K Udupa, University of Toronto, Toronto, ON, Canada
R Chen, University of Toronto, Toronto, ON, Canada; Toronto Western Research Institute, Toronto, ON, Canada

Glossary

CBI – Cerebellar inhibition; inhibition of motor cortex due to stimulation of the contralateral cerebellum.
CS – Conditioning stimulus; stimulus given prior to the test stimulus and is designed to the response to test stimulus.
ICF – Intracortical facilitation; facilitation of the motor cortex by a subthreshold conditioning stimulus delivered 8–30 ms before a test stimulus.
IHI – Interhemispheric inhibition; inhibition of the motor cortex produced by stimulation of the contralateral motor cortex at interstimulus intervals between 6 and 50 ms.
LAI – Long latency afferent inhibition; inhibition of the motor cortex by contralateral median nerve stimulation ~200 ms earlier.
LICI – Long interval cortical inhibition; inhibition of the motor cortex by suprathreshold conditioning stimulus to the motor cortex ~50–200 ms earlier.
LIHI – Long interval interhemispheric inhibition; IHI at long intervals of ~40 ms.
M1 – Primary motor cortex.
MT – Motor threshold; the lowest stimulus intensity capable of eliciting small motor-evoked potentials.
SAI – Short latency afferent inhibition; inhibition of the motor cortex by contralateral median nerve stimulation ~20 ms earlier.
SICF – Short interval intracortical facilitation; facilitation of the motor cortex by two suprathreshold to threshold second stimuli at ISIs of 1.1–1.5 ms (SICF-1), 2.3–3.0 ms (SICF-2), and 4.1–5.0 ms (SICF-3).
SICI – Short interval intracortical inhibition; inhibition of the motor cortex by a subthreshold conditioning stimulus delivered 1–6 ms before a test stimulus.
SIHI – Short interval interhemispheric inhibition; IHI at intervals of 8–12 ms.

Definition and History

The use of paired transcranial magnetic stimulation (TMS) to study cortical inhibition and facilitation was first described by Kujirai et al. in 1993. Many other protocols have since been described. Paired TMS involves delivering two TMS pulses at different interstimulus intervals (ISI) to study the physiology of intracortical circuits. The first pulse is known as the conditioning stimulus (CS) and the second as the test stimulus (TS). Motor cortical excitability is usually calculated as the ratio of motor evoked potential (MEP) amplitude or the area produced by CS followed by TS to that of TS alone. The cortical circuits activated depend on the stimulus intensities (different thresholds for different circuits), ISI, area of stimulation, and coil orientation (activation of specific neuronal populations is sensitive to current direction). The different protocols can be broadly classified as shown in **Figure 1**. The methodology and properties of these protocols and the findings in several common movement disorders are summarized in **Table 1** and are discussed below.

Parkinson's Disease (PD)

Short interval intracortical inhibition (SICI): Several studies found reduced SICI in resting PD patients in the off state and normalized in the medication state. However, some studies reported normal SICI and reduced SICI may be due to increased facilitation rather than reduced inhibition. Active SICI appeared unchanged in PD. Since SICI is reduced prior to and during voluntary movement, reduction of SICI in PD may be a compensation for bradykinesia to make movement easier, and may explain the normal active SICI.

Long interval cortical inhibition (LICI): Some studies found increased and others found decreased rest LICI in PD. Active LICI was found to be increased. These abnormalities normalize with dopaminergic medications. The opposite findings for SICI and LICI may be because LICI inhibits SICI.

Intracortical facilitation (ICF): In advanced PD, ICF was reduced.

Interhemispheric inhibition (IHI): IHI was reduced in PD patients without mirror movement, especially at long ISIs of 20–50 ms.

Short and long interval afferent inhibition (SAI & LAI): In PD, SAI was found to be normal in patients off medications but levodopa administration reduced SAI. In contrast, LAI is reduced in PD and is unaffected by medications.

Effects of deep brain stimulation (DBS): Internal globus pallidus (GPi) DBS may increase SICI in patients off medications. Subthalamic nucleus (STN) DBS increased SICI in PD patients on and off medications, similar to the effects dopaminergic drugs. GPi and STN stimulation have different effects on cortical circuits and may be related to their different clinical effects. STN DBS normalized both SAI and LAI in PD patients.

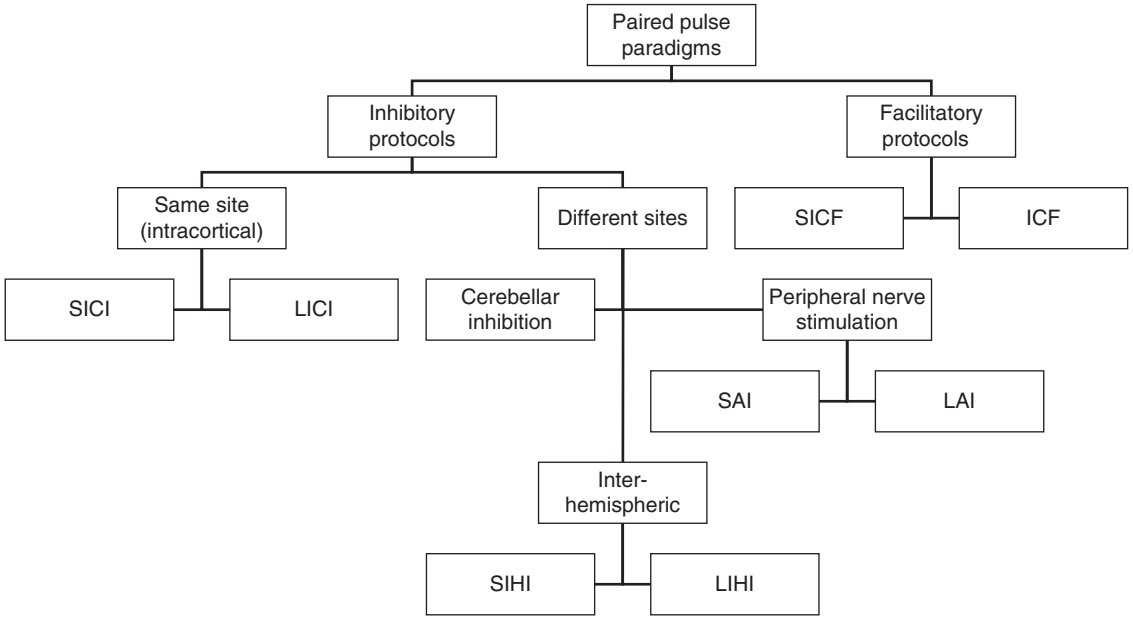

Figure 1 Classification of different paired pulse paradigms. CBI, cerebellar inhibition; ICF, intracortical facilitation; LICI, long interval intracortical inhibition; LIHI, long interval interhemispheric inhibition; LAI, long latency afferent inhibition; SAI, short latency afferent inhibition; SICI, short interval intracortical inhibition; SICF, short interval intracortical facilitation; SIHI, short interval interhemispheric inhibition.

Table 1 Summary of the properties of different forms of cortical inhibition and facilitation and their findings in several common movement disorders

Dystonia

SICI: SICI is decreased in resting hand muscles in upper limb dystonia, blepharospasm, cervical dystonia, Dopa-responsive dystonia, asymptomatic carriers of the DYT1 gene as well as in psychogenic dystonia. Therefore, intracortical inhibition is reduced when patients with dystonia are at rest and not expressing symptoms, in unaffected body parts and in asymptomatic gene carriers. The modulation of SICI by voluntary movement is also impaired in focal hand dystonia (FHD).

SAI and LAI: In FHD, LAI is diminished whereas SAI is normal. Other studies showed altered responses to sensory stimuli and surround inhibition. In a study of sensorimotor integration, focal muscle vibration reduced SICI in healthy subjects but not in writer's cramp patients. Patients with musician's cramp patients exhibited reduced SICI in both vibrated and nonvibrated muscles. These findings suggest different underlying pathophysiology for these types of FHD.

LICI: Resting LICI is reported to be normal in writer's cramp, and decreased in a group of mixed dystonia subjects and in psychogenic dystonia. LICI during voluntary activity was found to be decreased in writer's cramp but increased during slight contraction in a mixed group of dystonic subjects.

ICF: ICF was found to be normal or slightly increased in dystonia.

Chorea

SICI and ICF: In symptomatic Huntington disease (HD), SICI was reduced while ICF was enhanced in one study. SICI and ICF changes were related to clinical rating of chorea, but not to HD severity. However, in another study of chorea due to various etiologies (including HD), the time course and amount of SICI were normal. A more recent study observed decreased ICF and only a tendency for reduced SICI in HD. ICF correlated with the functional capacity scores of the Unified Huntington Disease Rating Scale (UHDRS). These different results may be due to different underlying diseases, disease stages, and study methods.

Tourette Syndrome

Several studies demonstrated reduced SICI in Tourette syndrome (TS). In untreated TS patients, SICI thresholds measured with a range of conditioning intensities were similar to controls, but at higher intensities, SICI was recruited more gradually than controls. Reduced intracortical inhibition may release involuntary movements in TS.

Myoclonus

SICI: SICI is reduced in various conditions associated with myoclonus such as progressive myoclonic epilepsy (PME) and juvenile myoclonic epilepsy (JME). Reduced SICI in cortical myoclonus likely represent impaired GABAergic inhibition that may be a mechanism of myoclonus, whether of epileptic origin or not. Interestingly, reduced SICI was associated with the spread of cortical hyperexcitability, suggesting that reduced inhibition may facilitate the spread of cortical activity responsible for the jerk. Recently, reduced SICI and normal ICF were also observed in familial cortical myoclonic tremor with epilepsy, a condition characterized by postural and action tremor, myoclonus, epilepsy, and cognitive impairment with autosomal dominant inheritance.

LICI and ICF: LICI was found to be normal in patients with JME, but reduced in patients with PME. ICF was normal in most cases of myoclonus.

SAI and LAI: Patients with PME had MEP facilitation rather inhibition following peripheral nerve stimulation.

IHI and IHF: Patients with benign myoclonic epilepsy had increased IHF and reduced IHI, which may play a role in the spread of myoclonic activities. TMS studies also provided evidence for cortical involvement of myoclonus in corticobasal degeneration, consistent with hyperexcitability of the sensorimotor cortex.

Essential Tremor

TMS studies showed normal cortical excitability in essential tremor (ET) and primary writing tremor.

Ataxia

SICI and ICF: SICI is normal in various forms of ataxias whereas ICF was reduced, which may be due to the reduced excitatory drive from deep cerebellar nuclei. Interestingly, ICF was reduced in spinocerebellar ataxia (SCA) 2 and SCA3, but not in Friedreich's ataxia, SCA1, or SCA6, suggesting that reduced ICF may be linked to the genotype. However, ICF did not correlate with the disease severity.

Conclusions

Paired pulse TMS techniques demonstrated abnormalities of SICI, LICI, ICF, SAI, LAI, and IHI in patients with movement disorders (**Table 1**). The most consistent finding is the reduction of SICI reported in dystonia and cortical myoclonus. A limitation for using SICI in

diagnostic workup is that SICI can be abnormal in different types of movement disorders. In addition, the variability of SICI can be high and SICI measures often overlap between patients and normal subjects. Paired pulse studies are, therefore, not of sufficient specificity to distinguish different movement disorders. However, the study of cortical inhibition and facilitation using paired TMS had provided important information on the pathophysiology of different movement disorders.

Palatal Myoclonus

E M J Foncke, VU Medical Center, Amsterdam, The Netherlands

Glossary

EPT – Essential palatal tremor (rhythmic movements of the soft palate, usually with an ear click).
PT – Palatal tremor (rhythmic movements of the soft palate).
SPT – Symptomatic palatal tremor (rhythmic movements of the soft palate, and often other brainstem innervated or extremity muscles).

Definition and History

Palatal myoclonus is a rare movement disorder consisting of brief and rhythmic movements of the soft palate. It was described in 1886 by Spencer. Initially, it was most commonly referred to as 'palatal myoclonus,' but at the First International Congress of Movement Disorders in 1990, it was renamed 'palatal tremor.' The difficulty in phenomenological classification is due to the combination of tremor and myoclonus characteristics of the palatal

movements. The movements are less 'shock-like' and more regular and continuous than that are typically seen in myoclonus. The frequency of the tremor is highly variable among different patients and may vary within a single individual, illustrating the atypical features of the tremor.

There are two different forms of palatal tremor: essential palatal tremor (EPT) and symptomatic palatal tremor (SPT). In EPT, palatal tremor and ear clicks are the sole clinical manifestations of the disorder, whereas in SPT, tremor may involve facial, ocular, and extremity muscles. Ear clicks are usually absent. The underlying cause of EPT remains largely elusive, whereas in SPT, very often a causative lesion can be demonstrated in the dentato-olivary tractus, leading to olivary pseudohypertrophy. Early references of such hypertrophy already date from 1887 from Thomas and Marie and Guillain and subsequently from van Bogaert and Bertrand in 1928.

Pathogenesis and Pathophysiology

About 75% of PT cases are considered symptomatic (SPT) because of structural lesions of the brainstem or the upper cerebellar peduncle (within the Guillain–Mollaret triangle) with subsequent hypertrophic olivary degeneration. Microscopically, the neurons of the inferior olive are enlarged with cytoplasmic vacuolation. Hypertrophy develops ~3 weeks after the lesion, and symptoms start after a variable time delay from 2 to 49 months. Multiple causes for the structural lesions have been described, but in the majority of cases, a vascular lesion can be demonstrated. Multiple sclerosis, metastatic and astrocytic tumors, syringobulbia, and trauma have been occasionally reported as other causes.

The development of SPT after disruption of the dentato-olivary tract is thought to result from a reduction in inhibitory GABAergic input from the dentate nucleus and a successive increase in synchronization of the olivary neurons, leading to an autonomously working olivary oscillator. This is supported by the persistence of PT during sleep and the observation that the rhythm of SPT does not change after a masseter or blink reflex stimulus. The abnormal rhythm of the olivary oscillator is carried through the inferior cerebellar peduncle to the contralateral cerebellar hemisphere and subsequently interferes with the cerebelloreticular systems, leading to the rhythmic activity of brainstem muscles.

In 25% of PT cases, a structural lesion cannot be identified and PT is classified as 'essential' (EPT). However, 'essential' PT differs from other 'essential' movement disorders that are idiopathic, often familial, disorders with well-defined natural histories. In the case of EPT, 'essential' is better considered to be synonymous with 'isolated', meaning that tremor occurs in the absence of other neurological symptoms. The pathophysiological mechanism in EPT is unknown. EPT is clearly not a simple functional variant of SPT, because the palatal muscles that are activated in the two conditions are different. EPT is considered to be a heterogeneous disorder with a considerable proportion of EPT cases having 'voluntary' control over the movements. This voluntary control may be the result of a special skill to open and close the Eustachian tube, which has been reported in scuba divers. On the other hand, a psychogenic origin must be suspected in EPT patients with voluntary control over the palatal movements, especially in the context of other features, suggesting a psychogenic origin.

Epidemiology, Clinical Features, and Diagnostic Criteria

Prevalence data of PT are lacking. In literature, a few hundred cases have been described. The male:female ratio is about 1:1 with a male preponderance in SPT. Age of onset ranges from 4 to 74 years. The movements in PT may be uni- or bilateral and completely or only partially rhythmic (irregular). In EPT tremor ceases during sleep, whereas in SPT tremor may persist. The muscle involved in EPT is the tensor veli palatini, which is innervated by the fifth cranial nerve and is supposed to induce the ear clicks because of the opening of the Eustachian tube by its contraction. Other muscles restricted to the oropharyngeal region may be involved. Ear clicks are often the only complaint, but may be very distressing. In SPT, the levator veli palatini muscle, which is innervated by the ninth and tenth cranial nerves is responsible for the movements of the soft palate. Frequently, extrapalatal muscles are involved, including ocular and extremity muscles. Typically, additional signs of cerebellar or brainstem dysfunction such as ataxia or nystagmus are present in SPT and are the major cause of discomfort and disability.

Differential Diagnosis

As outlined above, PT is phenomenologically classified as tremor. Associated brainstem or cerebellar symptoms separate SPT from EPT (**Table 1**). Some EPT patients can suppress the palatal movements by changing neck position or by digital pressure behind the mastoid, which could be considered as sensory tricks. This may suggest that EPT is a pure dystonic tremor. PT patients may have an urge to perform the movements and are able to voluntarily suppress the movements for a few seconds, suggesting that EPT is a tic disorder. However, continuous rhythmic movements are seldomly described as a form of tic. The diagnosis of psychogenic PT must be considered in the presence of red flags for a psychogenic movement disorder (**Table 2**)

Table 1 Characteristics of SPT and EPT

	SPT	*EPT*
Cause	Cerebrovascular disease, degenerative, multiple sclerosis, trauma causing a lesion in the dentato-olivary pathway	Unknown
Presenting symptom	Usually not ear click	Ear click
Other symptoms	Ataxia, dysarthria or nystagmus	None
Muscles involved	Levator veli palatini and frequently extrapalatal	Tensor veli palatini and/or adjacent muscles
Presence in sleep	Often	Rarely
MRI	Olivary hypertrophy causative lesion	Normal

Table 2 Red flags suggesting a psychogenic origin of PT

Distractibility
Variability
Involvement of extrapalatal muscles clinically distinct from those seen in SPT
Emotional trigger (acute onset)
Trivial trauma preceding onset
Response to verbal suggestion or hypnosis
Response to nonphysiological treatment or placebo
Long lasting benefit from short-acting drugs (prolonged submission after a single treatment with botulinum toxin
Presence of other psychiatric features

Source
Zadikoff C, Lang AE, and Klein C (2006) The 'essentials' of essential palatal tremor: a reappraisal of the nosology. *Brain* 129: 832–840.

Diagnostic Work-up

In SPT, magnetic resonance imaging (MRI) of the brain frequently shows a hyperdense signal of the ventral upper medulla, that is olivary pseudohypertrophy, on T2-weighted or proton density images. Sometimes, the causative lesion in the dentato-olivary tract can also be demonstrated. In EPT, no structural abnormalities are shown on brain MRI. Laboratory findings are normal. Brainstem reflex patterns may be studied but usually do not give additional information for the diagnosis in clinical practice. Neurophysiological studies, including entrainment, may be helpful in the diagnosis of psychogenic PT.

Management and Prognosis

PT is generally considered a lifelong disorder although in rare cases spontaneous remissions have been reported. Treatment is based on anticonvulsants or sedatives with often disappointing effects. Single cases have been described with a favorable response to clonazepam, trihexyphenidyl, or valproate. Surgical therapeutic options have been tried, but none with reproducible results. Injections with botulinum toxin have been successful in a few published case series, and it is considered the treatment of first choice by some physicians.

Palatal Tremor

W G Ondo, Baylor College of Medicine, Houston, TX, USA

Glossary

Guillain–Mollaret triangle – The pathway interconnecting the dentate nucleus of the cerebellum, the red nucleus of the midbrain, and the inferior olivary nucleus of the medulla.

Definitions

Palatal tremor (PT) and palatal myoclonus (PM) are the same entity. Although initially always called myoclonus, the consistent rhythmicity has spawned the 'tremor' description. That said, other segmental myoclonus is rhythmic, PT does not oscillate around a point, which

tremor normally does, and the quick myogenic bursts are consistent with myoclonus. We will subsequently refer to this entity as tremor but rhythmic myoclonus may be a more accurate description. PT is observed as upward or lateral deviation of the soft palate. The frequency usually ranges from 0.5 to 3 Hz. Patients may or may not feel the movements, and occasionally they are painful or result in subjective respiratory difficulty or dysphagia. The cycle of PT is not reset by stimulation of trigeminal afferents nor does Valsalva maneuver consistently affect the rhythm or frequency.

Differential Diagnosis

The differential diagnosis for involuntary palatal movements is minimal, but includes tics (usually not rhythmic), myokymia (more continuous), fasciculations (not rhythmic), and psychogenic/volitional cases. PT is considered uncommon but formal epidemiology is lacking. PT is also segregated into essential or primary (EPT) when the PT occurs in isolation without evidence of other neurological problems or cause, and secondary or symptomatic (SPT) when PT occurs as part of a larger illness. SPT is more common than EPT.

Primary versus Secondary PT

The cause of EPT is not known, and some postulate multiple pathophysiologies. One concordant pair of monozygotic twins has been reported. One case of EPT and epilepsy demonstrated serum autoantibodies directed against glutamic acid decarboxylase. No actual pathology has been identified.

In contrast, SPT results from lesions within the dentato-rubro-olivary pathway 'Guillain–Mollaret triangle' (**Figure 1**). Other CNS anatomy is occasionally reported. Stroke, hemorrhage, neoplasm, abscess, arteriovenous malformations, ectatic arteries, and trauma are the most common etiologies. Usually, the SPT presents weeks to a year after the original insult. Other subacute and less-localized 'lesions' have also been associated with SPT. Reported causes include heat stroke (associated with Purkinje cell loss), Hashimato's encephalopathy with antithyroid antibodies, celiac disease (associated with cerebellar ataxia), IgM M-protein that specifically bound to GM1 in the inferior olive nucleus (ION) and dentate nucleus, Alexander's disease in children and adults, epilepsy partialis continuum, and neuroferritinopathy.

Clinically, there are several differences between EPT and SPT (**Table 1**). Because EPT mostly involves the Guillain–Mollaret triangle, which opens the eustachian tube, it is classically associated with ear clicking that may even be audible to others. A separate tinnitus is also occasionally reported although some literature reports clicking and tinnitus synonymously. Auditory acuity is usually normal. In many cases these auditory symptoms are the most disabling feature. EPT is almost always bilateral and stops during sleep.

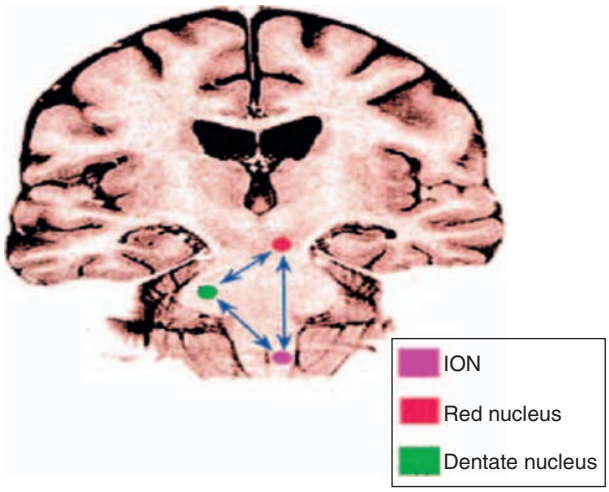

Figure 1 Dentato-rubro-olivary pathway, 'Guillain–Mollaret triangle.'

Table 1 Comparison of primary (Idiopathic) PT and secondary (Symptomatic) PT

	Essential PT	*Symptomatic PT*
Muscle	Tensor Veli Palatini (elevates)	Levator Veli Palatini (elevates)
Cranial Nucleus	V	VII and IX
Ear clicks	Yes	No
Inferior olive hypertrophy	No	Yes
Side	Always bilateral	Unilateral or bilateral
Age	Younger age	Older age
Sleep	Variable persistence during sleep	Persists during sleep

Modified from Deuschl et al.

SPT may be unilateral or bilateral, is not usually associated with clicking, may persist during sleep, and may involve extrapalatal anatomy. Synchronized ocular, facial, platysmal, neck/shoulder, and even arm myoclonus are reported with SPT. The ocular movements are variably described as ocular bobbing, pendular nystagmus, or ocular myoclonus. The extrapalatal anatomy may spread over time. In the absence of underlying neurological symptoms from an underlying lesion or extrapalatal anatomy, SPT may be relatively asymptomatic. Cases are often identified on examination in follow-up after patients had presented with a stroke or some other underlying pathology.

The most striking feature of SPT is the inferior olivary nucleus degenerative hypertrophy (IOHD) observed on T2 MRI and pathological examination (**Figure 2**). Most cases of SPT demonstrate this, and the anatomy correlates

Figure 2 MRI showing modest bilateral degenerative hypertrophy of the inferior olive.

with the clinically involved side when unilateral. Radiographic IOHD precedes the development of SPT in most cases but both may resolve over months to years.

Radiographic IOHD does not necessarily result in SPT. One 12-patient series evaluating IOHD on MRI after a clinical insult to the Guillain–Mollaret triangle found only a single case of clinical SPT. The lesions resulting in IOHD (9 unilateral and 3 bilateral) were in the contralateral dentate nucleus (8), ipsilateral central tegmental tract (5), and contralateral superior cerebellar peduncle (2). The IOHD occurred within 3 weeks in the one case, and the radiographic signal intensity often lessened over years. Another series reported that 8 out of 16 subjects with IOHD and brainstem lesions had PT, appearing 1–2 months after insult in 7 out of 8 cases.

Pathologically, IOHD demonstrates marked neuronal loss in the inferior olivary nucleus (ION), gliosis, and degeneration of both the myelin and the axons of efferent fibers from the olivary neurons. Electromicroscopy shows numerous round, homogeneously electron-dense granules located within expanded cisternal profiles of rough endoplasmic reticulum (RER). These granules may consist of proteinaceous secretion of the RER. Other electron microscopic features of neurons of the hypertrophied olive are neurofilamentous hyperplasia, vacuoles of intermediate and large (up to 15 μm) size, and prominent intracytoplasmic protrusions by boutons containing dense core vesicles. Mitochondria also strikingly proliferate in the reactive astrocytes.

Although somewhat speculative, the ION abnormality is thought to result from loss of inhibition from cephalid structures. This results in toxicity and cell death within the ION. The remaining cells show increased activity and their output may subsequently damage cerebellar structures in some cases. In support of this, a 2-[18F]fluoro-2-deoxy-D-glucose PET study of six SPT and one EPT showed increased metabolic activity in the ION compared to controls. Functional MRI in one case of EPT also revealed increased putaminal activity, thought to result from disinhibition. Another study evaluating IOHD found that the dentate nuclei opposite of the affected ION showed mild-to-moderate shrinkage of the normal low-signal areas and increases in signal intensity on T2-weighted images in 4 of 5 patients. The cerebellar cortices on the same sides as the involved dentate nuclei showed atrophic changes in 4 of 5 patients.

Palatal Tremor/Ataxia Syndrome

Many patients with SPT have mild ataxia on examination. This is seen contralateral to the IOHD in unilateral cases. However, a subset of patients demonstrate an unexplained progressive ataxia associated with a variety of eye movement abnormalities and radiographic IOHD. Familial cases, possibly Alexander's disease, have been reported. Imaging may also demonstrate cerebellar atrophy, which is hypothesized to result from altered signaling from the IO. No specific treatments for the ataxia exist.

Treatment

Treatment for PT should only be initiated if the movements or ear clicking are problematic. There are no large treatment series or controlled trials to guide treatment decisions. A variety of pharmacologic interventions are occasionally effective, but results often lessen over time. SPT may respond better to pharmacotherapy, although small case series and reports often do not distinguish between them. Clonazepam and other benzodiazepines, high-dose piracetam (24–36 g per day), opioids, anticholinergic medications, baclofen, lamotragine, carbamazepine, phenytoin have been reported to improve PT. Sumatriptan transiently improved one case of EPT.

Volitional mouth movements and neck postures that presumably affect the eustachian tube and individually fitted dental appliances may improve the ear clicking. Botulinum toxin injected into the tensor veli palatini or levator veli palatini improves some cases of PT. This can be a delicate procedure, typically using only 2.5–10 units per side to minimize the risk of dysphagia. Unilateral injections are better tolerated. Radiofrequency ablation improved subjective clicking and observed movements in one case.

Pallido-Nigro-Luysian Degeneration

Y Mizuno, Juntendo University School of Medicine, Bunkyo, Tokyo, Japan

Glossary

Hallervorden-Spatz syndrome – is a genetic disorder associated with brain iron accumulation. The features include dystonia, dysarthria, pigmentary retinopathy and characteristic MRI changes. Mutations in the gene encoding pantothenate kinase 2 underlie this disorder, now referred to as pantothenate kinase-associated neurodegeneration or PKAN.

Progressive supranuclear palsy (PSP) – is a pathologically defined, primary neurodegenerative disease characterized by motor disturbance, postural instability, cognitive dysfunction and eye movement abnormalities.

Supranuclear eye movement control – There are six extraocular mucscles innervated by the three cranial nerves, 3, 4, and 6. These control simple eye movements. The complex and precise array of eye movements that secure clear vision result from the supranuclear eye movement control centers that provide the oculomotor system the ability to maintain a target upon the fovea of the retina.

Definition and History

Pallido-nigro-luysian degeneration (PNLD) is a rare sporadic neurodegenerative disorder of adult age. PNLD has also been called as 'pallido-nigro-luysian atrophy (PNLA).' The term 'pallido-luysian atrophy' was used by Van Bogaert to report two patients with chorea and ballism; this term should not be confused with PNLD. The term 'progressive pallidal atrophy' (Progressive Pallidumatrophie in German) was used by Jellinger to include both pure pallido-nigro-luysian atrophy and extended forms of PNLA. The extended forms represent PNLA associated with degeneration of other systems. Neurodegenerative changes in the pallido-nigro-luysian system may be seen in association with other established condition such as motor neuron disease. It is not clear whether or not these extended forms can be included in the entity of PNLD. Also, the term 'pure pallidal degeneration' was used to report a patient with marked bradykinesia and dystonic posture in the neck and the trunk with marked pallidal degeneration without neuronal loss in the nigra and the subthalamic nucleus. Hunt also used the term 'progressive atrophy of the globus pallidus' for a patient with tremor dominant young onset parkinsonism.

But at that time, 'globus pallidus' included striatum as well; actually he described putaminal neuronal loss in his patient. These conditions should not be confused with PNLD. PNLD is rare but is a clear clinical and pathologic entity different from other system degenerations.

Pathology and Epidemiology

The core pathologic feature of PNLD consists of simple atrophy of the substantia nigra, globus pallidus, and the subthalamic nucleus (**Figure 1**). The substantia nigra shows severe depigmentation. Both segments of the globus pallidus show severe neuronal loss, fibrous astrocytosis, and loss of myelinated fibers (**Figure 2**). Argyrophilic neurons can be seen in the nigra, globus pallidus, midbrain tegmentum, and the pons and accumulation of tau protein can be demonstrated when immunohistochemical staining is used; however, neurofibrillary tangle formation is absent or rare, and even if present, its distribution is not typical of progressive supranuclear palsy (PSP). Spheroids may be seen but mainly in the globus pallidus and they are of the foamy type. In addition, some of the pathologically proven PSP cases show predominant involvement of the pallido-nigro-luysian system. In PNLD, usually neurofibrillary tangles and tufted astrocytes, which are pathologic hallmarks of PSP, are absent; another difference from PSP is the absence of grumose degeneration in the dentate nucleus of the cerebellum in PNLD; such pathologic differences discriminate PNLD from PSP. Iron may accumulate in the internal segment of the globus pallidus, but not so prominent as in Hallervorden–Spatz syndrome or pantothenate-associated neurodegeneration (PKAN). There is no epidemiological study on the prevalence of PNLD.

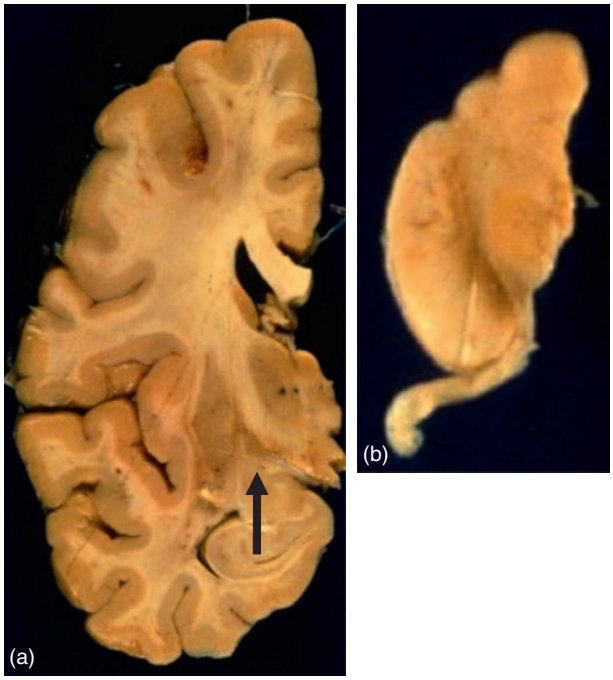

Figure 1 Macroscopic finding of the globus pallidus (a) and the substantia nigra (b). The globus pallidus looks smaller than normal indicating the atrophy (arrow). Marked depigmentation is seen in the substantia nigra.

Clinical Features and Diagnostic Criteria

The core clinical feature is parkinsonism consisting of bradykinesia, rigidity, postural instability, and rest tremor in some patients. The age of onset is usually between mid-fifties and mid-sixties. Initial symptom is either rest tremor or bradykinesia in one hand or gait disturbance starting on one side. Initial symptom can be frozen gait and start hesitation or palilalia. Supranuclear vertical gaze paresis, dystonic features, dysarthria, dysphagia, cognitive impairment, or muscular atrophy may set in some patients during the course of the disease. Clinical features mimic Parkinson's disease (PD) or PSP.

Diagnostic Work-up/Tests and Differential Diagnosis

Neuroimaging of PNLD is not specific. Atrophy of the midbrain tegmentum and the dilatation of the third ventricle, which are characteristic features of PSP, are not seen in PNLD. The eyes-of-the tiger pattern, which is a characteristic MRI finding of PKAN is not seen. Brain MRI can be essentially normal. No report is available on cardiac metaiodobenzyl guanidine (MIBG) scintigraphy in autopsy-proven PNLD; but I would assume MIBG uptake would be normal in PNLD. Cardiac MIBG diminishes in Lewy body PD and dementia with Lewy bodies (DLB) and in some advanced cases of multiple system atrophy (MSA).

Differential diagnosis includes PD, MSA, PSP, corticobasal degeneration (CBD), adult onset Hallervorden–Spatz syndrome, vascular parkinsonism, and drug-induced parkinsonism. Differential diagnosis of PD and DLB is usually not difficult. PD-patients respond to dopaminergic treatment and cardiac MIBG uptake is diminished. Differential diagnosis of PSP is at times not easy. Clinical features are similar, but supranuclear gaze paresis is usually absent or

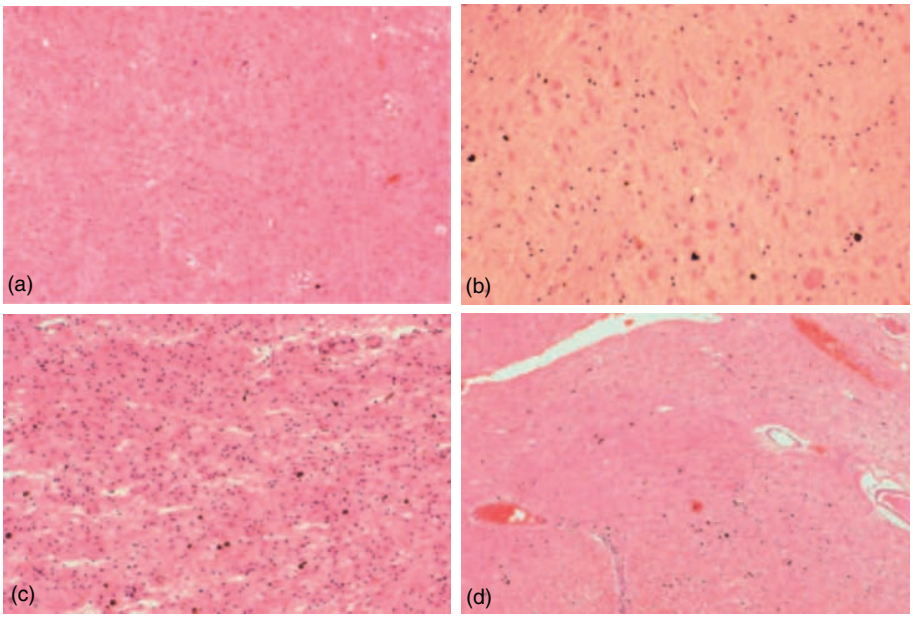

Figure 2 Histology of the internal segment of the globus pallidus (a), the external segment of the globus pallidus (b), the substantia nigra (c), and the corpus Luysi. Marked neuronal losses are seen in these structures, but no Lewy bodies or neurofibrillary tangles are seen. A few spheroids are seen in the external segment of the globus pallidus (c).

mild in PNLD. But some PSP patients show normal ocular movements, and in such case, differential diagnosis is almost impossible. There are cases where differentiation from PSP is difficult even after postmortem examination.

Management and Prognosis

No established treatment is available for PNLD. Dopaminergic drugs for the treatment of PD should be tried in PNLD, but usually the response is limited.

Pallidotomy for Parkinson's Disease

M I Hariz, University College London, London, UK

Glossary

Dyskinesias – Involuntary movements provoked by levodopa.

Definition and History

In January 1985, Lauri Laitinen in Umeå, Sweden, inaugurated the renaissance of surgical treatment for Parkinson's disease (PD) by resurrecting 'Leksell's posteroventral pallidotomy (PVP)' published by Svennilson et al. in 1960. Following his publications of its results in 1992, pallidotomy experienced a worldwide spread. A few years later, pallidotomy became the first evidence-based surgical procedure for PD, and the first modern surgical procedure for PD with published outcome beyond 5 years and with documented improvement of the quality of life. Since the end of the 1990s, deep brain stimulation (DBS), especially DBS in the subthalamic nucleus (STN) has become the dominant surgical procedure for PD. However, pallidotomy remains an alternative surgical procedure, although very rarely performed nowadays. This chapter summarizes the rationale and indications for pallidotomy. Its effects and side effects are detailed, and some reasons for the decline of its use in surgical treatment for PD are described.

Rationale for Pallidotomy

When Leksell performed his pallidotomies in the 1950s, and moved his target progressively further posterior and ventral in the pallidum, treatment with levodopa was not available then, and there were no animal models. The PVP was a result of the surgical serendipidity, and the observation that the outcome was better led to more posterior and ventral pallidotomy lesion being made. Aditionally, when Laitinen rediscovered Leksell's PVP, nobody knew what its effect on levodopa-induced dyskinesias (LID) would be. Clinical observation and serendipidity confirmed, again, the excellent effect of PVP on LID. The information about the pallido-thalamo-cortical circuitry, obtained later on through experimental studies on nonhuman primate models of PD, confirmed the clinical observations and experience of Leksell and Laitinen, that is, the posteroventral pallidum was 'sensorimotor' and that a stereotactic lesion in that area could alleviate not only the cardinal symptoms of PD, but also the LID.

The animal model of PD can be summarized roughly as follows: dopamine deficiency in the putamen provokes (through a γ-aminobutyric acid (GABA)ergic direct pathway to the globus pallidus internus (GPi) and an indirect GABAergic and glutamatergic pathway through external pallidum and STN) a pathological pattern of (over)activity of the GPi, which provokes an inhibition of the initiation of movements by inhibiting the thalamocortical circuitry. This inhibition may account for the development of akinesia, rigidity, and probably tremor in PD. The dyskinesias seen in PD patients after long-term levodopa treatment may be mediated by an underactivity of the STN leading to a pathologically decreased pattern of activity of the GABAergic pallidothalamic projections. As a result, glutamatergic thalamocortical projections exhibit abnormally increased firing patterns, leading to the initiation of choreoathetotic and dystonic movements, that is, dyskinesias. Therefore, a lesion in the posteroventral sensorimotor part of the globus palldus internus GPi may contribute to decrease the pathological pattern of neuronal activity of the GPi and a 'normalization' of the thalamocortical activity, accounting for symptom improvement.

Indications for Pallidotomy

Patients suffering from L-dopa sensitive PD symptoms, with motor fluctuations, ON–OFF phenomena, and dyskinesias, and who have a preserved cognition, may benefit from PVP. There is an impact profile of PVP: dyskinesias respond best; rigidity and tremor do mostly respond, while the effect on akinesia, and especially gait freezing is clearly less robust. A second contralateral pallidotomy should not be performed routinely. It may be performed at least 6 months after the first one, if absolutely needed, and only if the first pallidotomy has been without side effects, and has been verified to lie entirely within the posteroventral pallidum without involving the internal capsule. Bilateral staged pallidotomies may increase the risk for dysarthria, dysphonia, and cognitive decline.

Surgical Procedure

The surgery starts with stereotactic visualization of the pallidal target and its surroundings using dedicated MRI sequences. The author uses a proton density, 2 mm thick

axial, and coronal scans, enabling visualization in the individual patient of internal and external pallidum, lamina medullaris, putamen, internal capsule, and optic tract (**Figure 1**). Hence, there is no need to relate the position of the brain target to third ventricle landmarks and stereotactic atlas.

At surgery, one can use microelectrode recording (MER) techniques for physiological confirmation of the target, prior to performing the lesion, but these techniques may harbor increased risks of bleeding without guarantee of increased accuracy in hitting the target and in confining the lesion to the intended structure.

The present author does not use MER. At surgery, impedance recording is used to differentiate between grey matter, white matter, and CSF space. Impedance recording, macrostimulation, and lesioning are carried out with a noninsulated electrode tip of 2 mm in length and 1.5 mm in diameter. The main aim of stimulation is not primarily to elicit a block of the symptoms (like tremor arrest during thalamic stimulation) but to avoid internal capsule and optic nerve. If stimulation (500 μs, upto 5 mA at 100 Hz or 1000 μs upto 10 mA at 6 Hz) does not give rise to undesirable reactions (capsular, optic, mental), 2–4 radiofrequency lesions, 2 mm apart, are produced with 75–80 °C during 60 s, using a 1.5 mm thick electrode with a 2 mm long noninsulated tip. The effect of a successful pallidotomy is often visible on the operating table. Movements such as cycling with the leg and finger taps are faster than those before the lesioning. To confirm the lesion's location, a thin slice MR scan is done, preferably weeks or months after surgery when the perilesional edema has resolved (**Figure 1**).

Side Effects of Pallidotomy

Pallidotomy may provoke worsening of memory, injury to optic tract, paresis, depression, stroke, drooling, confusion, dysarthria, and dysphonia. Some side effects of pallidotomy may become evident only days or weeks after surgery. As for one of the most feared risks of this surgery, bleeding in the brain, the Toronto group provided the following details: in 1959 patients from 85 papers from 40 centers in 12 countries, MER was used in 46.2% and

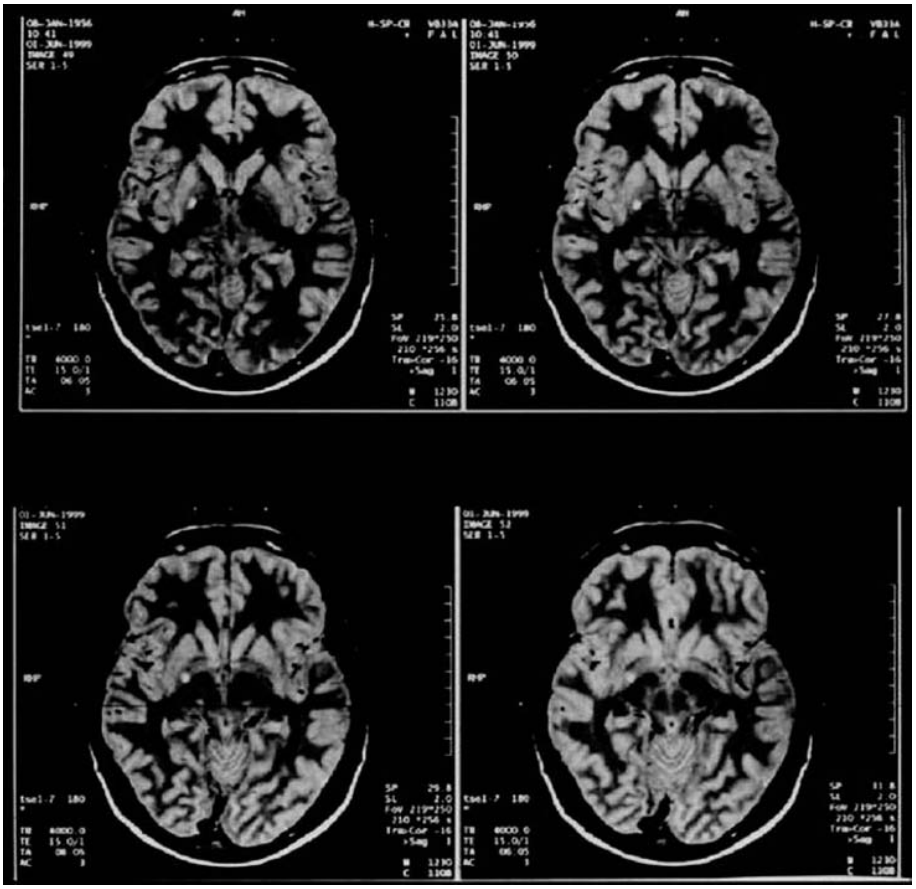

Figure 1 Stereotatic MRI using a proton density sequence performed 1 year after surgery: four contiguous axial 2 mm thick scans showing subdivisions of the pallidii, and a right-sided pallidotomy confined to the posterior and ventral internal pallidum.

macrostimulation in 53.8% of the patients. Cerebral hemorrhage occurred in 2.7% of MER patients and in 0.5% of macroelectrode patients. Overall complications occurred in 26% of MER patients and in 19.2% of macroelectrode patients.

Results

The results of pallidotomy depend on the symptoms that are assessed. The degree of improvement of the symptoms, dyskinesias excepted, may be variable. Following pallidotomy, 'ON–OFF' fluctuations may still occur; however, the 'ON' periods generally last longer and provide better mobility without dyskinesias, and the 'OFF' periods usually are not as profound and as long-lasting as the periods before surgery. The most consistent finding in the literature is that pallidotomy exerts its main effect on contralateral limb dyskinesia/dystonia, rigidity, and tremor, in that order, and least on gait freezing and other axial symptoms. Although the percentages of improvement in various aspects of the Unified Parkinson's Disease Rating Scale (UPDRS) reported in the literature were rather disparate, this disparity was not between reports from MER groups versus non-MER groups, but within either group, as has been shown by Starr et al. in their comprehensive survey on the effects of unilateral pallidotomy. In general, pallidotomy provides a 20–30% improvement on the motor part of the UPDRS, at 6–12 months after surgery. At longer follow up, results are inconsistent among authors with exception for long-lasting effect on tremor and especially on dyskinesias.

What Future for Pallidotomy?

In 2001, Mahlon DeLong defended pallidotomy, arguing that it is less expensive than DBS, without need for battery replacement or time consuming adjustment of stimulation parameters, and is without risk of infection and hardware problems. Recently, Gross also advocated that pallidotomy should remain in the surgical armamentarium for treatment of PD. Pallidotomy is safe and allows continuation or even increase of dopaminergic medication without fear for dyskinesias. It is well tolerated even by elderly patients, with few of the nonmotor side effects inherent to STN DBS. It is readily accessible for patients living far away from movement disorders centers or in areas and countries lacking means for sophisticated expensive healthcare. It is certainly not as safe as DBS if performed bilaterally, but even when unilateral, evidence shows that it is still by far better for patients with advanced PD than medications alone. For pallidotomy to remain a viable surgical alternative, the new generation of DBS-oriented movement disorder neurologists should be aware of its indications and its documented effects. Additionally, the new generation of functional neurosurgeons should learn – or relearn – the skills of performing proper stereotactic lesions in the pallidum. In experienced hands, it has been shown that a unilateral pallidotomy does not harbor more risks than DBS.

PANDAS

D S Wolf and H S Singer, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Glossary

Chorea – Irregular, changing movements that flow between body areas, with unpredictable timing, and an asymmetrical and asynchronous pattern.
Cytokines – Protein molecules secreted by cells that influence and regulate the immune system.
Compulsions – Repetitive, purposeful behaviors usually performed in response to an obsession, or according to certain rules, or in a repetitive fashion.
Obsessions – Recurrent ideas, thoughts, or impulsions that intrude on conscious thought.
Tics – Involuntary, sudden, rapid, repetitive, nonrhythmic stereotyped movements or vocalizations.

Introduction

The number of proposed poststreptococcal movement disorders continues to expand from the archetype of Sydenham's chorea (SC) to a list that now includes tics, Tourette syndrome (TS), obsessive–compulsive disorder (OCD), dystonia, myoclonus, Parkinsonism, opsoclonus myoclonus, and paroxysmal dystonic choreoathetosis. In each, it is hypothesized that symptoms result from a Group A β-hemolytic streptococcal (GABHS) activation of the adaptive immune system. The proposed mechanisms include the induction of antibodies that in turn cross-react against neuronal tissue (molecular mimicry) and the production of secreted proteins that mediate and regulate immunity and inflammation (cytokines and chemokines). For most of these disorders, however, required criteria to confirm a pathogenic role for the immune system (see **Table 1**) have not been firmly established or accepted.

In 1998, Swedo and colleagues proposed that SC was not the only immune-mediated central nervous system (CNS) manifestation of GABHS and described their diagnostic criteria for Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal infection (PANDAS). In this report, based on 50 cases recruited from a nationwide search, they suggested that a systematic clinical evaluation of children with OCD and tic disorders, including TS, defined a homogeneous subgroup in which symptoms were associated with a streptococcal infection (**Table 2**). Boys were affected more frequently than girls (ratio 2.6:1) and the mean age of onset for tics was 6.3 years and OCD 7.4 years. In general, children were normal prior to the explosive symptom onset, and tics, typically motor, were noted in 80%. The primary obsessive–compulsive behavior focused on contamination concerns with hand washing/cleaning. Numerous psychiatric comorbidities were noted, including separation anxiety, emotional lability, bedtime rituals, and oppositional behaviors. Confirmation of GABHS infection was found in 72% of patients, with 42% having definitive infection.

In subsequent reports, proponents have clarified several requirements. For example, diagnosis necessitates atleast two exacerbations of neuropsychiatric symptoms with distinct intervening periods of remission during which throat cultures and antistreptococcal antibody titers are negative. Explosive tic exacerbations are defined as the simultaneous appearance of several different motor and phonic tics with an intensity that causes parents to seek immediate medical attention. Acute recurrences must begin simultaneously with a positive throat culture or within 7–14 days after the infection. Lastly, choreiform movements that are included in the movement disorder repertoire of PANDAS have been further defined as fine piano-playing finger movements.

Even with these criteria, the existence of PANDAS is controversial, with advocates and opponents taking firm positions on either side of the clinical issue. Support for

Table 1 Criteria for establishing a pathogenic role for autoantibodies

1. Identification of autoantibodies
2. Presence of antibodies at the pathologic site
3. Induction of symptoms with autoantigens
4. Passive transfer of the disorder to animal models
5. Positive response to immunomodulatory therapy

Table 2 PANDAS criteria

1. Presence of OCD and/or tic disorder (based on Diagnostic and Statistical Manual criteria)
2. Prepubertal age at onset (between 3 years of age until start of puberty)
3. Sudden 'explosive' onset of symptoms and a course of sudden exacerbations and remissions
4. Temporal relationship between symptom onset and exacerbations and GABHS infections
5. The presence of neurologic abnormalities including tics, hyperactivity, and choreiform movements during exacerbations.

PANDAS is derived from the description of additional cohorts; familial studies showing that first degree relatives of children with PANDAS have higher rates of tic disorders and OCD than found in the general population; expanded expression of a trait marker for susceptibility in rheumatic fever (the monoclonal antibody D8/17) in individuals with PANDAS; and MRI volumetric analyses of 34 children with PANDAS showing that the average size of the caudate, putamen, and globus pallidus, but not thalamus or total cerebrum, was significantly greater in PANDAS than in healthy children. No correlation between basal ganglia size and symptom severity was observed.

Critics of PANDAS as a nosological entity emphasize that the diagnostic criteria established for PANDAS are potentially confounded by several factors: phenotypic variability commonly associated with tic disorders, such as a normal fluctuation in the frequency and severity of symptoms or exacerbation of tics by stress, fatigue, and illness; the finding of 'sudden, abrupt' onsets and/or recurrences of tics in non-PANDAS subjects; suggestions that first degree relatives with tics and OCD indicate a familial disorder (i.e., TS) rather than a tendency to PANDAS; the absence of cardiac abnormalities and other systemic manifestations; and the lack of a precise definition for associated neurological conditions (i.e., the presence of chorea indicating the diagnosis of SC not PANDAS).

Streptococcal Infection

A recently published American Heart Association report on rheumatic fever emphasized several important points: GABHS pharyngitis is clinically difficult to differentiate from pharyngitis due to other pathogens without a throat culture; antistreptococcal antibody titers (antistreptolysin O (ASO) and antideoxyribonuclease B) reflect past, not present, immunological events and cannot be used to determine whether an individual with pharyngitis and even a positive throat culture is truly infected or merely a streptococcal carrier; streptococcal antibody titers are often misinterpreted due to the failure to recognize that normal levels of these antibodies are higher among school-age children than among adults.

Epidemiological studies of PANDAS have produced conflicting results. In a case control study in children, patients receiving their initial diagnosis of TS, tic, or OCD were more than twice as likely to have a prior streptococcal infection in the 3 months before the onset of symptoms. This observation, however, is in contrast to a case control study using a very large primary care dataset that showed no increased exposure to streptococcal infections in individuals with OCD, TS, or tics. Some investigators have shown higher ASO titers in adult TS subjects as compared to controls; however, there was no association between levels of ASO titers and clinical symptoms. In other studies, no association was detected between streptococcal markers and tics or OCD in pediatric or mixed pediatric/adult populations. No significant difference was seen in ASO titer when comparing children with OCD-alone and OCD plus PANDAS. As noted, longitudinal laboratory data, rather than studies that use only a throat culture or only a single antistreptococcal titer, are necessary to confirm the presence of a previous GABHS infection. Lastly, in a longitudinal study of PANDAS subjects, only 6 of 65 documented exacerbations were associated a streptococcal infection.

D8/17 Antibody

As most children who get GABHS infections do not develop PANDAS, it has been theorized that an inherent genetic vulnerability may play a role. The monoclonal antibody D8/17, directed against B-cells, is a known susceptibility marker for rheumatic disease, including SC. Children with PANDAS were highly positive for the D8/17 marker (85%) as compared to healthy children (17%). An elevated expression of D8/17 is also seen in children with TS and/or OCD, although D8/17 positivity alone did not predict an increased rate of tics or OCD. In contrast to prior studies, a prospective longitudinal study using flow cytometry to quantify B-lymphoctyes expressing a known marker for GABHS infection (D8/17) found no clear relationship between new GABHS infections or amplification of B-lymphocyte populations relevant to new GABHS infections, amplification of B-lymphocyte populations relevant to GABHS infections, or tic symptom exacerbations.

PANDAS: An Autoimmune Disorder?

Background Issues

Mechanistically, if bacteria are not immediately eliminated by the innate immune response, antigens are carried by macrophages to lymph nodes. Presentation of these antigenic fragments to their cognate CD4+ T cells triggers their differentiation into either helper T_1 or T_2 cells, thus initiating the adaptive immune response. Activated T_1 cells secrete cytokines IL-2 and interferon-γ (INF-γ) which work to activate macrophages and cytotoxic T-cells. The cellular immune system is further enhanced by factors that stimulate acute phase reactions (tumor necrosis factor-α, TNF-α) and serve as chemotactic agents for T cells (regulated on activation, normal T expressed and secreted, RANTES) and macrophages (monocyte chemotactic protein-1, MCP-1). Activated helper T_2 cells secrete cytokines IL-4,-5,-6, and-10 and also trigger the proliferation and differentiation of B cells and plasma cells

that secrete immunoglobulins (humoral system). If two antigens share an identical epitope or if two different epitopes have similar shapes and charges, it is possible that an antibody produced against a GABHS epitope could cross-react with neuronal tissue, through the process of molecular mimicry (see **Figure 1**).

Autoantibodies

If serum antineuronal antibodies (ANAb) contribute to the pathogenesis of PANDAS, it would be hypothesized that individuals with these disorders should have elevated autoantibodies in their serum which cross-react with components of the CNS and, in particular, with brain regions thought to be involved in the generation of tics/OCD. To test this hypothesis, investigators have used three approaches to measure antinuclear antibodies: enzyme-linked immunosorbent assay (ELISA), Western immunoblotting, and indirect immunofluorescence (IF).

Several studies have measured ANAb in children with PANDAS, usually on single-point-in-time samples unrelated to the presence of a GABHS infection or the timing of clinical exacerbations. Results in these studies have been inconsistent and controversial. Several investigators have suggested, based on ELISA or immunoblotting, that this cohort is readily differentiated from a variety of disease controls. For example, analysis of antibodies by Western immunoblotting identified significantly more reactive bands at 60, 45, and 40 kDa in poststreptococcal subjects. These antigens were subsequently defined as the neuronal glycolytic enzymes pyruvate kinase M1, a doublet of nonneuronal- and neuronal-specific enolase, and aldolase C, respectively. In contrast, other researchers, using ELISA and immunoblotting against a variety of brain epitopes, were unable to distinguish PANDAS subjects from children with TS or controls. Immunoreactivity suggested neither diagnostic specificity at previously reported molecular weights nor to their putative antigenic proteins.

Few studies using the IF methodology of Husby have been published in children with PANDAS. In one, approximately two-thirds of 22 children and adolescents with this disorder had positive detectable staining at a 1:10 serum dilution, as did a small number of TS cases possessing positive putative antibodies determined by immunoblotting assays. In contrast, in a study comparing 30 cases of PANDAS, TS, and controls, using double staining with anti-glial fibrillary acidic protien (GFAP) (glial) and anti-microtubule associated protien-2 (MAP2) (neuronal) to establish localization of the IF, no association was identified between IF positivity or localization and the diagnosis of PANDAS or TS. Further, IF reactivity did not correlate with tic severity, titers of antistreptococcal antibodies, the presence of immunoblot reactivity against human caudate, or the putative antigens pyruvate kinase M1 and aldolase C.

Three reports, using pediatric OCD as the primary inclusion factor, have identified disparate alterations of immunoreactivity against striatal tissues. In one, immunoblotting showed the presence of antibasal ganglia antibodies in 42% compared with 2–10% in pediatric autoimmune, neurological and streptococcal control groups; reactive immunoblot bands were more common in the OCD cohort at 40, 45, and 60 kDa. In a second study, immunohistochemistry failed to differentiate cases from controls, but immunoblotting identified two proteins at molecular weights of 55 and 86 kDa in some prepubertal-onset OCD patients. Lastly, a third study showed no differences among groups for immunohistochemical staining and ELISA. Immunoreactivity against hypothesized putative specific antigens (α and γ-enolase, aldolase C, and pyruvate kinase M1) did not differentiate PANDAS, though more cases than controls had bands against caudate at 27, 36, and 100 kDa.

In order to avoid the multiple unknowns associated with single-point-in-time investigations, a multicenter longitudinal study provided the opportunity to evaluate the association of immune factors to clinical symptomatology and to changes at the time of a GABHS infection. In brief, using quantitative measures of autoantibodies obtained by three separate methodologies, ELISA, and immunoblotting against three brain regions as well as putative specific antigens, and competitive inhibition with lysoganglioside, investigators confirmed the presence of autoantibodies in children with PANDAS, but were unable to identify definitive increases in ANAb or an association with clinical worsening, with or without a GABHS infection. Hence, this study was consistent with the findings of others who reported that the presence of antineuronal antibodies at 40, 45, and 60 kDa detected against basal ganglia do not predict a specific tic phenotype, phenomenology, severity, or duration.

Another requirement for determining an autoimmune disease is the demonstration that the passive transference of antibodies to an unaffected host elicits the disease state. The microinfusion of sera from children with PANDAS into rodent striatum did not change the number of observed motor stereotypy behaviors.

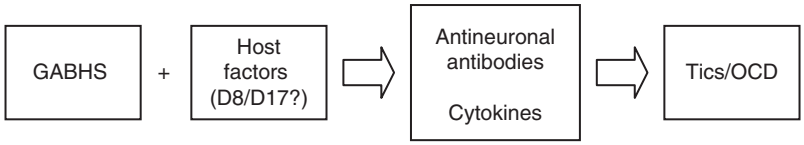

Figure 1 Proposed pathophysiologic mechanism underlying PANDAS.

Cytokines

Although much of the focus has been on autoantibodies, pathophysiological mechanisms could involve immune abnormalities associated with cytokines or lymphocyte dysfunction. Cytokines IL-4 and-10 are elevated in the cerebrospinal fluid (CSF) of about 30% of patients with acute SC. Quantification of serum proinflammatory cytokine levels suggest that elevations in IL-12 and TNF-α accompany tic exacerbations in TS but not PANDAS patients. Serial analyses of cytokines in longitudinal study showed no meaningful differences between PANDAS groups, with or without exacerbation associated with streptococci, and no definite increases during exacerbations. The lack of validity of serum cytokine measurements as accurate predictors of activity in the CNS has been noted in the literature.

Lysoganglioside G_{M1}

In SC, investigators have identified a monoclonal antibody that has specificity not for a brain protein, but for *N*-acetyl-β-D-glucosamine (GlcNAc), a streptococcal surface antigen, plus mammalian lysoganglioside G_{M1} and G_{M1} ganglioside. In a study of 15 patients with PANDAS, a competitive-inhibition ELISA assay showed that serum IgG reacted with lysoganglioside G_{M1} and GlcNAc in 73% of subjects. In a longitudinal study, 50% of PANDAS subjects had a positive competitive-inhibition assay in at least one serum sample, but only one showed values that correlated with clinical exacerbation. Other recent studies focusing on the specific target site of the autoantibodies in rheumatic fever have suggested β-tubulin, a molecular mimic of the Group A streptococcal carbohydrate epitope, GlcNAc. Sera from children with PANDAS are currently being evaluated for tubulin binding.

Regulatory T Cells

Children with TS have significantly decreased numbers of regulatory T cells (CD4+, CD25+). Regulatory T cells are thought to prevent autoimmunity by potently inhibiting both CD4+ and CD8+ T lymphocytes. These cells are reduced in other autoimmune diseases such as multiple sclerosis.

Future Perspectives

PANDAS is an intriguing diagnosis with a unique acronym. Much debate, however, exists pertaining to the validity of the condition as a distinct etiology for tics or OCD. To date, none of the five criteria supporting a role for the immune system in PANDAS have been satisfied unequivocally. Whereas it appears that an infection, be it viral or bacterial, can exacerbate tics, there exists no consistent evidence of an autoimmune process as the underlying pathophysiological mechanism in either TS or PANDAS. Given that confirmation of the concept of a postinfectious autoimmune tic/OCD disorder would have broad neurobiological, epidemiological, and treatment implications, research efforts continue to focus on the PANDAS as a potential model of neurological illnesses.

Treatment

In rheumatic fever, the reduction of recurrences by antibiotic prophylaxis against GABHS was an important factor in confirming a pathogenic association with streptococci. In a double-blind, placebo-controlled crossover trial with oral penicillin (250 mg penicillin V) undertaken to prevent recurrences of PANDAS, no significant change in severity of either obsessive–compulsive or tic symptoms occurred between the active and placebo arms. However, because an acceptable level of streptococcal prophylaxis was not achieved, no firm conclusions were possible. One study has shown that penicillin and azithromycin decreased streptococcal infections and neuropsychiatric symptoms, but several investigators have raised concerns about serious shortcomings in study design and suggested that the results be interpreted with great caution.

Indirect support for an immune hypothesis is derived from a single study showing that a small number of patients with PANDAS responded to immunotherapy with intravenous immunoglobulin (IVIG) and plasmapheresis (PEX). Twenty-nine children with PANDAS recruited from a nationwide search were randomized in a partially double-blind fashion (no sham apheresis) to an IVIG, IVIG placebo (saline), and PEX group. One month after treatment, the obsessive–compulsive symptoms were reduced by 58% and 45% in the PEX and IVIG groups, respectively, compared with only 3% in the IVIG control. In contrast, tic scores were significantly improved only after PEX treatment, with reductions of 49% (PEX), 19% (IVIG), and 12% (IVIG placebo). In this study, however, there were several methodological concerns: the small number of subjects (10 or less per group), the limited comparisons with controls, and side effects that occurred in about two-thirds of individuals receiving active therapy. At this time, the National Institute of Health (NIH) recommends that immunotherapy in PANDAS be reserved for patients participating in controlled double-blind protocols.

Paraneoplastic Movement Disorders

A Videnovic, Northwestern University, Chicago, IL, USA

Paraneoplastic Movement Disorders

The term 'paraneoplastic syndrome' refers to symptoms and signs caused by remote effects of cancer that are not caused by metastasis, coagulopathy, infection, or treatment side effects. Paraneoplastic syndromes can affect most organs and tissues, including both the peripheral and the central nervous systems.

The most common paraneoplastic neurological syndromes are sensory neuropathy, Lambert–Eaton myasthenic syndrome (LEMS), cerebellar degeneration, and limbic encephalitis.

Movement disorders have been rarely reported as a remote complication of malignancy.

In this article, we review the most commonly reported paraneoplastic movement disorders.

Chorea

Progressive paraneoplastic chorea, initially described by Albin and colleagues, represents a rare presentation of paraneoplastic central nervous system disease. Most reported cases of paraneoplastic chorea do not represent an isolated choreiform disorder, but rather have multifocal neurological symptoms, including dystonia, ataxia, sensory neuropathy, and cranial nerve palsies.

The most common malignancy associated with chorea is small-cell lung carcinoma.

Breast carcinoma, thymoma, non-Hodgkin's lymphoma, renal cell carcinoma, and primary cerebral lymphoma have also been associated with paraneoplastic chorea.

Vernino and colleagues reported the largest series of 16 patients presenting with chorea in a paraneoplastic context. All patients were smokers. In 11 patients, involuntary movements were the initial or the most prominent symptoms. Additional neurological manifestations present in 14 patients included vision loss, progressive peripheral neuropathy, limbic encephalitis, cerebellar ataxia, LEMS, and myelitis. Eleven patients had biopsy-proven small-cell lung carcinoma. Cancer diagnosis preceded the onset of chorea in only two patients.

Paraneoplastic chorea usually relates to collapsin response-mediating protein-5 (CRMP-5), a neuronal cytoplasmic protein related to the collapsing-mediator protein family. In the largest reported series of 121 patients who

were CRMP-5 seropositive, chorea was found in 11 % of the patients. The serum titers of CRMP-5-IgG do not correlate with the severity of chorea or the severity and nature of the accompanying neurological manifestations. Paraneoplastic chorea has also been linked to the anti-CV2 antibody initially assigned to an antibody with oligodendrocyte-restricted immunoreactivity. The anti-Hu antibody (ANNA-1), the most common marker of autoimmunity related to small-cell lung cancer, has been associated with chorea as well.

Neuropathological studies in patients with paraneoplastic chorea are sparse. Neuropathological findings are nonspecific and include marked neuronal loss, gliosis, mocroglial activation, perivascular lymphocytic infiltration, and microglial nodules within the basal ganglia. The most common magnetic resonance imaging (MRI) findings include nonenhancing T2 hyperintensities in the caudate and putamen, the thalamus and cortex being spared. In some cases, however, brain MRI is normal at presentation.

Treatment is directed at the underlying malignancy, and treatment outcomes vary. Although some report improvements in chorea in the majority of patients treated with symptomatic therapy, chemotherapy, or intravenous methylprednisolone, others document treatment failure.

A subacute onset of chorea in adults should raise the possibility of a paraneoplastic cause. Computerized tomography of the chest and a serological evaluation should strongly be considered in these patients.

Dystonia

Dystonia has been rarely described in paraneoplastic syndromes. In these sporadic cases, dsytonia coexists with other involuntary movements, mainly chorea and parkinsonism. Cerebellar degeneration, peripheral and cranial neuropathy, and other neurological signs may be present as well. Although dystonia may be an initial neurological manifestation of a paraneoplastic process, it usually emerges during the course of the illness. Jaw opening dystonia and laryngospasm are common in paraneoplastic syndromes associated with type 2 antineuronal nuclear antibody (ANNA-2), also known as 'anti-Ri'. In a series of 28 ANNA-2 positive patients, 7 (25 %) had laryngospasm and jaw opening dystonia leading to stridor and impairment of nutrition. The few available autopsy data of patients with dystonia in the setting of a paraneoplastic syndrome failed to reveal the neuropathological changes in the basal ganglia systems. Treatment is not effective.

Opsoclonus–Myoclonus Syndrome

Opsoclonus–myoclonus syndrome (OMS) is a rare neurological disorder characterized by an acute onset of opsoclonus and myoclonus. Opsoclonus consists of involuntary, irregular, chaotic, continuous, large-amplitude multidirectional saccades. It is present during fixation, smooth pursuit, and convergence and persists during sleep or eyelid closure.

Myoclonic movements in OMS involve the limbs and the trunk. Patients may have associated encephalopathy, ataxia, or tremors. The etiology of OMS may be idiopathic, paraneoplastic, postinfectious, or toxic-metabolic.

In cases of pediatric paraneoplastic OMS, the most common underlying neoplasm is neuroblastoma. While approximately 50 % of children with opsoclonus are found to have a neuroblastoma, opsoclonus may be the presenting sign of an occult neuroblastoma in 2–5 % of cases. In adults, the most common OMS-associated neoplasms are small-cell lung cancer, breast cancer, and ovarian cancer. Cases of paraneoplastic OMS have been reported with non-Hodgkin's lymphoma, malignant melanoma, and renal adenocarcinoma as well. Occult malignancies are found in approximately 20 % of adults presenting with OMS.

Humoral and cell-mediated immune mechanisms have been implicated in paraneoplastic OMS. Most patients with OMS test negative for antineuronal antibodies. Cases of OMS associated with anti-Ri, anti-Hu, anti-Yo, anti-Ma1/2, anti-amphyphysin, anti-CRMP-5, and anti-Zic2 antibodies have been reported.

A thorough diagnostic evaluation for the presence of tumor is necessary in all patients with OMS. In children, a search for occult neuroblastoma is essential. A complete screening protocol includes urine vanillylmandelic and homovanillic acid, MRI of the neck, chest, abdomen and pelvis, and metaiodobenzylguanidine (MIBG) whole body scintigraphy if MRI is unrevealing. Computerized tomography of the chest, abdomen, and pelvis should be done in adults. Gynecological examination and mammography are obligatory in women. If conventional imaging is negative, whole body 18F-fluoro-2-deoxyglucose-positorn emission tomography scan should be considered.

The mainstay of the treatment is the resection of the primary tumor. In children, corticosteroids, intravenous immunoglobulin (IVIG), and adrenocorticotrophic hormone (ACTH) are the most commonly used treatment options. Rituzimab has been used as an adjunctive therapy. Treatments with steroids and ACTH are associated with long-term adverse side effects. Residual motor, behavioral, speech, and sleep disorders are commonly present. The removal of neuroblastoma itself does not improve the symptoms in most patients. In adults, there is little evidence that immunotherapy is useful in treating OMS. Nystagmus and oscillopsia may respond to propranolol, baclofen, clonazepam, and thiamine. Myoclonus can be treated with antiepileptic drugs.

Paraneoplastic Cerebellar Degeneration

Cerebellar degeneration is one of the most common paraneoplastic syndromes characterized by a subacute development of a severe pancerebellar dysfunction. Initially, patients develop symptoms that mimic a viral-like illness, such as dizziness, nausea, and vomiting. This is followed by a subacute onset of gait ataxia, and subsequently, truncal and limb ataxia, dysarthria, and dysphagia. Neuroophthalmological manifestations are common and include nystagmus, ocular dysmetria, saccadic pursuit, saccadic intrusions and oscillations, and skewd deviation. Mild cognitive deficits have been described in a minority of affected patients. The clinical course is usually rapidly progressive, leading to severe functional disability within few weeks to months.

Paraneoplastic cerebellar degeneration (PCD) is most commonly associated with small-cell lung cancer, ovarian and breast carcinoma, and Hodgkin's disease. Cerebellar degeneration may precede the tumor by many years. Only about 50 % of patients with suspected PCD test positive for antineuronal antibodies in serum or cerebrospinal fluid (CSF). The most common onconeuronal antibodies associated with a pure paraneoplastic cerebellar syndrome are anti-Yo and anti-Tr antibodies. Anti-Yo is usually related to the presence of breast or ovarian cancer in postmenopausal women. Anti-Tr antibodies are markers of patients with PCD in Hodgkin's disease. Small-cell lung cancer is associated with several antibodies, including anti-Hu, voltage-gated calcium channel antibodies (VGCC), and anitibodies against CRMP-5, or ANNA-3. When VGCC antibodies are present, LEMS may coexist with PCD. Paraneoplastic OMS may coexist with the cerebellar degeneration in patients with breast or lung cancer associated with anti-Ri antibodies.

Brain MRI in PCD is initially normal, but can demonstrate cerebellar atrophy in later stages of the disease. CSF examination shows mild lymphocytic pleocytosis with elevated protein, oligoclonal bands, elevated immunoglobulin synthesis, and negative cytology in about 60% of patients. The neuropathological hallmark of the PCD is diffuse cerebellar Purkinje cell loss with a proliferation of Bergmann glia. Inflammatory infiltrates are occasionally present in the cerebellar cortex, deep cerebellar nuclei, and inferior olivary complex.

Treatment is directed at the underlying malignancy. In most cases, PCD does not improve with cancer treatment. Immune therapy is rarely effective, although there are reports of an improvement with plasmapheresis, immunosuppressive treatment (cyclophosphamide, tacrolimus), or IVIG. Symptomatic treatment involves neurorehabilitation with speech and swallowing therapies.

Prognosis in anti-Yo and anti-Hu-associated PCD is generally poor, and many patients are nonambulatory within 3 months. Patients with anti-Tr antibodies and Hodgkin's disease are more likely to improve than those with other antibodies. Patients with PCD associated with small-cell lung cancer and the absence of onconeuronal antibodies may have much better recovery after tumor treatment compared with patients with antibodies.

Patients with paraneoplastic cerebellar degeneration need thorough and continued monitoring aimed at cancer detection at an early stage, since this may increase the chance of meaningful recovery.

Parkinsonism

Parkinsonism is a very rare manifestation of a paraneoplastic nervous system disorder. Only a few cases of paraneoplastic parkinsonism have been reported in association with multiple myeloma, lymphoma, breast carcinoma, and bronchial carcinoma. Parkinsonian symptoms precede the diagnosis of cancer from 3 months to 2 years, and manifest as rapidly progressive symmetric parkinsonism. Paraneoplastic parkinsonism can mimic progressive supranuclear palsy. Other movement disorders, such as painful dystonia and myoclonus, may coexist with parkinsonism. Additional clinical features include cerebellar dysfunction, myopathy, cardiomyopathy, neuropathy, and autonomic dysfunction.

Antibodies to the Ma2 onconeuronal proteins that usually cause paraneoplastic limbic or brainstem encephalitis have been linked to several cases of paraneoplastic parkinsonism. Most of these patients had testicular germ-cell tumors or small-cell lung cancer. It is speculated that patients with anti-Ma2 encephalitis are more likely to develop parkinsonian-hypokinetic features than patients with other paraneoplastic disorders. CSF analysis is usually normal, and brain imaging unremarkable. Postmortem brain examination reveals astrocytosis in globus pallidus, loss of nigral neurons (mainly pars reticulata) without signs of inflammation, and a loss of Purkinje neurons. Parkinsonism usually does not improve with the cancer treatment. Rapidly progressive parkinsonism should raise the suspicion of a paraneoplastic disorder.

Stiff–Person Syndrome

Stiff–Person syndrome (SPS) is a rare neurological disorder characterized by muscle stiffness and painful spasms, initially described by Moersch and Woltman in 1956. The onset of SPS is usually during the third to sixth decade. Women appear to be affected more than men. Stiffness and muscle spasms are prominent in axial and proximal limb muscles, resulting in lumbar hyperlordosis. Muscle spasms are precipitated by sudden movement, noise, or emotional upset. Symptoms are absent during sleep or anesthesia.

Approximately 70 % of patients with SPS have a non-paraneoplastic form of this disorder associated with antibodies against glutamic acid decarboxylase (GAD). An autoimmune etiology of SPS is proposed based on its association with autoantibodies and other autoimmune diseases, and its response to immunomodulatory therapy. Electromyogram (EMG) reveals the existence of continuous motor unit activity in the affected muscles at rest. The cornerstone of the treatment represents symptomatic care with benzodiazepines and baclofen. Other options include IVIG, steroids, and plasma exchange.

In about 20% of patients, SPS develops as a paraneoplastic neurological disorder associated with elevated amphyphysin autoantibodies. Amphyphysin is a presynaptic nerve terminal protein critical for neuronal synaptic vesicle endocytosis. Antibodies to amphyphysin may be directly pathogenic in at least some cases of paraneoplastic SPS. Paraneoplastic SPS is rarely associated with anti-GAD antibodies. Malignancies most commonly associated with SPS are breast carcinoma, small-cell lung carcinoma, and lymphoma. SPM has also been reported in patients with thymoma and renal cell and colon carcinoma. Prominent clinical features of paraneoplastic SPS are the involvement of the upper extremities and less prominent spinal lordosis. Advanced age, subacute onset, rapid progression, and poor treatment response to benzodiazepines should raise the suspicion of a paraneoplastic SPS, and prompt a screening for neoplasm. The treatment of the neoplasm is critical. Symptomatic treatment options are similar to non-paraneoplastic SPS.

Paratonia (Gegenhalten)

N J Diederich, Centre Hospitalier de Luxembourg, Luxembourg-City, Luxembourg

Glossary

Frontal release signs – Primitive reflexes considered to reflect a disorder affecting the frontal lobes. These reflexes are physiological in the newborn. Their reappearance is due to a dysfunction of inhibitory pathways during late adult life.

Rigidity (or muscular rigidity) – An involuntary, *velocity-independent,* and sustained tonic muscular contraction, leading to a continuous resistance to passive movement throughout the range of motion; it is one of the clinical hallmarks of Parkinson's disease.

Spasticity – An involuntary, *velocity-dependent*, increased muscular resistance to stretch. Thus, the amount of resistance to stretching is at least partly determined by the speed with which a spastic muscle is stretched. In a clinical context, it is important to differentiate spasticity from rigidity.

History and Definition

In 1910, Dubré coined the French term 'rigidité paratonique'; and in 1927, Kleist the German expression 'Gegenhalten,' which literally means 'holding against.' Today, most clinicians use the term paratonia (PT). In the following decades, various definitions have been applied, making it almost obsolete to use such a poorly defined term. In 1998, Beversdorf proposed two types of PT, namely oppositional PT ('Gegenhalten,' 'paratonic rigidity') and facilitory PT ('Mitgehen'). The second type has been questioned, not only for linguistic reasons (the newly created word 'facilitory') but also because there may be overlapping of imitation behavior with echopraxia. In 2007, a consortium of experts came to a consensus that PT is a 'form of hypertonia with an involuntary variable resistance during passive movement.' In the following, we will focus on studies implicitly or explicitly applying this latter definition. Facilitory PT has only been discussed as an allied condition (see **Table 1**).

Pathophysiology

Since Denny-Brown's (1950) seminal work on motor dysfunction due to cerebral lesions, PT has been associated with frontal lobe dysfunction and considered as a cortically generated frontal disinhibition sign. As pointed out by Chatterjee, frontal lobes regulate, among others, goal-directed behaviors, a hierarchy of reflexive movements, approach and avoidance behaviors, response inhibition, and perseverations. After frontal damage, a patient may have trouble in both generating actions in the absence of stimuli and inhibiting them in the presence of stimuli. Consequently, PT may result from defective inhibition of a reflexive movement, secondary to a proprioceptive sensation or a passive movement. It is thus a motor perseveration. The hypothesis of PT as a frontal disinhibition sign is largely predominant in the scientific literature, but some authors have also emphasized that PT shows a strong dependence on the environment and can be considered as an imitation behavior. So far, there has been no proposal for the exact pathways involved in PT generation, although the requirement of bilateral frontal–subcortical lesions has been proposed. Chatterjee proposed that it should be studied if PT or the inability to inhibit simple movements in response to simple external stimuli also correlates with the inability to inhibit complex social behaviors in response to complex internal stimuli.

Prevalence and Risk Factors

There is no epidemiological study on the prevalence of PT, as defined above, in the elderly population. However, frequency of PT, defined as maintenance of an arm elevation after being released, has been studied by Tweedy et al. and Benassi et al. In both studies, it did not sufficiently discriminate between the elderly subjects without disease of the central nervous system and demented patients. Despite these restrictions, the impact of PT on prognosis and associated symptoms in dementia has been thoroughly studied. In a multiracial study of 80 patients with Alzheimer dementia (AD), Vahia and colleagues found an association with frontal symptoms as well as disease stage. PT was present in 48% of the patients with a moderate stage of the dementia and in 83% of patients with the most advanced stage of the disease. There was no link with age, race, sex, depression, physical health, neuroimaging, and neuropsychiatric symptoms. Risse and colleagues followed 28 patients with clinical AD diagnosis until death. PT was present in 18 out of 22 patients with pathological confirmation of the diagnosis. Conversely, PT was also present in five out of six patients with another pathological diagnosis. In the study by Franssen and colleagues, the prevalence of PT in the AD population was 86%. When compared with other release signs, PT was most consistently present. However, the survey listed by Risse and colleagues illustrates a large range of prevalence of PT in the older literature (18–88% of the patients with AD). These authors concluded that PT is not a useful indicator of any specific pathological diagnosis. Case reports have also mentioned PT as a prominent finding in Creutzfeldt disease, hereditary spastic paraplegia with frontal lobe signs, Hashimoto encephalopathy, and in subacute sclerosing panencephalitis. Finally, 'Gegenhalten' has been used in the psychiatric literature to describe a feature of negativism in catatonia.

The Clinical Spectrum of PT

Patients with PT demonstrate an involuntary resistance against any passive movement of the limbs. Occasionally they are able to suppress the resistance when fully relaxed or when focusing their attention on the moving limb. The degree of resistance varies with the speed of the passive movements. It increases when the extremity is moved

more rapidly and decreases or even disappears when it is moved more slowly. PT increases with progression of dementia, from active assistance ('Mitgehen') to active resistance ('Gegenhalten'). Sometimes both features coexist in the same patient.

Diagnostic Work-up

PT is a bedside diagnosis. Usually, it does not require any supplemental diagnostic procedures. Recently, an assessment tool based on the consensus definition of PT and consisting of five criteria have been proposed. The interobserver reliability was high (see **Table 2**), and the authors considered this instrument 'a valid and reliable assessment tool for PT in elderly people with dementia' (see **Figure 1**).

Beversdorf and coworkers (1998) proposed a five-point scale modified from the Kral procedure (also described as 'motor perseveration') to rate the severity of the allied facilitory PT. The rating score correlated with other frontal motor signs, frontal cognitive signs, and dementia severity. The authors emphasized that severity of facilitory PT was also linked with echopraxia and the inability to inhibit eye movements to peripheral stimuli.

Table 2 Criteria of the paratonia assessment instrument (PAI)

- An involuntary variable resistance during passive movement
- Absence of the clasp-knife phenomenon
- Resistance to passive movement occurs in any direction
- Resistance must be felt in either one limb in two movement directions or in two different limbs
- Degree of resistance correlates with the speed of movement (e.g., a low resistance to slow movement and a high resistance to fast movement)

Source:
Hobbelen JSM, Koopmans RTCM, Verhey FRJ, Habraken KM, and de Bie RA (2008) Diagnosing paratonia in the demented elderly; reliability and validity of the PT assessment instrument (PAI). *International Psychogeriatry* 20: 840–852.

Differential Diagnosis

PT can be easily distinguished from the spastic clasp-knife phenomenon. The differentiation from Parkinsonian (lead pipe) rigidity is more challenging. PT shows a variable degree of resistance, depending on the speed of the applied passive movements, whereas in Parkinsonian rigidity, the degree of resistance is constant, whether the limb is moved slowly or rapidly. PT does not show any exacerbation during contralateral reinforcement. Cogwheeling is not a helpful diagnostic sign because it reflects the combination of tremor or myoclonus of any cause with PT or Parkinsonian rigidity. In the most advanced cases of dementia, the paratonic resistance is so pronounced that the examiner is no more able to further accelerate the movement and thus adequately differentiate from Parkinsonian rigidity. The special subtype of eyelid PT or resistance to passive opening of the eyes has to be distinguished from blepharospasm.

Allied Features

Considered to be a frontal release sign, PT has been linked to glabellar blink, snout, sucking, rooting, grasping, and palmomental reflex. It has also been associated with dyspraxia or the inability to copy gestures and commands, despite intact muscle strength, coordination, and sensation. Within the wider spectrum of pathological motor behaviors induced by prefrontal lesions, PT has been mentioned side by side with the tendency to imitate the examiner's gestures, to compulsively manipulate objects in front of the patient (imitation and utilization behavior;

Figure 1 Evaluation of paratonia with the paratonia assessment battery (PAI). The examiner performs passive movement of the shoulders, elbows, and hips in flexion and extension. Reproduced from, Hobbelen JSM, Koopmans RTCM, Verhey FRJ, Habraken KM, and de Bie RA (2008) Diagnosing paratonia in the demented elderly; reliability and validity of the PT assessment instrument (PAI). *International Psychogeriatry* 20: 840–852, with permission from Cambridge University Press.

echopraxia), to instinctively grasp these objects, and to show motor perseverations, motor impersistence, or reduced motor activity.

Management

There is no treatment to abate PT. We even do not know if passive movement therapy, currently used in patients with late stage dementia, enhances or ameliorates PT. Currently, Hobbelen and coworkers (2008) are conducting a large randomized clinical trial to study the potential efficacy of this treatment on the severity of PT.

Prognosis

It is unknown whether the occurrence of PT in the elderly population *without* dementia has any prognostic significance. In AD, PT is usually more pronounced in the later stages of the disease and has thus been reported to predict a worse disease prognosis.

PARK1, Alpha Synuclein

M R Cookson, National Institute on Aging, Bethesda, MD, USA

Glossary

Gene mutation – A variant that differs from the ancestral form and can be passed on to subsequent generations. Mutations can be beneficial, neutral or detrimental, for example when associated with a specific disease phenotype.

Lewy bodies – Protein- and lipid-containing cellular inclusion bodies that are characteristic of Parkinson disease and related disorders. Related structures called Lewy neurites are swollen axons or dendrites that, like Lewy bodies, are highly positive for α-synuclein.

Protein aggregation – The tendency of some proteins to self-associate, forming species that are initially relatively soluble but eventually mature into higher molecular weight insoluble forms called fibrils.

Synucleins – A group of small proteins found in most vertebrates that were named for their localization to synapses and nuclei. Mutations in the α-synuclein gene, *SNCA*, cause Parkinson disease and related disorders in humans.

Although Parkinson disease (PD) is a relatively common disorder, the underlying cause of most cases is not known. Since the early descriptions of PD, ideas about etiology have developed and, over time, several have been proposed, discarded, and rediscovered. Although very rare, several genetic forms of PD have been found that cause disease in given families. Of these, the first to have been discovered was a point mutation in the gene *SNCA*, which codes for a small synaptic protein, α-synuclein. α-Synuclein is important for understanding the relationship between familial and sporadic, or non-inherited, forms of PD but also gives us some clues as to the otherwise apparently distinct events in PD, namely the clinical symptoms and the pathology of the disease. However, as important as α-synuclein is to our understanding of PD, there remain an important series of unknown aspects related to how, precisely, altered synuclein protein causes disease.

What is Known About α-Synuclein

Genetics

The first discovery of a mutation in the α-synuclein gene, *SNCA*, was reported in 1997 by Polymeropoulos and colleagues. Several families were found where a single amino acid change, substituting Alanine 53 for a Threonine in the protein, segregated with disease in a dominant fashion. Since then, two other point mutations have been found, A30P and E46K, where a single copy of the mutation causes disease. These mutations are important because they show that PD can be inherited in a Mendelian fashion, even if this not always true.

Another important set of mutations are those where the protein sequence is identical to the wild-type human version, but there are extra copies of the whole gene, that is, multiplications. Families with one extra copy (i.e., a duplication) or two extra copies (triplication) on one chromosome are reported. These are predicted to increase the amount of protein by 50% and 100%, respectively, which has been confirmed at least for the triplication cases. These mutations are important because they show us, very clearly, that the normal protein can be associated with PD. This implies that more subtle misregulation of the normal protein might be important in the lifetime risk of PD, even in people without mutations.

What is not true is that α-synuclein mutations always cause PD, at least not in the sense of typical sporadic PD. Several individuals in the families with point mutations show symptoms that indicate involvement of the cerebral cortex, including dementia that precedes the movement disorder typical of PD. This is perhaps best illustrated by the multiplication mutations. Duplications of α-synuclein are associated with a disease where the brainstem, specifically the substantia nigra, is predominantly affected. However, triplication cases have much more widespread pathology, including a more substantial involvement of the cerebral cortex. This is consistent with the idea that PD spreads from the brainstem out toward the cortex, a hypothesis proposed by Braak from observations of the pathology of sporadic PD cases.

As well as familial cases, α-synuclein may also be a risk factor for sporadic PD. Several studies have identified common genetic variants (polymorphisms) around the normal synuclein gene that are associated with lifetime risk of PD. If 50% increases in the amount of α-synuclein in the brain are causal for PD, then perhaps more subtle increases would change the relative risk over lifetime.

In summary, mutations in α-synuclein support the idea that rare genetic variants can be helpful in understanding the causation of common diseases.

Protein Chemistry

How, then, do mutations or increased amounts of α-synuclein act on the protein to trigger a neurological disease? Much of our current thinking about this problem relates to the physical properties of the protein, which is quite unusual.

α-Synuclein and its close relatives have evolved to have a high degree of flexibility in their structure. Most proteins have a limited repertoire of folded structures that they can adopt. In contrast, α-synuclein is capable of adopting one of several forms, depending on the context. In solution, in a context outside of the cell, α-synuclein adopts an open, flexible conformation and is therefore referred to as one of the class of natively-unfolded proteins.

Within a neuron, α-synuclein protein is predominantly found in association with presynaptic vesicles where neurotransmitters are stored. This is likely a result of the ability of the protein to associate with lipids, which it does by folding into a broken α-helix. The c-terminal region of α-synuclein, which is heavily negatively charged, projects out from the surface of lipid vesicles into the cytosol.

α-Synuclein can also form a number of aggregated forms that are stabilized by β-sheet like interactions. The process of protein aggregation is fairly well characterized in cell free systems and involves the formation of initially small oligomers that then seed the formation of larger structures. Over several days, this process results in the formation of highly stable fibrils that resemble structures isolated from Lewy bodies (see section Pathology: α-Synuclein Deposition as a Marker of the PD Process).

The aggregation process follows concentration-dependent kinetics and we can extrapolate that mutations that result in higher protein concentrations are associated with an increasing tendency to form aggregates. Two point mutations, A53T and E46K, also shift the dynamics of this process toward fibril formation. The third dominant

mutation, A30P, decreases lipid binding and promotes the formation of relatively soluble oligomers. This observation is one line of evidence suggesting that the mature, very insoluble, fibrils are not necessarily the damaging form of the protein in diseased brains but rather than the intermediates for protein aggregation may be more relevant.

Overall, these data suggest that a likely way in which mutations in α-synuclein cause disease is to promote protein aggregation although this hypothesis is tentative because the data to support or refute the idea in more intact systems is somewhat equivocal.

Pathology: α-Synuclein Deposition as a Marker of the PD Process

In addition to the genetic data, the neuropathology of PD also provides a link between α-synuclein and sporadic PD. The principal reason for this is that Lewy bodies, a characteristic pathological hallmark of PD and related diseases, are readily stained with antibodies against α-synuclein. Currently, PD is a clinical and pathological diagnosis, which requires both the clinical syndrome of a movement disorder and the presence of Lewy bodies in the *postmortem* brain. The term parkinsonism is preferred for cases with the clinical symptoms of PD where Lewy bodies are absent or unknown whereas Parkinson disease should be reserved for Lewy-body positive parkinsonism.

Therefore, and this is a definitional argument, α-synuclein deposition into Lewy bodies is a required event in sporadic PD. Although the number of cases is low, autopsied individuals carrying α-synuclein mutations have a high density of Lewy bodies and other α-synuclein positive lesions. Furthermore, the density of Lewy body staining is at least partially correlated with the major symptoms. Persons who had PD tend to have Lewy bodies in surviving neurons in the substantia nigra whereas patients with diffuse Lewy body disease (DLBD) where pathology is found in the cortex are also affected with dementia.

α-Synuclein can be biochemically isolated from the brain of patients with PD or DLBD. The forms of the protein recovered are often relatively insoluble and carry a number of posttranslational modifications. Lewy bodies contain α-synuclein positive fibrillar structures that may be related to those that can be generated *in vitro*. There is also a more limited amount of data showing that oligomers, which are of intermediate solubility, can be recovered from brains of patients with synucleinopathies.

Collectively, these observations suggest that the pathological process is shared between inherited and sporadic PD and that α-synuclein is, at least, a good marker of the process in both situations. Furthermore, the transformation of α-synuclein from soluble, monomeric α-synuclein through oligomers to deposited fibrils that occurs in laboratory settings may be relevant to the pathology of PD.

What is Unknown, or Unclear, About α-Synuclein

Normal Function

One consideration that arises from the identification of cases with multiplications of α-synuclein is that the difference between normal and abnormal concentrations of the protein is surprisingly modest. In the triplication families, twice as much α-synuclein as normal is associated with a very aggressive, early onset disease and, as discussed above, it is likely that quite small differences in overall expression is associated with risk of sporadic PD. α-Synuclein is a relatively abundant protein in many organs and is especially highly expressed in the brain. This leads to several outstanding questions in the field. Why is α-synuclein present in the brain? Can we remove it and decrease risk for PD or will this cause damage to the brain? Both of these questions can be reduced to one critical one: what is the normal function of α-synuclein?

One way to address this is to remove the gene by making a knockout mouse. Such animals are viable and apparently normal from birth through their normal lifespan. Subtle differences in synaptic function have been noted in some studies, but there are no dramatic phenotypes. This might be related to the fact that there are two homologuous genes, β- and γ-synuclein which may compensate for lack of α-synuclein, but double knockouts have only a similarly modest phenotype. This suggests that α-synuclein and its near homologues do not have an essential role in the nervous system, a contention possibly supported by the fact that invertebrates such as *Drosophila* with functional nervous systems lack recognizable synuclein genes.

α-Synuclein is only loosely attached to membranes such as synaptic vesicles and synaptic activity can cause the protein to lose lipid interaction, which then reassociates with vesicles only slowly. This does not tell us what the normal function of synuclein is, but may support the idea above that α-synuclein has a modulatory role and further suggests that understanding the relation between α-synuclein and electrical activity may be productive.

The normal function of α-synuclein is therefore somewhat mysterious outside of a potential connection to neuronal activity. This may become a critical question if we want to develop was to deal with α-synuclein in a therapeutic way for PD/DLBD patients. For example, can we remove all α-synuclein and leave brain function intact? Part of the answer to this question also depends on understanding why α-synuclein is associated with disease and, therefore, whether normal function is at all relevant to the disease process.

Dysfunction and Death

Because mutations in α-synuclein are associated with progressive neurodegenerative disease, and because the

same protein is found in cases with sporadic PD, it can be reasonably inferred that the protein is associated with neuronal damage in some way. However, this leaves a number of open questions as two exactly how and why neuronal damage occurs, how we might model that process and how to stop it.

Because of the evidence that mutations are associated with protein aggregation, it has been suggested that the aggregated α-synuclein triggers neuronal damage. Reasonable candidates for such a toxic agent are the relatively soluble oligomers that form along the way to mature fibrils. If true, this implies that a mature Lewy body, with heavily aggregated α-synuclein, might not be the actual toxic agent and might actually represent an attempt of a neuron to detoxify the partially aggregated species. However, this hypothesis is hard to test directly as few model systems reported to date reproduce both neuronal cell loss and mature Lewy body formation and it thus remains uncertain what form of α-synuclein mediates toxicity and whether Lewy bodies represent a cause or consequence of disease. It does seem reasonable that mature Lewy bodies take a long time to form, perhaps several years, based on results in grafts in the human brain.

Also uncertain are the processes by which α-synuclein in any form causes damage to neurons. Mutant α-synuclein has been reported to affect many functions of the cell, including protein turnover pathways, mitochondria and responses to other detrimental agents such as oxidative stress or ion homeostasis. Some of these may be especially important in neurons. Based on the observation that α-synuclein is involved in synaptic function, it is interesting that neurons in the substantia nigra that are relatively vulnerable in PD have a high autonomous electrical activity that is dependent on calcium influx. We might even speculate that such neurons that play important roles in the maintenance of posture may be working especially hard in obligate bipeds such as humans or other primates. However, there is currently no specific target of α-synuclein toxicity that readily explains why the brain is especially vulnerable to its effects.

Presumably, these two questions, understanding what the toxic species of α-synuclein is, and why this causes toxicity, are related to one another. They also underpin attempts to both develop models for the phenomenon and ways to interfere with the process and develop new ways to treat PD. These remain important challenges for the PD field.

PARK2, parkin

B A Chase, University of Nebraska, Omaha, NE, USA
K Markopoulou, University of Thessaly Medical School, Larissa, Greece

Clinical Phenotype

Mutations in the *parkin* gene (the PARK2 locus) were originally described in Japanese kindred where parkinsonism is inherited as an autosomal recessive trait. The phenotype seen in these kindred is early-onset parkinsonism – the most common age of onset is between 20 and 40 years, but cases younger than 10 years have been reported. Therefore, this form of parkinsonism was termed autosomal recessive juvenile parkinsonism (ARJP). Affected individuals have a slow disease progression and good response to levodopa therapy. Additional symptoms include hyperreflexia, diurnal variation with sleep benefit (motor symptoms may improve after sleep), dystonia, early postural instability, freezing, festination or retropulsion, and autonomic dysfunction. Motor complications of levodopa therapy such as ON–OFF fluctuations are common and occur earlier than in idiopathic Parkinson's disease (PD). Although dementia is not usually observed, psychiatric symptoms, including anxiety, psychosis, obsessive–compulsive disorder, and behavioral abnormalities, are common. These psychiatric symptoms are not specifically associated with *parkin* mutations as they can also be observed in other early-onset forms of Parkinson's disease (EOPD). Another interesting finding is that olfactory function is preserved in *parkin*-associated PD, whereas it is decreased in typical PD and autosomal dominant forms of PD.

Imaging

Parkin-associated PD cases have been studied by functional imaging using positron emission tomography (PET) with ^{18}F-dopa and ^{11}C-raclopride. Findings in affected *parkin* homozygotes, unaffected *parkin* heterozygotes, and unaffected compound heterozygotes were compared with those of healthy control subjects and cases of sporadic, idiopathic PD. Compared with healthy controls, *parkin* homozygotes and unaffected compound heterozygotes showed a decreased ^{18}F-dopa uptake in the putamen that was more prominent posteriorly. In addition, they showed a decreased ^{11}C-raclopride binding. The pattern is similar to that observed in the sporadic PD individuals and is suggestive of presynaptic-striatal dysfunction and alterations in the level of postsynaptic-D2-receptors. In asymptomatic *parkin* heterozygotes, there was a significant difference in ^{18}F-dopa uptake in the striatum. This suggests that asymptomatic mutation carriers have an ongoing neurodegenerative process and provides support for haploinsufficiency as a potential mechanism. Another interesting insight gained from these studies is that PET abnormalities may not correlate with disease severity.

Neuropathology

The neuropathological findings in ARJP associated with homozygous *parkin* mutations consist predominantly of severe neuronal loss in the substantia nigra (SN) pars compacta, with the most severe loss seen in the medial and ventrolateral regions. There is less pronounced neuronal loss in the locus ceruleus (LC) and the SN pars reticulata is usually spared. Although Lewy bodies are absent, neurofibrillary tangles (NFT) are seen in the SN, LC, hippocampus, and cortex. However, the NFT burden is considerably less than that associated with Alzheimer's disease (AD) pathology. In some cases, diffuse tau-positive astrocytes were observed in the caudate, putamen, and subthalamic nucleus, and a few in the SN. In other cases, there were α-synuclein-positive and ubiquitin-positive inclusions in the pedunculopontine nucleus, but not in the SN, LC, or subthalamic nucleus. In contrast to *parkin* homozygotes, Lewy bodies were found in a *parkin* compound heterozygote.

Genetics

Linkage analysis of 17 Japanese families with ARJP revealed that the parkinsonian phenotype maps to the long arm of chromosome 6 at 6q25.2–27. Through positional cloning, the *parkin* gene was identified. Over 100 different types of mutations in *parkin* have been described to date, including point mutations, deletions, and copy number abnormalities. Since its original description in the Japanese population, many different *parkin* mutations have been described in different ethnic populations. Indeed, mutations in the *parkin* gene are the most common cause of familial PD that is inherited as an autosomal recessive trait worldwide. *Parkin* mutations have also been associated with ~10–20% of apparently sporadic cases with an early disease onset of <45 years. In addition, heterozygotes and compound heterozygotes have been reported. Multiple *parkin* mutations segregate

in some kindred. There are kindred in whom different members have homozygous and heterozygous copy number abnormalities, while another member is a compound heterozygote. Heterozygosity for a *parkin* mutation may be a risk factor for PD and also appears to significantly influence the age of PD onset – individuals with two *parkin* mutations had an earlier age at disease onset and longer disease duration than those with just one mutation. That heterozygotes for some *parkin* alleles develop late-onset parkinsonism suggests that haploinsufficiency of *parkin* function may underlie the development of PD.

Copy number abnormalities are common in EOPD, occurring in up to 60% in some studies, and may exist in combination with point mutations or deletions. It is therefore important to assess *parkin*-copy number in EOPD patients. It is interesting to note that an increased number of parkin mutations predisposes individuals toward earlier disease onset, increased prevalence of dystonia, and positive family history.

Gene Structure and Expression

The *parkin* gene is among the largest human genes, second in size to the *dystrophin* gene. It spans 1.3 Mb of genomic DNA and its 4.5-kb transcript, generated from 12 exons, encodes a protein product of 465 amino acids. It is present in many human tissues, and in particular, is expressed in different regions in the brain, including the SN.

A molecular genetic analysis of the chromosomal region that includes *parkin* revealed that two genes, *parkin* and *parkin coregulated gene* (*PACRG*), share a common promoter region. More specifically, *parkin* and *PACRG* are arranged head-to-head on opposite DNA strands and share a common 5′-flanking promoter region. This bidirectional transcription activation region contains a transcription factor AP4-like site, a GC-rich region, and an oncogene MYC-like site.

In certain ethnic populations, the region of the bidirectional transcriptional activation appears to be associated with susceptibility to leprosy. This effect appears to be population specific and has been identified in Vietnamese and Brazilian, but not in Indian populations. Both *parkin* and *PACRG* are expressed in a wide range of tissues, including Schwann cells and macrophages, the primary host cells of *Mycobacterium leprae*, the causative agent of leprosy.

The Parkin protein contains an N-terminal ubiquitin-like domain (UBL) followed by a linker and two C-terminal RING finger domains that are separated by an in-between ring (IBR) domain. The RING–IBR–RING (RBR) structure is found only in eukaryotes in which it appears to be highly conserved. Given the similarity of the UBL to ubiquitin, Parkin is thought to function as an E3-ligase. E3-ligases conjugate ubiquitin moieties to proteins that are targeted for degradation through the proteasome. Mutant Parkin from ARJP patients shows a loss of the ubiquitin-protein-ligase activity, supporting the postulated E3-ligase function.

The Parkin protein is found in both cell bodies and processes of neurons, but not in glia, in the midbrain, basal ganglia, cerebral cortex, and cerebellum.

Parkin–Protein Interactions

Parkin's size and domain structure facilitate its participation in multiple protein interactions. Characterization of the three-dimensional structure of an IBR domain isolated from Parkin revealed that it contains two zinc-binding sites that are required for correct folding, which in turn is necessary for proper Parkin–protein interactions.

Numerous studies have identified protein interactions in which Parkin participates. Some of the most important interactions are described as follows.

Parkin binds to the E2 ubiquitin-conjugating enzyme-8 (UBCH8); ubiquitinates itself; and promotes its own degradation. It interacts with the Parkin-associated endothelin-receptor like receptor (Pael-R). The accumulation of Pael-R can lead to cell death, and the insoluble form of Pael-R accumulates in the brains of ARJP patients. Parkin ubiquitinates Pael-R and promotes degradation of its insoluble fraction, thus suppressing cell death. Interestingly, Pael-R, Parkin, α-synuclein, and ubiquitin accumulate in Lewy Bodies and neurites. Pael-R is localized within the core of Lewy Bodies, whereas Parkin and α-synuclein accumulate in the halo and in neuronal cell bodies and processes. Parkin also interacts with carboxy terminus of Hsc70-interacting protein (CHIP), a mammalian E4-like molecule that positively regulates Parkin E3-ligase activity.

Parkin functionally interacts with a glycosylated form of α-synuclein (α-Sp22), with loss of *parkin* function leading to the pathologic accumulation of α-Sp22. Parkin also interacts with synphilin, an α-synuclein-interacting protein. Coexpression of α-synuclein, synphilin-1, and Parkin leads to the formation of Lewy body-like, ubiquitin-positive, cytosolic inclusions.

The *parkin* gene is located at a fragile site and many copy number abnormalities have been associated with ARJP. The *parkin* gene has been implicated in tumorigenesis as a likely tumor suppressor gene. It appears that *parkin* inactivation may contribute to the initiation and progression of cancers, as tumor-derived cell lines contain *parkin* deletions or duplications.

Parkin is S-nitrosylated in vitro and in vivo in a mouse model of PD and in the brains of patients with PD and diffuse Lewy body disease (DLB). The enhancement of Parkin's E3-ligase activity by S-nitrosylation may be an important mechanism by which Parkin function is

regulated. Parkin S-nitrosylation enhances its E3-ligase activity at earlier time points but inhibits its E3-ligase activity at later time points, suggesting that alterations of the ubiquitination of Parkin substrates may underlie the neurodegenerative process. Parkin may protect against dopamine toxicity by decreasing oxidative stress and interfering with the activation of apoptotic programs such as the MAPK8/caspase pathway.

The DJ-1 gene, another gene linked to early-onset PD, interacts with Parkin. Parkin binds to monomeric DJ-1 and prevents DJ-1 homodimer formation.

Synaptotagmin XI (SYT11) interacts with Parkin, suggesting a role for Parkin in the regulation of the synaptic vesicle pool and in vesicle release. Parkin binds to synaptotagmin XI's C2A and C2B domains, resulting in synaptotagmin's polyubiquitination and enhancing its turnover. Truncated and missense-mutated Parkin proteins reduce parkin-synaptotagmin XI binding affinity and ubiquitination. In sporadic PD brain sections, synaptotagmin XI is found in the core of Lewy bodies.

Parkin interacts with p38 (JTV1), a structural component of the mammalian aminoacyl-tRNA synthetase complex, as well as with Bag5, a negative regulator of heat shock protein 70 (Hsp70) and Parkin.

Endogenous dopamine can covalently modify Parkin in rodent and human dopaminergic cells. Dopamine-induced loss of Parkin may represent a potential mechanism contributing to the selective degeneration of dopaminergic neurons.

Parkin interacts with another key player in PD pathogenesis, leucine-repeat-rich kinase 2 (LRRK2). LRRK2 interacts preferentially with the C-terminal R2 RING finger domain of Parkin, and Parkin interacts with the COR domain of LRRK2.

Parkin can interfere with epidermal growth factor receptor (EGFR) internalization and degradation and promote phosphoinositol-3K (PI3K)/AKT (protein kinase B) signaling.

Parkin's interaction sites have been mapped using genome-wide high-throughput analysis of protein–protein interactions. Parkin's UBL domain interacts with UbCH7, UbCH8, and the SKP1/CUL1/F-box (SCF)-like, ubiquitin-ligase complex, the subunit of 26S proteases. The linker region interacts with Bag5, 14–3–3 and the form of DJ-1 mutated in DJ-1-linked PD, synaptotagmin XI, and the p38 subunit of amino acyl tRNA synthetase. The IBR domain interacts with the 20S protease subunit α4. Finally, the RING domain interacts with synphilin. The spatial specificity of interactions that occur within the Parkin protein and the large number of interactors results in a complex pattern of interactions that may also be temporally and spatially regulated. It is conceivable that Parkin enters into different protein interactions at different points in time and different tissues.

Animal Models

Both invertebrate and vertebrate model systems have been developed to investigate the possible functions of Parkin. As many *parkin* mutations are loss-of-function alleles, these models have been useful to analyze how a loss of *parkin* function might underlie a disease mechanism.

Several different *parkin* knockout mouse models have been generated. None of the mouse models shows any neuronal loss in the SN. However, some, but not all knockouts, exhibit more subtle phenotypes that include motor and cognitive deficits and physiologically affect neurotransmission.

The excellent genetics of the fruitfly *Drosophila melanogaster* has been useful to develop a model system to assess *parkin* function. A characterization of the interactions of *parkin* and *Pink1* mutants supports the view that *parkin* acts downstream of *Pink1* in a linear pathway. While loss of either *parkin* or *Pink1* function results in a similar phenotype involving mitochondrial dysfunction, Parkin overexpression is able to rescue the muscle defects of *Pink1* mutants, but not vice versa. The involvement of the *Pink1–parkin* pathway in regulating mitochondrial function provides support for the view that mitochondria play an important role in PD pathogenesis.

Concluding Remarks

The isolation and characterization of *parkin* have contributed significantly to our understanding of the pathogenesis of PD. Mutations in *parkin* are a common occurrence in EOPD, but they also appear to be involved in PD cases having later disease onset.

The *parkin* gene is large and its protein product is involved in an extensive array of protein–protein interactions. From the available information, two patterns are emerging about the cellular functions of Parkin: The first is its involvement in protein degradation via its ubiquitin-ligase activity. The second is its involvement in pathways regulating mitochondrial function via its interaction with Pink1 and DJ-1.

Several questions concerning *parkin* remain to be elucidated. These include how the expression of this rather complex gene is regulated, how extensively it functions in tumorigenesis or signaling pathways, whether its differential temporal and spatial regulation contributes to its involvement in cellular processes in addition to the extensive array of those already known, and whether, given its association with pathogenesis in EOPD, *parkin* is involved in developmental processes. Future research will more fully elucidate the function of *parkin* and its links to the different cellular processes that underlie the pathogenesis of PD.

PARK3

T Gasser, University of Tübingen, Tübingen, Germany

Glossary

Dopamine – Important neurotransmitter involved in multiple brain functions.
Gene – DNA-sequence bearing the building code for a protein.
Linkage analysis – Statistical method to identify the localization of the gene responsible for an observable trait, for example, a genetic disease.
Parkinson's disease – Common neurodegenerative disorder caused by a degeneration of dopaminergic neurons.
Sepiapterine reductase – Enzyme critical to the synthesis of tetrahydrobiopterine, a cofactor of dopamine synthesis.

Parkinson's disease (PD) is a common neurodegenerative movement disorder, characterized clinically by akinesia, rigidity, and rest tremor. Pathologically, neuronal loss, predominantly of dopaminergic neurons of the substantia nigra, but also in many other brain areas, is usually accompanied by α-synuclein positive inclusions in cell bodies and neurites (so called Lewy pathology). The disease commonly occurs as a sporadic disorder, but several loci and genes have been discovered to cause Mendelian forms of PD.

A dominant locus has been mapped to chromosome 2p13 (PARK3) in a group of families of European ancestry. In these families, the clinical and pathologic features relatively closely resemble those of sporadic PD. A common haplotype identified in two of the families, whose ancestors could be traced to a relatively small region in Northern Germany and Southern Denmark, suggested a common founder and supported the linkage results. The haplotype was refined to a region of about 2.5 Mb, but so far the causative gene in these families has not yet been identified. Several candidate genes in the region, including those for transforming growth factor-α (TGFα), sideroflexin-5, and several others have been excluded.

Further evidence for an involvement of the PARK3-locus in PD came from a large collaborative European study, using a whole genome association approach in a cohort of sib-pairs. One of the most prominent linkage peak of this study mapped close to the PARK3 region.

As already the initial linkage study provided evidence for a reduced penetrance of the putative mutation at the PARK3-locus, subsequent work focused on its potential role as a risk factor in sporadic PD. Interestingly, two

independent studies implicated the PARK3-locus as a disease modifying locus influencing age at onset in two sib pair cohorts with PD. Specifically, DeStefano et al. found evidence for association between a later PD age at onset and allele 174 of marker D2S1394, which is contained within the original linked haplotype. Pankratz et al. performed a genome screen to identify genes influencing the age at PD onset using 276 families. Significant evidence of linkage to chromosome 2p near the PARK3 locus (logarithm of odds [lod] = 4.8) was observed. Karamohamed et al. extended the work of DeStefano by genotyping additional single nucleotide polymorphisms (SNPs) in the vicinity of marker D2S1394. They reported association of one SNP and a haplotype across the gene for sepiapterine reductase (SPR) with age of onset in sibships of North American origin. This finding was confirmed in a further study thoroughly assessing the SPR gene haplotype structure, and its contribution to PD by studying a cohort of 600 sporadic PD cases ascertained from Germany as well as in familial PD samples from five different European countries. This study again demonstrated an association with age of onset at the markers D2S2110 and rs1876487 in the familial data set, as well as an association with PD susceptibility to several intercorrelated SNP markers and haplotypes in an LD block spanning the SPR gene in the sample of sporadic PD patients.

Given all converging evidence, DNA variant(s) in or around the SPR gene appears to influence PD onset. Coding regions of potential PARK3 candidate genes, including SPR have been screened for pathogenic mutations in PD families. The failure to detect such mutations could indicate that the functional variant affects expression or splicing regulation rather than the protein structure itself.

A recently published study has revealed a mutation in the 5′ UTR of the SPR gene as a cause of dopa-responsive dystonia. SPR is an interesting candidate gene, because it catalyses the conversion of 6-pyrovyl-tetrahydropterin (PTP) to tetrahydrobiopterin (BH4). Functional variants in the SPR regulatory regions may, therefore, modify the age of onset of PD.

Previous studies have shown that BH4 acts not only as a cofactor for tyrosine hydroxylase (TH) and is, therefore, important for dopamine biosynthesis, but also stimulates NOS isoforms (inducible(iNOS), neural(NOS), and endothelial (eNOS)). It has been suggested that iNOS confers protection to PD.

In summary, there is evidence from multiple studies that the PARK3 locus on chromosome 2p13 contributes to, and/or modulates sporadic and familial PD. At present, SPR is the most likely candidate gene in this region.

PARK5, UCH-L1

E Dardiotis and K Markopoulou, University of Thessaly Medical School, Larissa, Greece

Genetics

The gene encoding ubiquitin carboxy-terminal hydrolase L1 (UCH-L1, also known as ubiquitin carboxyl-terminal esterase L1 and ubiquitin thiolesterase) was identified as the *PARK5* locus (OMIM 191342), using a candidate gene approach focusing on genes involved in ubiquitin-mediated protein degradation. The *UCH-L1* gene is located at 4p14 and contains 9 exons spanning 11.5 kbp of DNA. A heterozygous mutation in exon 4 of *UCH-L1* that resulted in a Ile93Met missense mutation was found in a German sibling pair affected with Parkinson's disease (PD). Two deceased members of the family, the paternal grandmother and a paternal uncle, were also affected. However, the father of the affected siblings was asymptomatic, although he was positive for the mutation. This suggests either that the mutation shows an autosomal dominant mode of inheritance with incomplete penetrance or that another unknown, pathogenetic factor contributes to the disease in this family. Despite extensive genetic screening in families with autosomal dominant PD, the Ile93Met mutation has not been found in other patients. However, the Ile93 residue is highly conserved: it is found in the paralogous gene UCHL3, the rat and mouse orthologs of UCHL1, and the homologous genes in yeast and the plant *Arabidopsis thaliana*. Therefore, either the Ile93Met substitution in UCH-L1 gene is a rare cause of familial PD or it is inherited with the parkinsonian phenotype as a result of a coincidental genetic mutation.

Clinical Phenotype

The parkinsonian phenotype in the German family is similar to sporadic Parkinson's disease (PD) and included resting tremor, rigidity, bradykinesia, postural instability, and good therapeutic response to levodopa. The disease onset was approximately at age 50.

Neuropathology

To date, there are no reported neuropathological findings as none of the gene-positive individuals has come to autopsy.

Genetic Association Studies in Sporadic PD

Numerous association studies have evaluated whether the *UCH-L1* gene plays a role in the sporadic form of PD. Most have focused on the potential importance of a non-synonymous polymorphism in exon 3 of *UCH-L1* that appears in about twenty percent of the Caucasian population and results in a Ser18Tyr amino acid change. An initial study in European sporadic PD patients found that this polymorphism was underrepresented in PD patients (odds ratio of 0.53; 95% CI = 0.30–0.94; $p = 0.03$). Although conflicting results were obtained in additional studies, a meta-analysis that pooled data from 11 association studies (1970 cases and 2224 controls) found an inverse association of the Ser18Tyr polymorphism with PD. There, 18Tyr carriers had an odds ratio of 0.84 (95% CI = 0.73–0.95), homozygotes had an odds ratio of 0.71 (95% CI, 0.57–0.88), and the 18Tyr allele showed a stronger association with early onset PD. However, these findings have not been reproduced in additional studies. A large case–control study (3023 sporadic PD patients) did not find that the Ser18Tyr variant was protective against PD under any mode of inheritance, screening of haplotype tags in the *UCH-L1* gene did not detect any other associated variants, and an updated meta-analysis that included 6594 individuals did not observe an association with PD. Given the meta-analyis results, it appears unlikely that the PARK5 locus is implicated in sporadic PD pathogenesis. However, polymorphisms in the UCH-L1 gene may play a role in PD pathogenesis in distinct ethnic groups.

Biochemical Functions of UCH-L1

UCH-L1 belongs to a family of deubiquitinating enzymes that recycle ubiquitin monomers from polypeptide–ubiquitin chains in the proteasome. UCH-L1 is normally expressed in neurons and testis and it is almost absent from other tissues. Indeed, it is highly abundant in the brain, constituting 1–2% of total soluble protein, and its 1.3-kb transcript is particularly abundant in the substantia nigra. It is a component of Lewy bodies. It has a molecular weight of 24.8 kDa and contains 223 amino acids.

Three distinct biochemical activities are associated with UCH-L1. UCH-L1 monomers catalyze the hydrolysis of ubiquitin–peptide polymers in vitro to free ubiquitin monomers. This activity is important in vivo for

recycling ubiquitin monomers from polypeptide–ubiquitin chains in the proteasome. It can also form dimers in vitro that have an ubiquitin–protein ligase activity that is capable of promoting α-synuclein aggregation. Thus, UCH-L1 acts as a hydrolase in its monomeric form and as a ligase in its dimeric form. The third UCH-L1 function is independent of its enzymatic activities. UCH-L1 can bind to mono-ubiquitin molecules in vivo. This leads to stable neuronal mono-ubiquitin levels by inhibiting their degradation in the brain.

Biochemical support that the Ile93Met mutation could cause PD in the German family has come from investigations assessing the impact of this mutation on the enzymatic functions of UCH-L1. Ile93Met UCH-L1 is associated with a marked decrease in ubquitin hydrolase activity, suggesting that *PARK5*-associated PD might result from insufficiency in the recycling of ubiquitin. An alternative possibility is that this mutation increases α-synuclein aggregation by altering the monomer to dimer ratio and increasing UCH-L1's ubiquitin-ligase function to promote α-synuclein aggregation. Transgenic mice expressing Ile93Met UCH-L1 show age-dependent loss of dopaminergic neurons: a pathological hallmark of PD.

In contrast to the biochemical findings for Ile93Met UCH-L1, Ser18Tyr UCH-L1 has an unchanged hydrolase activity and a reduced ubiquitin-ligase activity for α-synuclein in vitro. This may account for a protective effect of the 18Tyr variant in PD.

As might be expected, loss-of-function mutations in UCH-L1 do not recapitulate the likely gain-of-function phenotype that is associated with the apparent dominant allele leading to Ile93Met UCH-L1. Mouse UCH-L1 loss-of-function mutations (generated from an in-frame deletion of exons 7 and 8) confer a gracile axonal dystrophy (gad) phenotype, which is characterized by sensory and motor ataxia due to peripheral nerve axonal degeneration. Although degenerating neuronal axons accumulate amyloid Aβ-protein and ubiquitin–proteasome-positive deposits, brain neurons show no neurodegenerative features, and no parkinsonian phenotype develops.

There is additional evidence that UCH-L1 plays an important role in neurodegenerative processes. Absence of UCH-L1 protects cells from acute, stress-induced apoptosis, and administration of UCH-L1 alleviates the β-amyloid-induced synaptic dysfunction and memory loss in a mouse model of AD.

Conclusion

UCH-L1 is clearly an important protein for normal neuronal function. There is no clear-cut genetic association between polymorphisms at the *PARK5* locus and PD. If *UCH-L1* mutations do contribute to the pathogenesis of PD, they are rare, and their mechanisms of action are not yet fully elucidated.

PARK6, PINK1

B A Chase, University of Nebraska at Omaha, Omaha, NE, USA
K Markopoulou, University of Thessaly, Larissa, Greece

Glossary

Haploinsufficiency – A disease state that results when a single functional copy of a gene in a diploid organism cannot produce enough gene product to provide for a normal phenotype.

Genetics and Clinical Features Associated with PINK1 Mutations

Homozygous mutations in the phosphatase and tensin homolog (*PTEN*) *induced putative kinase 1* (*PINK1*) gene were initially identified in three consanguineous Italian kindreds in which parkinsonism was inherited as an autosomal recessive trait. Both nonsense (W437X) and missense (G309D) mutations were identified in the *PINK1* gene, located at 1p36. The parkinsonian phenotype in *PINK1* kindreds is milder than that of idiopathic Parkinson's disease (PD) with earlier disease onset (age 20–40), slower progression, and good therapeutic response to lower doses of levodopa. The *PINK1*-associated phenotype shares similarities with that of *parkin*-associated phenotypes, including focal dystonia and sleep benefit. Since the original description of the W437X and G309D mutations, additional mutations have been described in both Caucasian and Asian populations. In addition to the originally identified homozygous mutations, heterozygous and compound heterozygous mutations have been described. Heterozygous *PINK1* mutations may predispose individuals to PD, although this finding is still controversial. Heterozygous mutations in *PINK1* have been associated with a PD phenotype, raising the possibility of haploinsufficiency as an underlying mechanism. Interestingly, in contrast to homozygotes, a compound heterozygote had a later disease onset than *PINK1* homozygotes. While most of the mutations described to date are missense or nonsense mutations, deletions have also been reported, and these are associated with dementia. This may suggest that more substantial decreases in *PINK1* function are associated with more severe PD phenotypes. The pathology underlying *PINK1*-associated parkinsonism with homozygous mutation remains unknown as no cases have yet come to autopsy.

Imaging studies have been performed in homozygous and heterozygous *PINK1* individuals. Homozygotes show an ^{18}F-dopa uptake pattern similar to that seen in idiopathic PD with 80–85% reduction of uptake in the caudate and putamen, whereas heterozygotes show 20–30% reduction in the same regions.

The Function of PINK1

The function of the PINK1 protein, which is highly conserved among metazoans and has been identified in both vertebrates and invertebrates, has not yet been fully elucidated. It is a serine–threonine kinase localized to the intramembrane region of the mitochondria and is associated with the inner mitochondrial membrane. Several reports suggest that PINK1 is also present in the cytoplasm. The presence of PINK1 in the cytoplasm may be linked to proteasomal inhibition. Given that the mutations associated with PD are recessive and loss-of-function mutations, it is conceivable that the cytoplasmic PINK1 fraction is the PINK1 that accumulates in the cytoplasm because of defective degradation due to proteasomal dysfunction.

The Regulation of *PINK1*

PINK1 expression appears to be regulated in several ways. In humans, it is differentially expressed in both the brain and body at the mRNA and protein levels. In humans, the highest levels of *PINK1* mRNA expression primarily are seen in neurons and less in glia in the hippocampus, substantia nigra, and cerebellar Purkinje cells. In the brain, PINK1 protein is detected in all cell types, primarily in a cytoplasmic pattern consistent with mitochondrial localization. It is detected in Lewy bodies in sporadic PD as well as in *PINK1* heterozygotes.

The transcriptional regulation of *PINK1* has been investigated. One report suggests that the abundance of *PINK1* mRNA is at least partly regulated by the presence of a noncoding antisense transcript that under physiological conditions positively influences the abundance of the cis-transcribed *PINK*1 mRNA. *PINK1* genomic variants are associated with altered *PINK1* transcript levels, indicating additional levels of control over *PINK1* mRNA expression. Differential mRNA splicing has also been implicated in the regulation of *PINK1* expression. In a sporadic parkinsonian patient, a splice-site mutation leads to several aberrant mRNAs. A naturally occurring

splice-site variant contains only the final four exons of the *PINK1* gene.

The PINK1 protein may be regulated at the level of the proteasome, as proteasomal inhibition leads to an increase of cytosolic PINK1.

Endogenous PINK1 is proteolytically modified at its amino terminus to produce a mature protein – the immature form is a 581 amino acid proprotein that is cleaved at position 77 to yield a 504 amino acid mature protein. In addition, the levels of functional PINK1 may be regulated by other proteins, such as heat-shock protein Hsp90 (Hsp90/Cdc 37), which appears to regulate the ratio of processed to unprocessed protein.

PINK1-kinase activity is regulated at multiple levels, apparently through intramolecular interactions. Removal of either the C- or the N-terminus impacts on PINK1-kinase activity by increasing its autophosphorylation activity. Removal of its N-terminus may interfere with its ability to be translocated into the mitochondria.

Proteins Interacting with PINK1

The interactions of PINK1 with other proteins offer additional insights into its normal biological roles and how their disruption may lead to PD. To date, PINK1 has been shown to interact with the TNF receptor associated protein 1 (TRAP1), DJ-1, and HtrA2. TRAP1 is a mitochondrial chaperone that is also identified as heat shock protein 75 (Hsp75). PINK1 binds TRAP1 and phosphorylates it both in vitro and in vivo. PINK1 phosphorylation of TRAP1 protects it against oxidative-stress-induced cell death by suppressing the release of cytochrome c from the mitochondria. The ability of PINK1 to promote TRAP1 phosphorylation is impaired by the presence of mutations that have been associated with PD (G309D, W437X, and L347P).

PINK1 and DJ-1 interact at both the biochemical and genetic levels. PINK1 has been shown to interact with DJ-1 in cotransfection experiments; coexpression of wild-type PINK1 and DJ-1 suppresses MPP^+-induced cell death, whereas coexpression of mutant PINK1 and DJ-1 enhances susceptibility of cells to MPP^+-induced cell death. Furthermore, familial PD patients have been described with heterozygous mutations in both *PINK1* and *DJ-1*.

More recently, the mitochondrial serine–protease HtrA2 (Omi) has been shown to interact with PINK1. Interestingly, heterozygous mutations in this gene identified in German PD patients result in defective activation of the protease activity of Omi/HtrA2. Cells overexpressing one of the mutations (S399) exhibited mitochondrial dysfunction, altered morphology, and were also more susceptible to stress-induced cell death. Because of its association with PD, the gene for Omi/HtrA2 has been named the *PARK13* locus. Other studies have shown that Omi/HtrA2 is phosphorylated via the activation of the p38 pathway in a PINK1-dependent manner. HtrA2 phosphorylation is decreased in the brains of PD patients carrying *PINK1* mutations. PINK1-dependent phosphorylation of HtrA2 may regulate the proteolytic activity of HtrA2 and contribute to increased resistance of cells to mitochondrial stress conditions.

Summary and Conclusion

In summary, PINK1 appears to have an important role in maintaining mitochondrial integrity under conditions such as oxidative stress and proteasomal dysfunction. Despite the considerable information provided by the studies described above, several questions regarding the function of PINK1 remain unanswered. Since PINK1 is a PTEN-induced kinase, one question is whether PINK1 has a role in the phosphatidyl-inositol-3 kinase (PI3K) signaling pathway. PTEN has been implicated in regulating the oncogenic PI3K/Akt signaling pathway, in angiogenesis, and in the formation and maintenance of neuronal circuits in the brain. Dysregulated PI3K/PTEN signaling has been implicated in neurogenesis and neuronal connectivity. While PINK1 may exert its function through the maintenance of mitochondrial integrity, in light of recent data implicating neurodevelopmental processes in PD pathogenesis, it may also be that other aspects of its function relating to its potential association with the PI3K/PTEN pathway may contribute to neurodegeneration in PD.

PARK7, DJ1

V Bonifati, Erasmus MC, Rotterdam, The Netherlands

Glossary

Dimer – Complex formed by two simpler protein components (monomers). A dimer is termed homo-dimer or hetero-dimer when the two monomers are constituted by identical or different protein species.
Genotype – The observed characteristics or status present at a given genomic position.
Monogenic (Mendelian) – Normal or pathologic trait determined by the effects of a single gene or chromosomal locus.
Phenotype – The observed characteristics (normal or pathologic) at biochemical, cellular, or whole organism level (with the exception of the genotype).
Sporadic – Adjective used to indicate a phenotype (e.g., a disease) that is not known to have occurred in other family members (as opposed to Familial). Sporadic is not synonymous of nongenetic. A sporadic disease can be entirely genetic in origin (e.g., autosomal recessive diseases).

Definition and History

The gene termed *DJ-1* was first described in 1997 as a putative oncogene. However, the interest in the biology of *DJ-1* gained momentum in 2003, with the discovery that its mutations cause a form of early-onset human parkinsonism, leading to its current designation as *PARK7*. The link between *DJ-1* and parkinsonism was found by genetic analyses of families in which several subjects developed early-onset parkinsonism in association with inherited loss-of-function mutations in the gene.

Parkinsonism is defined by the clinical combination of slowness of movement (also termed bradykinesia), tremor at rest, and muscular rigidity. When no causes are identifiable, the disease is defined as primary or idiopathic. Parkinson's disease (PD, idiopathic parkinsonism) is the most common form of primary, degenerative parkinsonism, currently defined by the presence of this syndrome in the absence of other atypical clinical signs, and with beneficial response to dopamine-replacement therapy. This clinical entity is associated with the progressive loss of dopamine-producing neurons in the brain and (usually) with the presence of protein inclusions (termed Lewy bodies) in the surviving neurons.

PD is uncommon before the age of 40-years, and its incidence increases with age. If the symptoms start before the age of 40 years (45 for other Authors), the disease is referred to as 'early-onset PD.' In most cases PD occurs in sporadic form, but about 10–15% of patients report one or more affected relatives. The cause of PD remains still unknown in most patients. However, several Mendelian forms of the disease have been identified, which are transmitted in either an autosomal dominant (*PARK1*, *PARK8*) or an autosomal recessive (*PARK2*, *PARK6*, *PARK7*) fashion. *PARK7* is one of the genes known to cause autosomal recessive forms of degenerative parkinsonism with early-onset.

The *PARK7* gene (also termed *DJ-1* or *DJ1*) (OMIM #606324) is abundantly and ubiquitously expressed in the brain and other body tissues, and encodes a protein of 189 amino acids, which bears the same name (PARK7 or DJ-1). The protein belongs to a large superfamily named after a shared, evolutionary conserved domain (ThiJ/PfpI), and its subcellular localization includes

cytosol and mitochondria. In normal conditions, two PARK7 protein monomers associate to form homodimers. Moreover, there is evidence that posttranslational modifications (mainly oxidation) produce several PARK7 protein variants. Despite cellular abundance, evolutionary conservation, and ubiquitous presence, the exact function of the PARK7 protein remains unknown.

Pathogenesis

The pathogenesis of this form remains poorly understood, but is believed to be primed by the loss of the normal function of the PARK7 protein. On the basis of the currently available data, the PARK7 protein appears to be a multifunctional neuroprotective molecule that includes antioxidant and molecular chaperone properties. This is intriguing, as there is evidence of oxidative stress and protein misfolding occurring in the brain of patients with common forms of PD and other neurodegenerative disorders. The chaperone activity of PARK7 seems redox dependent, being activated in response to oxidative stress. One possibility to explain the seemingly multiple effects of PARK7 is offered by the known capacity of this protein to bind mRNA species, thereby being potentially able to influence disparate cellular pathways. The homologs of the *PARK7* gene have been knocked out in different model organisms, including mouse, fruit fly, zebrafish, and nematode. Overall, these models failed to recapitulate the features of human disease, but they highlighted important roles of the PARK7 protein in the physiology of the brain dopaminergic systems, as well as in the protection of neurons from oxidative stress. Understanding the function of the PARK7 protein and how its dysfunction cause disease might provide clues into the mechanisms of neurodegeneration also in more common forms of parkinsonism. However, whether the pathogenesis of the disease caused by the PARK7 defect overlaps with the other forms of autosomal recessive, early-onset parkinsonism or with that of the common, late-onset forms of PD, remains unclear at this juncture.

Epidemiology

The disease causing, homozygous or compound-heterozygous mutations in *PARK7* are rare, being detected in only 1–2% of patients with early-onset PD. Moreover, in a similar percentage of patients, only a single-heterozygous mutation is detected, the role of which in the disease causation remains doubtful. They might represent just rare disease-unrelated variants. However, some of these single-heterozygous mutations might cause disease by affecting the PARK7 dimer formation or function (a mechanism termed 'dominant negative'). More than 20 different *PARK7* mutations have been identified in patients with parkinsonism (**Table 1**), including point mutations (missense, truncating, splice site mutations), and large genomic deletions or duplication. However, only 13 mutations were found in homozygous or compound-heterozygous state, and are therefore more likely to be disease causing. The mutational spectrum of *PARK7* is therefore broad, and the screening of this gene is complex, requiring copy number assay (gene dosage) in combination with direct sequencing, in order to achieve high sensitivity. *Parkin (PARK2)* gene mutations are a much more common cause of autosomal recessive early-onset parkinsonism than are mutations in *PARK7* or *PARK6 (PINK1)*. The screening of *PARK7* and *PARK6* might be therefore appropriate especially if *parkin* mutations are not found.

Clinical Features, Differential Diagnosis, Management

The current knowledge about the clinical phenotype associated with *PARK7* mutations is limited by the small number of patients with clear disease-causing mutations, and by the wide phenotypic variability present even in patients from the same family. Overall, the patients with disease-causing homozygous or compound-heterozygous *PARK7* mutations resemble those with mutations in the other genes for early-onset parkinsonism (*parkin* or *PINK1*). Parkinsonism symptoms appear usually before 40 years of age, and they are exquisitely responsive to L-dopa or dopamine agonists, with, in some patients, development of L-dopa-related motor fluctuations and dyskinesias. The progression of the parkinsonism is slow in most cases.

In a single consanguineous family from Southern Italy, *PARK7* mutations have been detected in association with a broader phenotype, including early-onset parkinsonism, motor neuron disease, and behavioral and cognitive disturbances. The clinical spectrum of the *PARK7*-related disease might therefore be broader than the pure parkinsonism. In patients with *PARK7* mutations, structural brain imaging with computed tomography (CT) or magnetic resonance imaging (MRI) scans have been unremarkable. Functional brain imaging with positron emission tomography (PET) or single photon emission computed tomography (SPECT) showed the abnormalities of the nigrostriatal dopaminergic system that are classically seen in patients with PD. Therefore no clinical or imaging features allow distinguishing the patients with mutations in the *PARK7* gene from those with mutations in *parkin* or *PINK1*, or from those without identifiable gene mutations, indicating that genetic testing is essential for an accurate etiologic diagnosis.

The pathology associated with *PARK7* mutations remains unknown as necropsy studies in patients with this form have not been reported so far. Lewy bodies in patients with idiopathic PD contain no substantial PARK7

[a]Promoter (g.168_185dup) mutation and missense (p.E163K) mutation, detected both in homozygous state, in patients with parkinsonism–dementia–amyotrophic lateral sclerosis complex.
[b]The c.56delC;c.57G→A and the IVS6–1G→C mutation were detected in the same patient with early-onset parkinsonism.
[c]Found in combination with a single-heterozygous mutation (p.P399L) in the *PINK1* gene in two Chinese sibs with early-onset parkinsonism.
[d]The g.159C→G and IVS4 + 3insA mutations were detected in the same patient, and shown to be in compound heterozygosity. The g.159C→G mutation lies in the promoter and might affect gene expression; IVS4 + 3insA might affect mRNA splicing.
[e]Silent mutation; effects on mRNA splicing, mRNA stability, translation efficiency, cannot be excluded.
[f]Mutation in the 3′ untranslated region; effects on mRNA stability cannot be excluded.

immunoreactivity. However, PARK7 immunoreactivity is present in the neuronal inclusions that characterize other neurodegenerative diseases, collectively known as tauopathies, and in the multiple system atrophy, suggesting a possible participation of the PARK7 protein in their pathogenesis. Unless novel therapeutic or neuroprotective strategies become available on the basis of the specific disease etiology or pathogenesis, the therapeutic approach to the patients with *PARK7* mutations is not different from the approach to any patients with early-onset PD. Whether the prognosis of this form is different from the other forms of early-onset PD remains unknown due to the small number of patients reported with *PARK7* disease-causing mutations and to the wide clinical variability.

PARK8, LRRK2 (Dardarin)

B A Chase, University of Nebraska at Omaha, Omaha, NE, USA
K Markopoulou, University of Thessaly, Larissa, Greece

Glossary

Paralog – Genes related by duplication within one genome. Orthologs retain the same function in the course of evolution, whereas paralogs evolve new functions, even if these are related to the original one.
Ortholog – Genes in different species that evolved from a common ancestral gene by speciation. Normally, orthologs retain the same function in the course of evolution.

PARK8 (*LRRK2* Gene)

Genetics

The *PARK8* locus was originally identified in a Japanese kindred transmitting a Parkinson's disease (PD) phenotype in an autosomal dominant manner. Linkage analysis mapped the locus to chromosome 12p11.2–q13.1, and several years later, through studies of 51 families associated with autosomal dominant PD, mutations in the gene leucine-rich repeat kinase 2 (*LRRK2*) were identified. Since then, at least 20 different mutations have been

described in *LRRK2*. Mutations in *LRRK2* have a worldwide distribution and account for ~7% of familial PD cases and have also been identified in sporadic PD cases. A large study of *LRRK2*-associated PD revealed that six of the mutations described to date can be considered pathogenic, the most common being G2019S. This mutation is found in 4% of familial PD cases and 1% of sporadic PD cases. There are different frequencies of the familial mutations in different ethnic populations. An apparent geographic latitude gradient exists: the highest frequency of mutations is seen in the Middle East, and a decreasing frequency is seen in more northern latitudes in Europe. Approximately 30–40% of familial PD cases in Arab and Ashkenazi Jewish populations are associated with *LRRK2* mutations, while this number is ~6% in the European population.

Clinical Phenotype

The PD phenotype associated with the *PARK8* locus originally described in the Japanese kindred is indistinguishable from that of sporadic PD. The phenotype seen in most *LRRK2* kindreds consists of tremor that is often asymmetrical, rigidity, bradykinesia, and a good response to levodopa therapy. In one study, the parkinsonian phenotype of both motor and nonmotor symptoms was more benign than that of idiopathic PD. The disease has usually a late onset (>50 years). Penetrance appears to be age dependent ranging from 28% at the age of 59 to 74% at the age of 79. There is no clear-cut difference between the phenotypes of heterozygotes and homozygotes.

The phenotypic similarity of *LRRK2* families to idiopathic PD also extends to findings from imaging studies. ^{18}F-dopa PET studies have revealed that individuals with *LRRK2* mutations exhibit a pattern of uptake that in most cases is indistinguishable from that of idiopathic PD, with a maximum reduction of ^{18}F-dopa uptake in the putamen. Some variability in the functional imaging findings in *LRRK2* cases is seen and is consistent with the compensatory changes. These include downregulation of the dopamine transporter (DAT) and upregulation of decarboxylase activity.

Neuropathology

The neuropathology associated with *LRRK2* mutations is pleiomoprhic, both within the same and among different kindreds. Even though individuals carry the same mutant *LRRK2* allele, different neuropathologies have been observed. In some cases, there is neuropathology consistent with Lewy body PD; in some other, diffuse Lewy body disease (DLB); in a few other, there is only nigral degeneration; and in yet other cases, findings consistent with progressive supranuclear palsy (PSP). There are synuclein-positive and tau-positive inclusions, and LRRK2 protein can be detected in the Lewy bodies (LB) and in dystrophic neurites in the brainstem. Interestingly, LRRK2 protein is not restricted to the brain regions that are associated with pathology in PD. Its subcellular localization includes the nuclear envelope and cytoplasm. Furthermore, in one study, there were LRRK2-positive-globular inclusions with punctate α-synuclein-positive staining in the lower brainstem (dorsal motor nucleus of the vagus). This finding raises the possibility of an association between early α-synuclein pathology and *LRRK2* function.

The *LRRK2* Gene

Structure, expression, and protein product

The *LRRK2* gene is large (144 kb) and has a coding region of 7.4 kb comprised of 51 exons. It is expressed in regions affected by PD such as the striatum, substantia nigra pars compacta, and cortex. The regulation of *LRRK2* mRNA expression and message stability has not yet been elucidated.

The LRRK2 protein has also been called dardarin, as some of the families in which mutations were identified were of Basque origin, and darda is the word for tremor in the Basque language. Dardarin is a large, 2527 amino-acid protein that contains seven different domains: starting near the N-terminus are armadillo repeats, then an ankyrin (ANK) repeat domain followed by a leucine-rich repeat (LRR) domain, a Ras of complex protein (ROC) GTPase domain, a C-terminal of Roc (COR) domain, a kinase domain similar to that found in members of the tyrosine kinase-like (TKL) subfamily, and finally a C-terminal WD40 domain.

The different domains suggest that dardarin is a multifunctional protein that is involved in multiple protein–protein interactions. ANK repeats are repeated amino-acid motifs that serve as a protein–protein interaction module and serve in a wide range of cellular functions. A number of human diseases are associated with defects in proteins containing ANK repeats. Armadillo repeats are tandem repeats of 42 amino acids that mediate interactions with other proteins. They have been identified in proteins involved in transcriptional activation, nuclear transport, signaling, and cytoskeletal regulation. The LRR domain contains LRRs arranged in tandems of two or more repeats, resulting in a solenoid structure that is conducive to protein interactions. The Roc and COR domains characterize proteins that belong to the ROCO protein family. In invertebrates, members of this family are involved in cell division, chemotaxis, and development. In humans, they have been implicated in epilepsy and cancer. These proteins also appear to have the ability to activate intramolecular kinase domains. Indeed, it appears that *LRRK2* mutations such as G2019S and I2020T have a kinase-activating effect. This is consistent with the genetic data that, given the dominant inheritance of the parkinsonian

phenotype, support a gain-of-function disease mechanism. Proteins containing WD40 domains are also involved in protein interactions and especially in processes such as cell cycle progression and histone binding.

The rather complex structure of the LRRK2 protein product suggests that it has a multifunctional role. Besides the obvious kinase and GTPase functions, it has the potential to bind a wide range of proteins including transcription factors and signaling molecules.

There is a paralog of *LRRK2*, *LRRK1*, which also encodes a rather large protein of 2052 amino acids. It is located on chromosome 15q26.3. The two genes are evolutionarily conserved in vertebrates and appear to share a common ancestral gene. In the two invertebrate model systems, *Drosophila melanogaster* and *Caenorhabditis elegans*, there is only one *LRRK* ortholog. To date, mutations in *LRRK1* have not been associated with PD.

LRRK2 domains and mutations associated with PD

The multiple structural motifs included in LRRK2 make it very likely that it is involved in multiple protein–protein interactions. Its motifs can be identified both in prokaryotes and eukaryotes, and their evolutionary conservation suggests that they play important roles throughout the evolution.

From the study of other protein kinases, we know that the kinase catalytic domain consists of N-terminal and C-terminal lobes that are connected by a hinge-like region. This structure forms a cleft in which the protein substrate can bind along with Mg^{2+} and ATP. Within the C-terminal lobe lies an activation sequence consisting of 20–35 residues. The C-terminus of the molecule is also required for autophosphorylation. Phosphorylation of the activation sequence alters its conformation. Phosphorylation is required for kinase activation, as the conformational change allows access of the substrate and is required for catalysis. The mutation most commonly associated with PD, G2019S and the less frequently PD-associated mutation, I2020T, lie at the N-terminal boundary of the activation segment and therefore are likely to interfere with kinase activation. While the genetic data described above support an activating role for the G2019S substitution, a decrease in kinase activity may also be consistent with a gain-of-function mechanism, given the multitude of potential protein interactions.

The seven-ANK repeats of LRRK2 form antiparallel helices followed by a β-hairpin loop. These can be stacked together to form a curved structure. These repeat domains apparently undergo a two-state folding transition. Studies of other proteins containing ANK repeats show that the number of ANK repeats is a molecule affects its energetics. The addition or removal of repeats may alter the folding process of the protein molecule. For example, the folding pathway of the ANK repeats in Notch, a protein involved in multiple cell-fate decisions throughout development, is selected based on the local energetics. Differential folding will impact the protein interactions in which the molecule participates. One of the PD-associated *LRRK2* mutations, R793M, is located within the ANK domain. It is not yet clear how this substitution affects the folding pathway or protein interactions utilizing the ANK domain.

Multiple amino acid substitutions caused by *LRRK2* mutations associated with PD are located in the LRR domain. Four mutations (R1067Q, S1096C and S1228T, I1122V) are located at the surface of the structure formed by the LRR repeats. These may interfere with the as yet unidentified protein interactions.

Other PD-associated mutations are located in the WD40 domain. Proteins containing WD40 domains are functionally diverse, making it difficult to predict the function of this domain in LRRK2. The three-dimensional structure of the WD40 repeats consists of a propeller-like structure formed by four-stranded antiparallel β-pleated sheets. At least one of the amino-acid substitutions associated with PD is located at the surface of the structure formed by the WD40 domain. It is conceivable that this amino-acid substitution interferes with interactions between the WD40 domain and an unidentified protein.

Recent studies have shown that LRRK2 exists as a dimer under native conditions. This state appears to be stabilized by the interactions between multiple structural domains.

In cell cultures, LRRK2 is localized to the Golgi apparatus, plasma membrane, and synaptic vesicles. It can resist solubilization from the membrane suggesting that it is associated with lipid rafts. This association does not appear to be influenced by the I2020T mutation. It suggests that LRRK2 is involved in signal transduction, membrane trafficking, and cytoskeletal organization. Interestingly, alpha-synuclein also localizes to the presynaptic cell membrane and is associated with lipid rafts. LRRK2 has also been localized to lysosomes, endosomes, and mitochondria. An interaction of the ROC domain of LRRK2 with parkin has been reported.

LRRK2 is also a member of the receptor-interacting protein kinase (RIPK) family. Members of this protein family can function as sensors of cellular stress and integrators of different cellular functions implicated in inflammation and cell survival. Members of this protein family are involved in the nuclear translocation of the NF-κB transcription factor and in the activation of mitogen-activated protein kinase (MAPK) pathways including the extracellular signal-regulated kinase (ERK), the c-Jun amino terminal kinase (JNK), and the p38 MAPK. The MAPK pathways are three-tiered pathways involving an MAPK kinase kinase (MAPKKK), an MAPK kinase (MAPKK), and an MAPK. This is a kinase cascade in which the kinase in each level activates the kinase in

the successive level by phosphorylation. Transcription factors, mitochondrial and cytosolic proteins are likely substrates of these kinases.

Given the LRRK2's multiple protein domains and its possible plethora of protein–protein interactions, identifying genes whose expression is affected by the absence of LRRK2 function can provide insight into LRRK2's cellular functions. Gene expression profiling using microarray analysis in neuroblastoma cell lines with suppressed endogenous LRRK2 mRNA revealed changes in 187 genes. These genes are involved in axonal guidance, nervous system development, cell cycle control, cell differentiation, cell communication, the MAPKKK cascade, and Ras-protein-signal transduction.

Summary and Conclusion

The identification and characterization of *LRRK2* have provided significant insights into the potential mechanisms underlying PD pathogenesis. Its localization in the lower brainstem with punctuate α-synuclein staining may implicate it in the temporal and spatial sequence of neuropathological stages that have been associated with sporadic PD.

LRRK2 is a rather complicated gene with complex regulation and a large potential for protein–protein interactions. Its multiple functional domains most likely impact multiple different pathways. At this point, we have only a partial understanding of its potential protein–protein interactions. Elucidating the nature of these interactions, and how they are affected by *LRRK2* mutations will provide significant insight into our understanding of PD pathogenesis.

The pleiomorphic pathology observed within one kindred, as well as between different kindreds, for a single dominant mutation suggests that multiple, distinct cellular processes can be affected by a single *LRRK2* mutation. It is unclear whether this reflects a stochastic process involved in one or more cellular processes impacted by the *LRRK2* mutation or reflects genetic or potentially subtle environmental differences. In any case, given the frequency of *LRRK2* mutations leading to PD, it will be important, and a significant challenge, to identify modifiers of LRRK2 function at both the genetic and environmental levels. This information will also add an important dimension to our understanding of the complexity of PD pathogenesis.

LRRK2's ability to form a dimer under native conditions adds further complexity to its role in the etiology of PD, as its functional ability may be related to its ability to maintain a dimeric structure. In individuals with *LRRK2* mutations, multiple types of dimers may be formed between potentially and differently structured LRRK2 proteins.

LRRK2's multiple domains may be used to facilitate its interactions with different proteins at different time points or in different cell types. Consequently, it is possible that *LRRK2* participates in different cellular processes at different times during development than it does later in adult life. Further delineation of the cellular processes and gene networks involving *LRRK2* in different cells and at different times will undoubtedly contribute to elucidating the mechanisms underlying neurodegeneration in PD.

Parkinson Hyperpyrexia Syndrome

O Klepitskaya, University of Colorado at Denver Health Sciences Center, Aurora, CO, USA

Glossary

Akinesia – The inability to initiate movement due to difficulty in selecting and/or activating motor programs in the central nervous system. Common in severe cases of Parkinson's disease akinesia is a result of severely diminished dopaminergic stimulation.
Dopamine – A neurotransmitter activating five types of dopamine receptors in the human brain. Dopamine is produced in several areas of the brain, including the substantia nigra and the ventral tegmental area and hypothalamus. It is responsible for the mediation of motor control, behavior, and emotions.
Creatine phosphokinase – An enzyme expressed by various tissue types, mostly muscles. It catalyzes the conversion of creatine and serves for intracellular energy transport. Clinically, creatine kinase is assayed in blood tests as a marker of myocardial infarction (heart attack), rhabdomyolysis (severe muscle breakdown), muscular dystrophy, and in other diseases.
Hyperpyrexia – An excessive and unusual elevation of set body temperature to greater than or equal to 41.1 °C (106 °F), or extremely high fever, that is often fatal.
Neuroleptic malignant syndrome – A life-threatening condition caused by an adverse reaction to antipsychotic drugs, that is characterized by muscle rigidity, fever, autonomic instability, and cognitive changes and is associated with an elevated creatine phosphokinase (CPK) level.
Rhabdomyolysis – The rapid breakdown of skeletal muscle tissue due to injury to muscle tissue caused by physical (e.g., crush injury), chemical, or biological factors, leading to the release of breakdown products of damaged muscle cells into the bloodstream. Some of these, such as myoglobin, are harmful to the kidney and may lead to acute kidney failure.

Definition and History

Parkinsonism-hyperpyrexia syndrome (PHS) is an acute life-threatening condition in patients with Parkinsonism exposed to dopamine replacement therapy (DRT) that is characterized by high fever, muscle rigidity, alteration of consciousness, and autonomic instability. The first case was described in 1973 under the name of 'akinetic crisis.' In 1981 clinical similarity to neuroleptic malignant syndrome (NMS) was pointed out. Since then, this condition has been reported under multiple names: Neuroleptic malignant-like syndrome, malignant syndrome of Parkinsonism, acute akinesia, levodopa-withdrawal hyperthermia, dopaminergic malignant syndrome, and finally, PHS.

Epidemiology

Although PHS is a rare complication of Parkinson's disease (PD), its true incidence is unknown and is likely underestimated. Reports suggest that 0.3–3.6% of all PD patients develop PHS each year. This number includes only severe cases that require hospitalization; many others may remain unrecognized. There are reports of PD patients who had frequent or even daily mild episodes of PHS that eventually became severe and fatal. Patients with idiopathic PD at any stage and other parkinsonian disorders, such as multiple system atrophy, progressive supranuclear palsy, dementia with Lewy bodies, etc. can develop PHS. Patients on high doses of DRT with prominent wearing-off phenomenon, young-onset idiopathic PD, and more advanced stages of the disease are at higher risks. Males develop PHS more frequently than females.

Risk Factors

In the first reports, withdrawal from DRT was considered to be the sole cause of this syndrome, as most patients

developed PHS during 'levodopa holidays.' It is now recognized that not only rapid discontinuation of DRT but also any abrupt changes in medication regimen can provoke PHS. Some examples include changes from rapid release to slow release carbidopa/levodopa, discontinuation of tolcapone or amantadine, change from carbidopa/levodopa to dopamine agonists, change from one agonist to another, or simply changes in daily schedule of medications intake. Most patients who develop PHS are on high doses of levodopa, but some are on other medications for PD, such as dopamine agonists or amantadine alone. Changes in diet, worsening of constipation, bowel obstruction, and other factors affecting medication absorption can also provoke PHS. The time from the changes in medication to the onset of the symptoms can be as short as several hours and as long as 7 days. Medication withdrawal or change is responsible for about 30% of all cases. Any other physiological stressors can precipitate PHS. Among them are infection, surgery, injury, hypo- or hypernatremia, dehydration, heat stroke, overheating, anorexia or poor food intake, perimenstrual period, and others. In about 5% of cases, wearing-off symptoms alone trigger PHS, therefore putting the patients with advanced disease and severe motor fluctuations at higher risk for PHS. Another 5% of patients develop PHS in the absence of any obvious triggers. Recent expansion of surgical treatment for PD presents new risk factors for PHS. Sudden discontinuation of medications after deep brain stimulation (DBS) surgery was reported to provoke PHS. However, in other cases, DBS was shown to be protective against PHS, either preventing it or making symptoms milder. DBS hardware failure can cause PHS, and therefore, should be considered a neurosurgical emergency. PHS can happen more than once in the same patient with a different provoking factor for each event.

Pathophysiology

Although the pathophysiology of PHS is not completely understood, it is considered to be a state of acute functional dopamine deficiency in the basal ganglia and hypothalamus, with transient refractoriness to DRT. This feature is very important as it differentiates PHS from the wearing-off phenomenon. The latter responds to the administration of DRT, specifically levodopa and apomorphine. Patients with PHS, in contrast, demonstrate transient unresponsiveness to the escalating doses of dopaminergic treatment. It was documented that PHS symptoms were present despite high serum levels of levodopa. Patients who are susceptible to PHS have baseline alteration of dopaminergic neurotransmission with narrow safety margins to any changes of their dopaminergic tone. Disturbance of dopaminergic neurotransmission in the hypothalamic thermoregulatory system is likely responsible for severe hyperthermia in PHS. In addition, abnormalities in muscle membrane permeability, surge of calcium from sarcoplasmatic reticulum, changes in central and peripheral sympathetic outflow, and central serotonin mechanisms had been implicated.

Clinical Picture

PHS is characterized by very high fever, extreme muscle rigidity, autonomic instability, and altered consciousness. Hyperpyrexia was reported to be as high as 41.7 °C. Muscle rigidity almost universally leads to rhabdomyolysis with a marked elevation in creatine phosphokinase (CPK) up to $50\,000\ \mathrm{U\,l^{-1}}$. Autonomic dysfunction can present as blood pressure instability, tachycardia, nonparalytic ileus, diaphoresis, or anhydrosis. Changes in cognition are ranging from agitation and hallucinations to confusion, stupor, and even coma. Leukocytosis is frequent. Serious complications are common and include acute renal failure, disseminated intravascular coagulation, autonomic instability, aspiration pneumonia, respiratory distress, and infections. The length of the single episode can range from several hours to several days, the longest reported being 29 days.

Treatment

PHS should be treated as a neurological emergency. The key to success is an early recognition and the initiation of treatment. DRT should be reinstituted as soon as possible with escalating doses and frequency of medication administration. Bromocriptine should be added at 2.5 mg t.i.d. initially and then titrated upwards as needed. Subcutaneous apomorphine or lisuride infusions can be considered. Due to dysphagia and high risk of aspiration pneumonia, the medications have to be given via a gastric infusion. Initiation of parenteral feeding, needed in many patients during prolonged episodes, might result in sudden changes in medication levels and potential worsening of the symptoms. Therefore, feeding should be started slowly and preferably at night time when the body's requirements for dopamine are lower. Symptomatic treatment with adequate hydration, hemodynamic support, and prevention and management of systemic complications, such as aspiration, infection, thromboembolism, should be started immediately. Dantrolene sodium $10\ \mathrm{mg\,kg^{-1}\,day^{-1}}$ in divided doses can be used for muscle relaxation. Hyperpyrexia should be treated aggressively with antipyretics, cooling blankets, etc. In addition to these well-accepted steps in the management of PHS, attempts have been made to treat it with methylprednisolone pulse therapy, electroconvulsive therapy, the NMDA-antagonist memantine, and other measures. These, however, must be studied further.

Prevention

Patients at risk should be identified and educated about PHS. Sudden medication changes should be avoided. The patients and their caregivers should be instructed to continue uninterrupted administration of DRT during any concomitant illness, surgeries, etc. All potentially precipitating events should be avoided if possible. This includes motor fluctuations with wearing off. DBS should be considered earlier in the patients at risk, as it was shown to minimize risks for PHS by decreasing wearing off phenomena.

Prognosis

Morbidity from PHS is high. Among the patients who survive PHS, about 30% have worsening of symptoms of Parkinsonism and never return to their pre-PHS baseline. Mortality from PHS is reported to be between 4% for treated and 20% for untreated episodes.

Parkinson, James

C G Goetz and J G Goldman, Rush University Medical Center, Chicago, IL, USA

Glossary

Parkinson's disease – A neurodegenerative disorder characterized by tremor, slowness (bradykinesia), rigidity, and balance compromise.

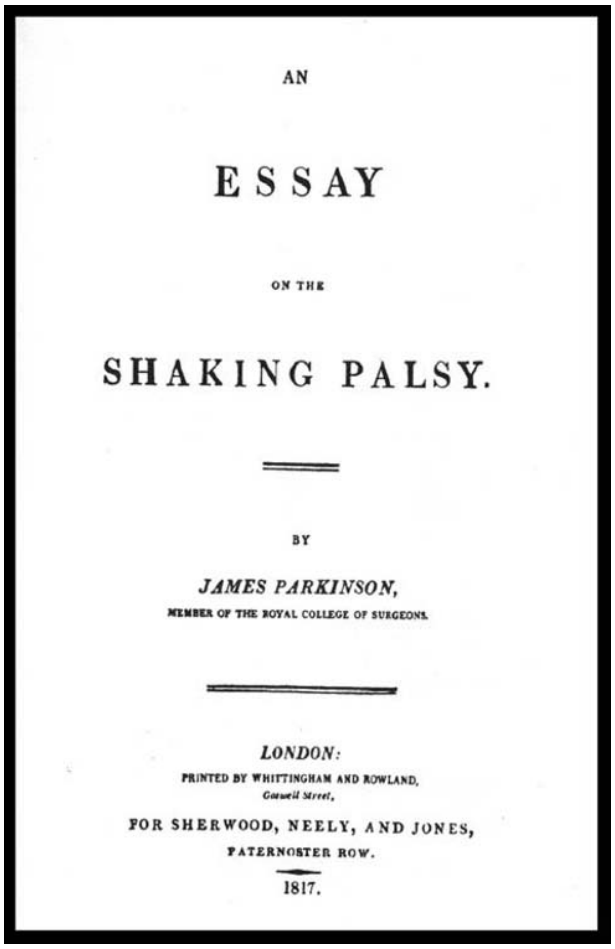
Biographical Details

James Parkinson (1755–1824) was born on 11 April 1755 at No. 1 Hoxton Square in the parish of St. Leonard's, Shoreditch, England (today part of central London) to John and Mary Parkinson. His father was an apothecary, surgeon, and anatomical warden. The young James served as an apprentice to his father and often joined him on resuscitation and recovery operations for the Royal Humane Society. James Parkinson continued the family medical tradition and practiced in an office behind the main house at No. 1 Hoxton Square.

Parkinson studied at the London Hospital Medical College for 6 months in 1776 as one of the school's earliest medical students. Other medical experiences included an apprenticeship with his father and rescue missions for the Royal Humane Society. He obtained his diploma of the Company of Surgeons in April 1784 shortly after his father's death and was elected Fellow of the Medical Society of London in 1787 after the delivery of his first paper, 'Some Account of the Effects of Lightning' describing the dermatological and neurological sequelae. Even in this early work, Parkinson demonstrated his keen observational skills, breadth of medical knowledge, and humble writing style.

An Essay on the Shaking Palsy

An Essay on the Shaking Palsy (1817) is considered to be Parkinson's greatest contribution to medicine and his only contribution to the field of movement disorders (**Figure 1**). The 66-page octavo volume described a series of six cases,



AN

ESSAY

ON THE

SHAKING PALSY.

BY

JAMES PARKINSON,

MEMBER OF THE ROYAL COLLEGE OF SURGEONS.

LONDON:

PRINTED BY WHITTINGHAM AND ROWLAND,

Goswell Street,

FOR SHERWOOD, NEELY, AND JONES,

PATERNOSTER ROW.

1817.

Figure 1 Front piece from James Parkinson's seminal work, *An Essay on the Shaking Palsy*.

three of which were never actually examined by Parkinson, but rather observed on the street. The cases differed in severity of disease and depth of observation, but Parkinson's astute clinical descriptions captured the insidious onset and long duration of disease, asymmetry of motor signs and rest tremor, sense of weakness, flexed posture, and festinating gait. He noted the progressive disease course with increasing immobility and dependence, disturbances of sleep, speech and bodily functions. In his view, there was sparing of the 'senses and intellect.' In the *Essay*, Parkinson also discussed the historical knowledge of tremor and gait disorders, possible etiologies, neuroanatomical localization, and proposed treatments. His succinct description of the salient features of tremor, slowness, propulsive gait, and balance difficulties is evoked in his short summary that is commonly cited:

> Involuntary tremulous motion with lessened muscular power in parts not in action and even when supported; with a propensity to bend the trunk forward and to pass from a walking to a running pace.

Parkinson did not provide his readers with any recommendations on treatments. He acknowledged that bleeding and vesicatory therapy had been advocated by others. While discussing 'considerations respecting the means of cure,' he wrote with a vision of the challenges that modern neurologists and researchers still face:

> . . . There appears to be sufficient reason for hoping that some remedial process may ere long be discovered, by which, at least, the progress of the disease may be stopped.

Reviews of the *Essay* in London medical journals were overall praiseworthy, although some criticized Parkinson's view on anatomy and causation. Although copies were difficult to find, the knowledge of the *Essay* and of paralysis agitans as a clinical disorder spread throughout the medical community. The celebrated French neurologist Jean-Martin Charcot obtained a copy from Dr. Windsor, Librarian at the University of Manchester, after a frustrating search and encouraged his pupils to translate the highly informative work. In the 1860s, Charcot coined Parkinson's disease as an eponym for paralysis agitans and added other key descriptions, including rigidity to the phenotype of the disease. This eponym has remained in the nosographic vocabulary into the twenty-first century.

Other Contributions

In addition to *An Essay on the Shaking Palsy*, Parkinson made numerous other contributions to medicine and science. Environmental injuries and accidents comprise a common theme in his works. Highlights of his early medical career include his first paper, 'Some Account of the Effects of Lightning' (1789). The potential dangers and injuries associated with childhood play and pranks are enumerated in the serious but artistic literary tale, *Dangerous Sports* (1808).

Parkinson's medical works included handbooks for the lay public and scientific reports of medical problems ranging from hydrophobia to trismus. He sought to improve the general medical and social welfare of laborers, with better designed trusses. His monograph on gout included personal experiences with his father's and his own afflictions with gout.

Parkinson was well known in the fields of chemistry and geology. His interest in chemistry sparked a fascination with geology and led to his acquisition and scientific analysis of specimens from the London terrain. He amassed a notable collection of fossils, shells, metals, coins, and medals at No. 1 Hoxton Square. As a renowned oryctologist, Parkinson was a founding member of the Geological Society in 1807. His first book on geology, *Organic Remains of a Former World* (1804), became a standard text on paleontology for half a century. In a style similar to that of other works, Parkinson composed *Organic Remains* in letter format rather than scientific chapters to appeal to a more general readership.

Parkinson's publications in the first decade after beginning his medical career focused on politics. In the climate of dramatic political changes, reforms, and revolutions occurring in France and England at the end of the eighteenth century, Parkinson espoused his political beliefs by distributing multiple pamphlets written under the pseudonym 'Old Hubert.' His political endeavors culminated in his role of witness before the Privy Council in a trial for High Treason regarding the Pop-Gun Plot in 1795.

In spite of Parkinson's successful career, multifaceted interests, and prominent place in his era, no portrait exists. The Parkinson heritage extended for several generations of physicians, and the name Parkinson's disease is one of the most celebrated and widely used designations in movement disorder neurology.

Parkinson's Disease Quesionniare-39 (PDQ-39)

A Siderowf, Parkinson's Disease and Movement Disorders Center, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Glossary

Disease-specific HRQL scales – These scales are designed to be used in a specific disease state (e.g., Parkinson's disease). Disease-specific scales are likely to be more sensitive to the impact of moderate to small differences in disease severity than *generic* instruments. By contrast, *generic* HRQL scales allow comparisons of patient groups with different diseases.

Health-related quality-of-life (HRQL) – Reflects a patient's health status and how he/she functions in his/her social roles. HRQL can be measured by instruments that focus on physical health and the overall functional ability.

Quality-of-life (QOL) – Tends to focus on psychological and sociological factors in addition to physical function. No consensus exists about what constitutes QOL or how best to measure it.

Definition and History

The Parkinson's Disease Questionniare-39 (PDQ-39) was developed by the Health Services Research Unit at the University of Oxford. It was extensively validated (see later section), and has been used as an outcome measure in epidemiological studies of health burden and in clinical trials. It is among the most widely used and cited health-related quality-of-life (HRQL) measures for Parkinson's disease.

HRQL refers to the impact that health (or disease) has on an individual's ability to complete daily routine activities satisfactorily and function in his/her social roles (i.e., family member, employee). HRQL scales capture information related to these areas from the patients' perspective. HRQL is distinguished from the concept of quality-of-life (QOL). QOL is not defined specifically by issues related to health, and is a more subjective sense of happiness or life satisfaction. There are two major categories of HRQL scales: disease-specific and generic. Disease-specific scales may be more sensitive to small differences in status within a given disorder. The advantage of generic measures is the possibility of comparisons of impact across different medical conditions.

Scale Description

The PDQ-39 derives its name from the fact that it contains 39 items. Each item is rated on a 5-point scale. An example of an item from the scale is shown in **Figure 1**. Eight domains are represented in the PDQ-39, including mobility (10 items), activities of daily living (6 items),

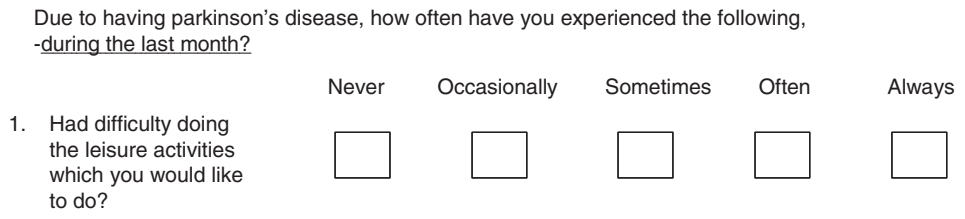

Figure 1 A representative item from the PDQ-39.

emotional well being (6 items), stigma (4 items), social support (3 items), cognition (4 items), communication (3 items), and bodily discomfort (3 items). A separate score can be derived for each domain. These scores range from 0 (no impact) to 100 (highest impact). A summary score can also be calculated by taking the simple average of the eight domain scores. A brief version of the PDQ-39, the PDQ-8, includes one item from each domain. The PDQ-8 produces a single summary index that correlates closely with the full PDQ-39 summary score.

The PDQ-39 went through a rigorous process of development and validation. It was validated in a sample of 146 patients from outpatient clinics in Anglia and Oxford. Patients were evaluated twice at a 4-month interval, the PDQ-39, the SF-36, and clinical evaluations being performed by a neurologist. The validity relative to generic HRQL and symptom burden were derived from this study. Sensitivity to change over a brief period of time as also established. A large amount of useful information may be accessed at http://www.publichealth.ox.ac.uk/units/hsru/PDQ/Intro%20pdq.

The PDQ-39 has been translated into over 50 languages. It is suitable for postal surveys as well as in person administration. Patient self-completion usually requires about 10–15 min. Recent psychometric studies of the PDQ-39 have focused on methods of imputing missing data and establishing minimally clinically significant scores.

The PDQ-39 has been used in a wide range of clinical studies. It has been used to identify which impairments contribute most substantially to HRQL in patients with Parkinson's disease. Measures of depression, cognition, and postural instability correlate most consistently with the PDQ-39 summary index score, indicating that these areas contribute to reduced HRQL. The PDQ-39 has also been an outcome measure in a number of clinical trials. In one example, patients randomized to deep brain stimulation surgery had improvements relative to best medical management in all PDQ-39 domains with the exception of communication, cognition, and social support.

Summary

The PDQ-39 is a widely used and highly feasible disease-specific HRQL measure for Parkinson's disease.

Parkinson's Disease: Definition, Diagnosis, and Management

J Pagonabarraga, Hospital Sant Pau, Barcelona, Spain

Glossary

Bradykinesia – Slowness in initiation of voluntary movement with progressive reduction in speed and amplitude of repetitive actions.
Dementia – Decline in intellectual functioning that is severe enough to interfere with the ability to perform routine activities of the daily living.
Freezing of gait – Paroxysmal events in which a subject is unable to initiate locomotion, to make a turn, or to walk through narrow spaces (i.e., a doorway) smoothly.
Lewy bodies – Large intraneuronal inclusions of aggregated α-synuclein.
Nigro-striatal pathway – Pathway connecting the substantia nigra pars compacta with the striatum.
Parkinsonism – Motor syndrome characterized by muscular rigidity, bradykinesia, and/or tremor.
Psychosis – Thought disorder in which objective reality testing is distorted or diminished.
Rigidity – Increase in resistance to passive movements about a joint involving both agonist and antagonist muscles supplying the joint.
Striatum – Part of the basal ganglia consisting of the caudate nucleus and the putamen.
Substantia nigra – A dark band of gray matter within the midbrain where dopamine is synthesized and released.
Tremor – Rhythmic, involuntary back-and-forth oscillation of agonist and antagonist muscles.

Definition and History

Parkinson's disease (PD) is a neurodegenerative disease characterized by the hallmarks of bradykinesia, rigidity, tremor, and postural instability. The cardinal motor features of the disease are produced by the progressive degeneration of the dopaminergic neurons of the substantia nigra pars compacta (SNc), resulting in depletion of striatal dopamine.

PD is considered an α-synucleinopathy affecting the nervous system beyond the SNc. Decreased clearance of α-synuclein within the neuronal cytoplasm is associated with widespread neuronal dysfunction and degeneration both in the central and peripheral nervous system. Involvement of areas outside the SNc likely leads to nonmotor symptoms and motor symptoms unresponsive to levodopa.

In 1817, James Parkinson published '*An Essay on the Shaking Palsy*' and described patients with resting tremor, rigidity, and postural instability. He attributed these symptoms to a lesion in the *medulla oblongata*. Fifty years later, Jean-Martin Charcot defined the cardinal features of so-called 'paralysis agitans.' He differentiated bradykinesia from rigidity, and described the association of PD with pain and dysautonomia. He was the first to suggest the term 'Parkinson's disease.'

In 1969, Hoehn and Yahr described the natural history of PD and proposed a staging scale that is still useful in the clinical setting. As early as in the nineteenth century, Bell, Meynert, and Edinger described macroscopic interconnections between the basal ganglia, but the precise function of the cortico-subcortical circuits implicated in the execution of movements was not disentangled until the second half of the twentieth century. In 1913, the deposition of intracellular Lewy bodies was firstly associated with the neuronal degeneration of SNc, but the relationship between parkinsonism and the degeneration of different nuclei in the brainstem was not clearly stated until 1953 by Greenfield. In the 1960s, Ehringer and Hornykiewicz showed that dopaminergic depletion in the striatum due to neuronal degeneration of the SNc occurred in PD. These findings led to the use of levodopa, the precursor to dopamine, to treat the motor symptoms of PD. In 1983, the discovery that an opiate derivative, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), could induce SNc degeneration helped to develop animal models of PD. This step has been essential to understand the functional anatomy of the basal ganglia and the pathophysiological bases of PD-related motor signs, fluctuations, and dyskinesias. This knowledge was also essential in the development of deep brain stimulation (DBS) as an effective therapy. Over the last 10 years, recognition of the importance of cognitive, psychiatric, and other nonmotor PD features (sleep problems, dysautonomia, visual disturbances) has broadened the phenotype of PD, so that today, PD is considered a multisystem neurodegenerative disease involving different neurotransmitters, neocortical, and subcortical encephalic regions, and the peripheral nervous system.

Pathogenesis and Pathophysiology

PD is a chronic, progressive, neurodegenerative disease with a likely multifactorial etiology, but regardless of

genetic or environmental influences, abnormal protein aggregation within neurons with synuclein accumulation appears to underlie neurodegeneration. It has been suggested that this process begins in the olfactory bulb, dorsal motor nucleus of the vagus nerve, and enteric plexus and then moves higher in the nervous system to involve the SNc and later the cortex. Recent clinico–pathological data indicate that the proposed hierarchical pattern of disease progression can be effectively reproduced in PD patients with a younger onset, but in PD patients with an older onset ($\geq$70 years), the sequence may involve neocortical regions early-on.

Dopamine regulates excitatory and inhibitory outflow of the basal ganglia. The basal ganglia consist of four main nuclei: the striatum (caudate nucleus, putamen), the globus pallidus (GP), the subthalamic nucleus (STN), and the substantia nigra. Most information to the basal ganglia arises from glutamatergic inputs originating in the cerebral cortex. The basic functional connections within the basal ganglia are based on a direct and an indirect pathway. The direct pathway enhances the execution of the motor programs originating in the supplementary motor area and the premotor cortex, while the indirect pathway – through the STN – inhibits the activity of the direct pathway.

The direct pathway is rich in D1 receptors and is composed of the GP pars interna (GPi) and the SN pars reticulata (SNr), with connections to the thalamus (VA/VL). The indirect pathway is rich in D2 receptors and is composed by the GP pars externa (GPe) and the STN, which activates the inhibitory action of GPi/SNr to the thalamus. The putamen is the main nucleus to receive the glutamatergic input from the cortex. Then, inhibitory striatopallidal connections from the putamen are directed to both the GPi (direct) and the GPe (indirect pathway). In the parkinsonian, the decrease of dopamine release to these circuits inhibits the execution of movements, and treatment with levodopa partially restores the flow of information from the cortex to the direct pathway (**Figure 1**).

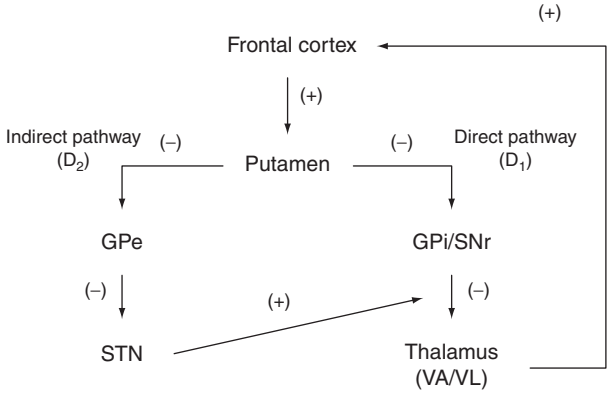

Figure 1 Schematic of basal ganglia connections.

Epidemiology and Risk Factors

PD is the second most common neurodegenerative disease after Alzheimer's disease. PD is associated with a significant increase in morbidity, disability, and mortality compared to the general population. Aging, environmental factors and genetic susceptibility appear to interact in determining individual susceptibility to PD. Higher age and male sex are associated with an increased risk of PD, age being the most determinant factor. Currently, there are between one and two million people with PD in the United States. Age of onset is usually ~65, but in up to 10%, the onset occurs before 45 years of age. Incidence rates increase after the age of 50, especially in men, and rapidly increase after age 75.

The environmental and lifestyle risk factors that have been associated with the development of PD are rural living, exposure to pesticides/herbicides, well-water drinking, and working with solvents. In opposition, epidemiological studies have shown a reduced risk of PD related to smoking habit, coffee consumption, current long-term use of calcium channel blockers, and hyperuricemia.

Genetic factors play also a role. In 1996, Polymeropoulos et al. reported linkage to chromosome 4q21–23 (*Park 1*) for a large family in whom pathologically proven PD was inherited in an autosomal dominant fashion. The *Park 1* gene codes for alpha-synuclein. Other genes have been implicated, including the *Park 2* and the *LRKK2* genes. *LRRK2* has been identified as a genetic cause of familial and sporadic PD. Several pathogenic mutations in *LRRK2*, particularly the variant G2019S, have been reported in different populations with prevalence in PD cohorts ranging from ~2% in sporadic disease in North American whites, to 40% in familial and sporadic PD in North African Arabs. The clinical features of parkinsonism and the response to levodopa treatment in patients with *LRRK2* mutations are largely indistinguishable from those of classic PD. Several other genetics links have also been identified. Monogenic forms of PD account, however, for less than 10% of PD cases.

Clinical Expression and Course

Four cardinal motor manifestations are the central features of PD: resting tremor, bradykinesia, rigidity, and postural instability with impairment of postural reflexes.

PD motor symptoms usually begin unilaterally and gradually spread to the contralateral side, yet maintaining their asymmetry over the course of the disease. Resting tremor is present in 70–80% of PD patients and mainly involves the thumb or wrist. This 'pill-rolling' tremor increases with mental stress (counting backwards) or when movements of another body part are performed.

Tremor also can involve the legs, jaw, and tongue. Tremor is more likely to be the presenting symptom in younger patients, whereas older patients may have a more prominent rigid-akinetic phenotype. Tremor may be the most visible sign of PD, but it rarely causes major disability.

Bradykinesia and postural reflex impairment are the more disabling symptoms of PD, because gait difficulties cause falls and increase the risk for fractures and injuries. Bradykinesia is usually present in the form of micrographia, impairment in the execution of fine motor tasks, reduced arm swing, hypomimia, difficulty turning over in bed, arising from a chair, gait disturbance (short-steps, festination), hypophonia, tachyphemia/stuttering, or dysarthria. Freezing, or the difficulty in initiating locomotion, making turns, or passing through narrow spaces, is also a well-known clinical feature in PD, but it is mainly present in the advanced stages of the disease.

The clinical course of PD is not limited to motor symptoms. A variety of nonmotor symptoms and disorders (**Table 1**) are common and impact on quality of life and functional disability even to a higher degree than motor symptoms themselves. Depression and dementia are the PD symptoms with a greatest impact on both quality of life and functional disability.

Most PD patients have olfactory disturbances that likely begin in the very early stages of the disease, possibly preceding the appearance of the first motor signs by a few years. As many as 70% of PD patients report hyposmia at the onset of motor deficits, while it is only found in 3% of matched healthy subjects. Olfactory dysfunction in PD has been correlated with Lewy bodies deposition and neuronal loss in the olfactory bulb.

The overall prevalence of sleep disturbances in PD varies from 60 to 95%. Nocturia (45%) and sleep fragmentation (60%) are the most commonly reported problems. Nocturnal awakenings may be prolonged, resulting in a reduction of total sleep time with consequent daytime fatigue and sleepiness. Sleep fragmentation and REM Sleep Behavior Disorder (RBD) are attributed to involvement of brainstem structures (nucleus subcoeruleus, pendunculo-pontine nucleus). RBD is often present in the early stages of PD and can precede motor symptoms by several years. Patients with 'idiopathic' RBD may also convert to PD. Excessive daytime sleepiness (EDS) is a complex phenomenon, because both disease-related disturbances and the effects of dopaminergic medications (i.e., dopamine agonists (DA)) play a role in its genesis. Restless legs syndrome (RLS) and periodic limb movement during sleep (PLMS) can also cause sleep disruption in PD and they both have been reported to be increased in PD compared to the general population.

Although early and prominent dysautonomia in a patient with parkinsonism suggests the diagnosis of multiple system atrophy (MSA), autonomic disturbances are also typical of PD and become more evident and severe in the advanced stages of the disease. Dysautonomia in PD is very similar to that in primary autonomic failure or MSA, with episodes of orthostatic hypotension, micturitional urgency, and erectile dysfunction. Several epidemiological studies have shown that constipation can precede the motor symptoms of PD by many years, an observation consistent with recent findings of α-synuclein deposition at the enteric plexus in PD patients.

Some degree of cognitive impairment is common in PD, and dementia occurs in 24–31% of patients. Between 25 and 55% of nondemented PD patients show mild cognitive defects even in the early stages of PD, characterized by frontal–subcortical impairments in attentional, executive, visuospatial, and memory functions. Cognitive impairment in PD follows a progressive evolution, and dementia appeared to be an almost inevitable outcome of PD (up to 85% of patients) in a prospective longitudinal study with a follow-up of 15–20 years. Neuroimaging studies have shown that conversion to dementia is characterized by the focal degeneration of the limbic/paralimbic and medial temporal cortices, supporting the hypothesis that dementia in PD is directly related to the propagation of the disease to neocortical structures.

Neuropsychiatric disturbances are also integral components to PD. Apathy, depression, irritability, and anxiety are present in 40–60% of patients. In fluctuating patients, mood swings and anxiety are frequent and sometimes severe, and may be as disruptive as motor symptoms. Depression can also precede the onset of motor symptoms in PD. Apathy in PD can occur independently of depression. Up to 25% of PD patients report apathy without depression, and this problem may relate to both executive dysfunction and dysfunction of the limbic circuits connecting the amygdala to the medial prefrontal cortex.

Table 1 Common nonmotors symptoms in PD

1. Olfactory dysfunction: hyposmia, cacosmia
2. Sleep problems: sleep fragmentation, REM sleep behavior disorder, excessive daytime sleepiness, restless legs syndrome, periodic limb movements
3. Dysautonomia: orthostatic hypotension, micturitional urgency, nycturia, erectile dysfunction, constipation
4. Cognitive impairment: subtle cognitive defects, dementia
5. Neuropsychiatric disturbances:
   (a) Emotional disorders: depression, apathy, anxiety, irritability
   (b) Psychosis: hallucinations (visual, auditory, tactile), delusions (delusional jealousy, paranoid), delusional misidentification syndromes (Capgras, Frégoli, reduplicative paramnesia, intermetamorphosis)
   (c) Impulse control disorders: pathological gambling, hypersexuality, punding, hedonistic homeostatic dysregulation (levodopa addiction), binge eating
6. Visual disturbances: color discrimination deficits, blurred vision, diplopia

Hallucinations are also characteristic of PD, especially patients treated for prolonged periods of time with dopaminergic medications. The frequency of hallucinations increases as the disease progresses. In the early stages of the disease minor hallucinations appear. The phenomenology of minor hallucinations is fairly stereotyped among different patients. Some PD patients report visual illusions, the feeling that someone is behind or besides them (presence hallucinations), or the fleeting vision of a person, an animal or an object coming backwards from the periphery of the visual field (passage hallucinations). These hallucinations are short-lasting (1–2 s) and the patient is absolutely aware of their unreality. Later, patients have repetitive and well-formed hallucinations that are initially recognized as hallucinations, but later can be associated with loss of insight, and delusional thinking. Hallucinations in other sensory modalities (auditory, tactile) also can occur as well as delusional misidentifications syndromes (Capgras, reduplicative paramnesia).

Impulse control disorders (ICD) have been increasingly associated with PD and dopaminergic treatment. While psychosis is more likely to be present in older and demented patients, ICD usually develop in younger and cognitively intact subjects. They seem to be also especially prevalent with the use of DA. From 5 to 10% of PD patients may develop pathological gambling, hypersexuality, binge eating, computer addiction, punding, or excessive hobbyism. Subjects with a past history of addictive behaviors or with a novelty-seeking personality are more prone to suffer these complications.

Finally, the clinical description of PD must take into account the development of motor symptoms poorly responsive to levodopa. After 10 years of disease duration, PD patients gradually develop motor symptoms that likely relate to dysfunction outside the dopaminergic nigro-striatal pathway. Some of these symptoms, especially poor postural reflexes, have a strong impact on functional disability. The progressive development of hypophonia, dysphagia, freezing, truncal flexion ('camptocormia'), and postural instability point towards a severe degeneration of the brainstem nuclei and transition to an advanced stage of PD where dopaminergic treatment cannot control these signs.

Differential Diagnosis

Because there are no biological markers for the antemortem diagnosis of PD, clinical signs, medication response, and progression guide the clinician to the diagnosis. Clinico-pathological studies have shown significant false-positive and false-negative rates for diagnosing these disorders, and misdiagnosis is especially common during the early stages of these diseases, even among movement disorder specialists.

Several sets of clinical diagnostic criteria for PD have been proposed. The UK Parkinson's Disease Society Brain Bank (UK-PDSBB) clinical criteria for PD are the most accepted and used in clinical research. The UK-PDSBB criteria require the presence of bradykinesia and $\geq$1 of the other cardinal features of the disease (rest tremor, rigidity, postural instability) (**Table 2**).

Applying these criteria, the presence of asymmetrical parkinsonism (tremor or rigidity), rest tremor, gradual

Table 2 UK Parkinson's Disease Society Brain Bank clinical diagnostic criteria

Inclusion criteria	*Exclusion criteria*	*Supportive criteria*
Bradykinesia (slowness of initiation of voluntary movement with progressive reduction in speed and amplitude of repetitive actions) And at least one of the following: • Muscular rigidity • 4–6 Hz rest tremor • Postural instability not caused by primary visual, vestibular, cerebellar, or proprioceptive dysfunction	History of repeated strokes with stepwise progression of parkinsonian features History of repeated head injury History of definite encephalitis Oculogyric crises Neuroleptic treatment at onset of symptoms More than one affected relative Sustained remission Strictly unilateral features after 3 year Supranuclear gaze palsy Cerebellar signs Early severe autonomic involvement Early severe dementia with disturbances of memory, language, and praxis Babinski sign Presence of cerebral tumor or communicating hydrocephalus on CT Negative response to large doses of levodopa (if malabsorption excluded) MPTP exposure	$\geq$3 required for the diagnosis of PD Unilateral onset Rest tremor present Progressive disorder Persistent asymmetry affecting side of onset most affected Excellent response (70–100%) total levodopa Severe levodopa-induced chorea Levodopa response for 5 year or more Clinical course of 10 year or more

motor progression, and levodopa response (moderate to excellent response or levodopa-induced dyskinesias) are the most predictive clinical signs for a correct diagnosis of PD.

The clinical heterogeneity of PD is relevant in the differential diagnosis of the disease. Tremor dominant parkinsonism (TDP) is characterized by initial prominent resting and action tremor, mild parkinsonism, unpredictable responses to dopaminergic medications, and a better prognosis than typical PD. It can be easily confounded with essential tremor (ET). However, ET patients have a predominant postural tremor and if they develop rest tremor, it occurs after several years of disease.

In the differential diagnosis of the akinetic-rigid and postural instability and gait disorder variants of PD, we need to include the Parkinsonism-plus syndromes, MSA, progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), and secondary forms of parkinsonism related to vascular, drug-induced, metabolic, infectious, and toxic causes (**Table 3**).

MSA is a sporadic neurodegenerative disorder clinically characterized by various combinations of parkinsonian, cerebellar, autonomic, and pyramidal signs. It may be difficult to differentiate from PD because rest tremor, asymmetric akinesia, and rigidity can occur in both conditions. In the early stages, 30% of MSA patients respond to levodopa treatment. About 25% of cases with pathological evidence of MSA have a clinical diagnosis of PD during life.

PSP is characterized by the early appearance of postural instability and falls during the first year of the disease, with associated supranuclear gaze palsy. Some PSP patients may not develop gaze disturbances in the first 10 years of the disease, and one third can also respond to dopaminergic therapy at least transiently.

CBD usually has an asymmetric rigid-akinetic onset that can also improve on levodopa, which can lead to the erroneous diagnosis of PD before atypical signs arise (dystonia, apraxia, myoclonus, oculomotor disorders).

Table 3 Differential diagnosis of PD

- *Tremor dominant parkinsonism*
  - Essential tremor.
  - Dystonic tremor.
  - Psychogenic parkinsonism.
- *Rigid-akinetic parkinsonism*
  - Parkinson-plus syndromes: Multiple system atrophy, progressive supranuclear palsy, corticobasal degeneration.
  - Vascular parkinsonism.
  - Drug-induced parkinsonism.
  - Normal-pressure hydrocephalus.
  - Metabolic, infectious, toxic parkinsonism.
  - Spinocerebellar atrophy (SCA 2, 3).
  - Psychogenic parkinsonism.

Drug-induced parkinsonism (DIP), usually from dopaminergic receptor antagonists like antipsychotics and metaclopramide, can be indistinguishable from PD. Although DIP can exhibit atypical parkinsonian features, such as bilateral and symmetric parkinsonism with postural tremor more severe than rest tremor, it can also have an asymmetric onset with predominant rest tremor and a progressive course. The association of oral-lingual dyskinesias, choreic movements, and distal athetosis suggest tardive dyskinesia, which can also occur with chronic dopamine receptor antagonists, and therefore suggest DIP. Both vascular parkinsonism and normal-pressure hydrocephalus (NPH) exhibit lower-body gait impairment. MR scans help document abnormalities to suggest these diagnoses. In NPH, gait apraxia, freezing and turn hesitation, along with micturitional urgency and cognitive impairment occur. Although these features make the differential diagnosis easier, they can be confounded with the akinetic-rigid form of PD, especially in older patients.

Some phenotypes of spinocerebellar ataxia, specifically spinocerebellar atrophy (SCA) 2 and 3, may be very similar to PD. An autosomal dominant inheritance or the appearance of clinical features more common in SCA (i.e. ataxia, supranuclear ophthalmoplegia, lid retraction, bulging eyes, diplopia, faciolingual fasciculations), help establish the correct diagnosis.

Diagnostic Work-up

Blood Tests

- *Thyroid hormones (T3, T4, TSH):* Hypothyroidism causes slowness and apathy and these signs can be confused with parkinsonism.
- *Bone and mineral metabolism:* When calcifications in the basal ganglia and dentate nucleus are observed by neuroimaging, testing for calcium, phosphate, and PTH levels in peripheral blood is mandatory.
- *Polycythemia vera:* The finding of high levels of hemoglobin has been associated with the development of leukoaraiosis and vascular parkinsonism.
- In cases of young-onset parkinsonism, ceruloplasmin levels will aid in testing for Wilson's disease.

Structural Neuroimaging

In patients with typical PD, performance of a brain CT scan or magnetic resonance image (MRI) is recommended to rule out secondary causes of parkinsonism.

- *CT scan:* This test will document brain tumors (i.e., meningioma), basal ganglia calcifications, cerebral vascular disease, and suggest NPH.

- *MRI:*
  - T1/T2/FLAIR:
  - In the diagnosis of vascular parkinsonism, these techniques are sensitive for detecting leukoaraiosis or focal lesions in the midbrain or basal ganglia.
  - In the differential diagnosis of PD versus MSA, some specific signs with low sensitivity (40–50%) but a high specificity (90%) have been described to predict the presence of MSA. T2-hypointensity in the posterior part of putamen, T2-hyperintense rim at the lateral edge of the dorsolateral putamen, T2-'hot cross bun' sign in the pontine basis, T2-hyperintensity of the middle cerebellar peduncles (MCPs), and cerebellar atrophy suggest MSA.
  - Diffusion-weighted imaging (DWI)/apparent diffusion coefficient (ADC).
  - Early neuronal degeneration may be assessed by measurement of the ADC in brain regions more sensitive to neuronal damage. In early PD, there seems to be little focal degeneration in the putamen or the MCP. Conversely, MSA and PSP patients show a significant neuronal loss in the posterior putamen in the early disease stages, and MSA patients also exhibit major degeneration in the MCP. Regional measurement of ADC (rADC) in the posterior putamen may help to differentiate PD from both MSA and PSP, and rADC in the MCP accurately differentiates MSA from PSP.

Functional Neuroimaging

- *DAT-SPECT and ^{18}Fluorodopa PET:* DAT-SPECT and ^{18}Fluorodopa PET studies document apparent neuronal loss that occurs in SNc in PD and other parkinsonian syndromes. DAT-SPECT and ^{18}Fluorodopa PET differentiate PD and atypical parkinsonism from ET, vascular, drug-induced, and psychogenic parkinsonism, but PD cannot readily be differentiated from MSA, PSP, and CBD.
- *^{123}I-MIBG cardiac scintigraphy:* As PD is associated with preganglionar dysautonomia, and MSA, PSP, and CBD are more likely to be associated with preganglionar dysautonomia without involvement of the peripheral noradrenergic system, the uptake of ^{123}I-MIBG, an analogue of noradrenaline/norepinephrine, has been used in the differential diagnosis of different types of parkinsonism. Nonetheless, further studies are needed to determine the actual value of ^{123}I-MIBG cardiac uptake in routine clinical practice.

Transcranial Ultrasound

Increased echogenicity of the SNc, as determined by transcranial sonography (TCS), is characteristic of idiopathic PD. The finding of SN hyperechogenicity helps differentiate PD from ET, vascular, and DIP. The technique may also help to differentiate PD from atypical parkinsonian syndromes (MSA, PSP, CBD). TCS is easy to implement, noninvasive, and inexpensive.

Management

Management of Motor Symptoms

- *Levodopa:* L-dopa is still the most efficacious drug in the control of PD motor symptoms. In the CALM-PD and REAL-PET studies, L-dopa showed a significantly greater improvement of the mean unified Parkinson's disease rating scale (UPDRS) score change compared to the DA, pramipexole, and ropinirole. In these studies, the main limitation of L-dopa was its higher relative risk for dyskinesias and motor fluctuations compared to DA. Several studies indicate that patients treated with levodopa do well over many years, but no study demonstrates that it has any effect on the underlying neurodegeneration.
- *Catechol-amine methyl transferase inhibitors (COMTI):* These drugs are used in association with levodopa and are not used without levodopa. In fluctuating PD patients, the use of both entacapone and tolcapone increases in daily 'on' time by a mean of 1–1.7 and 2–3 h, respectively. Changes in daily 'on' time have been related to a significant improvement in scales assessing functionality in the activities of daily living. However, the appearance of fulminant hepatitis in three patients and the frequent finding of elevated transaminases have limited the widespread use of tolcapone. Currently, with regard to safety issues, tolcapone is considered acceptable but requiring special monitoring in fluctuating patients who have failed other therapies. Since levodopa is the most efficacious dopaminergic drug both on motor symptoms and functional disability, it has been hypothesized that the use of levodopa + carbidopa + entacapone in stable and 'de novo' PD patients could prevent motor complications to the same extent that DA do. Before the publication of the results of ongoing clinical trials focused on this issue, no recommendations can be given in regard to the use of levodopa + carbidopa + entacapone in 'de novo' PD patients.
- *Monoamine oxidase inhibitors (MAOI):* Selegiline has a mild therapeutic effect on motor symptoms. It is typically used early in the disease. Initial monotherapy with selegiline does not prevent motor complications once L-dopa is initiated. It can be used to treat motor fluctuations and prolong 'on' time. Rasagiline is a new selective and irreversible MAO-B inhibitor 10-fold more potent than selegiline and is not metabolized to amphetamine derivatives. Rasagiline is effective in monotherapy in early PD, providing a modest yet clinically meaningful benefit. Data on the neuroprotective

role of this drug are waiting for the results of the clinical trial ADAGIO. In the LARGO study, rasagiline showed a comparable effect to entacapone in the improvement of daily 'on' time.

- *Dopamine agonists (DA):* DA are efficacious for the treatment of parkinsonism. The main DA are pramipexole and ropinirole, although rotigotine and apomorphine as well as other agents less widely used are available. Starting treatment with DA instead of levodopa decreases the risk of motor fluctuations and dyskinesias after 5 years of follow-up. DA have also shown to improve daily 'on' time among patients with motor fluctuations. In particular, the intermittent use of apomorphine dramatically rescues patients from 'off' periods. With regard to safety, ergot-based DA (cabergoline, bromocriptine, lisuride) have been associated with valvular heart disorders and annual echocardiograms are needed for monitoring. Daytime sleepiness can be caused by any DA, and monitoring of driving capacity is important. Disruptive neuropsychiatric symptoms, both in young-onset and older PD patients can occur with DA. ICD (gambling, hypersexuality, punding/hobbyism) are more likely in younger and cognitively intact patients, while older patients are more likely to develop hallucinations and delusions.
- *Amantadine and anticholinergics:* Amantadine is likely efficacious in improving symptomatic control of parkinsonism, both as monotherapy or in combination with other symptomatic drug. Along with clozapine, amantadine is the only drug to have demonstrated an efficacy in reducing levodopa-induced dyskinesias. Anticholinergic medications are clinically useful in the symptomatic treatment of PD, both as monotherapy and when used with other drugs. The utility of these agents, however, is limited because motor efficacy is usually only mild to moderate, and occurrence of adverse reactions such as confusional state, acute urinary retention, and blurred vision are frequent. Further, one study suggested that chronic use of anticholinergic agents is associated with a greater relative risk of developing dementia.
- *Surgical treatments:* DBS of both the globus pallidus pars interna (GPi) or the STN are efficacious in treating motor signs of PD. They induce a lower incidence of motor, behavioral, and cognitive adverse effects than ablative procedures and can be done bilaterally, so that surgical treatment in PD in most developed countries is largely confined to the use of DBS. DBS of either the STN or the GPi improves parkinsonism, motor fluctuations and dyskinesias. Although the efficacy of DBS of the STN and the GPi seems to be similar, DBS of the STN appears more likely to allow a considerable medication reduction. DBS can be associated with mechanical failures, operative complications, and infections as well as speech disturbances, eyelid apraxia, limb or facial dystonia, and apathy.
- *Intraduodenal infusion of L-dopa (Duodopa®) and apomorphine pump:* Intraduodenal infusion of levodopa (IILD), and apomorphine pumps can be used for the treatment of motor complications that cannot be controlled with optimized medical treatment. The administration of the IILD results in stabilization of levodopa levels in peripheral blood and can reduce motor fluctuations. The improvement in 'on' time achieved by the IILD is comparable to that obtained with STN-DBS, but DBS obtains better control on dyskinesias. No life-threatening adverse events have been reported with IILD, but it is expensive, requires substantial patient/caregiver education, and is not available in most countries. The apomorphine pump shows a similar profile of improvement with a similar benefit on motor fluctuations as seen with IILD and less control of dyskinesias than DBS. The development of nonmotor complications (hypersomnolence, hypersexuality, hypomania), skin nodules and the difficulties in handling the pump limit the use of this technique.

Management of Nonmotor Symptoms

Nonmotor symptoms have a great impact on quality of life and disability measures and management of these problems is paramount to overall management success in PD.

- *Depression:* is the most frequent neuropsychiatric disturbance in PD. Few randomized, controlled, double-blind studies have been performed. In controlled studies, tricyclic antidepressants (TCA – imipramine, nortriptyline, and desipramine) have been shown to be effective. However, the associated anticholinergic effects of TCA may worsen cognitive function and dysautonomia (hypotension, urological problems) in elderly PD patients. Selective serotonin reuptake inhibitors (SSRIs) are generally well tolerated in patients with PD, and do not appear to worsen motor symptoms. Although the actual efficacy of SSRIs in PD has not been well established, SSRIs are generally preferred for initial therapy because of their tolerability.
- *Apathy:* up to 35–40% of PD patients develop apathy, associated with or dissociated from depression. No pharmacological studies focused on apathy have been performed up to date. Based on studies performed in Alzheimer's disease, the use of cholinesterase inhibitors or methylphenidate may be effective.
- *Dementia:* The EXPRESS study, a multicenter double-blind placebo controlled study showed that rivastigmine (mean dose 8.6 mg day^{-1}) improves not only the cognitive function (in all cognitive domains explored), but also some of the behavioral disturbances (apathy, hallucinations) associated with PD with dementia. Clinical impression of change assessed by the caregivers

showed that the use of rivastigmine in Parkinson's disease dementia (PDD) results in an improvement of dementia in 40% of patients. Smaller studies using donepezil and galantamine show also a beneficial effect.

- *Psychosis:* Treatment of psychosis in PD with antipsychotic drugs is complicated by the risk for negative effects on PD motor symptoms. As a first step, the physician must check that there is no medical illness or other explanation for a 'toxic encephalopathy' causing hallucinations. Then, drugs used for treating motor symptoms in PD that may be exacerbating psychosis should be reduced or stopped. To avoid worsening of motor function, the proposed order to withdraw parkinsonian medications is: anticholinergic agents (including those used for treatment of urinary incontinence), selegiline, rasagiline, amantadine, catechol-O-methyltransferase inhibitors, DA, and finally levodopa. If the patient cannot tolerate lower doses of dopaminergic drugs because of the PD itself, then an antipsychotic agent should be added. Typical antipsychotic agents, such as haloperidol, will likely worsen PD symptoms. From the atypical antipsychotic agents, low-dose clozapine has been demonstrated to be effective, although low-dose quetiapine is widely used in clinical practice. The use of cholinesterase inhibitors may also be effective in the treatment of visual hallucinations in PD patients with comorbid cognitive impairment.
- *Impulse control disorders (ICD):* The best treatment of ICD is to avoid their appearance. Addictive behaviors are difficult to reverse once they have emerged. DA in younger patients seem to be the main risk factors for the development of ICD, while a past history of ICD before the onset of PD (alcoholism, gambling), and certain personality traits (novelty-seeking) add to this risk. Because there is no established treatment for ICD in PD, careful screening of these factors before exposure is advised.

Glossary

α-synucleinopathies – A class of neurodegenerative disorders marked by abnormal inclusions containing α-synuclein in selected populations of neurons and glia. These disorders include Parkinson's disease, multiple system atrophy, dementia with Lewy bodies, and others.
Frontotemporal dementia with parkinsonism-17 (FTDP-17) – A neurodegenerative disorder described by researchers who had studied families in which dementia and parkinsonism occurred, all of which were linked to chromosome 17. Mutations in the genes encoding the microtubule-associated protein tau (MAPT) or progranulin were later found to be causal in separate families.
MAPT – A highly soluble protein that is abundant in neurons and plays an important role in the assembly of microtubules. In the human adult brain, there are six tau isoforms. Misfolded tau protein can form insoluble aggregates that are the major constituents of intraneuronal and glial fibrillar lesions described in Alzheimer's disease and numerous neurodegenerative disorders referred to as tauopathies.
Progranulin – A growth factor involved in multiple physiological and pathological processes including tumorigenesis. Mutations in the progranulin gene have been identified in some MAPT-negative FTDP-17 families.
Tauopathies – A class of neurodegenerative disorders marked by the presence of intracellular accumulations of abnormal filaments of insoluble MAPT. These disorders include some forms of FTDP-17, progressive supranuclear palsy, and corticobasal degeneration. Alzheimer's disease shows both tau and amyloid pathology.

Introduction

Parkinsonism refers to a category of movement disorders marked by at least two of the core clinical features of Parkinson's disease (PD), including rigidity, bradykinesia, gait difficulties, and postural instability. Parkinsonism includes PD as well as dementia with Lewy bodies (DLB), multiple system atrophy (MSA), frontotemporal dementia with parkinsonism-17 (FTDP-17, also referred to as pallidopontal degeneration), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), some spinocerebellar ataxias (SCAs), variants of Huntington's disease (HD), and several other disorders. In addition, some individuals with pathologically confirmed Alzheimer's disease exhibited clinical features of parkinsonism. Clinical clues pointing toward parkinsonism other than PD include gaze palsy (PSP), early autonomic failure (MSA), early falls (PSP and MSA), ataxia (MSA and SCAs), and early dementia (DLB and FTDP-17). In contrast to the asymmetry characteristic of PD, most of the non-PD parkinsonian disorders tend to be symmetrical; an exception is CBD, which is also dramatically asymmetric. In non-PD parkinsonism tremor may only be slight or completely absent. With the exception of DLB, all forms of non-PD parkinsonism are minimally responsive or unresponsive to dopamine replacement therapy. While PD is the most prevalent form of parkinsonism, exposure to certain medications, in particular dopamine antagonists, which are still in use for psychiatric illness and as antiemetics, is also a major cause of parkinsonism.

Dementia with Lewy Bodies (DLB) *OMIM #127750*

DLB is a form of parkinsonism that is clinically characterized by progressive dementia, fluctuating cognition, visual hallucinations, and parkinsonian motor symptoms. Following Alzheimer's disease, it is the second most common form of neurodegenerative dementia in the elderly. The defining neuropathological features of DLB are the Lewy body and the Lewy neurite, abnormal filamentous inclusions that contain α-synuclein as their major component. DLB is thus classified as an α-synucleinopathy, a class of neurodegenerative disorders that also includes PD and MSA. In addition, DLB is often accompanied by Alzheimer's disease pathology including amyloid deposits.

Although DLB is generally considered as a sporadic disorder, a small number of DLB families have been described, suggesting that genetic factors contribute to DLB pathogenesis. Indeed, mutations in genes previously implicated in autosomal dominant and sporadic PD have also been linked to familial DLB: an observation that supports the notion that PD and DLB are the same

disorder on a spectrum. For example, *α-synuclein* (*SCNA*) mutations and multiplications have been associated with both PD and DLB. Similarly, mutations in the *leucine-rich repeat kinase-2* (*LRRK2*) gene, currently recognized as the most common genetic cause of familial and sporadic PD, have been identified in some DLB patients. Furthermore, mutations in the *glucocerebrosidase (GBA)* gene, the causative gene of the autosomal recessive disorder Gaucher disease, have been linked to parkinsonism including PD and DLB. These findings demonstrate that heterozygosity for a Mendelian disorder can confer susceptibility to seemingly unrelated complex disorders; they also suggest that *GBA* loss-of-function ultimately leads to neurodegeneration. In addition, a recent multigenerational mapping study identified a novel locus for familial DLB on chromosome 2q35-q36 although a causative gene in this region has not yet been identified. Moreover, there is some evidence linking *β-synuclein* (*SCNB*) mutations with DLB although co-segregation with the disease has not been established with certainty.

Multiple System Atrophy (MSA)

MSA is a progressive neurodegenerative disorder with an estimated prevalence of 1.9–4.9 cases in 100 000. Clinical features include autonomic failure, poorly levodopa-responsive parkinsonism, and cerebellar ataxia. MSA pathology is defined by glial cytoplasmic inclusions composed of filamentous α-synuclein deposits and several other proteins, while Lewy bodies are typically not found. MSA therefore represents a mostly nonneuronal α-synucleinopathy.

MSA is a late-onset sporadic disease and its etiology is still unknown. Familial MSA is exceptionally rare, and causative or predisposing gene mutations remain elusive. The 'Online Mendelian Inheritance in Man (OMIM)' database, which is a comprehensive up-to-date catalog of all known Mendelian disorders, currently does not include MSA.

Frontotemporal Dementia with Parkinsonism-17 (FTDP-17) *OMIM #600274* and *#607485*

FTDP-17 is an adult-onset neurodegenerative disorder with clinical features including personality/behavioral changes, cognitive impairment, and parkinsonism. FTDP-17 is an autosomal dominant subtype of a broader syndrome referred to as frontotemporal lobar degeneration (FTLD), which is highly heterogeneous and the second most common cause of dementia in individuals <65 years of age. In 1998, missense and splice-site mutations in the gene encoding the microtubule-associated protein tau (*MAPT*) on chromosome 17 were identified in multiple FTDP families and since then, over 40 additional *MAPT* mutations have been linked to the disorder (see http://www.molgen.ua.ac.be/FTDmutations/). The intronic splice-site mutations modify the alternative splicing of *MAPT* exon 10, thereby disturbing the critical balance in the ratio of tau isoforms containing 3 or 4 microtubule-binding repeats. Overexpression of the 4-repeat isoform is thought to disrupt cellular microtubule dynamics, which ultimately results in neuronal death. Accumulation of the 4-repeat tau isoform is also observed in two other parkinsonian disorders, namely PSP and CBD (see below).

Pathologically, *MAPT*-linked FTDP-17 is characterized by filamentous tau inclusions in neurons and glia, and the disorder is therefore classified as a tauopathy. However, not all FTDP-17 cases have positive tau pathology, and a significant number of FTDP families with autosomal dominant inheritance show linkage to 17q21 in the absence of demonstrable *MAPT* mutations. Further analysis of the 17q21 region in these tau-negative families identified mutations in the gene coding for progranulin (*PGRN*), a growth factor involved in multiple physiological and pathological processes including tumorigenesis. Brain autopsies from *PGRN*-linked FTDP-17 patients show intra- and perinuclear inclusions that are immunoreactive to ubiquitin but devoid of tau or α-synuclein deposits. The ubiquitin-positive form of FTDP is therefore often referred to as FTDU-17. Clinically, there seem to be only subtle differences between *MAPT*- and *PGRN*-linked FTDP-17, and it is intriguing that mutations in two apparently unrelated genes, located in proximity on the same chromosome, can cause a very similar disease phenotype. In addition, some cases of ubiquitin-positive familial FTLD (FTLD-U) with varying phenotypes have been attributed to mutations in the genes encoding the charged multivesicular body protein-2B (*CHMP2B*), the valosin-containing protein (*VCP*), and another locus on chromosome 9p21–13 distinct from *VCP*. Clinically, these families present with frontotemporal dementia, and in some cases, with motor neuron disease, dystonia, and other symptoms, while parkinsonism is not typical. Intriguingly, the ubiquitin-positive pathology is characterized by the accumulation of TAR DNA-binding protein 43 (TDP-43), and hyperphosphorylated, ubiquitinated TDP-43 has recently been implicated as the common pathologic substrate of familial and sporadic FTLD-U as well as amyotrophic lateral sclerosis (ALS). These disorders are therefore referred to as TDP-43 proteinopathies. Of note, familial ALS linked to *Cu/Zn superoxide dismutase* (*SOD1*) mutations does not exhibit TDP-43 pathology, implying that this rare form of ALS is not simply a familial counterpart of sporadic ALS, which is TDP-43 positive.

Progressive Supranuclear Palsy (PSP) *OMIM #601104*

PSP is the most common cause of non-PD parkinsonism (other than medication-induced) with a prevalence of

6.0–6.4 cases per 100 000. The clinical disorder is characterized by progressive symmetric axial rigidity, vertical gaze palsy, dysarthria, and dysphasia. In addition, cognitive impairments may occur in the late stages of the disease. The disorder is only minimally responsive or completely unresponsive to dopamine replacement therapy. Pathological hallmarks include neuronal loss, gliosis, and neurofibrillary tangles containing tau aggregates in the basal ganglia, diencephalon, and brainstem; PSP is therefore classified as a tauopathy. The fibrillary tangles in PSP are predominantly composed of the 4-repeat tau isoform.

The etiology of PSP is still unknown, but there is evidence for familial clustering, which implies a genetic contribution. Indeed, the association of a specific allele of the *MAPT* gene, the A0 allele, with PSP in Caucasians was first described in 1997. The A0 allele, an intronic dinucleotide polymorphism, was soon found to be in linkage disequilibrium with other polymorphisms, leading to the definition of two distinct MAPT haplotypes, referred to as H1 and H2. These haplotypes cover a region of ~1.8 Mb at 17q21 and encompass the *MAPT* gene as well as several neighboring genes. The H1 haplotype is more common, and homozygosity for H1 has been associated with an increased risk of developing tauopathies including PSP and CBD, a closely related parkinsonian condition. The H1 haplotype can be further divided into various sub-haplotypes, and the H1c variant has been shown to be a more specific risk factor for PSP, CBD, and to a lesser extent, Alzheimer's disease. As mentioned earlier, yet another set of mutations in *MAPT* is associated with FTDP-17, thus demonstrating that different variants of a single gene can be risk factors for multiple forms of parkinsonism and even nonparkinsonian neurodegenerative diseases.

Efforts to identify genetic risk factors for PSP have also included a genome-wide association study (GWAS) that scanned over 500 000 single-nucleotide polymorphisms in a pool of 288 DNA samples from pathologically confirmed Caucasian PSP patients. This pooling-based GWAS confirmed the association of PSP with the *MAPT* H1 haplotype and also identified a second significant risk locus on chromosome 11p12-p11. This novel locus was subsequently refined to a single haplotype block containing two genes, the DNA damage-binding protein-2 (DDB2) gene and the lysosomal acid phosphatase-2 (ACP2) gene (*OMIM #610898*). In addition, a genome-wide linkage study of a large Spanish family with autosomal dominant inheritance of PSP revealed association with a candidate locus on chromosome 1q31.1 (*OMIM #609454*). No linkage to the *MAPT* gene was found in this family.

Corticobasal Degeneration (CBD) *OMIM #157140*

CBD, a relatively rare cause of parkinsonism, is clinically characterized by asymmetric rigidity, dystonia and dystonic tremor of the affected limbs, a lack of dopamine responsiveness, and prominent cortical features. The neuropathology is typically marked by focal asymmetric cortical atrophy with ballooned neurons, nigral degeneration, and glial and neuronal filamentous tau pathology, especially astrocytic plaques in the affected cerebral cortex.

CBD is a mostly sporadic tauopathy, and like PSP, it is associated with homozygosity for the *MAPT* H1 haplotype leading to accumulation of tau aggregates containing the 4-repeat tau isoform. Although CBD and PSP can usually be differentiated on the basis of their clinical and pathological features, there is a considerable degree of overlap, especially in more atypical cases. Based on this overlap of clinical and pathological features as well as the genetic similarities between these two disorders, it has therefore been suggested that CBD and PSP correspond to different phenotypes of the same disease process, which is subject to additional genetic and/or environmental modifying factors. How this shared etiology can lead to such phenotypic heterogeneity will likely be the subject of future studies.

Other Mendelian Disorders Associated with Parkinsonism

Parkinsonian features have also been noted in several other late-onset Mendelian disorders, including SCA2 (*OMIM #183090)* and SCA3 (also known as Machado–Joseph Disease, *OMIM #109150*) and HD (*OMIM #143100*).

Conclusion

Parkinsonism refers to a heterogeneous group of neurodegenerative movement disorders, each marked by specific clinical, neuropathological, and genetic characteristics. Despite this heterogeneity, genetic studies have revealed several intriguing themes that are common to subgroups of these disorders. The terms 'synucleinopathy', 'tauopathy', 'amyloidopathy,' and 'TDP-43 proteinopathy' have become common parlance in the field of neurogenetics and highlight the biological hallmarks, namely abnormal protein deposits, rather than the clinical manifestations of these disorders. Using this framework, PD, DLB, and MSA are classified as synucleinopathies; *MAPT*-linked FTDP-17, PSP, and CBD as tauopathies; and FTDP-U, along with ALS and the broader syndrome of FTD-U, as TDP-43 proteinopathies. Alzheimer's disease represents both an amyloidopathy and a tauopathy. These distinct classes of proteinopathies are all thought to be disorders of dosage, where increased quantities of normal or posttranslationally modified protein lead to disease. Therapeutic strategies are therefore being developed to block or slow down the formation of these aberrant protein aggregations. Such interventions are hoped to be effective in all classes of

proteinopathies rather than in single, clinically defined disorders within these classes. Taken together, advances in understanding the genetics of parkinsonism have begun to provide insights into the pathogeneses of these disorders, thereby revealing potential therapeutic targets that will impact on the underlying causes, and not just the symptoms, of these disorders.

Parkinsonism: Vascular

T S Voss and E R Dorsey, University of Rochester, Rochester, NY, USA

Glossary

Cerebrovascular disease – Disease of the blood vessels and, especially, the arteries that supply the brain, usually caused by atherosclerosis. When blood flow is blocked, cell death can occur, causing sudden loss of oxygen and glucose to the brain.

Lacune – A type of stroke, generally caused by occlusion of the smaller vessels in the brain, that tends to occur in the brainstem and deep grey nuclei of the brain.

Parkinson disease – A degenerative disorder of the brain that results in tremor, stiffness, slowed movements, and trouble with gait, associated with Lewy body pathology.

Parkinsonism – Symptoms of tremor, stiffness, slowed movements, and walking difficulty, without a specific cause.

Definition and History

The term parkinsonism defines a syndrome consisting of tremor, rigidity, bradykinesia, and postural instability. Besides Parkinson's disease (PD), parkinsonism can result from several other causes. Vascular parkinsonism (VP), defined as parkinsonism due to cerebrovascular disease, is an uncommon cause of parkinsonism, occurring in 3–7% of cases (see **Figure 1**). VP was initially described by Critchley in 1929. After enjoying initial popularity, the existence of VP as a clinical entity was questioned, with dissenters arguing that the vascular changes seen were incidental findings and not a pathologic cause of parkinsonism. Their case was bolstered by the varying clinical manifestations of presumed VP and by the cooccurrence of vascular lesions in some cases of histologically-proven PD with Lewy body pathology. More recently, however, improved clinical criteria and pathology studies have reestablished VP as a clinical entity distinct from idiopathic PD and other forms of parkinsonism, with implications for disease pathology, management, and prognosis. Although the use of 'vascular' implies a specific disease with a known pathophysiology, VP is more properly considered a syndrome rather than a specific diagnosis. Cerebrovascular disease itself has several underlying etiologies, each with unique pathophysiology and therefore with individualized considerations for management.

Epidemiology

The prevalence of VP varies widely depending on the specific definition used. However, studies relying on imaging or pathologic data to support the diagnosis estimate a prevalence of 3–7% among causes of parkinsonism. In the older population, the prevalence of parkinsonism ranges from 15 to 52% depending on the age and population studied, and the prevalence of VP is expected to rise with the escalating burden of hypertension, diabetes, and cerebrovascular disease worldwide. The prevalence and incidence of VP increase with male gender and increasing age, and patients with VP tend to be older than those with idiopathic PD, with an average age of onset ranging from 65 to 82 years, compared with an average age of 55 years for PD.

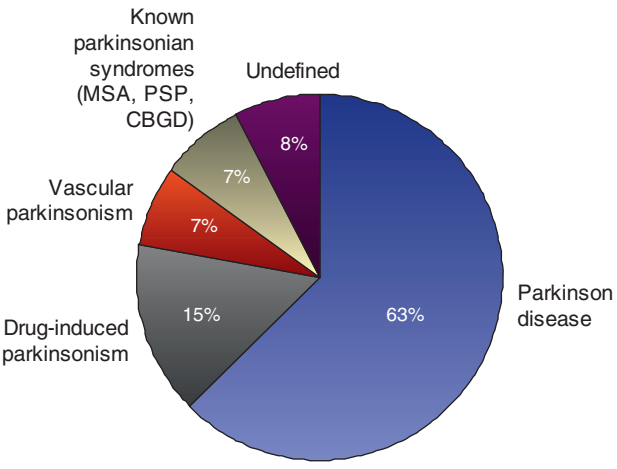

Figure 1 Most common diagnoses in parkinsonian disorders.

The proposed risk factors for VP arise from the underlying presumptive mechanism of ischemic brain disease. Of the vascular risk factors studied, hypertension and diabetes are the most consistent risk factors. Other consistent factors that have been less well-studied include heart disease, hyperlipidemia, and a positive smoking history. As compared to typical PD, Winikates et al. demonstrated that coronary artery disease was present in 30.4% of VP but only 6.9% of PD, significant carotid stenosis was present in 7.2% of VP but 0% of PD, and a positive family history of stroke was present in 37.7% of VP but 17.9% PD (all p-values <0.001). Huang et al. reported that anticardiolipin antibodies were present in 40% of their clinical VP population, as compared to a prevalence of 5% in the general population and 12% in the elderly. Although this finding is striking and has clinical implications for the management of VP, this association requires further investigation.

Despite the presence of these risk factors, a direct causal link between clinical strokes and subsequent parkinsonism remains elusive. Large striatal infarcts and territorial cerebral infarcts are an uncommon cause of parkinsonism, occurring in less than 10% of cases. When all types of ischemic stroke are examined, about one-third of patients develop parkinsonian signs and ~10% develop clinical parkinsonism. White matter lesions and small lacunar infarcts are highly associated with the development of clinical parkinsonism, with incidences of 38% for white matter lesions and 16% for lacunar infarcts in one study. Territorial strokes are often associated with parkinsonian signs but are much less commonly associated with a clinical diagnosis of parkinsonism (2.5%). Taken together, the available data implicate white matter lesions as a major risk factor for developing parkinsonism, but whether white matter lesions are causal or represent a confounding factor remains unknown.

Pathophysiology

VP is considered secondary to vascular disease, but how vascular insults cause parkinsonism remains unclear. Several ischemic pathologic changes, including lacunes, basal ganglia infarcts, and diffuse white matter lesions, occur in VP and may be associated with specific subtypes (see section Clinical Features and Differential Diagnosis). Ischemic changes are not universally associated with the clinical presentation of VP; however, these lesions occur

frequently in the elderly population without clinical evidence of parkinsonism. Due to this overlap, the clinical manifestations of parkinsonism cannot be predicted from the number, site, or size of vascular lesions. A more complete understanding of specific pathophysiology is also complicated by the coexistence of Lewy bodies and vascular lesions in PD, which occurs in up to 20% of cases examined in autopsy series. Whether and to what extent the coexisting vascular disease may modify the clinical manifestations and the course of typical PD are unknown and blurs the distinction between Lewy body PD and VP.

The variety of pathological subtypes of VP reflects the underlying heterogeneity of cerebrovascular disease. Although large (greater than 1.5 cm) focal basal ganglia lesions rarely induce parkinsonism, basal ganglia lacunes are common in VP, and the lentiform nucleus is the most common site. Chang et al. described three anatomical patterns of VP: basal ganglia infarcts; frontal lobe infarcts, and deep subcortical white matter lesions. Each type had similar clinical presentations but different prognoses, with the basal ganglia group doing the best and the subcortical white matter group doing the worst. Alternatively, Zijlmans et al. and Winikates et al. divide VP into two patterns: subcortical gray nuclei lesions of the striatum, globus pallidus, and thalamus, associated with an acute or subacute onset; and diffuse watershed lesions, associated with an insidious onset. A consecutive autopsy series by Jellinger divided VP into three pathologic patterns: subcortical vascular lesions (32%), lacunes in basal ganglia and brainstem (20%); and multiinfarct encephalopathy without nigral lesions (48%).

Table 1 Clinical differences between vascular parkinsonism (VP) and idiopathic PD

	Vascular parkinsonism	*Idiopathic PD*
Demographics		
Age	Mean 65–82	Mean 55
Sex	1:1	Male predominance
Cardinal features		
Tremor	Uncommon (30%) Postural, kinetic	Common resting
Rigidity	Present	Present
Bradykinesia	Present	Present
Postural instability	Early, common (70%)	Late, less common
Other features		
Gait disorder	Early, common (90%)	Late
Symmetry	Symmetric	Asymmetric
Limbs involved	Lower body predominant (60%)	Unilateral or upper body predominant (90%)
Corticospinal findings	Common (30–60%)	Rare
Nonmotor features		
Dementia	Early, common (45%)	Late, less common
Hyposmia	Absent	Present
Depressive symptoms	?	Common (50%)
Pseudobulbar affect	10%	Rare
Management		
Progression	Acute or step-wise	Insidious, chronic
Levodopa response	Poor, transient (<25%)	Good, sustained

Clinical Features and Differential Diagnosis

By definition, VP and other forms of parkinsonism share similar signs and symptoms, making it difficult to differentiate VP on clinical grounds alone. Still, VP and typical PD differ clinically in several ways, allowing a clear distinction in prototypic cases (**Table 1**). Differentiating VP from other forms of atypical parkinsonism is more difficult. VP is usually symmetric, similar to multisystem atrophy (MSA) and progressive supranuclear palsy (PSP). However, VP tends to predominate in the lower limbs and has a relative absence of signs in the upper body, in contrast to MSA and PSP as well as PD. Other features that define MSA and PSP, such as cerebellar signs, orthostatic hypotension, and ocular movement abnormalities, are rarely described in VP. Still, the diagnosis of VP cannot be made based on the presence or absence of a single clinical sign; rather, a clinical diagnosis of VP is made based on the convergence of appropriate clinical and imaging characteristics and a reasonable effort to exclude other forms of parkinsonism, especially drug-induced parkinsonism and other neurodegenerative parkinsonisms such as PSP, MSA, and corticobasal degeneration. Less common causes of parkinsonism should be considered in the appropriate clinical situation and include carbon monoxide, cyanide, or manganese poisoning, prion disease, chronic subdural hematoma, Wilson's disease, and normal pressure hydrocephalus.

Several clinical subtypes of VP have been described. The acute subtype occurs in ~25% of cases and is associated with the acute development of parkinsonism within 1 month of stroke onset. This subtype is more likely to have an asymmetric presentation with lesions identified in the contralateral basal ganglia on imaging. More commonly, VP presents insidiously in a stepwise progression, with symmetric bradykinesia, early gait disorder, and postural instability. Tremor is infrequent and when present is often postural or kinetic. Early dementia, corticospinal signs, early incontinence, and pseudobulbar palsy (dysarthia, dysphagia, drooling, and emotional incontinence) are all more common in VP than PD.

Diagnostic Evaluation

Diagnosing VP in the clinic remains challenging. The readily apparent group differences between PD and VP, noted above, may not be clearly present in a particular individual. To standardize the clinical diagnosis, vascular rating scales, initially developed for dementia, have been adapted for use in the parkinsonian population (**Table 2**). However, these vascular scales have not yet been validated against postmortem pathological examinations.

Imaging studies can assist in the diagnosis of VP, and magnetic resonance imaging (MRI) or computed tomography (CT) evidence of cerebrovascular disease is considered essential in most proposed diagnostic criteria. However, the presence of cerebrovascular disease does not exclude the diagnosis of PD. In studies using vascular scoring systems or clinical history of stroke without imaging criteria to define VP, MRI or CT evidence of ischemic injury was present in over 95% of patients, and no patient with VP had a normal imaging study. Evidence for vascular disease in multiple vessel territories is present in over 70% of patients. In addition to cerebrovascular disease, other abnormalities on imaging include hydrocephalus, atrophy, and nonspecific white matter changes.

Functional neuroimaging (SPECT) using ligands for the dopamine transporter (DAT) may provide additional diagnostic clues in VP. Several researchers have found that DAT imaging is abnormal in neurodegenerative parkinsonisms (PD, MSA, and PSP) but is usually normal in VP due to the preservation of presynaptic dopamine neurons. However, other studies have demonstrated that focal basal ganglia infarcts can produce DAT abnormalities indistinguishable from the pattern seen in neurodegenerative parkinsonism. The use of functional imaging in the routine assessment of VP therefore remains unclear.

Assessment of olfactory function may also help differentiate VP from PD. Although impaired olfactory function is associated with idiopathic PD, smell testing was found to be normal in patients with VP in one study of 32 subjects. Olfactory testing is simple, inexpensive, and readily available. However, this option needs to be validated in larger trials, and no data are available on whether it can successfully distinguish among other forms of atypical parkinsonism.

Table 2 Vascular rating scale for the diagnosis of VP

Clinical history	*Score*
Pathologically or angiographically proven diffuse vascular disease	2
Onset of parkinsonism within 1 month of clinical stroke	1
Personal history of two or more strokes	1
Personal history of two or more risk factors for stroke	1
Neuroimaging evidence of vascular disease in two or more territories	1
Diagnosis of VP: Patients with parkinsonism and a total score of two or more	

Source: Winikates J and Jankovic J (1999) Clinical correlates of vascular parkinsonism. *Archives of Neurology* 56: 98–102.

Management and Prognosis

Overall, parkinsonism is associated with a twofold increase in mortality, with gait dysfunction having the most significant impact on mortality and progressive disability. Compared to PD, individuals with VP are generally older and present with early falls, dementia, and poor levodopa response. All of these factors are generally associated with a poorer prognosis, and several studies suggest that VP progresses more rapidly than PD. A small subset of individuals, who present acutely with asymmetric symptoms, may remain stable or even improve spontaneously. If it occurs, spontaneous improvement is usually seen within 1–2 years.

Scant evidence is available to guide the management of individuals with VP. Principles of management have therefore been formed from clinical experience and logical extrapolation from the stroke literature. Individuals with VP generally respond poorly and transiently to dopaminergic therapy. However, Zijlmans et al. have described a subset of VP individuals, with lesions centered in the substantia nigra, who demonstrated an excellent and sustained response to dopaminergic therapy. In the absence of other symptomatic therapy, patients with VP should therefore receive a full therapeutic trial of dopaminergic therapy – generally 1 g of total daily levodopa, if tolerated, for at least 2 months.

Although no studies have examined the effects of vascular risk reduction on VP disease progression, it seems reasonable to identify and reduce the vascular risk factors in this population in the hopes of slowing further vascular lesion burden. Clinicians caring for these patients could consider an evaluation of previously undiagnosed vascular risk factors, including echocardiogram (EKG), carotid ultrasound, lipid profile, and glucose or hemoglobin A1C testing for diabetes. Individuals should be offered counseling for smoking cessation and to improve diet and exercise regimens, and known vascular risk factors should be controlled. Physical and occupational therapy can be helpful for those with early gait difficulties.

Summary

VP is an uncommon, but important cause of parkinsonism, with clinical features that can be distinguished from idiopathic Parkinson disease. MRI can help establish the presence of vascular disease but cannot exclude idiopathic

PD. Despite the association with vascular lesions, the underlying pathophysiology is poorly understood. Further research priorities include validating diagnostic criteria and diagnostic assessments, and rigorous evaluation of risk modification and potential therapeutic options for this increasingly common syndrome.

Parkinson's Disease: Animal Models

G Porras, P-O Fernagut, and E Bezard, Université Victor Segalen Bordeaux 2, Bordeaux, France

Glossary

1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) – A neurotoxin that kills cathecholaminergic neurons with a greater efficacy upon dopamine neurons. It is used for producing mouse and primate models of Parkinson's disease.
Lewy bodies – Pathological intracytoplasmic hallmark of Parkinson's disease that is an α-synuclein positive inclusion.
α-synuclein – Presynaptic protein which accumulation and mutations are associated with increased risk of Parkinson's disease. It was further shown to be the main component of the Lewy bodies;
Rotenone/paraquat – Pesticides blocking the mitochondrial respiratory chain used for modeling Parkinson's disease in animals. Suspected of acting as environmental toxins.

Introduction

Parkinson's disease (PD) is a progressive neurodegenerative disorder, affecting 1% of the population over 55. This pathology is primarily characterized by a progressive degeneration of the nigrostriatal dopamine (DA) system associated with the presence of intracytoplasmic α-synuclein positive inclusions known as Lewy bodies. Fully developed, PD comprises motor impairments, including bradykinesia, rigidity, tremor, and postural instability.

Whereas the etiology of idiopathic PD is still unknown, its pathophysiology has rapidly advanced due to the development of relevant mammalian models. Using these models, levodopa (L-3,4-dihydroxyphenylalanine or L-dopa) was first applied to compensate striatal DA deficiency associated with the motor symptoms of PD. Unfortunately, although effective in the early stages of PD, this symptomatic therapy loses efficacy over time due to the developments of severe side effects known as

levodopa-induced dyskinesia (LID). Experimental models of PD are thus needed to gain insights into the pathological mechanisms of the disease and to develop new therapeutic strategies. Ideally, for direct relevance to human PD, a model should have the following characteristics: (1) a chronically progressive loss of DA neurons, (2) motor symptoms clearly improved by levodopa treatment, (3) nonmotor symptoms such as cognitive impairments, sleep disorders, constipation, orthostatic hypotension, etc., (4) development of LID over time, and (5) lewy body inclusions. However, it is necessary to admit that there still a long road ahead of us. Some of the available models allow reproducing at least one or two characteristics of the disease. Further, some discrepancies exist between neuropathological data obtained in PD patients and data from experimental models. Indeed, PD is a chronic degenerative disease, whereas animal models could be produced either by acute lesion or by semichronic intoxication with specific neurotoxins. It is clear that we need animal models that will come closer to the gradual progression of DA neuronal death and the subsequent evolution of parkinsonian motor and nonmotor disabilities. Current evidence suggests an involvement of both environmental and genetic factors in the progression of PD. Future pathophysiological studies should take all these factors into account. PD cannot any longer be studied as a discontinuous pathology, in which the patient passes suddenly from a normal to a full parkinsonian state. The following nonexhaustive review looks at reversible pharmacological, toxic and genetic in vivo mammalian models of PD available today and proposes a brief assessment of their relative merits.

Pharmacological Model

Those models were the first to be developed and are still in use. Depleting brain stores of monoamines with the Rauwolfia alkaloid reserpine or administering a neuroleptic, for example, haloperidol, are two reversible pharmacological models, which induce transient functional disturbances by a temporary blockade of DA neurotransmission.

The Reserpine Model

It was the first PD animal model. Reserpine, by interfering with the storage of catecholamine, results in monoamine depletion in nerve terminals and induces a transient hypolocomotion with resultant hypokinesia, akinesia, and even catalepsy.

Most of the available pharmacological studies of reserpine-induced motor symptoms, focused on rigidity or the indirect evaluation of hypokinesia. Besides this model of parkinsonism, several studies have shown that rats treated with reserpine develop orofacial dyskinesia, which is considered as a good model of tardive dyskinesia.

The precise mechanisms underlying the effects of reserpine treatment have still not been elucidated but it has been shown that the depletion reaches not only DA but also the others monoamines. Although the use of this model has suffered of a certain disaffection due to its nonselectivity and its transient nature, it provides a useful tool to investigate the symptomatic antiparkinsonian activity of new chemical entities featuring DA activity, α-adrenoreceptor blockers and glutamatergic antagonists.

The Neuroleptic Model

Parkinsonian-like symptoms including akinesia, muscular rigidity, and tremor were induced by the majority of DA antagonists both in humans and in experimental models. Catalepsy, another major early side effect of neuroleptics is characterized by the inability to change an externally imposed posture. Numerous studies have investigated the ability of antiparkinsonian compounds to counteract neuroleptic-induced catalepsy: DA agonists and levodopa, anticholinergics Glutamate agents, and GABA antagonists. Most of these studies have been performed on rodents, very few on nonhuman primates.

Although neuroleptics induce extrapyramidal symptoms resembling those observed in human PD, their relevance for animal models of PD is limited. Their action is firstly transient and reversible. They can block DA transmission but cannot induce degeneration of DA nigrostriatal neurons. The applications of this model are therefore limited.

Relevance of Reversible Models

The reserpine and neuroleptic models of PD are not the only experimental pharmacological models of PD available. Animal models of tremor have also been developed, such as the model using oxotremorine, a selective cholinergic agonist acting on muscarinic receptors. Further, like reserpine, striatal DA depletion following administration of methamphetamine has prompted to propose this psychostimulant as a good candidate to modelling PD. None of these models, however, reproduce the degenerative process of PD. They remain relevant for the study of specific symptoms but cannot provide any further contribution to the development of dynamic animal models since their transient nature excludes de facto any degenerative evolution and their characteristics do not reproduce exactly the clinical features of human PD.

Neurotoxic Models

Although it is clear that the PD does not result only from the loss of nigrostriatal DA neuron, the common feature of all neurotoxin-induced models, namely those produced broadly by the toxins 6-hydroxydopamine (6-OHDA) or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP),

is that they all induce a massive and reproducible nigrostriatal degeneration.

The 6-Hydroxydopamine Model

For approximately the last 50 years, 6-OHDA has become the most commonly used model for PD due to its specific neurotoxic effects on catecholaminergic pathways. The 6-OHDA structural analogy with catecholamines facilitates its transfer and accumulation through the high-affinity transport system located on the plasma membrane. In these monoaminergic neurons, 6-OHDA induces neurodegeneration by oxidative stress through formation of reactive oxygen species and quinones. Many other mechanisms have been involved since then. To reduce damage on noradrenergic (NA) neurons which are more sensitive to 6-OHDA than DA neurons, a pretreatment with desimipramine, a selective inhibitor of NA-reuptake injected systemically, is required. The specificity obtained is still, however, not absolute, and nonspecific lesions of the serotoninergic or other catecholaminergic systems may occur.

Whereas the rat remains the species of choice, 6-OHDA is also effective in several other species from zebrafish to primate confirming that this toxin is a powerful experimental tool. Since the toxin is unable to cross the blood–brain barrier, 6-OHDA is injected intracerebrally under stereotactic guidance to target the nigrostriatal DA pathway. Several local approaches were thus considered and toxin can be administered at the distinct parts of this ascending DA pathway, uni- or bi-laterally. Following the princeps work of Ungerstedt who injected 6-OHDA bilaterally into the rat substantia nigra (SNc), models with bilateral DA lesion have been proposed. Nevertheless, wherever the 6-OHDA was administered, rats present akinesia, aphagia and adipsia and mortality increases significantly. More recent studies have proposed partial bilateral 6-OHDA lesions, particularly at the striatal level but this model, as good as it can be, must be a compromise between lack of induced mortality and sufficient DA depletion. Accordingly, the most practical and frequent application of the 6-OHDA-lesioned model is the unilateral intracerebral injection. This allows the assessment of rotational behaviour that correlates well with the degree of lesion, in response to drugs affecting DA transmission. Several additional motor tests have also been validated in 6-OHDA rats, including akinesia or LID.

Apart from the testing of a number of antiparkinsonian compounds, the so-called 'Ungerstedt model' has greatly improved our knowledge of the physiopathology of the basal ganglia. However, the 6-OHDA model is not able to replicate many of the neuropathological features of human PD. It does not alter other brain regions and to date, the formation of cytoplasmatic inclusions (Lewy bodies) has never been observed in this model. Further, rotational behaviour, although an interesting criteria for drug discrimination, does not allow estimating all human parkinsonian symptomatology such as the nonmotor symptoms. Finally, this acute model does not induce a slow progressive neuronal death which characterizes the pathophysiology of human PD, unless when injected into the striatum.

Despite these drawbacks, the stable lesions produced by the administration of 6-OHDA allow long-term studies. For this reason, 6-OHDA model has been particularly useful to quantify motor deficit, develop pharmacological screening as well as neuroprotective studies by testing cell transplantation or neurotrophic factors.

The 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine Model

The MPTP model is probably the best characterized and most used model of PD at present. In the early 1980s, several young Californian adults developed a severe parkinsonian-like syndrome after injection of a synthetic heroin contaminated by a meperidine analogue, MPTP. The active metabolite of MPTP, MPP^+ was accumulated in DA cells via the dopamine transporter (DAT) and induced mitochondrial complex I inhibition causing oxidative stress and cell death. MPTP induces symptoms virtually identical to those of idiopathic PD and this syndrome was considerably improved by the administration of levodopa or DA agents.

As in humans, the administration of MPTP in various animals has been shown to induce a selective degeneration of the DA nigrostriatal pathway with parkinsonian-like motor impairment. The most obvious impact of MPTP-based toxin models was the development of primate models, which come the closest to human PD. Rats remain relatively insensitive to the administration of MPTP and only specific strains of mice are sensitive to its action. Further, in comparison to the level that nigral degeneration obtains in monkeys, MPTP-induced DA depletion in mice, requires higher dose and permanent behavioral PD symptoms are rarely noticeable. This led to use this model for biochemical investigation of the neurotoxic action of MPTP.

Various doses and regimes of MPTP administration (route, number and frequency of injections) are used by different laboratories and can produce varying degrees of DA loss. The most frequently protocol used for the MPTP mouse model comprises four injections of MPTP ($20\,mg\,kg^{-1}$; intraperitoneally (i.p.)) at 2-h intervals. This produces a sharp decrease in striatal DA levels and leads to a loss of DA neurons in the ventral mesencephalon.

Among the various schedules of MPTP intoxication for primates, toxin could be administered either systemically (intraperitoneal (i.p.), intravenous (i.v.), intramuscular (i.m.), or subcutaneous (s.c.)) to achieve a bilateral lesion or through the carotid on one side when a hemiparkinsonian syndrome is preferred. In the former model, a supporting therapeutic trial with levodopa is required to allow MPTP-treated animals to maintain a normal nutrition. The second model has been useful in electrophysiological studies or for studying novel antiparkinsonian therapies.

In nonhuman primates, MPTP can produce a parkinsonian syndrome that replicates almost all of the features of PD, including bradykinesia, rigidity, and postural abnormalities. The resting tremor and the lewy body inclusion, are however hardly encountered in the MPTP-treated monkey. It would seem, however, that, rather than a question of strain, it is a question of schedule of MPTP administration. Indeed, old paradigms used high doses of MPTP administration to produce acute and severe DA loss, which failed to reproduce the progressive nature of PD. At present, long-term administration of low doses of MPTP seems to be a more accurate approach to mimic the human PD pathogenesis with a slow evolution of parkinsonian syndrome. This model has also been valuable for the study of dyskinesia, since regular use of levodopa or DA agonists induces these incapacitating side effects in the MPTP-treated monkey as it does in humans.

While nonmotor symptoms of PD were more and more acknowledged as debilitating and critical unmet needs for PD patients, the MPTP monkey model(s) has been further studied for establishing if they were present as well. In fact, to our surprise, the MPTP monkey model recapitulates most if not all the motor and nonmotor symptoms. Cognitive impairments have been the first to be acknowledged and a specific model, the so-called chronic low dose model has even been specifically developed to this aim. Interestingly, levodopa impairs cognitive capabilities in these MPTP monkeys while motor symptoms are improved, exactly as in PD patients. Accordingly, the sleep disturbances, excessive daytime sleepiness and rapid eye moment (REM) sleep deregulation that are among the most frequent and disabling nonmotor manifestations in PD are fully reproduced in MPTP monkeys offering the possibility to now investigate the pathophysiology of these disorders and to test putative therapeutics.

Currently, MPTP neurotoxicity is the best available animal model to evaluate the efficacy of neuroprotective and neurorestorative strategies of PD. Like the 6-OHDA model, the MPTP model has facilitated enormously the comprehension of the pathophysiology of the basal ganglia but also opened up new areas of research including drugs, transplants, and gene therapy. Observation of nonmotor symptoms in MPTP monkeys has also opened a new field of research and offers a platform for validating therapeutics aiming at controlling these symptoms.

Environmental Toxins Models

Several epidemiological and toxicological studies have suggested that pesticides and other environmental toxins could be involved in the pathogenesis of PD. Among the environmental toxin models of PD, paraquat, maneb (manganese ethylenebisdithiocarbamate), and rotenone have received the largest attention. One potential mechanism by which all these toxins may increase the risk for PD is through disruption of mitochondrial function.

In rodents, paraquat leads to SNpc DA neuron degeneration accompanied by α-synuclein containing inclusions. Combined with maneb, the effects on the loss of DA neurons and on reduced motor activity are greater than with paraquat alone. Nevertheless these studies are marginal and failed to provide conclusive evidence to consider pesticide model as reliable experimental model of PD.

Rotenone-infused rats resulted in a progressive formation of cytoplasmic inclusions and loss of nigral DA neurons leading to motor behavioral impairment. These motor abnormalities were reversed by levodopa. Although this model produced most of key features of PD, it originally suffered from much variability since some animals had lesions and others not. Further, rotenone induced a chronically progressive degeneration of DA neurons and also of non-DA neurons in both the basal ganglia and the brainstem. This model is thus more a multisystemic model of degeneration than originally proposed on DA neurons selectively. However, recent refinement of both the administration and the procedures have allowed to solve some of these issues, making rotenone appealing again especially considering it is multisystemic and its capacity to produce cytoplasmic inclusions.

Similarly to rotenone, chronic administration of annonacin, another inhibitor of complex I of the mitochondrial respiratory chain cause nigral and striatal (non-DAergic) neurodegeneration. Finally, proteasome inhibitors have been suggested as potential PD inducers. Several expert laboratories despite huge efforts did, however, not replicate this model.

Gene-Based Models

The discovery of several genetic alterations in familial forms of PD has enabled the development of a gene-based approach to create animal models. Genes involved in familial PD include α-synuclein, parkin, UCH-L1, PINK1, DJ-1, and LRKK2. The development of models of PD based on genes implicated in familial form has been carried out using either transgenesis or viral-mediated expression.

Transgenic Models

α-synuclein being the pathological hallmark of sporadic PD, it has been the focus of most endeavours to create a genetic model of the disease. In addition, the discovery of genomic multiplication of α-synuclein in some families demonstrated the pathogenicity of increased levels of the wild-type protein. Numerous lines expressing wild-type or mutated human α-synuclein have been generated. Most lines recapitulate the propensity of some neuronal populations to host protein aggregates (olfactory bulb, midbrain, cortex, etc.) as found in the human disease. Some lines also display nigrostriatal alterations as shown by a reduction of tyrosine hydroxylase (TH) positive

fibers in the striatum or progressive DA cell loss in the SNc. In one line, overexpression of truncated α-synuclein results in a loss of DA neurons in the SNc and a concomitant reduction of DA levels in the striatum. Several reasons may account for the lack of systematic DA neurodegeneration, including expression levels within the SNc, coexistence of human and mouse α-synuclein, upregulation of cellular defense mechanisms in response to constitutive over expression of the protein.

Among parkin knock-out models, two lines (exon 3 or 7 deletion) display alteration of DA release or metabolism and one of these lines also exhibit a loss of TH neurons in the locus coeruleus.

Two lines of DJ-1 mutant mice have been generated, with either targeted deletion of DJ-1 exon 2 or a stop codon inserted in exon 1. Both strategies failed to induce DA degeneration. However, one line showed an increased vulnerability to MPTP which could be reversed by viral-mediated expression of wild-type DJ-1.

Spontaneous in-frame deletion of UCH-L1 exons 7 and 8 leads to gracile axonal dystrophy (gad) in mice. These gad mice display tremor and ataxia due to axonal degeneration of motor and sensory neurons together with the accumulation of β-amyloid and ubiquitinated proteins. Expression of human mutant UCH-L1 (I93M) on a gad background led to a moderate loss of DA neurons in the SNc and DA in the striatum.

The justified disappointment in view of the lack of robust DA neurodegeneration in most transgenic models should be tempered by the fact that these models offer the opportunity to study molecular interactions between genes and pathways involved in the pathophysiology of PD. Also, understanding how mice can cope with genetic alterations that cause PD in humans will be a unique chance to explore future neuroprotective strategies.

Viral-Based Models

Viral-mediated expression of human α-synuclein (WT or A53T) has been shown to induce the formation of cytoplasmic inclusion, neuritic pathology and neurodegeneration in both rats and primates. Interestingly, this approach has been used to demonstrate the neuroprotective role of parkin in α-synuclein-induced DA degeneration. Thus viral-based models appear suitable to study the molecular mechanisms of α-synuclein-induced DA neurodegeneration and to test neuroprotective strategies but would now require much more attention that they have so far.

Conclusion

Currently available animal models of PD have lead largely to a better understanding of PD pathophysiology and pathogenesis as well as provide clues to novel targets for to the development of new or improved neuroprotective drugs. With regard to the development of symptomatic treatments, the MPTP primate models appear as mimicking more and more closely the human condition and represent therefore the gold standard for validating any symptomatic strategy. However, none of the currently available models reproduce the progressive loss of DA neuron that is characteristic of human PD. PD is a chronic and progressive disease whereas the numerous animal models at our disposal are produced either by acute lesion or by semichronic intoxication and thus, only offer stable models of nigral lesion. Transgenic models allow addressing complementary aspects of PD and will be important in understanding the aetiology and progression of PD. Although no perfect animal model of PD exists yet, future models could include a combination of both neurotoxin and genetically induced changes considering that both environmental and genetic factors are involved in the pathogenesis of PD. The benefit of this research will not be limited to PD. A clearer understanding of the dynamic process of neurodegeneration – the impact of the death of certain neurones on the entire neuronal system – will shed light on the whole field of neurodegenerative pathologies.

Glossary

Autosomal dominant (AD) – A pattern of inheritance in which an affected individual has one copy of a mutant gene and one normal gene on a pair of autosomal chromosomes. Individuals with autosomal dominant diseases have a 50–50 chance of passing the mutant gene and therefore the disorder on to each of their children.

Autosomal recessive (AR) – In order for an individual to be affected, an individual must have two copies of the mutated gene (or carry two alleles with different mutations in the same gene). An individual carrying a single altered gene will himself/herself not be affected, but, when two carriers of the same altered gene have offspring, there is a 25% chance of an affected child.

Haplotype – The combination of alleles at several loci on a single chromosome – a set of closely linked genes or DNA polymorphisms inherited as a unit.

Linkage analysis – Genetic loci on the same chromosome are physically connected and tend to stay together during meiosis and are thus genetically linked. Alleles for genes on different chromosomes are usually not linked, due to independent assortment of chromosomes during meiosis. Linkage analysis is a gene-discovery technique that traces patterns of heredity in large families with apparent mendelian inheritance, in an attempt to locate a disease-causing gene mutation by identifying traits that are coinherited (which cosegregate) with it.

Single nucleotide polymorphism (SNP) – SNPs are markers that are randomly, but not evenly, spaced throughout the genome, making it possible to scan the genome for differences between cases (individuals affected by a given complex disorder) and controls (unaffected individuals). Statistical analyses of differences in the occurrence of particular SNPs between cases and controls are done to determine the loci of putative risk factor genes. SNPs are not typically mutations in risk factor genes themselves, but are simply nearby, and as such, are markers for risk of disease, though they do not contribute to risk of disease themselves per se.

Genetic Overview

PD was noted to have a familial component, as early as 1880. The discovery of Mendelian mutations in *α-synuclein* and subsequently, other genes, was a major step forward that revolutionized beliefs regarding PD etiology. Epidemiological surveys suggest that although PD beginning at age < 50 years is highly genetic, the later the onset of disease, the less so. However, longitudinal evaluation of twins with late-onset PD, via 18F-dopa positron emission tomography, suggests that cross-sectional studies may overlook presymptomatic disease. These data support the idea that the contribution of genetics to parkinsonism, including PD, may be greater than appreciated. Indeed, blood relatives of affected individuals are at a 3–4-fold increased risk for PD compared to the general population.

Disorders with a heritable component can be categorized as either Mendelian (causal) or non-Mendelian (complex). Mendelian gene variants are responsible for a small fraction of all PD (perhaps 5%). However, causal genes for PD have taught us a great deal regarding the biological pathways leading to PD and other neurodegenerative disorders. For example, it is now known that Lewy bodies stain with α-synuclein and ubiquitin antibodies. Identification of α-synuclein mutations that are causal in familial PD and the presence of this protein in pathological deposits not only in brain sections from individuals with PD but also from individuals with other parkinsonian disorders emphasize the biological importance of traditional gene discovery in research to understanding the pathogenesis of PD.

While pathological studies link typical PD to α-synuclein, there are cases of PD that do not demonstrate synuclein pathology. This point emphasizes that PD is not due to a single molecular abnormality, but rather, is a final clinical manifestation of diverse processes. It is believed that most PD is caused by multiple genetic and environmental factors, most remaining unknown. This situation places PD squarely in the category of complex human disorders (which also include Alzheimer's disease (AD), stroke, and many other disorders). Advances in technology have driven the advent of high throughput genetic studies designed to address challenges of understanding complex disease, which in turn are hoped to identify pathways and targets for therapeutic intervention. Genome-wide association studies (GWAS) allow inroads into this effort, and PD is among the first disorders

with biospecimens linked to phenotypic and SNP data to support high throughput approaches designed to discover genetic risk factors.

Mendelian Parkinson's Disease (PARK 1–13)

PARK1/α-Synuclein (SNCA)

In 1996, genetic linkage to chromosome 4q was found in a large Italian family (the 'Contursi kindred') with apparent autosomal dominant (AD) Lewy body PD. The following year a causal mutation was found in the α-synuclein gene (*SNCA*), A53T. Surprisingly, the mutation in humans is the normal sequence in mouse; thus, the pathogenic mutation is 'revertant.' A fragment of α-synuclein (also known as 'nonamyloid component of plaques,' or NACP) was previously described in Alzheimer's disease. The role of NACP in this latter neurodegenerative disease, however, remains largely unknown. The normal function of α-synuclein is also unknown. The gene is a member of a gene family reported to control inhibition of phospholipase D2 selectively and has a role in regulating synaptic transport of vesicles and/or plasticity. It has been suggested that pathogenic mutations may inhibit these functions. In vitro data suggest that the mutant protein is prone to fibrillogenesis, which may be the key feature leading to Lewy body formation.

The A53T mutation is almost fully penetrant (i.e., PD is seen in almost all of those who carry it). Most affected individuals develop PD by age 45 or younger. However, there is variability in age of onset as well as in other features, suggesting modifying genes or environmental factors. For example, one mutation-bearing individual had no symptoms at age >90 years. Another has only action tremor with no parkinsonism, and a third has clinical and pathologically confirmed dementia with Lewy bodies. The A53T mutation has subsequently been identified in affected individuals in several other families of Mediterranean origin, suggesting a founder effect. In some of these, the phenotype is broader than originally described, and includes myoclonus, severe central hypoventilation, and orthostatic hypotension. A second mutation in SNCA, A30P, is believed to be the cause of PD in a family of German origin. Moreover, genetic variability in the α-synuclein haplotype has been shown to be a risk factor for apparently sporadic PD, underscoring the biological importance of SNCA in this complex disorder.

An *α-synuclein* triplication has been reported in a large North American family (the Iowa kindred, also known as the Spellman–Muenter and Waters–Miller kindreds). This family was originally linked to another region on chromosome 4 termed PARK4. The clinical and pathological features range from PD to DLB. The age of onset in this family is usually in the fourth decade, ranging from the third to the sixth decade. These data and other data suggest that genetic variability in the *SNCA* promoter contributes to PD risk. They also support the growing body of literature suggesting that the difference in mutant α-synuclein from wild-type is quantitative rather than qualitative. Finally, the data suggest the disease process in this family is conceptually similar to the occurrence of Alzheimer's disease in Down syndrome, where overexpression of a gene (APP), is the key event.

Transgenic *α-synuclein* models have been created. Mice lacking this gene have functional deficits in the nigrostriatal system. Some groups report α-synuclein pathology in *α-synuclein* transgenic mice, while others see no changes. Transgenic *Drosophila melanogaster* cannot climb properly, and have intracellular inclusions resembling Lewy bodies in some dopaminergic neurons. Because of its relationship to idiopathic PD pathogenesis via Lewy bodies, it is hoped that these and other genetic models will reveal pathogenic mechanisms that provide therapeutic trial substrates for PD.

PARK2/Parkin

Autosomal recessive (AR) juvenile parkinsonism (ARJP) was linked to 6q25–27 in 1997. Compound mutations and homozygous deletions of the parkin gene were subsequently reported. Since then, parkin mutations have been found to be responsible for a wide phenotypic range, including clinical features identical to idiopathic PD. Those with ARJP typically develop parkinsonism before age 40; dystonia, especially foot dystonia, may be prominent. Additional features include insidious progression, sustained levodopa response, early and severe levodopa-induced motor complications, diurnal symptom fluctuations, sleep benefit, and hyperreflexia. Pathological studies have demonstrated highly selective degeneration of dopaminergic neurons in the SNpc and the locus coeruleus, classically without Lewy bodies or tau positive staining tangles (see below).

Parkin is a component of a multiprotein E3 ubiquitin ligase complex involved in the targeting of substrate proteins for degradation by a proteosomal mechanism. The phenotype associated with parkin mutations appears to be due to partial, if not complete, loss of function of the parkin protein. Most affected individuals described to date have either a homozygous deletion or compound point mutation and deletion, although in several small kindreds, only heterozygous mutations (affecting one allele of the gene) have been found. A case report showed parkin mutations to be associated with typical Lewy body PD, implying a connection between parkin and synuclein. This, along with a report suggesting that α-synuclein is a substrate for parkin, is further evidence that the ubiquitin pathway is part of the pathogenic pathway for idiopathic disease. In addition, parkin mutations have been found to be associated with tau pathology (the causal gene in

frontotemporal dementia with parkinsonism linked to chromosome 17), suggesting that parkin may be involved in multiple pathogenic routes to parkinsonism.

PARK3/Chromosome 2P

A susceptibility locus for apparent AD PD on chromosome 2p13 occurs in some families of northern European descent. The identity of this gene is not yet known. Penetrance is 40% or lower. The age of onset is in the fifth decade or later, like sporadic PD, and displays typical PD progression. Postural tremor and dementia are detected in some individuals, either in isolation, or with the PD phenotype. Postmortem data revealed pathological findings similar to those of sporadic PD in an affected individual. Finally, a genome-wide linkage analysis in a population of affected relatives (mainly affected sibling pairs) participating in a large study (GenePD) revealed that the 2p locus may be in linkage disequilibrium with a mutation influencing PD susceptibility or age at onset of PD.

PARK4/Chromosme 4P (See PARK 1)

PARK5/Ubiquitin Carboxyl-Terminal Hydrolase L1

A putative mutation in exon 4 of the ubiquitin carboxy-terminal hydrolase (UCHL1) gene was noted in an affected sib-pair with probable PD and apparent AD inheritance. Further implicating UCHL1 dysfunction in PD, case–control association studies suggest that a common variant in the UCHL1 gene, S18Y, might be protective. UCHL1 is found throughout the brain, and immunoreactivity for this protein is seen in Lewy bodies. Furthermore, like parkin (see above), it is involved in the ubiquitin-dependent pathway of proteolysis. Since the pathogenesis of PD may be related to abnormal aggregation of α-synuclein protein, which is degraded via this pathway, this fits with of PD pathogenesis involving synuclein.

PARK6/PINK1

A consanguineous family from a genetically isolated community in the southwestern region of the Netherlands has four individuals with a form of early-onset PD (PARK6). The onset of symptoms is < 40 years, and, in addition to features of PD, some subjects showed psychiatric symptoms, including psychotic episodes but no other atypical features. The causal gene is a mutation in PTEN-induced putative kinase 1 (*PINK1*). *PINK1* encodes a protein associated with mitochondrial membranes and cytoplasm and contains a putative serine-threonine kinase domain. The PINK1 protein is thought to protect against cellular, particularly oxidative, stress.

PARK7/DJ-1

A unique single kindred with early-onset parkinsonism from a genetically isolated community in the Netherlands showed evidence of linkage to chromosome 1p36. Because the disease haplotype was separated by at least 25 cM from the PARK6 locus, it was designated as a discreet locus (PARK7), and mutations in DJ-1 were subsequently found to segregate with disease. Like PINK1, PARK7 (DJ-1) localizes to mitochondria, cytoplasm, and nucleus. Also like PINK1, it is a putative neuroprotectant against oxidative stress. No DJ-1 mutations were found in a screen of 118 familial and 7 sporadic PD subjects from Europe, South America, Lebanon, Asia, Turkey, and North Africa (age at onset 12–78 years), suggesting that it is not a common cause of familial PD.

PARK8/LRRK2/Dardarin

A large family from Western Nebraska, in which 18 members spanning six generations had slowly progressive apparent AD with PD, showed linkage to chromosome 12.2q, designated PARK8. Pathological examination revealed Lewy body pathology in some but not all, and in some, tau pathology occurred alone or in combination with Lewy body pathology. Linkage to the PARK8 locus was also reported in a Japanese family. In 2004 mutations in the Leucine-Rich Repeat Kinase 2 (LRRK2) gene were reported in both the Japanese and US PARK8 families. In parallel, families of English and Basque ancestry were also discovered to harbor mutations in the LRRK2 gene, and named the relevant protein dardarin, derived from the Basque *dardara*, meaning tremor. LRRK2 mutations have variable penetrance.

The G2019S mutation is the single most prevalent pathological mutation identified in LRRK2 and is the most prevalent known genetic cause of PD, accounting for ∼3–6% of familial and 1–2% of sporadic cases of PD among Europeans and North Africans. The G2019S mutation has a geographic gradient, being highest in North African and Southern European, less so in Northern European, and very low in Asian populations. However, in Asia, other LRRK2 mutations are more common (e.g., G2385R, R1628P). The prevalence of G2019S in LRRK2 in Ashkenazi Jewish subjects with PD ranges from 12–29.7%.

Haplotype data suggests at least three different founder events; one shared by Europeans and North Africans, one associated with the Jewish diaspora, and a third associated with Asian populations.

LRRK2 belongs to the Roco gene family and has a complex structure including two domains characteristic of this family: a Ras-like GTPase domain called Roc and a C-terminal domain of unknown function called COR. LRRK2 also contains a leucine-rich repeat, a kinase domain, an Andrin repeat, and a WD40 domain. The protein is present in the cytosol and the outer mitochondrial membrane. Northern blot analysis detected a ubiquitously expressed 9-kb mRNA transcript, including in the brain. How mutations in LRRK2 lead to PD is unknown.

PARK9/Kufor–Rakeb Syndrome

This AR form of parkinsonism, Kufor–Rakeb syndrome, does not cause typical PD, and therefore is beyond the scope of this chapter. For a further clinical description see Williams et al., and for a discussion of the gene discovery see Ramirez et al.

PARK10

A genomic screen for linkage to age of onset in Alzheimer's and Parkinson's disease identified evidence for linkage of age of onset of PD to chromosome 1p. A microsatellite marker-based screen of an Icelandic population including 117 subjects with typical late-onset PD and 168 of their unaffected relatives from 51 families demonstrated linkage to chromosome 1p32. Further analysis yielded a lod score of 4.9 near marker D1S2652 within a 7.6-cM segment, subsequently designated PARK10. The specific gene affected in PARK10 is not yet known.

PARK11

Using affected sib pairs, and subsequently, other families with PD with apparent AD transmission, linkage to 2q36–q37 was found and designated PARK11. In a genome-wide association study including 443 sib pairs discordant for PD and 332 case-unrelated control pairs, one of the SNPs studied tagged PARK11. PARK11 is due to mutations in the GIGYF2 gene, with 7 different heterozygous mutations discovered in 12 unrelated French and Italian families with typical PD. The GIGYF2 gene (Grb10-Interacting GYF Protein 2) is also known as TNRC15 (Trinucleotide Repeat-Containing 15). The function of this protein is unknown.

PARK12

Using a cohort of 160 multiplex PD families who had screened negative for parkin mutations, and then enriching that sample via specified additional clinical criteria, a locus on the X chromosome was identified, designated PARK12. Follow-up studies have also found linkage Xq21–25. The associated gene is unknown.

PARK13

PD 13 (PARK13) was discovered in four German subjects with typical PD, and is caused by a G399S mutation in the serine protease HTRA2. Age at disease onset ranges from 49 to 77 years. Heterozygous carriers of the A141S mutant allele also had typical PD findings. Immunohistochemistry and functional analysis in stably transfected cells revealed that G399S mutant HTRA2 and to a lesser extent the A141S risk allele polymorphism induced mitochondrial dysfunction associated with altered mitochondrial morphology. Cells overexpressing G399S mutant HTRA2 were more susceptible to stress-induced death than were wild-type cells.

Other Mendelian Disorders Associated with PD

Spinocerebellar Ataxias

PD has been described in several of the spinocerebellar ataxias (SCAs), particularly in SCA2 and SCA3, both of which are due to different trinucleotide expansions. Expansions in SCA2 are causal for ~10% of familial but otherwise typical PD cases in ethnic Chinese, and are also found in American Indian patients, but are extremely rare as a cause of PD in Caucasians. SCA3 may be more likely to cause typical PD in those of ethnic African origin than in Caucasians. Testing is commercially available. It is notable that the PD phenotype for both SCA2 and 3 may be more common in those with intermediate-range repeat numbers; this narrow range requires precise determination of repeat size, which is not done by all diagnostic laboratories. Therefore, when ruling out SCA2 and SCA3 as a cause of PD, it is important that methods which accurately assess the repeats in this intermediate, borderline range be used.

Gaucher Disease

Gaucher disease is an AR lysosomal storage disorder due to deficient activity of β-glucocerebrosidase. An association has been reported between typical PD and type I Gaucher disease.

Wilson's Disease

This AR disease results in systemic copper deposition, especially in brain and liver. Classic PD or parkinsonism with atypical features may occur. The presence of hepatic, extrapyramidal, or mood disorders in relatives of a patient with PD should lead to evaluation for Wilson's disease, since treatment is highly effective. The causal gene a copper-transporting P-type adenosine triphosphatase (ATPase). Many mutations are responsible for disease, making genetic testing impractical. However, screening with serum ceruloplasmin, 24-h urinary copper, and slit lamp examination are straightforward.

Huntington's Disease

Huntington's disease is an AD movement disorder with full penetrance, whose wide range of phenotypes can include parkinsonism, and rarely, typical PD. It is due to a CAG (polygutamine) repeat expansion in the *huntingtin* gene on chromosome 4p16.3, with abnormal being >40 repeats. Testing is commercially available.

Genome-Wide Association Studies (GWAs) in PD

In contrast to Mendelial (familial) PD, the etiology of apparently sporadic PD remains unknown. An extensive

literature exists both claiming and disputing putative risk genes for sporadic PD including both candidate gene studies and GWAS. However, meta-analyses of most of the polymorphisms genotyped in these studies provide little or no evidence for significant association of any marker with sporadic PD, and illustrate the need for larger-scale, unbiased genomic screens in the disease. GWAS are an approach that has been proposed and used to address this need.

Assessing the association between SNPs and disease phenotypes has become increasingly used towards the goal of discovering alleles predisposing to complex disorders. In contrast to family linkage-based methods and candidate gene approaches, which identify presumed causal genes, GWAS seek to detect genetic variants that only modestly contribute to disease susceptibility. It is currently believed that GWAS in most complex disorders are likely to require at least a thousand or more cases and control samples each to have adequate power. GWAS typically scan between 300 000 and 600 000 SNPs, which serve as surrogate markers for neighboring genetic variation.

The first GWAS in PD (known as the 'LEAPS' study) genotyped ~200 000 SNPs in two US cohorts of mostly European descent. Although a combination of tier 1 and 2 analyses identified 13 SNPs significantly associated with PD, none of these SNPs retained significance following Bonferroni correction. Furthermore, the findings of LEAPS failed replication by a number of other groups, suggesting that the results may have been false positives due to inadequate sample size. Meta-analyses, made possible by the posting of GWAS data to a public access database (dbGaP, see http://www.ncbi.nlm.nih.gov/gap), did not identify any SNPs significantly associated with PD after corrections for multiple testing.

This and other PD GWAS suggest that the effect size of genetic determinants for sporadic PD is relatively small (i.e., odds ratios of less than 2), since effect sizes larger than this would have probably been detected. Furthermore, it is clear from these studies that there is not likely to be any single common genetic variant in PD with an effect on disease risk comparable to APOE-4 in Alzheimer disease. However, additional GWAS in larger cohorts have begun. For example, two family-based GWAS are being combined ('PROGENI' and '*Gene*PD') resulting in a sample size of more than 1000 PD families. Unlike preceding studies, this study will be based on cases with a family history of PD, possibly enriching the sample set for gene discovery. The first study resulting from this collaborative effort is a candidate gene study of the *MAPT* (*tau*) gene, which found that the H1 haplotype of the *MAPT* region, as well as a novel H1 subhaplotype, are significantly associated with PD. Mutations in this gene are known to be causal for AD parkinsonism (Frontotemporal dementia with Parkinsonism linked to chromosome 17, FTDP-17) and *MAPT* alleles have previously been implicated as risk factors for progressive supranuclear palsy (PSP). Intriguingly, in contrast to PSP and FTDP-17, PD is not typically characterized by a neuropathology of abnormally aggregated tau protein; therefore, it will be interesting to see how tau function influences PD biologically.

Future Directions

Genetics has revolutionized neurological research. In concert with neuropathology, neurogenetics helps us understand the biology of the disease. Characterization of the protein products of genes associated with PD, including those yet to be discovered, their interactions, and the biochemical mechanisms affected, will direct future studies of therapeutic targets and gene–environment interactions.

Many known genetic loci causal for PD are incompletely penetrant. Further, the clinical manifestations of PD are not seen until over 70% of nigral neurons are destroyed, causing an ascertainment bias against detection of disease. It follows that twin studies may not show the level of concordance one would expect for a disease with a significant genetic component. This concept has therapeutic implications, since interventional strategies would ideally be used before that symptomatic threshold is reached. In the future, genetic factors may play an important role in early, even presymptomatic detection of PD. Additionally, disease due to Mendelian causal genes have phenotypic variations within and across kindreds. This suggests that genetic factors in *cis*, *trans*, and environmental factors influence phenotype (including age of onset, rate of progression, and manifestations of symptoms). Epigenetics, copy number variation, and environmental studies are important future directions in the study of PD genotype/phenotype.

Clues to the biological process underlying PD were revealed with identification of α-synuclein mutations. The subsequent identification of this protein in Lewy bodies suggests that PD due to α-synuclein mutations may share pathogenic mechanisms with idiopathic PD. Other gene discoveries suggest that the process leading to PD may include a synuclein–ubiquitin pathway to cell death, and oxidative stress pathways.

GWAS are increasingly being used for the discovery of common genetic risk factors of small influence in apparently sporadic, complex diseases. While initial studies are exciting, the true utility of this approach generally awaits to be borne out. Alternatively, other strategies based on new technology, or optimization of existing technology (e.g., resequencing) may evolve and replace GWAS as the high throughput method of choice.

PD in general is likely to depend on molecular features for accurate diagnosis in the future, because clinical features alone are not likely to accomplish biologically meaningful categorization needed for truly interventional treatments.

We must identify additional genetic factors, learn how the biological products interact, and also identify modifying environmental factors. A systematic approach will be the key to our developing preventative strategies for PD and related neurodegenerative syndromes. While current therapies are palliative, the aim of studying the genetics of neurodegenerative disease is to supplant palliative therapies with therapies aimed at pathogenesis, which are germane to impacting the course of the disease.

Acknowledgments

RC is supported by HHSN271200800033C (NINDS-NIH). We are grateful to the many patients and their families who have contributed to medical research by not only the authors but also by many others. Thanks to Sage Begolly for expert assistance in preparation of the manuscript.

Paroxysmal Exertion-induced Dyskinesia

S D Spacey, University of British Columbia, Vancouver, BC, Canada

Glossary

Dyskinesia – Excessive abnormal involuntary movements including chorea and dystonia.

Definition and History

The definition, classification, and names of the paroxysmal dyskinesias have changed over the years. This has been primarily due to the evolution of genetics and molecular

biology, which has allowed for the clarification of phenotypes and the identification of the underlying genes.

In the past, the paroxysmal dyskinesias have been categorized into four groups based upon triggers or precipitating factors. Paroxysmal kinesigenic dyskinesia (PKD) is induced by sudden movements, startle, or changes in velocity. Paroxysmal nonkinesigenic dyskinesia (PKND) is not triggered by movement or exercise, but can be triggered by alcohol and caffeine. Paroxysmal hypnogenic dyskinesia (PHD) arises out of sleep, and is now referred to as autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). Paroxysmal exertion induced dyskinesia (PED) is precipitated by 5–15 min of physical exertion. Although the term 'paroxysmal exercise induced dyskinesia' is most commonly used in the literature, the term 'paroxysmal exertion induced dyskinesia' is also used to describe the same condition.

Pathogenesis and Pathophysiology

While PED is characterized by dyskinesias triggered by prolonged exercise, PED can be associated with a broader phenotype of epilepsy, developmental delay, migraine, and hemolytic anemia with echinocytosis. In the majority of cases (although not all), this complex phenotype is associated with mutations in the *SLC2A1* gene, which encodes for the glucose transporter GLUT1. Many different mutations within the *SLC2A1* gene have been associated with the complex PED phenotype.

Functional studies in oocytes of the GLUT1 protein, the main transporter for D-glucose across the blood–brain barrier, have demonstrated marked reduction of glucose uptake. The mutations affected the intrinsic ability of GLUT1 to transport glucose across the cell membrane by reducing the maximum transport velocity. It is hypothesized that PED can be caused when the energy demand of the brain overcomes its supply after prolonged periods of exercise. The basal ganglia, an important area in the generation of dyskinesias, are particularly sensitive to hypoxia and energy deficits.

Epidemiology/Risk Factors

This condition is rare. There have been nine autosomal dominant PED families described, and penetrance is incomplete in this familial condition. Approximately 20 sporadic cases have been reported in the literature. Secondary causes of PED have been described and include, a case of posttraumatic PED involving a lower limb, a case of PED associated with hypoglycemia induced by an insulinoma, and moyamoya disease presenting with PED.

Clinical Features and Diagnostic Criteria

Onset is typically in child hood or adolescents (9–15 years) in the familial forms, and older onset has been reported in sporadic cases. Attacks are precipitated by prolonged walking (5–15 min), or other strenuous exercise such as lifting or chewing. The attacks range in duration from 5 to 30 min, and typically involve the region of the body active during the prolonged exercise, for example the hand after handwriting or the jaw after chewing. Most commonly, however, the attack is seen in the legs, and the attacks are typically dystonic and symmetric but asymmetrical unilateral attacks involving an arm and leg are described. The symptoms dissipate after rest, and patients may describe a prodrome of sensory symptoms in the limb prior to attack.

Differential Diagnosis

Any cause of dyskinesia should be considered as part of the differential diagnosis. Sporadic causes of paroxysmal dyskinesias include lesions of the basal ganglia caused by multiple sclerosis, tumors, and vascular lesions. Paroxysmal dyskinesias can be seen in association with rheumatic fever (Sydenham's chorea), systemic lupus erythematosus, diabetes mellitus, hypoparathyriodism, pseudohypoparathyroidism, and thyrotoxicosis. Chorea gravidarum can present with paroxysms of chorea in the first trimester of pregnancy, and usually resolves after delivery. Focal seizures can present with paroxysms of dystonia.

There are a number of hereditary conditions that can present with paroxysmal dyskinesias these include:

1. Paroxysmal nonkinesigenic dykinesia: characterized by unilateral or bilateral dyskinesias lasting minutes to hours in duration which can occur spontaneously or can be precipitated by alcohol, coffee or tea, excitement, stress, fatigue, or chocolate. Attacks do not commonly occur more than once per day, and age of onset is usually in childhood or early teens.
2. Familial PKD: characterized by unilateral or bilateral involuntary dyskinesias precipitated by sudden movements such as standing up from a sitting position, being startled, or changes in velocity. Attacks can be as frequent as 100 per day to as few as one per month. Attacks are usually a few seconds to 5 min in duration but can last several hours, and age of onset is typically in childhood and adolescence.
3. PHD: this condition now goes by the name 'autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE).' Attacks associated with PHD/ADNFLE range markedly, but include dystonia, chorea, and ballism. The episodes generally occur during Non Rapid Eye Movement (NREM) sleep. Individuals are able to recall the episodes in the morning. Precipitating factors include increased activity, stress, and menses.

There are a number of other hereditary conditions, which although associated with dykinesias are not typically

paroxysmal in their presentation, these include, Huntington's disease, Wilson's disease, and benign hereditary chorea.

Diagnostic Work Up/Tests

MRI of the brain is required to rule out lesions of the basal ganglia. Fasting serum glucose, TSH, anti-streptolysin O (ASO) titer, ANA, total and ionized serum calcium, magnesium, and phosphate are required to rule out metabolic and reversible causes. Interictal and ictal EEG can be useful in identifying seizures. Serum copper, ceruloplasmin, 24 h urine copper test should be performed for the investigation of Wilson's disease. Although mutations in the *SLC2A1* gene are responsible for the majority of cases of PED, testing is not readily available, and a diagnosis is based on the clinical history and exclusion of other causes.

Management

Typically, individuals with this condition avoid prolonged activity, which triggers the attacks. In three patients who have a demonstrated mutation in the *SLC2A1* gene, a ketogenic diet was effective in reducing their symptoms. One individual who had severe PED (4–5 episodes per day unable to walk >50–100 min without pausing or dystonia) had complete resolution of the PED, and was able to run long distances once ketosis was achieved. The other two patients with mutation suffered from seizures, and were seizure free on the ketogenic diet.

Although the *SLC2A1* mutation affects the ability of the GLUT1 to transport glucose across the cell membrane, an increase in a carbohydrate rich diet and frequent carbohydrate snacks failed to improve symptoms in patients with a *SLC2A1* mutation.

There have been sporadic reports in the literature on the benefits of anticonvulsants, although this does not appear to be a consistent finding. There is a report of improvement of PED with gabapentin. There has been no reported benefit of PED symptoms with levodopa. There is a single report of a patient improving with trihexyphenydil. Most patients tried on acetazolamide had no improvement, but there was a report of one patient improving on this medication.

Prognosis

Although PED can be debilitating in its extreme form, it generally can be prevented by avoiding prolonged activity. In some cases, the PED improves as the individual gets older.

Paroxysmal Movement Disorders

M K Bruno, University of Hawaii, Honolulu, HI, USA

Glossary

Allelic disease – Sometimes, more than one clinical syndrome arises from abnormalities of one gene. These multiple diseases are described as "allelic disease."

Ataxia – An inability to coordinate voluntary muscular movements.

Autosomal dominant – A pattern of inheritance, in which having only one copy of a particular gene mutation (heterozygotes), results in a phenotype. Sex chromosomes are excluded. Individuals with

autosomal dominant diseases have a 50–50 chance of passing the mutant gene and, therefore, the disorder onto each of their children.
Channelopathy – A group of disorders resulting from abnormalities in the flow of certain electrically charged particles (ions, such as calcium, potassium, sodium) across cell membranes.
Dyskinesia – A general term to describe any kind of hyperkinetic involuntary muscle movement. Dyskinesias may resemble other movement disorders, and be dystonic, choreic, ballistic, or occur in combination.
Episodic – Occurring or appearing at irregular intervals.
Idiopathic – Arising spontaneously or from an unknown cause.
Kinesigenic – Triggered by sudden body movements.
Kindred – A genealogical group.
Paroxysmal – Symptoms that occur only in episodes or "attacks," out of blue, suddenly and unpredictably, followed by a relatively rapid return to normal motor function and behavior.
Psychogenic – A term used to describe physical symptoms that are thought to originate in the mind, or from emotional conflict.
Secondary – Disease or state resulting as a consequence of another disease.
Sporadic – When a genetic disease occurs without any family history, it is described as "sporadic."

Definition and History

The majority of movement disorders are either continuous or progressive. In contrast, in paroxysmal movement disorders, sudden short-lived attacks of hyperkinetic involuntary movement attack arise against a background of relatively continuous normal motor behavior/neurological examination. Consciousness is preserved during these attacks. Paroxysmal movement disorders are a heterogeneous group of disorders but can be broadly divided into paroxysmal dyskinesias and episodic ataxias (**Table 1**).

Some movement disorders do have variability and fluctuation. For example, restless leg syndrome and dopa-responsive dystonia fluctuate depending on the time of the day. Task-specific dystonia and action myoclonus can be triggered by certain postures or tasks. Myoclonus and tics can occur intermittently. However, these phenomena/disorders are traditionally not included in the rubric of paroxysmal movement disorders (**Table 2**).

Table 1 Classification of paroxysmal movement disorders

Classification	*Alternative name*
1. *Paroxysmal Dyskinesias*	
Paroxysmal Kinesigenic Dyskinesia/ Choreoathetosis (PKD)	Episodic Kinesigenic dyskinesia 1 Paroxysmal kinesigenic choreoathetosis (PKC) Dystonia 10 (DYT10)
Paroxysmal non-Kinesigenic dyskinesia (PNKD)	Paroxysmal Dystonic Choreoathetosis (PDC) Familial Paroxysmal Choreoathetosis 1 (FPD1) Mount–Reback Syndrome Paroxysmal Dystonic Choreoathetosis of Mount and Reback Dystonia 8 (DYT8)
Paroxysmal Exertion-induced dyskinesia (PED)	Paroxysmal Exercise-induced Dystonia Intermediate form of paroxysmal dystonic choreoathetosis
Paroxysmal hypnogenic dyskinesia (PHD)	Paroxysmal nocturnal dystonia Nocturnal frontal lobe epilepsy Autosomal dominant nocturnal frontal epilepsy (ADNFLE)
2. *Episodic ataxias*	
Episodic Ataxia 1 (EA1)	Episodic Ataxia with myokymia Paroxysmal ataxia with neuromyotonia
Episodic Ataxia 2 (EA2)	Episodic ataxia with nystagmus Acetazolamide-responsive hereditary paroxysmal cerebellar ataxia (APCA)
Episodic Ataxia 3 (EA3)	Episodic ataxia with vertigo and tinnitus
Episodic Ataxia 4 (EA4)	Periodic vestibulo-cerebellar ataxia (PATX)
Episodic Ataxia 5 (EA5)	
Episodic Ataxia 6 (EA6)	
Episodic Ataxia 7 (EA7)	
3. *Miscellaneous*	
Paroxysmal torticollis of infancy	
Paroxysmal tonic upgaze of childhood	
Sandifer's disease (also in **Table 2**)	

Paroxysmal Dyskinesia

Paroxysmal dyskinesias are a heterogeneous group of disorders characterized by intermittent attacks of hyperkinetic involuntary movements. The abnormal involuntary movement can be choreic, ballistic, dystonic, or a combination thereof. Hence, the more general term "dyskinesia" is preferred. The most widely used classification divides paroxysmal dyskinesia into four categories based on triggers and characteristics of the attacks; paroxysmal kinesigenic dyskinesia (PKD), paroxysmal non-kinesigenic dyskinesia (PNKD), paroxysmal exertion-induced dyskinesia (PED), and paroxysmal hypnogenic dyskinesia (PHD). However,

Table 2 Conditions that can manifest to intermittent involuntary movements, but not considered to be ''paroxysmal movement disorders''

Action dystonia
Action myoclonus
Action/intention tremor
Cataplexy
Complicated migraine
Dopa-responsive dystonia
Drug-induced dyskinesias
Epilepsy
Hyperekplexia
Myotonia
Periodic movements in sleep
Periodic paralysis
Restless legs syndrome
Sandifer's disease
Streotypies
Task-specific Dystonia
Tetany
Tics
Transient ischemic attack (limb-shaking TIA)

this classification may need to be refined when genetic discovery is made. PKD and PNKD constitute the majority of cases. Pure PED is rare, and possibly a subset of PNKD. PHD is now thought to be a form of frontal epilepsy. Paroxysmal dyskinesia can be either idiopathic or secondary. Idiopathic cases can be familial or sporadic, and some of the sporadic cases can be psychogenic.

History

Gowers is credited for reporting the first case of paroxysmal dyskinesia in 1885; he reported two patients who had "movement-induced" seizures. However, both patients had atypical features, so it is unclear whether these cases represented true movement disorders. Subsequent to Gowers, in early to mid-1900s, various case reports described extrapyramidal epilepsy, striatal epilepsy, subcortical epilepsy, reflex tonic epilepsy, and movement-induced seizures, where patients had attacks of tonic contraction, sustained twisting, athetosis and chorea, without impairment in consciousness. As the name implies, these earlier reports considered the attacks to be related to epilepsy.

In 1940, Mount and Reback wrote a seminal paper reporting a family with involuntary movement attacks (chorea and athetosis), lasting from 10 min to a few hours. The condition was inherited in an autosomal fashion, with onset in infancy or early childhood. The attacks were precipitated by caffeine, alcohol, stress, and exertion. Mount and Reback called this condition "familial paroxysmal choreoathetosis", implying extrapyramidal origin.

In 1967, Keresetz first used the word "kinesigenic" (caused by movement) to describe 10 cases of paroxysmal kinesigenic choreoathetosis (current PKD). The term "kinesigenic" became a very useful label, as kinesigenic trigger is so characteristic in this condition.

In 1977, Lance wrote an important review paper. He tried to unify various intermittent involuntary movement attacks under the term "paroxysmal dystonic choreoathetosis." He classified this condition into three categories:

1. prolonged attacks,
2. intermediate form,
3. brief attacks.

Following this tradition, in 1995, Demirkiran and Jankovic reclassified paroxysmal dyskinesias into PKD, PNKD, PED and PHD. They proposed to use the term "dyskinesia" because the involuntary movements during an attack is often not witnessed by a physician to determine the exact movement type, and even in the witnessed case, tend not to fit into the strict definition of chorea, athetosis, dystonia or ballism. Demirkiran and Jankovic's nomenclature is currently the most widely used.

In 1991, the first channelopathy was discovered; hyperkalemic periodic paralysis was found to be caused by an abnormality in the sodium channel gene. Channelopathy became an attractive mechanism to explain various episodic neurological diseases, including epilepsy, migraine and paroxysmal movement disorder. With the advancement of linkage analysis technique, various researchers have been attempting to identify the genetic abnormalities of paroxysmal dyskinesia. This will be further discussed in the pathophysiology section.

Episodic Ataxia

Episodic ataxias are characterized by recurrent spells of incoordination and imbalance. The episodic ataxia can also be primary (idiopathic) or secondary. Currently, at least seven episodic ataxia syndromes have been described in Online Mendelian Inheritance of Man (OMIM) based on the genetic characteristics, but the majority of cases are either EA-1 or EA-2.

History

Parker described 6 patients in 4 families with idiopathic familial ataxia in 1946. The attack consisted of gait ataxia and dysarthria, and ranged from 30 s to 30 min. Subsequently, multiple families have been reported, with varying manifestations of episodic ataxia. Unlike PKD, subtle abnormality in the baseline neurological examination was noted; in one group, myokymia and in another, nystagmus. In 1986, Gancher and Nutt classified the hereditary episodic ataxias into three groups;

1. episodic ataxia associated with persistent myokymia and neuromyotonia;
2. episodic ataxia associated with interictal nystagmus (and clinically very responsive to acetazolamide);
3. episodic kinesigenic ataxia.

The discovery that abnormality in potassium channel gene accounted for EA1 (1994), and calcium channel gene for EA2 (1995), altered the classification scheme, and now classification is based on genetics. Episodic ataxia with myokymia and episodic kinesigenic ataxia are now both classified under EA1, and episodic ataxia with interictal nystagmus is now classified as EA2.

Miscellaneous

There are few pediatric conditions, which are sometimes classified under paroxysmal dyskinesias: Paroxysmal torticollis of infancy, paroxysmal tonic upgaze of childhood and Sandifer's syndrome. Sandifer's syndrome is characterized by head tilt after a large meal, caused by large hiatal hernia. Historically, Sandifer's syndrome has been listed both under paroxysmal movement disorders and under conditions that should not be included in paroxysmal movement disorders (**Table 2**). All of these conditions are self-limiting, and disappear after childhood; they will not be further discussed in the text.

Pathogenesis and Pathophysiology

Paroxysmal Dyskinesia

The pathogenesis of paroxysmal dyskinesia remains a controversy as to whether it is epileptic or extrapyramidal phenomena. These two views may not be mutually exclusive, however. From the time of Gowers, paroxysmal dyskinesia has been suspected to be "epilepsy of the basal ganglia".

Physiological studies and functional neuroimaging

Electroencephalogram readings are normal in the majority of cases (except for PHD, which is now thought to be a frontal epilepsy), even when recorded during attacks. There are some reports of abnormal EEG, but the abnormalities are generally nonspecific. One study attempted invasive EEG monitoring in a patient with PKD and demonstrated discharge from the caudate nucleus and supplementary motor cortex; the authors speculated abnormality in the basal ganglia circuit could be responsible for PKD.

Ideally, functional neuroimaging study would aid in elucidating the pathophysiology; the reported results generally suggest abnormality in the basal ganglia region (**Table 3**). However, only 1 or 2 patients are studied in each study and some studies report hypoperfusion, whereas other studies report increased perfusion, thus results are inconclusive and do not give a uniform explanation of pathophysiology.

Other neurophysiological studies reported include measurement of Bereitschaftspotential, continent negative variation, startle reflex and trans-magnetic stimulation studies, but the results are not replicated and are difficult to interpret or generalize.

Molecular genetics (Table 4)

The molecular genetics of paroxysmal movement disorder is a rapidly growing field, leading to advances but simultaneously some confusion of the classification and nomenclature. As in other area of movement disorders, the question is; should classification be done based on molecular genetics, or based on clinical phenomenology? At the chemical basis of pathogenesis, channelopathy is

Table 3 Summary of PET and SPECT studies in patients with paroxysmal dyskinesia

	Interictal SPECT and PET	*Ictal SPECT*
PKD	Hypoperfusion in the posterior caudate (16) Normal FDG PET (2)	Increased perfusion in posterolateral thalamus (1) Hypoperfusion in supplementary motor cortex. Sensorimotor cortex and pallidum was hyperperfused in one, but hypoperfused in the other (2) Increased perfusion of the contralateral basal ganglia (1) Hypoperfusion of contralateral basal ganglia (1) Hypoperfusion of contralateral caudate nucleus (1)
PNKD	Normal C-raclopride PET (1) Nomral FDG PET, but decreased presynaptic dopa decarboxylase activity in the striatum and increased density of postsynaptic dopamine D2 receptor based on 18FDOPA PET and C-raclopride PET (1)	
PED		Decreased perfusion in the frontal cortex and basal ganglia, and increased perfusion in the cerebellum, resembling pattern of dystonia (2)
Secondary	low metabolism of basal ganglia (1 patient with post-trauma)	increased activity in bilateral caudate (1 patient with subacute sclerosing panencephalitis) hyperperfusion in contralateral frontal cortex and hypoperfusion in contralateral basal ganglia (1 patient with hyperglycemia)

Numbers in parentheses indicate number of patients studied in each report.

Table 4 Summary of genetic abnormality in paroxysmal movement disorders

	OMIM	*Mode of inheritance*	*Chromosome locus*	*Mutated gene*	*Mutant protein*
PKD/ICCA syndrome	128200/602066	AD	16p11.2-q12.1 (EKD1)	Unknown	Unknown
PKD2	611031	AD	Possible second locus on 16q13-q22.1	Unknown	Unknown
PNKD	118800	AD	2q35	MR-1	Has not been determined yet
PNKD2	611147	AD	Possible second locus 2q31	Unknown	Unknown
ADNFLE 1 (PHD)	600513	AD	20q13.2–13.3	CHRNA4	Nicotinic acetylcholine receptor α-4 subunit

suspected to be responsible for the pathophysiology of paroxysmal dyskinesias.

In PKD families, linkage analysis mapped abnormality to chromosome 16p11.2–q12.1. This overlaps with a locus of another syndrome; infantile convulsion and choreoathetosis (ICCA) syndrome. In ICCA syndrome, epilepsy researchers were studying a familial benign infantile seizure syndrome, where seizure remitted after infancy. While taking their history, it was noted that some of the patients, as well as nonaffected family members experienced involuntary movement attacks, which resembled PKD attacks. During the investigation of PKD families, some of the patients, as well as nonaffected family members reported history of self-limited seizures during their infancy. Therefore, PKD and ICCA are now thought to be either the same disease or an allelic disease. The responsible gene has not been identified yet.

The gene responsible for paroxysmal non-kinesigenic dyskinesia (OMIM 118800) was identified on chromosome 2q35, myofibrillogenesis regulator 1 (*MR-1*) gene.

MR-1 itself is not a channel protein and the exact function of *MR-1* is unknown, but it is thought to be related to stress pathways.

Paroxysmal hypnogenic dyskinesia is now thought to be autosomal dominant nocturnal frontal epilepsy (ADNFLE), and at least 3 different genes, with possibility of additional loci are identified. All of the discovered gene abnormalities affect subunits of neuronal nicotinic acetylcholine receptors. In vitro and in vivo studies have shown that neuronal nicotinic acetylcholine receptors are abundantly expressed in the thalamus, and the mutation may cause gain of function; thus over-activating the ascending cholinergic pathway, and in turn enhancing the GABAergic function.

Other single families, with paroxysmal dyskinesia in their constellation of clinical syndrome, have been reported, with associated genetic abnormality (see **Table 4**).

Episodic Ataxia

Molecular genetics (Table 4)

Genetics of episodic ataxias are better elucidated, and shown to indeed be channelopathies. Episodic ataxia type 1 (OMIM 160120) is caused by mutation in the voltage-gated potassium channel (KCNA1) located on chromosome 12p13. In in vitro expression studies, all reported mutations impair voltage-gated potassium channel function, resulting in increased neuronal excitability.

Episodic ataxia type 2 (OMIM 108500) is caused by mutation in the subunit of P/Q type voltage gated calcium channel (CACNL1A4), located on chromosome 19p13. Over 50 mutations have been reported, with the majority of the mutations causing premature stop of the protein. Abnormality in the same CACNL1A gene can also cause familial hemiplegic migraine (FHM) and spinocerebellar 6 (CAG repeat expansion of the gene). These three disorders are allelic diseases, and there is considerable clinical overlap. P/Q type voltage gated channel is abundantly expressed in the Purkinje cells and neuromuscular junction. In EA2, intracellular pH of Purkinje cell is reported to be low. However, exactly how the abnormality in voltage gated calcium channel causes this three condition is still largely unknown. Mouse model with CACNA1A mutation has been developed and it is a subject of intense interest and research.

Other single or rare families are classified as EA3 to EA7 based on their genetic abnormality.

Epidemiology/Risk Factors

The exact incidence/prevalence of paroxysmal dyskinesias and episodic ataxias, is unknown. It is generally thought to be a rare disorder. The Consortium for Clinical Investigation of Neurological Channelopathies has estimated the prevalence of EA 2 to be lower than 1:100,000 population, based on the cases seen by experts in regional centers. However, paroxysmal movement disorders may be underreported in the medical community. If the symptoms are mild, or if patients speculate their diagnosis based on other family history, they may not seek medical attention.

Clinical Features and Diagnostic Criteria

PKD

Attacks of PKD are very brief; a few seconds to a few minutes, usually less than 1 min. The attacks are triggered by sudden movements after a period of rest, such as standing up from a seated position, initiating a stride, or starting a stroke in the pool. There may be a refractory period immediately after an attack. Some patients have multiple attacks a day, up to 100 a day. Many patients report "aura" or premonitory sensation before an attack. The attack can be unilateral, or bilateral, involving face, arm, leg, or combination of them. There is no pain. Onset is usually in early childhood, between 5 and 15 years old. Familial cases are transmitted in autosomal dominant fashion, but some patients with very classic PKD, indistinguishable from those with familial PKD, do not have a family history, and this raises the possibility of de novo mutations, or low penetrance. Some patients and/or non-affected family member may have "benign infantile convulsion."

Based on analysis of over 100 patients, a new diagnostic criterion for idiopathic PKD was proposed in 2004.

1. Identified kinesigenic trigger for the attacks
2. Short duration of attacks (<1 min)
3. No loss of consciousness or pain during attacks
4. Exclusion of other organic disease and normal neurological examination
5. Control of attacks with phenytoin of carbamazepine, if tried
6. Age at onset between 1 and 20 years, if no family history of PKD (this means that PKD diagnosis was unlikely if onset was >20 years old, unless family history exists).

PNKD

Attacks of PNKD are longer compared to PKD, and last a few minutes to a couple of hours. However, the duration of the attack alone does not separate PNKD from PKD, as shorter PNKD attacks are reported. As the name implies, PNKD attacks are not triggered by sudden movements. The precipitating factors include most commonly caffeine and alcohol, but also stress, fatigue, exercise and emotional overexcitement. Aura is reported in about half of the patients. The involuntary movements can be choreic, athetotic, dystonic, ballistic, in any limbs, and speech is

frequently affected. Some patients with PNKD report sleep-benefit; attacks would abort when falling asleep. Familial PNKD is inherited in an autosomal dominant fashion. The responsible gene was identified on chromosome 2 *MR-1* gene (see molecular genetics section above). However, not all familial PNKD kindreds harbor this mutation. In a phenotype–genotype analysis of families with *MR-1* mutation, the clinical presentation were homogeneous; some of the salient features include (1) onset of attacks in infancy and early childhood and (2) good clinical response to benzodiazepines.

Older ages of onset are reported in other atypical families, without the *MR-1* gene abnormality. Unlike PKD, a pure form of sporadic PNKD is rare and most cases of sporadic PNKD are eventually felt to be psychogenic. To date, there has been no report of positive *MR-1* gene mutation in a sporadic case of PNKD (personal communication), although *MR-1* gene testing is currently not available commercially.

PED

As opposed to PKD, attacks of PED are triggered by prolonged exercise, not by sudden movements. In some cases, exercise of one particular limb can cause attack on the same limb. Attack duration is usually between 5 and 30 min, and an attack gradually subsides when the exercise is stopped. Legs are more affected than arms, but this may be because legs are more exerted during prolonged exercise. There are familial cases, as well as sporadic cases. Some PNKD patients have their attacks triggered by exercise, and some family members of PNKD kindred report exertion cramps; thus some PED may be a subtype of PNKD.

PHD/ADNFLE

The attacks of PHD happens during sleep, and majority of PHD, especially cases with short-lasting attacks (a few seconds to a few minutes) are now thought to be frontal seizures. The attacks can vary from simple arousal to dramatic hyperkinetic involuntary movements with tonic, dystonic, or choreoathetotic features. The attack may sometimes appear bizarre or stereotypical, with ballism, pedaling movements, or pelvic thrusting. Patients may experience aura. Patients are usually awakened by an attack, and conscious to remember it, but fall back to sleep after the attack. The frequency may vary from a few times a night to a few times a year. Sleep studies show that attacks cluster in non-REM sleep, or during stage II sleep. Urinary incontinence, as well as secondary generalization may occur, in which case the seizure diagnosis is more obvious. A minority of patients may also have daytime seizures. Onsets of these attacks are usually from infancy to young adulthood.

Secondary Paroxysmal Dyskinesia

Various neurological, as well as metabolic diseases are reported to cause paroxysmal dyskinesias. The most commonly reported etiology is multiple sclerosis, which can cause both PKD and PNKD. The involuntary movement attack in multiple sclerosis is sometimes referred as "tonic spasm" or "tonic seizure." The attacks are most commonly precipitated by hyperventilation and can be extremely painful. It is thought to be a result of ephaptic transmission.

Another important cause, especially in the elderly is cerebrovascular disease. Other etiologies include metabolic disease, such as hypocalcemia, hypoglycemia and hyperglycemia. See **Table 5** for reported etiology of secondary paroxysmal dyskinesias. Many cases of PNKD, without family history are psychogenic in origin.

EA 1

The attacks of EA1 are brief, lasting seconds to minutes. However, atypical cases with longer attacks lasting up to 12 h are reported. The attacks consist of coarse tremor, dysarthria gait ataxia and limb ataxia, usually without vertigo or nystagmus. Attacks are typically triggered by fatigue, excitement, emotional and physical stress, but also sudden movements and startle, resembling PKD. In fact, some patients with EA1 are reported to have PKD attacks as well. Typically, attacks happen less than once a day, but can recur up to 30 times a day. The onset is early childhood, between 2 and 15 years old. One of the characteristics of EA 1 is interictal myokymia (also called neuromyotonia). This can be detected clinically as a constant fine skin rippling twitching, or by surface electromyography (EMG). Myokymia can happen in any limb or the face, but most notably in the periorbital, or perioral muscles, or in the fingers. Non-affected family members can have myokymia without ataxia. Other associated findings include co-existence of epilepsy, and shortened Achilles tendon on examination.

EA 2

EA2 is the most common form of episodic ataxia. The attacks are longer than that of EA1, lasting 15 min to a few days. Some patients have brainstem symptoms during their attack, including vertigo, tinnitus, dysarthria, nausea/vomiting, and oscillopsia. Some patients have hemiplegia and headache, resembling FHM, its allelic disease. During an attack, patients have spontaneous nystagmus. Patients also have interictal nystagmus, most commonly gaze-evoked nystagmus and downbeat nystagmus. Attacks can be precipitated by alcohol, caffeine, fatigue, stress and exercise. Frequency of attacks varies; it can range from a couple of times a week to a few times a year. Onset is usually between 5 and 20 years

Table 5 Causes of secondary paroxysmal dyskinesia

Paroxysmal dyskinesia	
Multiple Sclerosis	
Cerebrovascular disease	Putaminal infarct
	Thalamic infarct
	Medullary hemorrhage
	Limb-shaking TIA
	Moyamoya disease
Post-traumatic	Central
	Peripheral
Metabolic Disorders	Hypocalcemia (hypoparathyroidism and pseudohypoparathyroidism)
	Fahr's disease (basal ganglia calcification)
	Hypoglycemia
	Nonketotic hyperglycemia
	Thyrotoxicosis
Immune Disorders	SLE
	Rheumatic fever
	Antiphospholipid antibody syndrome
Infectious	HIV
	CMV encephalitis
	Meningovascular syphilis
Cerebral Palsy	
Cervical Cord Lesion	
Other	Kernicterus
	Lymphoma
	progressive supranuclear palsy
	Methylphenidate therapy
Episodic ataxia	
Multiple sclerosis	
Arnold–Chiari malformation	
Other intracranial lesion	Midbrain infarct
Mitochondrial	Pyruvate carboxylase deficiency
	Pyruvate dehydrogenase deficiency
Urea cycle	Ornithine transcarbamylase (OTC) deficiency (usually heterozygous females)
	Carbamoylphosphate synthetase deficiency
	Argininosuccinate synthetase deficiency (citrullinemia type 1)
	Arginosuccinase deficiency
	Arginase deficiency
Organic aciduria	Hartnup disease,
	Intermittent branched-chain ketoaciduria
	Isovaleric acidemia

old. About half of the patients with EA2 have migraine, and some patients develop progressive interictal ataxia, as well as interictal weakness. To complicate the matter, SCA6 patients can have intermittent "attack-like" episode of ataxia, causing clinical overlap between EA2 and SCA6.

EA3–7

Other single or rare families with episodic ataxia syndrome, without EA1 or EA2 mutation have been reported. EA3 was reported as a single Canadian family, with episodic vertigo, tinnitus and ataxia, lasting minutes. EA4 was reported in 2 families from North Carolina. Patients with EA4 have prominent vertigo, and this disease is also referred to as vestibulocerebellar ataxia. Of note, there was initial confusion regarding nomenclature of EA3 and EA4. Originally, the authors reporting the Canadian family referred to their disorder (current EA3) as EA4, and family from North Carolina (current EA4) as EA3. They later corrected themselves and OMIM adopted the current nomenclature; the Canadian family to be EA3, and the North Carolina family with vestibulocerebellar ataxia to be EA4.

EA5 clinically resembles EA2; genetic abnormality was found on calcium channel gene, but different subunit. EA6 was a single child with episodic and progressive ataxia, who also had seizures and hemiplegia. EA7 also resembled EA2 clinically, but had no interictal findings on neurological examination.

Secondary Causes of Episodic Ataxia

As in paroxysmal dyskinesia, neurological illness, such as multiple sclerosis, midbrain infarct and various metabolic diseases have been reported to cause secondary episodic ataxia (**Table 5**).

Differential Diagnosis

Paroxysmal Dyskinesia

Differential Diagnosis includes other intermittent neurological diseases such as seizures, migraines and pseudoseizures. It also includes conditions listed in **Table 2**, such as dopa-responsive dystonia, drug-induced dyskinesia, and tic disorders. Wilson's disease, benign hereditary chorea, and Huntington's disease may sometimes resemble PNKD. PED has been reported to be the presenting symptom of Parkinson's disease. In PHD/nocturnal epilepsy, differential diagnosis includes nightmares, night terrors, restless-leg syndromes, REM behavior disorders and other parasomnias. Disease that can cause secondary paroxysmal dyskinesia, listed in **Table 5** may need to be ruled out. Some of the cases may be psychogenic in origin.

Episodic Ataxia

Differential diagnosis of episodic ataxia includes other episodic disease, such as paroxysmal dyskinesia, seizures, or migraines. Patients with spinocerebellar ataxia syndrome (SCA) can have some fluctuation of their progressive ataxia, best known in the case of SCA6. Secondary causes of episodic ataxia may need to be ruled out.

Diagnostic Work-up and Tests

Paroxysmal Dyskinesia

Careful history taking and videotape documentation of the attack, if possible, are the most important first steps. Special attention needs to be paid in obtaining extensive family history; in some cases, relatives may have forgotten about their attacks in youth. If the attacks are frequent and epilepsy is suspected, electroencephalogram and video-EEG monitoring may be necessary to differentiate seizures. If the attacks happen during sleep, polysomnogram is recommended.

To investigate for secondary causes, neuroimaging and blood tests may be necessary. MRI and vascular investigation are done to rule out structural lesion, multiple sclerosis, and cardiovascular disease. Other metabolic assessments include blood glucose level, serum calcium and thyroid function tests.

Episodic Ataxias

As in paroxysmal dyskinesia, careful history taking, including family history is important. In addition, episodic ataxias have interictal abnormality in their examination; myokymia in EA1 and baseline nystagmus and mild progressive ataxia in EA2, which can aid the diagnosis. If myokymia is subtle and not observed clinically, surface EMG may help detect this. Commercial genetic testing is available for EA1 and 2. However, deletions, duplications and cryptic mutations in untranslated or intronic regions could be missed. Patients with later age of onset and progressive baseline ataxia should be screened for SCA6. Neuroimaging, such as MRI may be necessary to rule out structural causes, such as multiple sclerosis and Arnold–Chiari malformation. In addition, cerebellar vermis atrophy may be seen in EA2. Other possible metabolic assessments include serum ammonia, serum/urine amino acid level and serum pyruvate and lactate level after a glucose load.

Management

PKD

PKD responds extremely well to low dosage of antiepileptic medication, with near complete resolution of attacks. Phenytoin (dilantin) was the first reported agent that proved to be helpful, but currently, carbamazepine (tegretol) is the most widely used. Phenobarbital and valproate are also reported to be effective, as well as newer AED such as lamotrigine, oxcarbazepine, topiramate and levetriacetam. The dosage required is much lower than that used to treat epilepsy. For example, carbamazepine at the dosage of 200–400 mg day^{-1} may completely abort the attack. Thus, it is not necessary to either monitor blood level or try to push for therapeutic levels, except to monitor for compliance.

PNKD

The attacks of PNKD can respond to benzodiazepines, such as clonazepam or diazepam, although the clinical response is not as dramatic as the AED in PKD. Other medications that have been tried with mixed results include levodopa, haloperidol, anticholinergics and AEDs. Avoidance of precipitating factors such as alcohol and caffeine may help.

PED

Treatment of PED is unsatisfactory. There are isolated case reports of levodopa, acetazolamide, trihexyphenidel and benzodiazepine alleviating the attack to some degree. Avoidance of prolonged exercise may help. There is one report of posteroventral pallidotomy ameliorating the attacks of PED.

PHD/ADNFLE

The drug of choice for ADNFLE is carbamazepine. Roughly 70% of patients have remission of seizures with carbamazepine with relatively low doses.

Secondary Paroxysmal Dyskinesia

In paroxysmal dyskinesia secondary to multiple sclerosis, AED as well as acetazolamide can be helpful. AED and benzodiazepines may be helpful in other cause as well. If there is a metabolic abnormality, this needs to be corrected. Deep brain stimulation has been attempted in refractory case. One patient with PNKD secondary to a rotator cuff tear had complete resolution of attacks after globus pallidus internus stimulation. Another patient with painful PNKD secondary to brachial plexopathy had dramatic improvement after contralateral thalamic ventrointermediate (Vim) stimulation.

EA1

The attacks of EA1 can respond to both acetazolamide and AED. The kinesigenic attacks appear to respond well to the AEDs, especially carbamazepine and valproate, again resembling PKD.

EA2

The attacks of EA2 respond dramatically to acetazolamide. Acetazolamide is thought to alter the intracellular pH and as a result, change the transmembraneous potential in the Purkinje cells. It is started at a low dose, 125 mg a day, but some patients may need a higher dose, up to 500 mg twice a day. The effect may be transient in some patients. 4-Aminopyridine (4-AP), a nonselective potassium channel blocker, shows promise. In animal model of abnormal

CACNA1A mouse *tottering*, 4-AP and 3,4-diaminopyridine were helpful in preventing attacks. In one study, 4-AP prevented attacks in patients with EA 2, most likely by increasing the resting activity and excitability of the Purkinje cells.

Prognosis

In PKD, prognosis is good; it responds well to AED, and attacks tend to diminish over adulthood. In PNKD and PED, prognosis is more variable, with some remission reported. ADNFLE is usually lifelong but not progressive. As patient reaches middle age, attacks may become milder and less frequent.

For secondary dyskinesia, the prognosis depends on the underlying disease. Tonic spasms of multiple sclerosis tend to subside over time, even when the disease remains active.

EA1 usually remit in the second decade. EA2 also have a relatively good prognosis. It generally responds well to acetazolamide, and attacks can remit within few years after onset. Some patients, however, develop progressive underlying ataxia.

Pelizaeus–Merzbacher Disease

N I Wolf, VU University Medical Center, Amsterdam, The Netherlands

Glossary

GJA12 (Gap junction protein α-12) – Recessive mutations in this gene cause one form of PMLD.

MLPA (Multiplex ligation-dependent probe amplification) – Gene dosis can be precisely quantified, usually independently for each exon.

PLP1 (Proteolipid protein 1) – Main protein of myelin. Its gene is located on the X chromosome.

PMD (Pelizaeus–Merzbacher disease) – Hallmarks are nystagmus and spastic paraplegia in male patients.
PMLD (Pelizaeus–Merzbacher-like disease) – Resembles PMD, but its inheritance is autosomal recessive. Only one gene has been identified so far.

Definition and History

Pelizaeus–Merzbacher disease (PMD, OMIM 312080) is a rare, X-chromosomal disorder. It was first described by Friedrich Pelizaeus in 1885 in a large family. Neuropathological studies published by Ludwig Merzbacher in 1910 demonstrated near-complete absence of central nervous system (CNS) myelin, while myelin in the peripheral nervous system was intact.

The disease is caused by alterations (point mutations, duplications, and rarely deletions) of the proteolipid 1 (*PLP1*) gene, which was first described 1989 (point mutations) and 1994 (duplications). It is allelic with one form of the hereditary spastic paraplegias, SPG2.

There are also autosomal-recessive forms, which are called Pelizaeus–Merzbacher-like disease (PMLD). This is a heterogeneous group of disorders; only a minority of the cases are caused by mutations in the gene coding for a gap junction protein, *GJA12*.

Pathogenesis/Pathophysiology

The exact pathogenesis of PMD is not clear. PLP1 consists of 276 amino acids and is the most abundant protein of CNS myelin. It is produced by oligodendrocytes. The gene coding for PLP1 has seven exons and is extremely well conserved between species. Alternative splicing leads to the formation of a smaller protein lacking 20 amino acids, DM20; this is the predominant gene product during embryogenesis. PLP1 consists of four transmembrane parts and one intracellular and two extracellular and loops with both C- and N-terminal parts protruding into the cytoplasm and is extremely hydrophobic. After synthesis in the endoplasmatic reticulum, it is transported through the Golgi complex where it associates in membrane rafts with other myelin constituents as sulfatides, cholesterol, and galactocerebrosides. PLP1 is then transported to the plasma membrane.

Point mutations, which cause 10–20% of PMD cases, can give rise to a whole spectrum of symptoms ranging from the most severe form, connatal PMD, to X-linked spastic paraplegia (SPG2). If DM20 is not affected by a mutation, symptoms are relatively mild. However, there is no good genotype–phenotype relationship besides the observation that mutations in the N-terminal part of the gene usually lead to the more severe forms. Recently it has been shown that mutations in the extracellular loop can affect disulfide bridges, making correct folding impossible. If folding and intracellular transport of PLP1 are affected, the unfolded protein response (UPR) is activated and leads to severe intracellular disturbance and finally induce oligodendrocyte apoptosis.

Duplications of *PLP1* are the most common molecular abnormality in patients with PMD and cause up to 70% of cases. In animal models, severity of symptoms corresponds to the amount of *PLP1* overexpression. In humans, this has also been shown for the rare cases with *PLP1* triplications (about 1–2% of patients with PMD). Why PLP1 overexpression leads to disease remains unclear. It has been proposed that excessive amounts of PLP1 in the myelin rafts lead to an imbalance of other myelin constituents in the cell and adversely affects myelin assembly.

Heterozygote female carriers are usually asymptomatic. Mutations leading to mild disease in males can cause symptoms in female carriers, whereas mutations associated with severe disease do not cause symptoms in carriers. This seemingly paradox phenomenon is explained with the fact that in the case of severe mutations, oligodendrocytes where the X chromosome with the mutant allele is activated, die during myelination, and oligodendrocytes with the normal allele take over. This explains also the transient symptoms sometimes present in carriers of duplications. When mutations are not deleterious, carrier females have both normal and abnormal oligodendrocytes, which may lead to degenerative symptoms later in life.

Clinical Features and Diagnostic Criteria

Diagnosis of PMD is clinical: nystagmus and spastic paraplegia in a male patient evoke this diagnosis, MRI and genetic results can confirm it. Depending on severity and the age of onset, PMD is divided into a connatal (first described by Seitelberger in 1954) and a classical form; in between is the so-called transitional form. Isolated X-linked spastic paraplegia (SPG2, OMIM 312920) is not called PMD. There is a continuum of severity in between all these forms.

An important symptom in both forms, classical and connatal, is pendular nystagmus starting several weeks after birth. Retina and optic nerve are normal. In the connatal form, first symptoms are present shortly after birth and include stridor and severe muscular hypotonia. Sitting without support is not possible. In the classical form, infants

show muscular hypotonia that evolves later to spastic paraplegia with dystonic and ataxic components. Walking without support is usually not possible; if children learn to walk, they lose it after a few years. Cognitive abilities are much better preserved than motor features, but there is usually cognitive impairment also in the classical form of PMD. The most severe form of PMD is caused by triplications of PLP1. These children often have severe epilepsy, which is unusual in the other forms of PMD.

Children with PMLD show a similar clinical presentation although ataxia may be more prominent in some of these cases. They may also display mild neuropathy, which is usually not relevant. Mild epilepsy is common in children with *GJA12* mutations. They may experience deterioration, including the development of bulbar symptoms later in the course.

Differential Diagnosis

Children with PMD are sometimes misdiagnosed as having cerebral palsy (CP). The movement disorder resembles that of CP, but children with CP usually do not show nystagmus. MRI in CP is different and does not show hypomyelination. Vice versa, cases with hypomyelination in neuroimaging are often labeled as PMD, although clinical presentation is completely different. One example is 4H syndrome (hypomyelination, hypodontia, hypogonadotropic hypogonadism), also called ADDH (ataxia, delayed dentition, and hypomyelination).

Diagnostic Work-up/Tests

MRI will be the first and most important investigation. In almost all cases, it shows severe hypomyelination (**Figure 1**). If the patient is male, genetic testing for *PLP1* gene alterations comes next. Duplications should be looked for first; multiplex ligation-dependent probe amplification (MLPA) is an easy and reliable method to test for this. MLPA is also able to pick up triplications of *PLP1*. Interphase fluorescent in situ hybridization (FISH) can also detect duplications and would detect aberrant *PLP1* localization albeit this has been described in only one patient so far. If duplication studies are negative, sequencing *PLP1* is the next step. In affected females and if there is strong evidence for autosomal-recessive disease (or in a male patient with negative *PLP1* studies), *GJA12* should be sequenced. CSF studies, including measuring *N*-acetylaspartylglutamate (NAAG) levels, which have been shown to be elevated in children with PMD, are not part of the routine workup of a patient suspected of PMD. NAAG elevation is nonspecific and has also been demonstrated in other cases with hypomyelination.

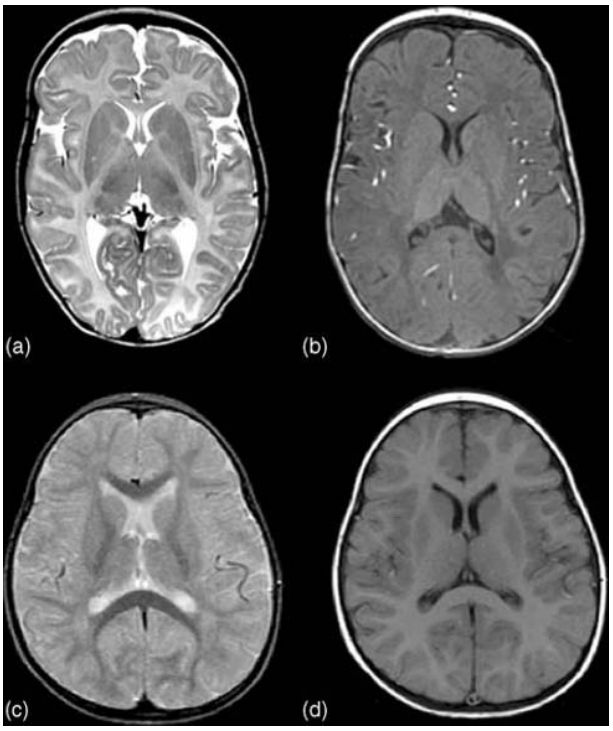

Figure 1 (A) T2w and (B) T1w axial MRI images of a 12-month-old boy with the connatal form of Pelizaeus–Merzbacher disease and a missense mutation in *PLP1*. Myelination is lacking completely in the T2w image and almost completely in the T1w image. For comparison, respective T2w and T1w MRI images of a healthy 12-month-old child (C + D).

Management

Management is supportive including physiotherapy, occupational, and speech therapy. Physiotherapy is important to avoid contractures and scoliosis and to provide adequate orthopedic support. Spasticity can be improved by baclofen. If epilepsy is present, it should be treated according to seizure type and EEG changes. Genetic counseling should be provided.

Prognosis

Prognosis depends on disease severity. In the classical form, life expectancy is not much reduced. There is evidence for a slow deterioration starting around adolescence and affecting mainly motor capacities. In the connatal form, life expectancy depends mainly on secondary complications and medical support and is very variable; death may occur already in early childhood, but also much later.

Periodic Limb Movements

P Hamilton-Stubbs, Sleep Clinic for Children and Adults, Richmond, VA, USA
A S Walters, Vanderbilt University School of Medicine, Nashville, TN, USA

Glossary

A11 region – A cluster of dopamine-containing cells located in the diencephalon with projections to the spinal cord.
BTBD9 – The symbol for (Broad-Complex-Tram-Track-Bric-A-Brac Domain 9) and is a gene encoding a BTB (Poz) domain on Chromosome 6p.
Cyclic alternating pattern (CAP) – A normal phenomenon of NREM sleep characterized by a repetitive biphasic pattern of K-complex, K-alpha, microarousals, or delta bursts that periodically interrupts the theta/delta background EEG of NREM sleep.
Periodic limb movements (PLMs) – Involuntary repetitive nonepileptiform movements that frequently occur as stereotypic triphasic events involving the great toe, ankle, and hip. PLMs involve the lower limbs, but can also involve the arms. The duration of a PLM is at least 0.5–10 s; it recurs in sequences of four or more events, at 5–90 s intervals; and is associated with an elevation of the electromyogram of at least 8 uV above the baseline. PLMs can occur either in sleep designated as periodic limb movements in sleep (PLMS) or during wakefulness denoted as periodic limb movements in wakefulness (PLMW).
Periodic limb movement disorder (PLMD) – Refers to PLMS and the clinical consequences of sleep disturbance that cannot be explained by the presence of another sleep disorder.
Restless legs syndrome (RLS) – A sensorimotor disorder with four essential diagnostic criteria: (1) an urge to move the legs usually accompanied or caused by uncomfortable and unpleasant sensations in the legs, (2) the urge to move or the unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting, (3) the urge to move or unpleasant sensations are partially or totally relieved by movement such as walking or stretching, at least as long as the activity continues, and (4) the urge to move or unpleasant sensations is worse in the evening or night than during the day or only occurs in the evening or night.

Definition and Historical Review

Periodic limb movements (PLMs) are involuntary repetitive nonepileptiform movements that frequently occur as stereotypic triphasic events involving the great toe, ankle, and hip. PLMs involve the lower limbs, but can also involve the arms. PLMs occur primarily during sleep and are termed periodic limb movements in sleep (PLMS) but can occur also during wakefulness and are termed PLMs while wake (PLMW). PLMW are most strongly associated with restless legs syndrome (RLS). PLMS are also most strongly associated with RLS but may be seen in healthy individuals, and a variety of sleep disorders, including narcolepsy, REM behavior disorder (RBD), and sleep apnea as well as in neurodegenerative diseases.

The duration of a PLM is at least 0.5 s and not longer than 10 s; it recurs in sequences of four or more events,

at intervals of 5–90 s; and is associated with an elevation of the electromyogram of at least 8 μV above the baseline. The term 'periodic limb movement disorder' (PLMD) appears in the *International Classification of Sleep Disorders Diagnostic Manual*, 2nd edn., 2005, and refers to the patient with PLMS and clinical sleep disturbance that cannot be explained by the presence of another sleep disorder.

In 1953, Sir Charles Symonds coined the term nocturnal myoclonus to describe involuntary nonepileptic clonic movements of the lower extremities during sleep. In 1959, Oswald differentiated PLMS from hypnic myoclonus and concluded that PLMS are normal and unlikely to be epileptic. In 1965, Lugaresi et al. documented the association of PLMS and RLS. In 1966, Lugaresi documented the presence of periodic leg movements during sleep in the absence of RLS.

'Nocturnal myoclonus' describes a variety of phenomena; tends to occur during sleep at intervals of 20–40 s; and is rarely myoclonic (<250 ms). Accordingly, Coleman suggested an alternative term 'periodic movements in sleep.' In 1975, Guilleminault et al., described PLMS as 'a rapid partial flexion of the foot at the ankle, extension of the big toe, and partial flexion of the knee and hip.' In 1979, the Association of Sleep Disorders Centers and the Association for the Psychophysiological Study of Sleep published the *Diagnostic Classification of Sleep and Arousal Disorders (DCSAD)*, which defined PLMS and RLS as two distinct phenomena. In 1980, Coleman et al. published evidence that PLMS are not limited to RLS but occur in a variety of sleep disorders as well as neurological disorders.

In 2004, de Weerd, Rijsman, and Brinkley studied 12 patients and evaluated 469 PLMS to define the sequence of muscle activation during PLMS. The researchers monitored six muscles on the right leg: extensor digitorum brevis (EDB), tibialis anterior (TA), biceps femoris (BF), tensor fasciae latae (TFL), quadriceps (Q), soleus (S), and the TA on the left leg. Of the 469 movements analyzed, 12% occurred as the classic description of EDB-TA-BF-TFL or a variant of this sequence. The most common sequences, 32%, involved the TA followed by EDB only or EDB plus another muscle. In addition, the researchers reported that some patients consistently contracted the same muscle or muscle groups and some patients always had the same sequence of muscle involvement. The researchers also documented a positive association between the number of muscles contracted and the occurrence of an arousal from sleep.

Using advances in technology, Ferri et al. evaluated the characteristics of leg movements (LM) in 65 RLS patients with PLMS and 22 normal controls. The duration, amplitude, interval between the onset of two consecutive LM, and the interval between LM were analyzed. Based on their findings, in 2006, Ferri et al. published a new index for PLMS, 'the periodicity index.' To confirm the validity of the periodic index, Ferri et al. analyzed the structure of the LM sequence by examining Markov chains, a sequence of values that have probabilities at a time interval dependent upon the value at the preceding time. The periodicity index allows prediction of candidate leg events for PLMS. When used with the diagnostic criteria for PLMS, the periodicity index allows differentiation between true periodic limb movements and movements that mimic PLMS. The periodicity index could possibly aid in identifying the specific characteristics of LM and PLMS and in understanding how the PLM motor pattern is influenced by precipitating factors.

The significance of PLMS remains unclear. PLMS may be a predecessor to RLS, represent a subtype of RLS, or may be a marker for RLS severity. Patients with RLS are at greater risk for hypertension and cardiovascular disease. PLMS are accompanied by marked increases in blood pressure and pulse rate. Whether there is a causal correlation between these changes and the increased cardiovascular risk in RLS is under investigation. Patients with end-stage-renal-disease (ESRD) and PLMS have a higher mortality rate compared with patients with ESRD without PLMS. Accordingly, PLMS may provide a unique prognostic indicator of mortality in renal failure.

Insomnia and hypersomnia are commonly associated with PLMS. However, this association is in most cases coincidental. It is now thought that PLMS in the absence of RLS is an uncommon cause of daytime dysfunction in adults. In other words, PLMS are common but PLMD is thought to be rare. However, PLMW are prominent in approximately 15% of people with RLS and in these cases are a definite cause of insomnia. In addition, although sleep disturbance is uncommon in patients with pure PLMS in the absence of RLS, it is not at all uncommon for the sleep of the spouse to be disturbed by the PLMS. In these cases, the diagnosis of environmental insomnia is made in the bed partner and treatment of PLMS may be considered in order to treat the bed partner's insomnia.

There is some evidence that PLMD may be more of a problem in children. PLMS are commonly seen in children with attention–deficit/hyperactivity disorder (ADHD). The significance of this association is uncertain.

Pathogenesis/Pathophysiology

Neither the pathogenesis nor the pathophysiology of PLMS is known. There are at least four hypotheses.

Hypothesis 1: PLMS are caused by disinhibition of spinal cord reflexes by the pyramidal tract or a subcortical area of the brain.

The cerebral cortex does not appear to be actively involved in the generation of the PLMs, because PLMS are not associated with EEG changes on back averaging. In addition, after complete transection of the spinal cord, PLMS occur distal to the transection. This data suggest that the cortex or subcortical areas could be involved in

the inhibition of PLMS that are generated at the spinal cord level. Additional evidence against a cerebral cortex generator for PLMS is the fact that PLMS rarely involve the face.

The motor pattern of PLMS is similar to the motor pattern of the Babinski sign. Both are characterized by dorsiflexion of the great toe, fanning of the smaller toes, and flexion at the ankle. The Babinski sign occurs after injury to the pyramidal tracts and is thought to be secondary to failure of the pyramidal tracts to inhibit a spinal polysynaptic reflex. The Babinski sign is a normal finding in newborns and gradually disappears with complete myelination of the pyramidal tracts. During the recovery phase from spinal anesthesia, a time when supraspinal control of the reflex mechanism is thought to be inhibited, the Babinski sign occurs as a temporary phenomenon.

There are case reports of the onset of RLS/PLMS after injury to subcortical structures. Three separate case reports of the onset of RLS/PLMS after strokes involved subcortical structures as follows: case 1 – the left corona radiate, case 2 – left pallidum and internal capsule, and case 3 – right basal ganglia.

Hypothesis 2: PLMS result from a hyperexcited sympathetic nervous system.

The oscillator for PLMS is thought to be subcortical. PLMS occur in association with phase A of the cyclic alternating pattern of sleep (CAP). CAP is a rhythm possibly generated by a thalamocortical pathway. In addition, the periodicity of PLMS of 20–40 s is similar to that of other autonomic rhythmic functions thought to be controlled by the brainstem such as respiration and blood pressure fluctuations. Therefore, PLMS may be due to a subcortical or brainstem oscillator or failure of a brainstem generator to inhibit motor function allowing activation of a secondary motor center in the lumbosacral spinal cord.

An interrelationship among subcortical areas of the brain, sympathetic nervous system, and dopaminergic systems may be responsible for PLMS.

Ware observed cold feet and poor pulse waves in the lower extremities among patients with PLMS. Ware hypothesized that PLMS are secondary to vasoconstriction caused by over activation of the sympathetic nervous system.

Norepinephrine (NE) is a mediator for the sympathetic nervous system. Ware described three situations possibly associated with increased PLMS due to an increased availability of NE. Specifically, PLMS increased (1) after administration of tricyclic antidepressants, (2) with aging, and (3) in patients with obstructive sleep apnea syndrome (OSAS). Aging is associated with increased NE levels. Ware suggested that OSAS elevated NE levels due to secondary hypoxemia.

Ware treated patients with phenoxybenzamine, an alpha 1 adrenergic postsynaptic blocking agent that causes vasodilatation. The PLM index decreased in patients treated with phenoxybenzamine.

Researchers do not agree on how opioids reduce PLMS. Ware hypothesized that opioids decrease the available NE, leading to vasodilatation and subsequent reduction in PLMS.

Hypothesis 3: Decreased CNS levels of dopamine and/or iron cause PLMS.

Dopaminergic agents and iron both suppress PLMS. Iron is deficient in RLS patients as determined by magnetic resonance imaging (MRI), cerebral spinal fluid (CSF), and autopsy data. Iron is intricately related to dopamine. The D2 dopamine receptor is a protein that contains iron and iron is a cofactor to tyrosine hydroxylase, an enzyme that controls the rate-limiting step in the conversion of tyrosine to levodopa, a precursor to dopamine. Iron deficit leads to alteration in dopamine receptor binding. Dopamine might be relatively deficient due to defective acquisition or utilization of iron by the brain. Dopamine deficiency in the descending A11 diencephalospinal pathway may also lead to sympathetic over activity leading to PLMS (see autonomic Hypothesis 2).

Walters observed that all opioids that effectively reduce RLS/PLMS are primarily mu opiate receptor agonists, and based upon receptor-blocking studies, they hypothesized that opiates act centrally to increase dopamine levels leading to a decrease in PLMS.

Hypothesis 4: PLMS are generated centrally but a stimulus to the central nervous system generator could originate from the peripheral nervous system.

Conceivably, an abnormal sensory input from damaged nerves could trigger a generator in the brain or spinal cord to initiate PLMS. The medical literature includes several case reports of patients with both RLS and PLMS preceded by peripheral neuropathy. Peripheral neuropathy is more common in RLS than the general population as determined by clinical examination and EMG nerve conduction studies. In addition, subclinical peripheral neuropathy may be present in some patients with RLS as determined by nerve biopsy. Support for this hypothesis is limited by observations that abnormal leg sensations are not always most intense prior to PLMS.

Epidemiology/Risk Factors

PLMs occur in all ages and in both genders. Thirty percent of people over 50 years of age have PLMS, suggesting that advancing age is a risk factor for PLMS. PLMS in children occur in RLS and ADHD. Other risk factors include the following.

Medications

Mood stabilizing medications such as lithium, clomipramine, fluoxetine, or venlafaxine increase PLMS. Also dopamine receptor-blocking agents such as haloperidol increase PLMS.

Family History of PLMS/RLS

A genetic risk factor for RLS with PLMS was identified in 2007. Stefansson et al. identified three PLM candidate genes: BTBDP9 (this gene was also identified by Winkelmann), and DNAH8. Stefansson et al. found that the frequency of PLMS correlated with the presence of allele A of marker rs3923809 in an intron of the BTB (POZ) domain-containing 9 gene on chromosome 6p21.2.

Restless Legs Syndrome

Although PLMS occur in a variety of medical conditions and sleep disorders, PLMS are most closely associated with RLS. Eighty percent of patients with RLS have PLMS.

Presence of Other Medical Disorders/Diseases Associated with a High Prevalence of PLMS

PLMS occur commonly in sleep disorders such as narcolepsy, RBD and sleep apnea. PLMS occur commonly in spinal cord damage. As with RLS, PLMS may be related to iron deficiency anemia.

Less commonly, PLMS have been reported in disorders such as dopa-responsive dystonia, Parkinson's disease, Huntington's disease, Stiff-person syndrome, Isaacs' syndrome, motor neuron disease, and hyperekplexia. PLMS are also observed less commonly in childhood leukemia, renal dysfunction, fibrositis, chronic obstructive pulmonary disease (COPD), alcohol dependency, and male erectile dysfunction. Unfortunately, many studies have only a few subjects and coincidental occurrence cannot be ruled out.

Clinical Features

PLMS are nonepileptiform repetitive movements frequently involving flexion of the toe, ankle, knee, and hip. Most patients with PLMS experience repeated flexion of the lower extremities, but some complain of arm movements too. PLMS are characterized by inter- and intraindividual night-to-night variability in the frequency and motor pattern. If a group of ten patients or more is tested, the average number of PLMS is the same for the group and this allows testing of the efficacy of therapy. Although some patients complain of difficulty in falling asleep or maintaining sleep, many become aware of their movements only because of a bed-partner or parent's observations.

PLMS may be associated with increased awakenings from sleep, fatigue, or mild daytime somnolence. However, most research indicates that insomnia or hypersomnia is coincidental. Neither the severity of PLMS nor the frequency of PLMS associated with arousals correlates with the severity of daytime sleepiness or insomnia complaints. PLMS can occur before, during, or after an arousal. Although PLMS is common, PLMD is thought to be rare.

In RBD, PLMS occur during REM sleep. In other disorders, PLMS occur predominantly during N1 and N2 sleep stages in close association with phase A (the arousal phase) of the cyclic alternating pattern (CAP) of sleep. PLMS may or may not be associated with an arousal, K-complex, awakening, or changes in the EEG. The frequency of PLMS is influenced by the time of night and the patient's sleep position. Although the prevalence of PLMS increases with age, the periodic limb movement index (number of periodic limb movements per hour of sleep) does not.

PLMS occur as one of two patterns. Type one involves early night peak frequency of limb movements, which decreases over time and occurs in people with idiopathic PLMS or RLS. In type two, PLMS are more evenly distributed over the night. The type two pattern occurs in sleep disorders such as sleep apnea and narcolepsy.

Differential Diagnosis

PLMS must be differentiated from respiratory-related leg movements in sleep (RRLMS). Other conditions that can mimic PLMS include sleep starts, epilepsy, spinal myoclonus, flexor spasms from spasticity, and myoclonus associated with neurodegenerative disorders such as Alzheimer's and Jakob–Creutzfeldt's disease. PLMS must be differentiated from painful legs and moving toes syndrome, akathisia and nocturnal leg cramps.

Diagnostic Workup/Tests

A history of kicking during sleep or wearing away of bed linen in a pattern consistent with repetitive foot movements is suggestive of PLMS. The presence of PLMS cannot be determined by history but must be documented by polysomnography.

Surface electrodes are placed on each anterior tibialis muscle 2–3 cm apart or 1/3 the longitudinal length of the muscle. A candidate leg movement is defined as an increase in EMG amplitude $\geq 8\,\mu V$ above the resting baseline and ends when the EMG amplitude decreases to $<2\,\mu V$ above the baseline and remains below that value for 0.5 s. The duration of a candidate leg movement event is at least 0.5 s and no longer than 10 s. A PLM is defined as a minimum of four candidate leg movement events recurring in sequence and separated by a minimum of 5 s and no more than 90 s. PLMW must meet the same criteria as PLMS occurring during sleep but allowances are made for shifts in the baseline associated with muscle tension. PLMS at a rate of 5 or more per hour are considered possibly abnormal in childhood and adolescence.

PLMS of 15 or more per hour are possibly abnormal in adults. However, a history of related daytime fatigue needs to be present before treatment is instituted. For research purposes, during polysomnography, an esophageal monitor or respiratory inductance plethysmography is useful to distinguish respiratory related limb movements (RRLMS) from true periodic limb movements.

Actigraphy provides another means to measure limb movements during sleep. Because actigraphy is recorded on multiple nights, actigraphy addresses inter- and intraindividual night-to-night variability in the frequency and motor pattern. Actigraphy does not allow differentiation of true PLMS from RRLMS nor does it allow the identification of associated EEG arousals. The actigraph should have a maximum recording time of 10 consecutive hours per night and should be able to record approximately the same EMG signal as the polysomnograph. A minimum of three nights' recording is recommended.

A ferritin level may help to identify PLMS secondary to iron deficiency.

Management

Pharmacologic Treatment

The decision to treat PLMS is based on complaints of insomnia or daytime fatigue that can be definitely attributed to the PLMS. In such a case, the diagnosis of PLMD is made. However, PLMD is thought to be rare. PLMS on the other hand commonly disrupt the bed partner's sleep. In such a case, the bed partner is diagnosed as having environmental insomnia. The decision to treat the patient in order to treat the bed partner's insomnia is made jointly between the physician and the couple. All medications used to treat PLMD should be started at the lowest dose and increased slowly to an effective dose.

L-Dopa and dopaminergic agonists

Analogous to therapy of RLS, we consider dopaminergic drugs (levodopa/carbidopa (Sinemet), bromocriptine (Parlodel), cabergoline (Dostinex), pramipexole (Mirapex), and ropinirole (Requip)) as first line pharmacologic therapy for PLMD. There are two types of dopaminergic drugs: ergot preparations and nonergot preparations. Bromocriptine, pergolide, and cabergoline are all ergot dopamine preparations. Ergot is a common name for fungus in the genus Claviceps used in the manufacturing of ergot dopaminergic drugs. Prolonged use of ergot preparations is linked to the scaring of the heart valves (cardiac valvular fibrosis) and the scaring of the lungs (pulmonary fibrosis). Therefore, ergot preparations are used with caution.

Analogous to RLS, we recommend Ropinirole as first line therapy for PLMS. Ropinirole is available in two forms: immediate release and extended release. As with the therapy for RLS, PLMS therapy is started with the immediate release form of Ropinirole at 0.25 mg 30 min before the onset of symptoms or 1–3 h before bedtime. On the third day of therapy, Ropinirole is increased to 0.5 mg day^{-1}. After 7 days Ropinirole is increased to 1 mg day^{-1}. If symptoms persist, increasing Ropinirole by 0.5 mg every week for 6 weeks to a maximum dose of 3 mg day^{-1} is continued. On week 7, if symptoms remain uncontrolled, Ropinirole is increased to a maximum dose of 4 mg.

To convert from immediate release Ropinirole to extended release Ropinirole, a once daily extended release dose that is approximately the same as the maximum daily dose of the immediate release Ropinirole is selected. Ropinirole is metabolized in the liver and should be used cautiously in patients with liver disease.

Similar to RLS therapy, we also recommend Pramipexole as first line therapy for PLMS. Pramipexole is available in multiple dosage strengths. Pramipexole is started at 0.125 mg once daily 2–3 h before bedtime. If symptoms persist, the dose is doubled every 4–7 days up to 0.5 mg day^{-1}. The manufacturer's recommended maximum dose is 0.5 mg day^{-1} but higher doses have been used (2 mg day^{-1}). Pramipexole is excreted through the kidneys and should be used with caution in patients with renal impairment.

Carbidopa/levodopa is an older dopaminergic with a short half-life that is sometimes used off label to treat RLS and PLMS. Carbidopa/levodopa is used when symptoms occur intermittently. PLMS may respond to Carbidopa 25 mg per 100 mg levodopa given 30–60 min before bedtime. The dose may be repeated once. Because of a tendency to cause augmentation of RLS and the high association between PLMS and RLS, daily use of levodopa/carbidopa in higher doses is not recommended.

Cabergoline is a long-acting dopaminergic agent that can be used to treat PLMS but seldom used in the United States due to cost and associated side effects.

Side effects of the dopaminergic drugs include nausea, light-headedness, daytime drowsiness, orthostatic hypotension, and sleep attacks. Chorea and hallucinations are common side effects of dopamine agonists in Parkinson's disease but rare in PLMS. Compulsive gambling and compulsive shopping have been reported.

Rebound and augmentation are complications seen in RLS when patients are treated with dopaminergic agents. Patients with isolated PLMS may develop RLS symptoms and this may be comparable to the rebound or augmentation seen in RLS. Rebound and augmentation have not been described in PLMS.

Opioids: codeine, propoxyphene, hydrocodone, methadone, oxycodone, or tramadol

In a double-blind study using oxycodone and another double-blind study using propoxyphene, both medications improved sleep efficiency and decreased PLMS-associated arousals. Only oxycodone decreased the number of PLMS. There is little risk of addiction or tolerance to opioids when

used to treat PLMD. Constipation, dizziness, nausea, and vomiting are side effects associated with opioids. Patients treated with opioids should be monitored for the development or exacerbation of sleep apnea.

Anticonvulsants: gabapentin (Neurotin)

There is insufficient evidence about the efficacy of anticonvulsants for PLMD therapy. However, research documents that gabapentin ($800–1800\,mg\,day^{-1}$) improves sleep efficiency and reduces PLMS.

Benzodiazepines: clonazepam (Klonopin), temazepam (Restoril), and triazolam (Halcion)

Benzodiazepines may help patients to sleep but only higher dosages of the longer acting benzodiazepines, like clonazepam, consistently reduce the frequency of PLMS. High doses of benzodiazepines cause carry-over effects such as morning drowsiness and decreased cognition. Benzodiazepines are not recommended in patients with untreated or inadequately treated sleep apnea, because benzodiazepines may increase apnea. Addiction and tolerance to benzodiazepines rarely occurs.

Non-benzodiazepine hypnotics: eszopiclone (Lunesta), zolpidem (Ambien)

Eszopiclone and zolpidem are sometimes prescribed to help patients to sleep. To the best of our knowledge, these medications do not reduce PLMS.

Muscle relaxants: Baclofen (Lioresal)

In a double-blind study, Baclofen reduced the amplitude of PLMS and consolidated sleep. Baclofen did not decrease the number of limb movements.

Other

Other medications reported to reduce PLMS include magnesium, bupropion, phenoxybenzamine, and iron.

Nonpharmacologic Treatment

In one study, the number of PLMS decreased 30 min after electrical stimulation to the dorsiflexors of the feet and toes. There are reports that thermal biofeedback and Yoga improve periodic limb movements.

Prognosis

PLMS may be a precursor to RLS as well as a unique prognostic indicator of mortality in renal failure. PLMS in childhood occur more frequently in children diagnosed with ADHD. Patients with PLMS and RLS have a higher incidence of cardiac disease and hypertension. There is a related increase in blood pressure and pulse rate associated with PLMS. The prevalence of PLMS increases with advancing age. Although PLMS occur in healthy individuals and other medical conditions, PLMS and PLMW are strongly associated with RLS. The prognostic implications of these associations are currently unknown but are the subject of further investigation.

Pesticides

E Cubo, Complejo Hospitalario Burgos, Burgos, Spain

Glossary

Biomarker – In movement disorder neurology, a biomarker is a molecule, neuroimaging pattern or other indicator of a disorder, even when the classical signs of that disorder are not present.
Dopamine – A neurotransmitter occurring in a wide variety of animals, including both vertebrates and invertebrates. In the brain, this catecholamine activates five types of dopamine receptors — D1, D2, D3, D4, and D5, and their variants. Dopamine is produced in several areas of the brain, including the substantia nigra and the ventral tegmental area.
Lipophilicity – The ability of a chemical compound to dissolve in fats, oils, lipids, and nonpolar solvents such as hexane or toluene.
Neurotoxin – A toxin that acts on the peripheral or central nervous system.
Nitric oxide synthase (NOS) – An enzyme in the body that contributes to transmission from one neuron to another, to the immune system and to dilating blood vessels.

A pesticide is an agent used to kill undesired organisms such as insects (insecticide), snails and slugs (molluscicide), rodents (rodenticide), plants (herbicide), or fungi (fungicide). Pesticides can be categorized in a number of ways, including their acute toxicity to humans, their chemical group, or their mode of action. Pesticides may be absorbed by inhalation, ingestion or, in some cases, such as the organophosphates, through the skin. Exposure and subsequent toxicity are influenced by the pesticide chemical itself, as well as its formulation (e.g., powder, granules, candles, liquid concentrate, premixed solution, and gas), method of application (e.g., spraying, fogging, dipping, dusting), use of protective equipment (gloves, goggles, impermeable clothing, respiratory masks), and prevailing weather. Pesticide exposures may arise not only through work but also in the home, for example, insecticides for human parasites, flea treatments on family pets, exposure to timber treatment agents, use of garden pesticides, and the ingestion of pesticide-contaminated water or food. Most developed nations regularly test foodstuffs for pesticide contamination, whereas less developed countries may not.

Poisoning by acute, high-level exposure to certain pesticides has well-known neurotoxical effects, which can range from a mild skin irritation to coma or even death. Whether chronic exposure to moderate levels of pesticides is also neurotoxic and associated with a risk of movement disorders is more controversial. Most studies have found increased prevalence of symptoms and changes in neurobehavioral performance following moderate pesticide exposure, reflecting cognitive and psychomotor dysfunction. Studies conducted in the early 1980s suggested that early age exposure to rural environments and consumption of well water, lifestyles in which exposures to pesticides are thought to be more prevalent than in urban environments were associated with later development of Parkinson's disease (PD). Epidemiologic studies have also shown that a history of farming or living on a farm is associated with increased risk of PD. A meta-analysis of 19 case-control studies of pesticide exposure and PD found an almost doubling of risk in pesticide-exposed groups. The association between pesticides and PD was of similar size when comparing North American (OR 2.15, 95% CI 1.14–4.05) and all studies (OR 1.94, 95% CI 1.49–2.53). One of the largest cohort studies carried out studied the relationship between pesticide exposure and PD in over 140 000 people drawn from the American Cancer Society's Cancer Prevention Study II Nutrition Cohort. That study, which was based on self-reported current or frequent past exposure to pesticides and self-reported PD diagnosis (validated in the majority of cases by a neurologist's diagnosis of 'definite' or 'probable' PD), found that the relative risk for PD among individuals exposed to pesticides was 1.7 (95% CI 1.2–2.3). As a result, researchers have examined paraquat, as well as other pesticides and herbicides, in both epidemiologic and animal model studies. The relationship between PD and pesticides appears strongest for exposure to herbicides and insecticides and weaker for fungicides. The association of PD with exposure is best document after long duration of exposure. Toxicological data suggest that paraquat, organochlorines, alkylated phosphate, and rotenone have neurotoxical actions that potentially play a role in the development of PD. Data are more limited for other pesticides. Two of the three widely used animal models of PD employ pesticides: rotenone and 1-methy1-4-pheny1-1,2,3,6-tetrahydropyridine (MPTP). One criticism of such laboratory animal models as a model of pesticide exposure and PD is that neither the dose nor the route of administration of pesticides is representative of likely human exposures. Likewise, in the absence of long-term biomarkers of exposure to most pesticides, organochlorines being a notable exception, associations

with specific agents may be confounded by exposure to other pesticides, making it difficult to identify a single causative agent.

Laboratory studies have identified a number of mechanisms by which pesticides might lead to PD including mitochondrial dysfunction (e.g., complex I inhibition), oxidative stress, protein aggregation, and altered dopamine levels. Several pesticides act by inhibition of mitochondrial enzymes, thus disrupting cellular respiration. MPTP is a mitochondrial complex I inhibitor as is rotenone. The risk from pesticides is increased in those who are poor CYP2D6 metabolizers. A review of analytic epidemiologic studies of PD cases examined both in which exposure to pesticides was queried directly and whole-animal studies for PD-like effects after systemic pesticide exposure. However, both the epidemiology and toxicology studies were limited by methodologic weaknesses. Particular issues of current and future interest include multiple exposures (both pesticides and other exogenous toxicants), developmental exposures, and gene–environment interactions. Animal studies have found evidence that male mice exposed to maneb in-utero are at increased risk of developing neurodegeneration if subsequently exposed, as adults, to paraquat. These laboratory findings have led to the speculation that pesticide-exposed children may be at increased risk of PD in later life, although evidence for this association is lacking. Equally, it can be hypothesized that in old age, a pesticide exposure might 'tip the balance' in an individual with preexisting dopaminergic cell depletion, thus leading to PD. At present, too little is known about the timing of pesticide exposures and the role this may play in the development of PD. A large prospective cohort study of children and their exposure to environmental pesticides is required to study the role of early life pesticide exposures.

Specific Agents

The pesticide, paraquat, has a close structural resemblance to the active metabolite of MPTP, 1-methy1-4-phenylpyridinium MPP^+. It had been thought, on the basis of the similarity in their chemical structure, that paraquat acted on the brain in a way similar to MPTP. However, in vitro research suggests that paraquat exerts its toxicity on dopaminergic neurons in a different way to MPP^+. Intranigral injection of paraquat can selectively destroy dopaminergic neurons and induce behavioral changes in animal models. Treatment with dopaminergic agents prevents paraquat toxicity, suggesting that the drug or a toxic metabolite is transported into the brain by the neutral amino acid transporter. Importantly, in vitro paraquat, as well as rotenone and dieldrin, increases α-synuclein fibril formation and aggregation. Decreased toxicity is associated with increased levels of HSP70, which is known to be associated with protection against paraquat toxicity. The potential toxicity of paraquat to dopaminergic neurons might be enhanced by other agrochemicals, and combined treatment with the dithiocarbamate fungicide, maneb, appears to have synergistic toxic effects.

Humans may be occupationally exposed to organochlorine pesticides, and chronic exposure may result in a 6–8-Hz action tremor which may be of such severity that it interferes with ordinary daily activities. Tremor onset is not necessarily immediate, and may be delayed by as long as 8 months after initial exposure. Postmortem studies have found that the brains of those who died of PD were more likely to have detectable levels of dieldrin than those who died of other illnesses. Elevated levels of lindane and dieldrin have been found in the substantia nigra in PD brains. Dieldrin can deplete brain dopamine content, induce abnormal motor behavior and α-synuclein aggregation, inhibit mitochondrial and proteasome function, and induce apoptotic mechanisms to dopaminergic cells in culture. The effects of dieldrin may be suppressed by antioxidants, suggesting the involvement of oxidative stress.

The pesticide, rotenone, is also toxic to dopaminergic neurons. Rotenone is highly lipophilic and a known inhibitor of complex I of the mitochondrial respiratory chain. It has been shown that focal injection of rotenone into the nigrostriatal pathway or chronic administration to animal models results in a destruction of the nigrostriatal pathway associated with the presence of α-synuclein and ubiquitin-positive inclusions. Damage extends beyond the dopaminergic system and affects 5HT, noradrenergic and cholinergic neurons. Since rotenone induces the enzyme, nitric oxide synthase (NOS) activity in both striatum and substantia nigra, the effects of rotenone are prevented by a neuronal NOS inhibitor 7-NI.

Maneb (active ingredient: manganese ethylene-bis-dithiocarbamate) is a fungicidal dithiocarbamate molecule that contains a manganese atom. Manganese toxicity is known to induce parkinsonism, but the neuronal degeneration is found primarily in the globus pallidus and not the substantia nigra. There have been case reports suggesting parkinsonism in agricultural workers exposed to maneb. However, the geographic overlap between paraquat and maneb utilization could indicate a 'multiple-hit' environmental model that ascribes combinations of exposures as responsible, rather than only one. In animal models, both paraquat and maneb are more toxic in combination compared to each chemical alone. In combination, they have similar neurotoxical effects as paraquat alone, with very young and very old animals being most susceptible to combined paraquat/maneb. It has been hypothesized that the increased susceptibility of the older and younger animals is the result of the lack of a compensatory mechanisms (e.g., increased striatal tyrosine hydroxylase (TH) enzyme activity) within neurons to increase dopaminergic levels.

The pyrethroid insecticide, permethrin, has been examined recently in association with Gulf War syndrome and

locomotor effects. Pyrethroid insecticides may also act as an inhibitor of complex I in mitochondria, and studies from the Bloomquist laboratory measured an increase in dopamine uptake in isolated striatal synaptosomal preparations. It seems also to increase expression of the dopamine transporter (DAT) protein and a transient increase in α-synuclein expression. However, permethrin seems to increase cortical acetylcholinesterase activity and causes variable neuronal degeneration in different brain regions, indicating that permethrin toxicity is not specific for dopaminergic neurons. Further clinical and laboratory studies are needed to define the importance of this pesticide to movement disorders.

Glossary

Huntington's disease-related pattern (HDRP) – A metabolic spatial covariance pattern identified in the brains of patients with Huntington's disease.
Parkinson's disease-related cognition pattern (PDCP) – A metabolic spatial covariance pattern identified in brain regions associated with the cognitive symptoms of Parkinson's disease.
Parkinson's disease-related pattern (PDRP) – A metabolic spatial covariance pattern identified in brain regions associated with the motor symptoms of Parkinson's disease.
Positron emission tomography (PET) – An imaging technique that produces a three-dimensional image or map of functional processes in the body/brain through the use of radionuclides which emit γ-rays.

Scans without evidence of dopaminergic deficit (SWEDD) – A term used to describe patients who have clinical signs of parkinsonism, but who have normal radiotracer uptake on imaging with fluorodopa PET.
Torsion dystonia-related pattern (TDRP) – A metabolic spatial covariance pattern identified in the brains of dystonia gene mutation carriers.

Definition and History

In recent years, a number of exciting developments have taken place in the application of positron emission tomography (PET) imaging for the study of movement disorders and their response to treatment. Various radiotracers are currently available for the in vivo assessment of abnormal neuronal function in the diseased brain. In particular, a hierarchical approach integrating quantitative parameter estimation at the voxel level with spatial covariance tools for pattern analysis has greatly enhanced the role of functional imaging in the study of these and other neurodegenerative disorders.

In this article, we summarize the recent advances in the clinical investigation of movement disorders utilizing PET techniques. Parkinson's disease (PD) is the best studied of these disorders and is discussed in detail. Moreover, rather than focus on the extensive literature that has appeared on abnormalities in motor activation in movement disorders, we will review the growing body of information that has appeared on abnormal resting brain function in these disorders. This article also discusses the role of these imaging measures as biomarkers for the objective evaluation of novel therapies for movement disorders.

Diagnosis of PD

Dopaminergic Imaging

Fluorodopa: Neurotransmitter uptake, metabolism, and storage

The original application of PET in PD was to detect presynaptic nigrostriatal dopamine (DA) dysfunction as a means of patient diagnosis. It is understood that injury to the substantia nigra causes defects in the storage and release of DA in the striatum. PET studies utilizing 6-[^{18}F]fluoro-L-dopa (FDOPA) measure the uptake of this tracer and its conversion to [^{18}F] fluorodopamine by the enzyme dopa decarboxylase (DDC) in the striatal dopaminergic nerve terminals.

Many studies have demonstrated that FDOPA PET yields quantitative parameters that can discriminate PD patients from healthy control subjects and correlate with independent disease severity measures. More importantly, it has been shown that putamen FDOPA uptake correlates with nigral DA cell counts measured in postmortem specimens. In patients with early stage of PD, FDOPA uptake is relatively preserved in the caudate and anterior putamen. This is in line with the pathological finding which showed that neuronal loss in early PD takes place in the ventrolateral tier of the substantia nigra, which projects to the posterior putamen. FDOPA PET has clinical utility in differentiating classical PD from alternate diagnoses such as psychogenic parkinsonism, essential tremor (ET), and secondary forms of parkinsonism. However, striatal FDOPA uptake in atypical neurodegenerative forms of parkinsonism is indistinguishable from that of PD, especially in the early stages of the disease.

6-[^{18}F]Fluorodopamine and PET are also used for the assessment of cardiac postganglionic sympathetic nerve terminal function in movement disorders, which could effectively differentiate movement disorders. Decrement of cardiac fluorodopamine has been shown in patients with PD and pure autonomic failure, but remains intact in multiple system atrophy (MSA) patients.

Other dopaminergic radiotracers

The development of radiotracers which bind to the striatal dopamine transporter (DAT) has led to another means for imaging the nigrostriatal dopaminergic system with PET or single photon emission computed tomography (SPECT). The most extensively studied agents in this category are the cocaine analogues, such as 2-β-carbomethyl-3β-(4-iodophenyl) tropane (βCIT) and its fluoroalkyl esters (**Figure 1**). The use of DAT tracers has several potential advantages over FDOPA: (1) although dopaminergic neurons decline in normal aging, striatal FDOPA uptake appears to be maintained by the upregulation of DDC activity, which is supported by postmortem study. Therefore, FDOPA PET may be relatively insensitive to age-related decrements in presynaptic dopaminergic function. By contrast, the DAT binding agents are more sensitive to age-related dopaminergic attrition. (2) The transport of 3OMFD across the blood brain barrier can affect the quantification of DDC activity with FDOPA PET. (3) Signal-to-noise is potentially higher for DAT imaging than for FDOPA PET. Despite these advantages, recent studies have raised the possibility that DAT binding may be altered by concurrent levodopa therapy. Additionally, presynaptic DAT density is shown to be downregulated in PD. More research is warranted to determine how these findings will influence the use of this tracer in future neuroprotection trials.

The presynaptic vesicular monoamine transporter (VMAT) is involved in the packaging and transfer of monoamines to storage vesicles located in nerve terminals. Radioactive ligands that bind to VMAT sites such as [^{11}C]-dihydrotetrabenazine (DTBZ) can be used as a reliable

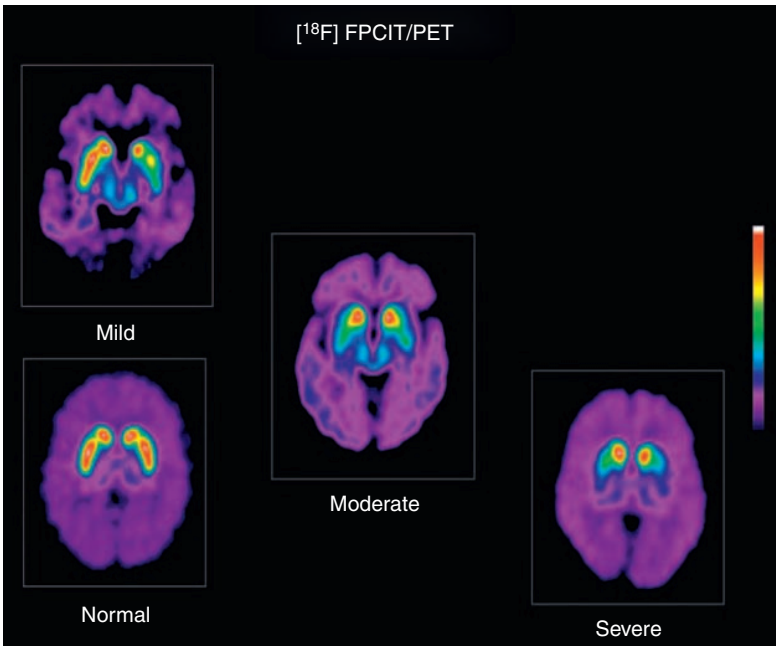

Figure 1 Images of striatal dopamine transporter binding obtained using ^{18}F-fluoropropyl-βCIT (FPCIT) and PET. Scans from patients with mild, moderate, and severe Parkinson's disease (PD) exhibit progressive declines in radiotracer uptake in the posterior putamen. Early disease is associated with marked asymmetry, which becomes bilateral with advancing motor symptoms. Caudate uptake is relatively preserved, until later stages of the disease. A scan from a normal volunteer (lower left) is included for comparison. Reprinted from Gilman S (2006) PET imaging is Parkinson's disease and other neurodegenerative disorders. *The Neurobiology of Disease*, 1st edn., pp. 821–828. Copyright 2006, with permission from Elsevier.

measure of monoaminergic and nerve terminal density. VMAT binding does not appear to be affected by concurrent antiparkinsonian dopaminergic therapy, giving it a potential advantage over other dopaminergic tracers. However, this method has comparably low signal-to-noise, and it may not be specific for dopaminergic terminals.

PET studies using ligands that bind selectively to D_1 and D_2 receptors in the striatum can be used to measure changes in postsynaptic dopaminergic function occurring during disease progression and pharmacotherapy. The radioligand [^{11}C] raclopride (RAC) can provide sensitive measures of local D_2 receptor density. It has been suggested that loss of dopaminergic nerve terminals in association with changes in the postsynaptic DA receptors underlies the motor complications that occur in the course of treatment. A relative increase of striatal D_2 receptor binding has been reported in early, untreated parkinsonian patients, particularly in the putamen contralateral to the more affected body side.

RAC is easily displaced by endogenous DA; indeed, an increase or decrease in RAC binding may not reflect D_2 receptor density. Rather, these changes may reflect alterations in the endogenous DA levels following amphetamine challenge, levodopa administration, placebo administration, motor tasks, or transcranial magnetic stimulation. In PD patients, levodopa-induced improvements in UPDRS motor ratings correlated significantly with reductions in putaminal RAC binding potential.

Metabolic Imaging

Utilization of ^{18}F-fluorodeoxyglucose (FDG) and PET have made it possible to map cerebral glucose metabolism. This imaging technique provides a measure of integrated regional synaptic activity of an afferent input neuron rather than the perikarya. Although the primary pathological motor dysfunction responsible in PD is confined to the substantia nigra, the degeneration of dopaminergic nigral projections to the striatum and other regions results in widespread alterations in the functional activity of cortico-striatopallido-thalamocortical (CSPTC) pathways.

Functional models of the basal ganglia generally predict that the loss of inhibitory dopaminergic input to the striatum causes increased inhibitory output from the putamen to the external globus pallidus (GPe), diminished inhibitory output from the GPe to the subthalamic nucleus (STN), and functional overactivity of the STN and internal globus pallidus (GPi). These changes result in decreased output from the ventrolateral thalamus to the motor cortex, which are accompanied by alterations in regional cerebral glucose metabolism. We have modeled such systems using spatial covariance methods in which principle components analysis is applied to combined samples of patient and control scans. Patterns with significantly different expression in the patient group are considered to be 'disease-related.' The PD-related spatial

covariance pattern (PDRP) is characterized (**Figure 2**) by pallidothalamic and pontine metabolic activity associated with reduced metabolism in the prefrontal cortices and parieto-occipital association cortex. The degree of PDRP expression is abnormally elevated in PD patients and correlates with disease severity and duration. In contrast to the neurochemical dopaminergic markers such as FDOPA or βCIT, PDRP expression has the attribute of increasing with disease progression. This may provide greater sensitivity in the detection of longitudinal changes in brain function, a critically important factor in the assessment of potential disease modifying agents.

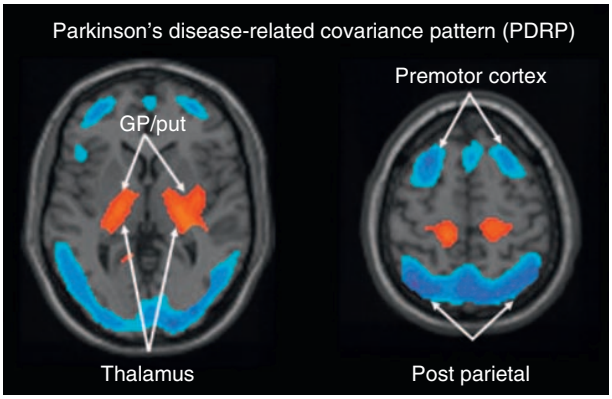

Figure 2 Parkinson's disease-related spatial covariance pattern (PDRP) characterized by pallidothalamic, pontine, and motor cortical hypermetabolism, associated with relative metabolic reductions in the lateral premotor and posterior parietal areas. (The covariance pattern was overlaid on T1-weighted MR-template images. The displays represent voxels that contributed significantly to the covariance pattern ($p < 0.001$) and that were found to be reliable on bootstrap resampling ($p < 0.05$). Relative metabolic increases are displayed in red; relative metabolic decreases are displayed in blue. The left hemisphere was cut in the transverse plane at $z = -5$ mm. The right hemisphere was displayed as a surface projection on the same brain template.)

Pattern analysis of FDG PET data can provide an accurate means of diagnosing atypical forms of parkinsonism (**Table 1**). Atypical neurodegenerative parkinsonian syndromes such as MSA, progressive supranuclear palsy (PSP), and corticobasal ganglionic degeneration (CBGD) are often difficult to distinguish from PD on clinical grounds. These diseases, however, have distinctive topographic features that can be used for differential diagnosis by metabolic imaging techniques. Single-case statistical parametric mapping (SPM) techniques can be used to categorize individual PET scans based upon characteristic disease templates (**Figure 3**). This pattern recognition approach correctly diagnosed 92.4% of the subjects in accord with clinical assessments made 2 years after PET imaging by blinded movement disorders specialists. Thus, FDG PET scans performed at the time of initial referral for parkinsonism accurately predicted the ultimate clinical diagnosis in the patients made at subsequent follow-up. Accurate differential diagnosis is also of particular importance in the context of clinical trials for parkinsonism. Inadvertent inclusion of atypical patients into pharmacological trials for PD is likely to reduce statistical power by increasing the heterogeneity of the treatment cohorts.

In the course of recent clinical trials of potential neuroprotective agents in PD, it was found retrospectively that 10–15% of enrolled subjects with clinical signs of parkinsonism had normal radiotracer uptake. Similarly, it was found that 14.6% of patients with parkinsonism

Table 1

Disease	*FDG*	*Striatal F-DOPA/DAT Binding*	*Striatal Raclopride*
Parkinson's disease	*Increased* in putamen, thalamus, brainstem, cerebellum, primary motor cortex *Decreased* in prefrontal, parietotemporal association cortices	Rostro-caudal gradient reduction. May show asymmetry in early stage	Up-regulated in early stage
Multiple system atrophy	*Decreased* in striatum, cerebellum, brainstem	Reduced ubiquously in striatum	Reduced
Progressive supranuclear palsy	*Decreased* in frontal cortex, midbrain	Mildly reduced	Reduced
Corticobasal degeneration	*Decreased* in striatum and parietal cortex on affected side	Mildly reduced	Possibly reduced
Huntington's disease	*Decreased* in striatum and temporal cortex	Normal (apart from atrophy)	Reduced
Primary dystonia	*Increased* in putamen, globus pallidus, cerebellum, supplementary motor area	Normal	Reduced
Dopa responsive dystonia	*Increased* in supplementary motor area and cerebellum *Decreased* in primary motor and premotor cortex	Normal	Up-regulated
Tourette syndrome	*Decreased* in thalamus, lenticular nucleus, hippocampus, midbrain	Normal	Normal
Essential tremor	*Increased* in cerebellum	Normal	?

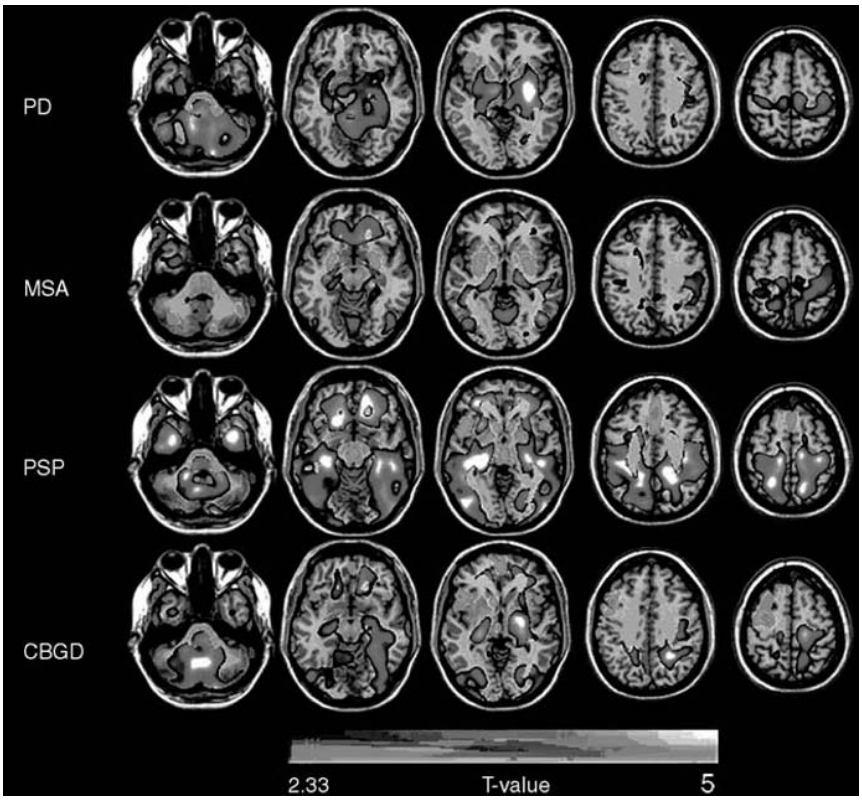

Figure 3 Templates of abnormal glucose metabolism in patients with PD, MSA, PSP, and CBGD identified by group analysis using SPM ($p < 0.01$). For image analysis, the hemispheres opposite the clinically more affected body sides appeared on the right. Reprinted from Eckert et al. (2005) FDG PET in the differential diagnosis of parkinsonian disorders. *NeuroImage* 26: 912–921. Copyright 2005, with permission from Elsevier.

referred to FDOPA PET because of diagnostic uncertainty had normal putamen radiotracer uptake. FDG PET was also conducted in a number of the same subjects at or near the time of dopaminergic imaging. PDRP expression was also normal in these subjects who had no evidence of dopaminergic deficit, that is, scans without evidence of dopaminergic deficit (SWEDD) on FDOPA PET. This suggested that the SWEDD patients were not likely to have classical PD. Indeed, these subjects did not progress at 1-year follow-up. They were found to have secondary nonprogressive forms of parkinsonism including drug-induced parkinsonism, vascular parkinsonism, dopa-responsive dystonia (DRD), and dystonic tremor. This illustrates that measurements of PDRP expression can be useful in differentiating PD from atypical parkinsonian variants, including secondary forms in which nigrostriatal dopaminergic terminals are relatively preserved.

Cerebral Perfusion Imaging

In most neurodegenerative disorders, regional cerebral blood flow and metabolism are coupled processes associated mainly with synaptic activity. We have found that PDRP expression measured off medication in cerebral perfusion images (e.g., ^{15}O-water PET, ^{99m}Tc-ethylene cysteinate dimes SPECT, arterial spin labeled [ASL] MRI, etc.) is highly correlated with network assessments in 'gold standard' FDG PET metabolic images. In a recent study, we found that the flow-metabolism couple was preserved during STN deep brain stimulation (DBS) treatment but was dissociated during levodopa administration. At the regional level, this 'uncoupling' related to treatment-mediated reductions in the putamen/GP and dorsal pons/midbrain and concurrent elevations in blood flow in these areas. Interestingly, patients with levodopa-induced dyskinesia and longer disease duration exhibited greater uncoupling at both the regional and network (PDRP) levels. The data suggest that levodopa gives rise to vasodilation in AADC-rich regions, resulting in a local oversupply of DA. For this reason, the results of cerebral perfusion studies in PD should be interpreted with caution, particularly in levodopa-treated patients.

The Role of Imaging in the Assessment of Therapy for PD

Reliable *in vivo* markers of neuronal activity are needed for the objective assessment of treatment outcome. Currently available clinical scales are relatively insensitive,

inherently variable, and potentially subjective if performed under unblinded conditions. By contrast, quantitative functional brain imaging markers may be suitable as outcome measures in trials of new symptomatic treatments for PD. Metabolic imaging biomarkers may also have a role in the objective assessment of disease modifying agents. In a recent study, rates of disease progression were assessed using FDG PET to measure longitudinal changes in PDRP expression, with ^{18}F-fluoropropyl-β-CIT to quantify DAT binding in the caudate and putamen as an index of presynaptic nigrostriatal dopaminergic dysfunction, and the motor UPDRS. We found that PDRP activity increased linearly over time, and was significantly elevated relative to healthy controls at baseline, 24 months, and 48 months. These longitudinal changes correlated with progressive declines in clinical ratings and in putamen DAT binding (**Figure 4**(**a**)). Though significant, these correlations were of modest size. This indicates that the clinical, dopaminergic, and metabolic biomarkers are not interchangeable and that each measure contributes unique information regarding disease progression.

Dopaminergic Medication

Metabolic imaging studies conducted on an off levodopa therapy have revealed localized reductions in the cerebellar vermis, putamen, globus pallidus, thalamus, and precentral gyrus. The changes observed in the activity of the PDRP network as a whole correlated significantly with clinical improvement in UPDRS motor ratings. Although not reaching statistical significance, the results of an FDG PET study with apomorphine showed similar metabolic reductions in the lenticular nucleus and thalamus, and in the occipital region. In animal models of PD, levodopa administration normalized preexisting elevations in pallidothalamic glucose utilization and reduced GPi firing rates. These findings, along with the PET results, support the notion that levodopa treatment reduces pathologically increased activity of excitatory projections to the GPi from STN.

Surgical Interventions

Surgical changes in regional glucose metabolism following GPi pallidotomy have been described in the ipsilateral motor cortex, lateral premotor, and dorsolateral prefrontal cortex – regions associated with volitional action and motor learning. Clinical improvement following this procedure correlated with reductions in the thalamic hypermetabolism and increases in lateral PMC metabolic activity. Similar regional findings were observed with GPi DBS. PDRP suppression was evident following both

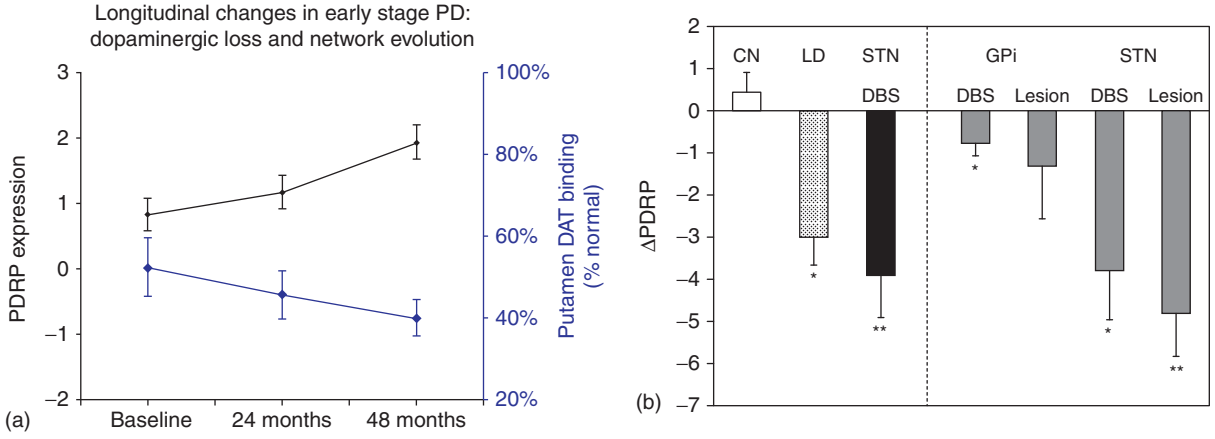

Figure 4 (a) *Top:* Mean expression of the PD-related metabolic covariance pattern (PDRP, see **Figure 2**) at baseline, and at the second (24 months) and third (36 months) time points as part of our longitudinal FDG PET study of early stage PD. PDRP values increased significantly over time ($p < 0.005$; repeated measures analysis of variance). *Bottom*: Mean putamen DAT binding measured by [^{18}F]-fluoropropyl βCIT PET in the same PD patients scanned longitudinally at the three time points. DAT binding was expressed as a percentage of the normal mean value for 15 age-matched control subjects. Unlike the longitudinal increases that occurred with PDRP expression, DAT binding declined over time ($p < 0.04$, reading a minimum of 30% normal for the putamen. Reprinted from Eckert T and Eidelberg D (2005) Neuroimaging and therapeutics is movement disorders. *NeuroRx* 2: 361–371. Copyright 2005, with permission from Elsevier and the American Society of Experimental Neuro therapeutics. (b) Bar graph illustrating treatment-mediated changes (±SE) in the expression of the PD-related metabolic covariance pattern (△PDRP). Difference in values from the levodopa infusion (LD; dotted), STN stimulation (DBS; black), and the test-retest control (CN; white) groups from the current study are presented in the left panel. These measures were compared to those computed on the basis of previous PET data (gray) from patient cohorts undergoing GPi and STN lesioning and stimulation. These comparison data are presented in the right panel. (△PDRP values were computed on a hemisphere-by-hemisphere basis for all treatment groups. For the unilateral surgical interventions, △PDRP reflects changes in network activity in the operated hemispheres. For the bilateral therapies, including levodopa infusion, PDRP changes were computed for each hemisphere and averaged. Asterisks represent p values with respect to the untreated condition (paired Student *t*-test). *$p < 0.05$, **$p < 0.01$ (paired *t*-test, ON versus OFF)). GPi lesioning and DBS, with comparatively greater network modulation following the former intervention.

The metabolic effects of STN lesioning (subthalamotomy) were studied at 3 and 12 months following surgery. Compared to baseline, cerebral metabolism at 3 months following surgery was significantly reduced in the ipsilateral midbrain (larger than actual ablation site), GPi, ventral thalamus, and the pedunculopontine nucleus (PPN), regions in which metabolic activity has been shown to correlate with intraoperative recordings of STN firing rate. PDRP activity was reduced ipsilateral, but not contralateral to subthalamotomy, and remained stable at 12 months. These network changes correlated with improvement in limb bradykinesia and rigidity. The extent to which PDRP expression is reduced during stereotaxic surgery is dependent on the target and the mode of treatment (**Figure 4(b)**). Of note, RAC PET showed no change in striatal binding potential with STN stimulation, indicating that this intervention is unlikely to trigger endogenous DA release as its mode of action.

A recent Phase I study of unilateral subthalamic gene therapy for advanced PD utilized adeno-associated virus-glutamic acid decarboxylase (AAV-GAD) to convert the phenotype of STN projections to GPi/SN from glutamatergic (excitatory) to gabaergic (inhibitory). In this study, 12 subjects were scanned with FDG PET at baseline, and at 6 and 12 months following gene therapy. The data revealed a significant change in PDRP expression on the treated side, but not on the unoperated side. Changes in network activity correlated with improvement in concurrently measured clinical motor ratings. These results indicate the potential use of network quantification in the objective assessment of novel PD therapies. Moreover, imaging is likely to play a decisive role in determining the efficacy of other gene therapy strategies for movement disorders.

DA Cell Implantation

FDOPA PET has proved valuable in determining graft viability in the context of several blinded trials of embryonic nigral cell implantation. Although changes in FDOPA uptake at the graft site are only weekly correlated with clinical outcome following transplantation, this imaging approach has been critical in examining the basis for transplant-related dyskinesias. In five transplant recipients with this complication, FDOPA uptake was elevated in discrete regions of the putamen relative to their counterparts without dyskinesia. In addition to the posterodorsal zone of the putamen (in which a prominent reduction in uptake was present at baseline), the dyskinesia group also displayed a relative increase ventrally, in which preoperative dopaminergic input was relatively preserved. Further, technological development is likely to optimize DA cell implantation so as to prevent the occurrence of this undesirable complication of treatment. Future studies of stem cell implantation are likely to be carried out once these technical issues are satisfactorily addressed.

Cognitive Impairment in PD

Cognitive dysfunction in PD is a topic of great interest given its implications for patient quality of life. The underlying pathophysiology of PD dementia is thought to be the involvement of mesolimbic and mesocortical DA systems, Alzheimer-type pathology, cortical/limbic Lewy body deposition, and brain cholinergic dysfunction.

With FDG PET, we reported that neuropsychological performance in nondemented PD patients correlated with the expression of a distinct metabolic covariance pattern that was unrelated to the PDRP. This PD-related cognitive pattern (PDCP) is characterized by reduced metabolic activity in the prefrontal and parietal cortices with relative increases in dentate nuclei and cerebellar hemispheres (**Figure 5**). PDCP expression was found to correlate with impairment in memory and executive functioning in these patients, and unlike PDRP expression, it was not altered by the treatment of motor symptoms with either levodopa, STN DBS or STN AAV-GAD gene therapy.

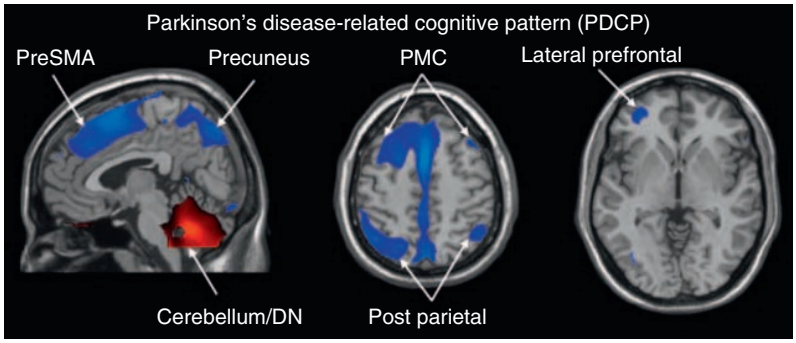

Figure 5 Parkinson's disease-related cognitive pattern (PDCP) characterized by hypometabolism of prefrontal cortex, rostral supplementary motor area (SMA), and superior parietal regions. Reprinted from Huang C, Mattis P, Tang C, Perrine K, Carbon M, Eidelberg D (2007) Metabolic brain networks associated with cognitive function in Parkinson's disease. *NeuroImage* 34: 714–723. Copyright 2007, with permission from Elsevier.

In a recent study, this pattern was found to be elevated in PD patients with clinically defined features of mild cognitive impairment (MCI) compared with patients of equivalent motoric severity who were cognitively intact. These findings suggest that the PDCP may be a useful biomarker of cognitive dysfunction at early stages of the disease.

Two novel radioligands developed for the clinical investigation of Alzheimer's disease (AD) have also provided insight into the mechanisms of cognitive dysfunction in PD. ^{18}FDDNP [2-(1-{6-[(2-[^{18}F]fluroethyl)(methyl) amino]-2-naphthyl}ethylidene)malononitrile] can be used to target neurofibrillary tangles and β-amyloid senile plaques. In a study of PD dementia with ^{11}C-PIB, there was evidence of prefrontal accumulation of radiotracer in the brainstem as compared to the cerebral cortex. Postmortem examination revealed ^{11}C-PIB uptake in Lewy bodies and in the neuromelanin of the substantia nigra in PD patients.

Other PET tracers to quantify brain acetylcholinesterase (AChE) activity (e.g., *N*-[^{11}C]-methylpiperidin-4-yl propionate (MP4P or PMP) or [^{11}C]-*N*-methylpiperidin-4-yl acetate (MP4A or AMP)) are also of interest. MP4P PET measures AChE activity in brain regions with low to moderate AChE activities such as cerebral cortex, thalamus, and cerebellum. Thalamic AChE reductions associated with relative preservation of AChE in cortex are a feature of PSP and MSA that may potentially be used for differential diagnosis in parkinsonism patients.

PET Imaging and Other Movement Disorders

Huntington's Disease

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder with pathological expansion of CAG/polyglutamine repeat that results in progressive impairments in behavior, motor function, and cognition. PET has provided important insights into understanding the pathological mechanism of HD. Decreased striatal D_2 receptor binding has consistently been demonstrated on RAC PET in HD patients and in presymptomatic HD (p-HD) gene carriers. A longitudinal study illustrated a progressive decrement of 6.3% per year. A negative correlation was found between age-normalized striatal D_2 receptor binding and CAG repeat length in both asymptomatic and symptomatic HD gene carriers. Network analysis of FDG PET scans from p-HD subjects and gene negative controls has indicated the presence of a significant reproducible disease-related spatial covariance pattern. This Huntington's disease-related metabolic pattern (HDRP; **Figure 6**) is characterized by covarying metabolic reductions in the caudate, putamen, and temporal cortex, with concurrent metabolic increases in the occipital lobe. Changes in HDRP expression with disease progression have been assessed in a longitudinal FDG PET study of 12 p-HD subjects. HDRP activity was found to increase between baseline and 18 months follow-up ($p < 0.003$), but interestingly declined at 44 months ($p < 0.04$). Striatal metabolism was abnormally low at all time points ($p < 0.005$). By contrast, thalamic metabolism was elevated at baseline ($p < 0.01$), but fell to subnormal levels in the p-HD carriers who subsequently developed hyperkinetic symptoms. Regional thalamic metabolic activity (and HDRP expression) may represent a compensatory mechanism in p-HD, which appears to fail as symptoms emerge.

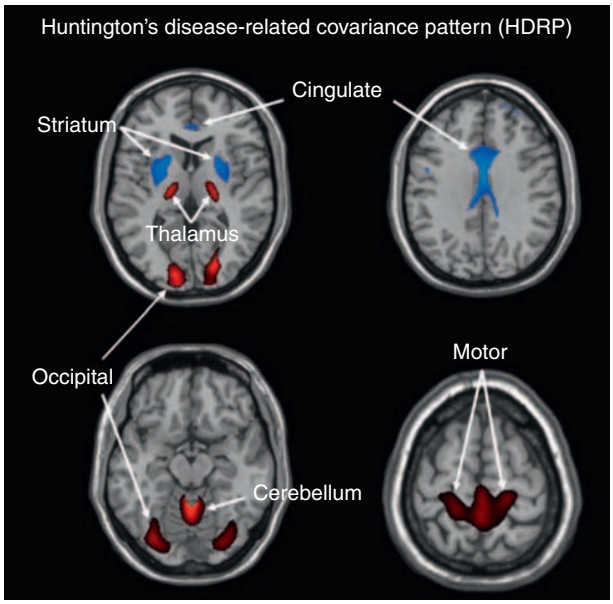

Figure 6 Huntington's disease-related spatial covariance pattern (HDRP) characterized by relative metabolic decreases in the striatum and cingulate cortex, associated with relative increases in the ventral thalamus, motor cortex, and occipital lobe. Reprinted from *Brain* 130 (Pt 11): 2858–2867. Copyright 2007, with permission from Oxford University Press.

Dystonia

Primary torsion dystonia is a chronic movement disorder manifested clinically by focal or generalized sustained muscle contractions and postures. FDG PET studies have indicated that *DYT1* gene carriers with and without clinical manifestations express an abnormal reproducible metabolic pattern characterized by covarying increases in the posterior putamen/globus pallidus, cerebellum, and supplementary motor area (SMA) (**Figure 7**). Indeed, elevated expression of this torsion dystonia-related pattern (TDRP) has been shown to persist following the suppression of involuntary dystonic movements by sleep induction. Abnormal TDRP expression is not specific for a particular primary dystonia genotype. It is present in carriers of the *DYT1* and *DYT6* mutations and in patients with blepharospasm. Despite these similarities at the network level, distinct differences in regional metabolism exist to distinguish dystonia subtypes based on genotype

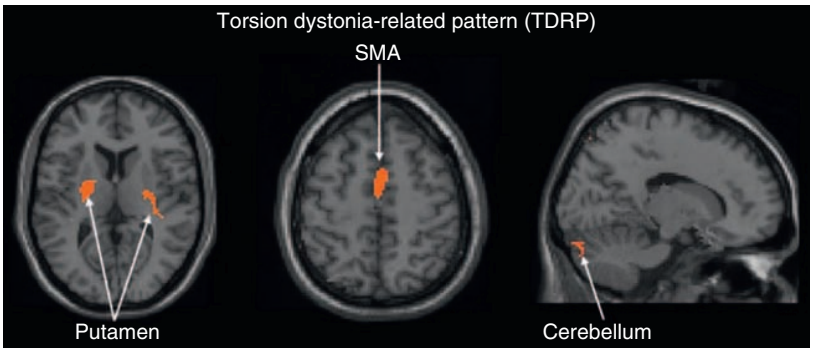

Figure 7 Torsion dystonia-related spatial covariance pattern (TDRP) characterized by relative metabolic increases in the putamen, extending into the globus pallidus (GP), the SMA, and the cerebellum. Reprinted from *Annuals of Neurology* 52: 853–856. Copyright 2002. Wiley-Liss, Inc.

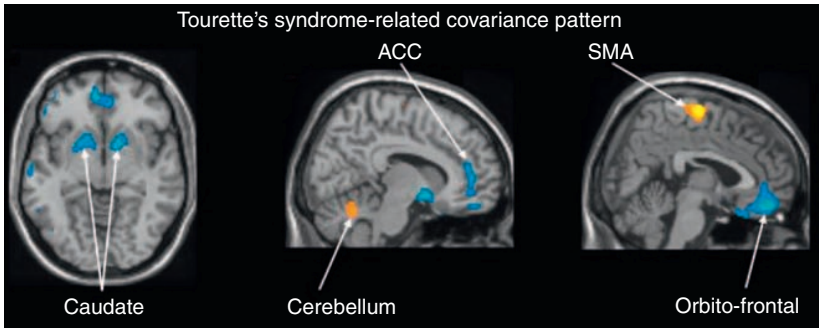

Figure 8 Tourette's syndrome-related pattern characterized by relative metabolic decreases in the caudate, anterior cingulate cortex (ACC), and orbitofrontal, associated with relative increases in the cerebellum and SMA. Courtesy of Dr. A. Feigin.

and phenotype. Interestingly, the TDRP network is not expressed in DRD, which is associated with a distinct spatial covariance pattern that is not expressed in *DYT1* or *DYT6* gene carriers. In spite of some clinical similarities with PD, that is, the presence of parkinsonian features and a marked response to levodopa, DRD patients do not express the PDRP network, in keeping with their intact presynaptic dopaminergic function. Striatal D_2 binding reductions are observed in both manifesting and nonmanifesting *DYT1* gene carriers, suggesting that this phenomenon is a trait feature of the *DYT1* genotype. By contrast, striatal D_2 binding in DRD is elevated in both nonmanifesting and manifesting subjects and was not affected by levodopa treatment.

Tourette's Syndrome

Gilles de la Tourette's syndrome (TS) is a chronic neurologic condition characterized by multiple motor and vocal tics of varying intensity, associated with behavioral disturbances. Network analysis has been applied to FDG PET data from TS patients revealing two distinct spatial covariance patterns in this disorder. The first metabolic pattern was associated with covarying increases in the lateral frontal cortex and paracentral regions, consistent with the presence of abnormal movements. A second TS covariance pattern was associated with metabolic reductions in the striatum, thalamus, and temporal lobe. The latter pattern correlated with the severity of TS symptoms, and relates the disorder to limbic CSPTC loops. A more recent network analysis using a voxel-based spatial covariance approach disclosed a similar metabolic pattern (**Figure 8**) in a subsequent population of TS patients. Given the absence of a specific neurochemical biomarker for TS, metabolic networks like these may prove useful as an adjunct to clinical evaluation in the assessment of new TS therapies.

Tremor Disorders

The pathophysiology of essential tremor (ET) is still poorly understood. Currently, ET assessment and diagnosis are established solely by clinical evaluation. No validated biomarkers are in use for the evaluation of this disorder. Striatal dopaminergic function in ET patients has been repeatedly demonstrated to be normal. Nonetheless, activation PET studies have provided valuable insights into the functional mechanism of ET and other tremor disorders. PET studies with ^{15}O-labeled water

($H_2^{15}O$) have revealed resting increases in cerebellar blood flow in ET, with abnormal red nucleus activation during arm extension. Cerebellar hyperactivation in ET can be reversed by ethanol ingestion with concurrent reduction of tremor. Interestingly, recent ECD-SPECT studies of ET patients and healthy controls conducted at rest have revealed that cerebellar–thalamocortical tremor-related networks identified in tremulous PD patients are similarly expressed in ET. That said, PDRP expression was elevated in the PD tremor cohort, but not in their ET counterparts.

High-frequency DBS of the ventral intermediate (Vim) nucleus of the thalamus can also alleviate tremor symptoms in ET patients. $H_2^{15}O$ PET has demonstrated increased cerebral blood flow during Vim stimulation and bilaterally in the anterior cingulate cortex (ACC). This was associated with decreased perfusion in the contralateral occipital cortex and ipsilateral inferior frontal cortex. Another $H_2^{15}O$ PET study of Vim DBS for ET revealed increased perfusion at the local surgical site and in the SMA, ipsilateral to stimulation.

Palatal tremor is thought to relate to the central inferior olivary nucleus, with hypersynchronous firing of dentatorubromedullary connections. FDG PET has demonstrated that medullary metabolism is increased in both primary and symptomatic palatal tremor patients.

Conclusion

Modern network-based approaches to functional imaging data have opened up new possibilities for the clinical investigation of PD and other movement disorders. In particular, these methods have allowed for high throughput image analysis to facilitate multicenter clinical trials of new therapies using network imaging biomarkers. Additionally, new radiotracers have been developed to quantify specific, localized neurochemical deficits in neurological disease. A combined *in vivo* imaging approach utilizing localized neurochemical assessments and whole-brain network measurements will help elucidate the abnormal structure–function relationships that underlie the various movement disorders. Quantifying changes in these relationships with therapy is likely to facilitate the development of new treatments for these disorders.

Pisa Syndrome

N J Diederich, Centre Hospitalier de Luxembourg, Luxembourg-City, Luxembourg

Glossary

Cholinesterase inhibitors – Are drugs that block the activity of the cerebral enzyme cholinesterase. Thus, more acetylcholine is available. They are used to treat early stages of Alzheimer and Lewy body dementia.

Dystonia – A neurologic syndrome characterized by sustained muscle contractions, producing twisting and repetitive movements or abnormal postures, or positions.

Neuroleptics – Medications used to treat psychosis and blocking dopamine D2-like receptors. The older or typical neuroleptics show more Parkinsonian side effects than the newer, atypical neuroleptics.

Definition and History

Pisa syndrome (PS) is a dystonic lateroflexion of the trunk, or lean to the side, or pleurothotonus. The term was coined by Ekbom and colleagues in 1972. The authors described PS as a medication side effect in three elderly women taking butyrophenones. Thereafter, PS was mainly described as a side effect of typical and atypical neuroleptics, and in patients taking cholinesterase inhibitors. There has been some debate whether PS can also occur as an idiopathic syndrome and whether there may be some overlapping with scoliosis or lateral flexion frequently encountered in Parkinson's disease.

Pathophysiology

The PS is considered to be mostly a medication-induced truncal dystonia. The debate continues whether this dystonia has to be considered an acute or tardive dystonia. According to the most tempting hypothesis, PS is due to an imbalance of the dopaminergic/cholinergic system, with relative excess of cholinergic transmission and relative decrease of the dopaminergic transmission. Theoretically, this imbalance can be caused by the addition or the discontinuation of neuroleptics (typical or atypical), cholinesterase inhibitors, or dopaminergic drugs. Practically, pharmacological dopaminergic blockade and degenerative dopamine depletion seem to be the most frequent cause in predisposed patients, who are no longer able to compensate for the presupposed neurochemical imbalance. These are mainly elderly female patients with organic brain disorders (see below). Some authors have also hypothesized that dopaminergic hypersensitivity induced by neuroleptic treatment, or noradrenergic or serotoninergic dysfunction plays a role. Interestingly, a myopathic cause has never been proposed, although the PS has some similarities with camptocormia, in which such a cause has been proven in numerous cases.

Epidemiology and Risk Factors

There are no epidemiological data on the incidence of PS in the general population, but there have been studies in the psychiatric population under *neuroleptic treatment.* Stübner and colleagues studied the prevalence of PS in a population of 45 000 psychiatric patients, monitored by a multicenter drug safety surveillance program for 5 years. They identified 20 episodes of PS in 17 patients. Thus, the prevalence was 0.04%. However, Yassa and colleagues reported a prevalence rate of 8% in high risk psychogeriatric patients; in their carefully observed cohort of 133 patients, 11 developed PS in 2–120 days (mean 26 days) after neuroleptics were started. Several risk factors for PS have been identified: previous treatment with classical neuroleptics, combined pharmacologic treatment, previous episodes of tardive dyskinesia, female gender, old age, and the presence of an organic brain disorder, including marked brain atrophy. In one study, abnormal findings on brain CT were found in half of the patients. Given these risk factors, PS can even occur in patients taking atypical neuroleptics.

More recently, PS has been reported in demented patients taking *cholinesterase inhibitors*, such as donepezil, rivastigmine, or galantamine. Several patients were under concomitant treatment with atypical neuroleptics; other putative risk factors in this population are unknown. There are no epidemiological data, but the syndrome seems to be less frequent than in patients taking neuroleptics. Vanacore and colleagues have estimated that there may be an incidence of two cases per 10 000 patients per year. There are a few case reports on PS in patients taking metoclopramide, tricyclic antidepressants, selective serotonin (5-HT) reuptake inhibitors (SSRIs), valproate acid, or in patients being treated by pallidotomy.

Idiopathic PS and PS occurring in *neurodegenerative disease,* without drug induction, have also been described, but the differential diagnosis is challenging. PS has been

reported in patients with Parkinson's disease and multiple system atrophy (MSA). As proposed by Duvoisin and Marsden in 1975, the laterality of the basal ganglia abnormalities (i.e., asymmetric putaminal lesions) may be the main contributive factor, and a partial overlap with the common but less pronounced scoliosis in Parkinson's disease has to be discussed. Finally, PS can be the leading feature in axial predominant adult-onset *primary dystonia.*

Clinical Features

Bending to one side of the upper thorax, the neck, and the head are the main features of the PS syndrome. Additionally, the patient may show some rotation or twisting of the trunk to the same side. The syndrome, although permanent, often aggravates during walking or sitting, and diminishes in the supine position. It can be momentarily corrected by passive mobilization of the trunk, although the patient goes back to the initial trunk position after this maneuver. There are no other dystonic features, with the exception of a possible forward inclination (camptocormia). Interestingly, the patient is often unaware of the abnormal position and is unlikely to complain of it. The statuette by Richer (at the end of the nineteenth century) from Hôpital Salpétrière, Paris is a remarkable illustration of combined PS and camptocormia in an elderly patient (**Figure 1**).

Differential Diagnosis

The scoliosis or lateral flexion, primarily occurring in Parkinson's disease, is related to the laterality of the disease and worsens in an insidious way. In most cases, the concavity is contralateral to the side initially and most severely affected. When this scoliosis develops more rapidly and vigorously, it may be difficult to differentiate from the PS, especially if the patient is also taking dopaminergic drugs that can induce an axial dystonia of the PS type. However, it is also possible that such a PS-like dystonia worsens in the OFF period and improves after levodopa, thus reflecting a medication-sensitive motor fluctuation. In patients without Parkinson's disease, other differential diagnoses such as vertebral diseases (fractures and osteoporosis), conversion reaction, or malingering should be ruled out easily (**Table 1**).

Diagnostic Work-up

In most cases, a precise history of the present and past medications, a withdrawal trial, if needed, and in rare cases, complementary radiological exams of the brain and spine, should be sufficient to make the diagnosis.

Management and Prognosis

In medication-induced PS, reduction in dose or discontinuation of the offending antipsychotic drug or cholinesterase inhibitor is the first-line treatment. Importantly, the complete resolution of the PS can occur within 24 h but may also take weeks or months. In some patients, switching from a typical to an atypical neuroleptic or from one atypical to another atypical neuroleptic may also be

Figure 1 Reproduction of a photograph showing the 'Statuette pathologique' by Paul Richer (1895). The patient with Parkinson's disease shows a mild inclination of the trunk to the left and a more marked anteroflexion of the trunk (camptocormia). Reproduced from Hobbelen JSM, Koopmans RTCM, Verhey FRJ, Habraken KM, and de Bie RA (2008) Diagnosing paratonia in the demented elderly: Reliability and Validity of the Paratonia Assessment Instrument (PAI). *International Psychogeriatrics* 20: 840–852.

Table 1 Etiology of the Pisa syndrome

Medication-induced dystonia
Neuroleptics: typical neuroleptics more frequently than atypical neuroleptics; combination therapy more frequent than monotherapy; especially in (female) psychogeriatric patients
Cholinesterase inhibitors: rare
Antiemetics, valproate acid, selective serotonin (5-HT) reuptake inhibitors (SSRIs), tricyclic antidepressants: very rare
Dopaminergic medication in Parkinson's disease: very rare
Primary dystonia
Sporadic adult-onset axial dystonia: very rare
Within a neurodegenerative disease, but without induction by medications
Parkinson's disease, multiple system atrophy: possible overlapping with disease-inherent scoliosis, contralateral to predominantly affected side

helpful. According to small series, ~40% of the patients show an excellent therapeutic response to anticholinergics. Some of these patients, already on a small dose of triheyphenidyl (6 mg), showed this favorable response only when the dose was doubled. However, the cognitive side effects of these medications may not be tolerated by elderly patients.

Postpump Chorea

F Cardoso, Internal Medicine Department, The Federal University of Minas Gerais, Belo Horizonte, MG, Brazil

Glossary

Chorea – Abnormal involuntary movements that are brief, random, usually distal, and without purpose.
Neuroleptics – Agents which block dopamine receptors.
Sydenham's chorea – Chorea resulting from autoimmune process triggered by β-hemolytic *Streptococcus*.

Definition and History

'Chorea' (derived from the Latin choreus meaning 'dance') refers to abnormal involuntary movements that are brief, random, usually distal, and without purpose. Postpump chorea (PC) is the term coined to describe chorea with onset within 2 weeks following cardiopulmonary bypass. The first cases were described in 1961 shortly after the introduction of the latter procedure under deep hypothermia to correct congenital heart disease. With

recognition of risk factors and improvement of technique, there seems to be a sharp decline in the number of cases of PC in the last years.

Etiology and Pathogenesis

Case–control studies have defined the existence of an association between PC with deep hypothermia, circulatory arrest, longer duration of the former two, age at surgery beyond early infancy, and cyanotic heart disease with systemic to pulmonary collaterals. The lack of vascular lesions on imaging studies suggests that there is a basal ganglia change related either to microemboli or a biochemical factor. It is presumed that these factors lead to hypoactivity of the subthalamic nucleus, which is well known to occur in patients with chorea, particularly of vascular cause.

Epidemiology

There are no recent epidemiologic investigations of PC. One study from a tertiary center active in the surgical treatment of congenital heart disease showed that this condition occurred in 1.2% of 668 children who underwent open cardiac surgery from 1983 to 1993. Based on the rarity of recent reports of PC in the literature, one may cautiously suggest that there is a decline in the incidence of this condition.

Clinical Features and Diagnostic Criteria

The typical features of PC are generalized chorea with onset 3–12 days following surgery. Other clinical features described in these patients are decreased muscle tone and cognitive decline. Age of onset is an important factor predictive of severity of PC: the older the patient, the more severe the chorea. Currently, there are no diagnostic criteria of PC. Diagnosis is based on the combination of the typical clinical features combined with the lack of alternative cause.

Differential Diagnosis

The close temporal relationship between onset of chorea and cardiopulmonary bypass with deep hypothermia is very specific of PC and renders unlikely diagnostic confusion with other conditions. Nevertheless, the most important differential diagnosis of PC is Sydenham's chorea (SC), the commonest cause of acute chorea in children where at least 60% of patients have cardiac lesions. In contrast to patients with PC, subjects with SC often have clinical and/or laboratory evidence of previous *Streptococcus* infection as well as of other rheumatic fever signs. Vascular lesions, which may also be a consequence of congenital heart disease, can cause chorea in children and are readily diagnosed with neuroimaging methods. Other alternative causes to be ruled out are systemic lupus erythematosus, primary antiphospholipid antibody syndrome, infections, acute disseminated encephalomyelitis, and exposure to drugs.

Diagnostic Work-up

Patients with de novo chorea whose onset is temporally related to cardiac surgery should undergo complete neurologic examination and diagnostic testing to investigate the number of causes of this hyperkinesia. Those are the tests helpful in the diagnostic workup of patients suspected to have PC: tests of acute phase reactants such as erythrocyte sedimentation rate, C-reactive protein, leukocytosis, rheumatoid factor, mucoproteins, protein electrophoresis, supporting evidence of preceding streptococcal infection (increased antistreptolysin-O, antiDNAse-B, or other antistreptococcal antibodies; positive throat culture for group A *Streptococcus*; recent scarlet fever); serologic studies for systemic lupus erythematosus and primary antiphospholipid antibody syndrome must be ordered to rule out these conditions; and neuroimaging, particularly magnetic resonance imaging, helps to define the vascular nature of chorea or if it is related to acute disseminated encephalomyelitis; spinal fluid analysis should be done if there is a possibility of central nervous system infection.

Management

Neuroleptics are the first choice of the pharmacological management of PC. Most of the experience refers to the use of haloperidol although any agent with powerful D2 receptor blocking action is expected to be useful in the symptomatic management of chorea.

Prognosis

The current evidence supports the notion that the long-term prognosis of PC is rather poor. In one series of eight patients, for example, five subjects had persistent chorea and one of them died. In another study there was a clear distinction between those eight patients with onset at earlier age (median 4.3 months), all of whom recovered fully, from 11 others, older (median age 16.8 months). Among the latter, four died and only one of the survivors

had a complete neurologic recovery. Other factors of poor prognosis are cyanotic heart disease and longer duration of the hypothermia during cardiac arrest.

Postural Tremor

M M Nashatizadeh, K E Lyons, and R Pahwa, University of Kansas Medical Center, Kansas, KS, USA

Glossary

Corticomuscular coherence – Electrical correlation between cortical brain activity and neuromuscular activity.
Deep brain stimulation – The surgical implantation of electrodes to specific targets deep within the brain as a treatment for various brain disorders.
Magnetoencephalography – A brain imaging technique used to measure the magnetic fields produced by electrical activity.
Postural tremor – Involuntary rhythmic oscillatory movement of a body part during maintenance of a particular posture.
Sensorimotor loop oscillations – Cyclical neuronal activity involving repetitive electrical impulse transmission between the sensory and motor systems of the brain through feedback loops.
Stereotactic thalamotomy – A minimally invasive surgical procedure using a three-dimensional coordinates system to lesion the thalamus used in the treatment of essential tremor.
Transcranial magnetic stimulation (TMS) – A noninvasive method to excite neurons in the brain using a strong magnet held outside the head.

Definition and Features

Postural tremor describes involuntary rhythmic oscillatory movement of a body part during maintenance of a particular posture. The regularity results from equal contraction of reciprocally innervated antagonist muscles. Variable frequency, amplitude, and direction can depend upon the location of involved muscles. Although tremor can simultaneously affect multiple body parts, physiologic evidence suggests that affected limbs on opposite sides demonstrate independent tremors.

Mechanisms

Postural tremor may be either pathologic or physiologic. Similar underlying mechanisms occur regardless of etiology and may be classified broadly into two groups:

1. mechanical-reflex or sensorimotor loop oscillations between the basal ganglia, thalamus, and cortex;
2. oscillatory central networks mostly involving cerebellar outflow pathways.

Awake mapping of the ventral thalamus prior to thalamotomy has been used to analyze neuronal activity. When postural tremor is present, more active neurons are typically observed in the ventral intermediate (VIM) thalamic nucleus receiving cerebellar fibers. Less neuronal activity is measured in the mostly sensory ventral caudal (VC) nucleus and the ventral oral posterior (VOP) nucleus receiving pallidal fibers. Advances in magnetoencephalography have lead to quantification and localization of these oscillatory networks with improved temporal and spatial accuracy.

Modifying Factors

Tremor parameters may be affected by internal perturbations, muscle-load mechanics, and neural feedback. The effects of internal perturbations often seem random and difficult to investigate but include cardiac rhythms and other natural postural fluctuations. The use of weighted

tools can often dampen the amplitude of disabling postural limb tremor, although the benefit appears less robust at greater amplitudes. Increasing muscle load in patients with very low amplitude postural tremor may actually increase tremor frequency. Although weights frequently dampen tremor frequency in patients with enhanced physiologic tremor, this change is not as obvious in essential tremor (ET) or Parkinson's disease (PD). Wrist splints used in conditions such as carpal tunnel syndrome also appear to diminish any significant effect of weight bearing on postural tremor. As younger adults are more likely to demonstrate healthy fluctuations in heart rate, pulsatile hormonal release, and variable electroencephalographic potentials, increasing age may be related to tremor due to progressive loss of neurophysiologic variability and therefore less adaptability to stress. Reduced motor adaptability may be associated with increased demand on task-specific motor output reorganization.

Measurement

One way to measure neural feedback from the neuromuscular system is to link cortical activity with electromyographic activity. These studies of corticomuscular coherence are based upon the observation that tremor amplitude increases proportionally with the square of electromyographic activity as related by a power function. Accelerometry can also measure the acceleration of a moving body part (mass) and its related force according to Newton's second law: [Force = mass × acceleration]. Because postural tremor by definition occurs with an affected body part maintained against gravity, the role of gravitational artifact should be considered particularly at lower tremor frequencies where results are more likely affected. Velocity time series can also be helpful in discriminating different types of postural tremor.

Causes

Enhanced Physiologic Tremor

An 8–12 Hz tremor is considered normal with the hands extended forward. The frequency often slows in people over 50 years old. Other body parts may have frequencies as slow as 6.5 Hz. Exercise, anxiety, stress, fatigue, and alcohol withdrawal can all increase the amplitude of physiologic tremor.

Essential Tremor

Essential tremor (ET) represents the most common pathologic cause of postural tremor. Although postural limb tremor is most frequent, postural tremor of the head, vocal apparatus, and trunk also occur. Voice tremor includes postural and/or kinetic tremor affecting muscles of the vocal cords, or transmitting from head or neck muscles.

Parkinsonism

While classic PD commonly presents with rest tremor, some patients have mild postural limb tremor for decades before other parkinsonian features appear. Postural tremor in PD may also indicate a genetic or shared hereditary mechanism; in one study, 70% of twins with postural or kinetic tremor had a twin with PD or were diagnosed themselves. Asymmetric postural tremor may be an early sign of unsuspected PD; one published review of 13 patients initially diagnosed with ET with a positive family history and alcohol sensitivity eventually met PD criteria.

Low amplitude postural tremor in PD may be due to multiple mechanisms as evidenced in one study by corticomuscular coherence at frequencies of 12–18 Hz, peaks in accelerometer frequency at 5–12 Hz unchanged with weight bearing, and peaks in accelerometer frequency at 5–8 Hz that shift with weight bearing. Although physiologic tremor in young and older people typically does not alter postural stance, PD patients with amplified postural tremor may have greater excursions from their center of gravity that might affect postural stability.

The term *benign tremulous parkinsonism* describes a group of patients who typically present with stable rest tremor and only mild progression of other parkinsonian features over at least 8–10 years. Over 80% of these patients have moderate to marked postural tremor and most do not respond as effectively to levodopa as classic PD patients. Dopamine agonists are often less effective than levodopa in treating PD postural tremor compared to rest tremor of the arms, head, or legs.

The term *'reemergent tremor'* describes postural limb tremor that resembles rest tremor in frequency but appears or 'reemerges' only after latency. This tremor typically responds to levodopa thereby suggesting that reemergent tremor and rest tremor have a similar pathophysiology. Quantification of hand and finger rest and postural tremor in PD patients showed similar characteristics in both tremor types suggesting that underlying neural mechanisms remain active despite postural change. Another study using a displacement laser transducer on the index finger found no significant difference in amplitude fluctuation, frequency dispersion, harmonic index, or proportional power between subclinical rest and postural tremor. When postural tremor without latency is observed in PD patients, the possibility of coexistent ET should be considered.

Although rest tremor is typically absent in vascular parkinsonism, postural limb tremor occasionally develops after one or more lesions in the basal ganglia, thalamus, or connecting pathways. Postural tremor is relatively infrequent in parkinson-plus syndromes possibly due to

extensive multisystem degeneration although some patients with progressive supranuclear palsy (PSP) can present with postural arm tremor with or without orthostatic tremor.

Axial Postural Tremor

Axial postural tremor refers to full-body oscillations in the standing position. This tremor can be distinguished from primary orthostatic tremor (14–16 Hz) by its typically lower frequency (8–12 Hz). Axial postural tremor may occur alone or in combination with palatal tremor and the frequent description of discrete cerebellar lesions in both axial postural and palatal tremor implicates cerebellar outflow pathways as the most likely sites of pathology.

Focal Lesions

Traumatic injury, brain tumors, abscesses, arteriovenous malformations, and other focal lesions that disrupt connections between the thalamus, cerebellum, basal ganglia, and cortex are capable of producing postural tremor.

Demyelinating and Autoimmune Disease

Multiple sclerosis (MS) and other autoimmune conditions can cause progressive destruction of cortical, subcortical, brainstem, and spinal cord white matter. Many patients with one or more lesions to central pathways involved in tremor develop rest or postural tremor. In one study, proximal and distal postural tremor was noted in 88% of MS patients that had tremor. Antiphospholipid antibody syndrome can present with movement disorders including tremor although chorea is a more common finding.

Neurodegenerative Ataxias and Dystonia

The heterogeneous clinical presentation of spinocerebellar atrophy type 2 (SCA2) yields many patients with postural tremor alone or parkinsonism responsive to levodopa. Despite phenomenological overlap between ET and SCAs, one study of 177 patients diagnosed with ET found only one patient (0.5%) with positive genetic evidence of SCA3 and no patients with SCA2. Children and young adults with SCA27 have a fibroblast growth factor 14 gene mutation and may have postural tremor, progressive ataxia and dyskinesia. More than 30% of Friedreich ataxia patients have postural tremor. Generalized and focal dystonia patients can have irregular, coarse head, or limb postural tremor. Wilson's disease patients may have postural hand tremor and dystonia along with behavioral changes and psychosis. A common presentation of Fragile X tremor ataxia syndrome (FXTAS) is that of a man between 40- and 60-year old with postural tremor, ataxia, and gait instability while his daughter may have premature ovarian failure and his grandson may have mental retardation.

Neuromuscular Disorders

Peripheral neurological conditions can present with postural tremor. In one study, six of seven patients with hereditary sensorimotor neuropathy (HSMN) had postural tremor. Roussy–Lévy syndrome is a dominantly inherited neuropathy that can present with gait ataxia, pes cavus, areflexia, and postural tremor but an otherwise good prognosis. X-linked bulbospinal neuronopathy (Kennedy disease) is a polyglutamine disorder characterized by slowly progressive bulbar and proximal limb weakness, muscle atrophy, fasciculations, gynecomastia, and postural tremor. Postural tremor can also be seen in other acquired causes of neuropathy including diabetes, porphyria, uremia, and immunoglobulin M paraproteinemias.

Drug-induced Postural Tremor

Several sympathomimetic drugs associated with increased noradrenergic activity tend to worsen physiologic and pathologic postural tremor. These include stimulants such as methylphenidate and amphetamines and β-adrenergic agonists such as albuterol and terbutaline. Similar exacerbation of tremor can be seen with methylxanthine derivatives such as caffeine and theophylline, which act on adenosine receptors although the clinical extent of this has been debated. The immunosuppressant drug cyclosporine can cause tremor in transplant patients.

Many anticonvulsant and psychotropic medications commonly cause postural tremor. Lithium may worsen postural tremor in more than half of patients taking normal therapeutic doses. Postural tremor is more commonly noted in patients receiving conventional valproic acid compared to a continuous release form despite equivalent dosing and plasma concentrations. In one study, of 201 epilepsy patients treated with valproate, 45% had postural tremor. Selective serotonin reuptake inhibitors are associated with dose-dependent tremor in 4–11% depending on the patient population investigated. Neuroleptic drugs are known for symmetric rest tremor but parkinsonian postural tremor can also occur. One randomized, placebo-controlled trial of amantadine in ET patients found 6 of 16 patients taking the drug had increased postural tremor.

Metabolic and Toxic Disorders

Hypoglycemia frequently exacerbates tremor. Thyrotoxicosis should be suspected in patients with postural tremor associated with nervousness, rapid heartbeat, heat intolerance, fatigue or weight loss or evidence of a goiter, exophthalmos, thinning hair, or smooth skin.

Hepatic encephalopathy patients develop postural tremor due to pathologic disruption of corticomuscular coherence and thalamocortical loop synchronization.

Cyclosporine causes tremor more often in liver (55%) than cardiac (31%) or kidney (21%) transplant patients.

While manufacturing prosthetic dental appliances, dental technicians may be exposed to numerous toxic solvents like *n-hexane* and heavy metals such as mercury, iron, chromium, cobalt, and nickel. One study of 14 dental technicians found four with postural tremor and one with parkinsonism. Workers with manganese toxicity often develop persistent postural tremor for 12 months after serum levels normalize. High amplitude postural hand tremor occurs with chronic paint sniffing along with kinetic hand tremor, mild dysmetria, dysdiadochokinesia, and positional nystagmus.

Psychogenic Tremor

Psychogenic tremor may present with a complex combination of rest, postural, or kinetic tremors. Distinguishing features often include distractibility with complex volitional movements, suggestibility and inconsistent frequency, amplitude and direction.

Treatments

Medications

Postural tremor due to pathologic conditions such as autoimmune or thyroid disease is most likely to respond to successful treatment of the underlying disorder. Treatment of drug-induced tremor usually begins with discontinuation of the provoking drug after considering the risks and benefits. If possible, an offending drug may be switched to a different class of medication that is not associated with tremor. Enhanced physiologic tremor patients frequently improve with various β-blockers. ET postural limb tremor often responds to propranolol, other β-blockers or primidone. Other options to consider include topiramate, benzodiazepines, gabapentin, and clozapine. While many with ET experience tremor resolution with alcohol, withdrawal may cause rebound tremor. Numerous medications have been used individually but larger trials are needed to determine efficacy. Head and voice tremor in ET are often resistant to medication. Axial postural tremor has been reported to respond to topiramate.

Botulinum Toxin Injections

A small randomized, double-blinded placebo-controlled trial of botulinum toxin type A injections for hand tremor in 25 patients with ET found no significant improvement on functional rating scales. A larger multicenter randomized, double-masked controlled trial of botulinum toxin type A injections in 133 patients with ET found evidence of significant improvement in postural tremor but not kinetic tremor at both low and high doses at 4 and 16 weeks follow-up.

Stereotactic Thalamotomy

Thalamotomy and similar surgeries can control ET postural tremor but this procedure has largely been replaced by deep brain stimulation (DBS) in order to circumvent permanent tissue destruction. Patients with MS who receive thalamotomy for postural tremor may initially experience improvement, but progressive demyelination can reduce effectiveness at long-term follow-up.

Deep Brain Stimulation

DBS of the thalamic ventral intermediate nucleus (VIM) can safely and effectively treat postural tremor in ET with greater functional improvement over patients who received thalamotomy. High amplitude motor evoked potentials from the motor cortex noted on transcranial magnetic stimulation (TMS) might indicate that VIM DBS activates rather than inhibits the target area. A nearly linear response between stimulation frequencies and tremor acceleration is noted between 45 and 100 Hz with graded benefit rather than all-or-nothing improvement. Maximal benefit is typically achieved at stimulation frequencies of 100–130 Hz. Using higher frequencies likely only shortens pulse generator battery life with little or no additional tremor improvement.

Subthalamic nucleus (STN) DBS is used for rest and postural tremor in PD. Patients with postural tremor who undergo STN-DBS often have reduced amplitude and increased frequency, suggesting the importance of STN in PD postural tremor pathogenesis. This unique frequency increase can improve patient function when compared to using medications alone. One SCA2 patient with rapid-onset disabling postural tremor had markedly improved function with STN-DBS. A recent small study of subthalamic area DBS shows greater tremor improvement over ventrolateral thalamic DBS. Another small study of bilateral caudal zona incerta DBS in MS saw postural tremor reduced by almost 60%.

Repetitive Transcranial Magnetic Stimulation (rTMS)

Although not widely used, postural cortical tremor has been reported to improve with 1 Hz rTMS over the premotor cortex but similar stimulation of primary motor cortex is ineffective.

Press-while-licking Task

J A Stanford and C S Bethel-Brown, University of Kansas Medical Center, Kansas, KS, USA
S C Fowler, University of Kansas, Lawrence, KS, USA

Glossary

6-Hydroxydopamine – A neurotoxin that, when administered into the brain, produces selective degeneration of catecholamine neurons. The 6-hydroxydopamine depleted rat is the most widely used preclinical model of Parkinson's disease.

Electromyography (EMG) – The measurement of electrical signals that are involved in activating motor units and muscle contractions. EMG can be conducted at the individual muscle fiber level by inserting needle electrodes into a muscle, or at a population level by attaching a surface electrode to the skin.

Fourier analysis – A set of operations for mathematically decomposing a time series of complex waveforms into combinations of separate, simple periodic components. In doing so, Fourier analysis extracts frequency (rhythmic) information from the data.

Instrumental – A measurement method that requires no direct human contact and is, therefore, not subject to bias.

Isometric force – Force resulting from contraction of a muscle or limb without a visible change in joint angle. Measurement of isometric force typically involves an immovable force transducer.

Ordinal data – Data ranked according to a scale that reflects intensity, with differences between values containing no information (e.g., ranking degree of satisfaction using a scale from 1 to 5).

Tremor – Involuntary rhythmic muscle contractions that produce oscillations of body parts. Tremors often indicate a pathophysiological state, but are also present in healthy organisms.

Definition and History

The press-while-licking task is a sensitive and clinically-analogous means to measure forelimb force control and tremor in rats. Like primates, rats use their forelimbs to manipulate objects. The same neural and muscular structures that play a role in limb use in primates are also involved in rats' limb use. More importantly, rats can be trained to produce desired movements, allowing measures of forelimb function that are analogous to those used in human studies. Although operant lever pressing has a long history in preclinical research, the biophysical properties of the press itself have generally not been of interest to the investigator. An underlying thesis of our work is that these properties can be exploited to reveal neuromuscular function.

Grip force is often used to assess muscle strength in rodents, while tremor assessment typically involves visual observation or the use of electromyography (EMG). Commercially available grip force measures can provide valuable information and are relatively simple to implement. However, testing usually requires direct experimenter involvement, and is, therefore, subject to investigator bias and other confounds unrelated to muscle strength. Tremor measurements typically involve visual observation and scoring intensity along an ordinal data scale, or the use of EMG. The press-while-licking task was developed as an alternative way to measure forelimb force and tremor in a noninvasive but instrumental manner.

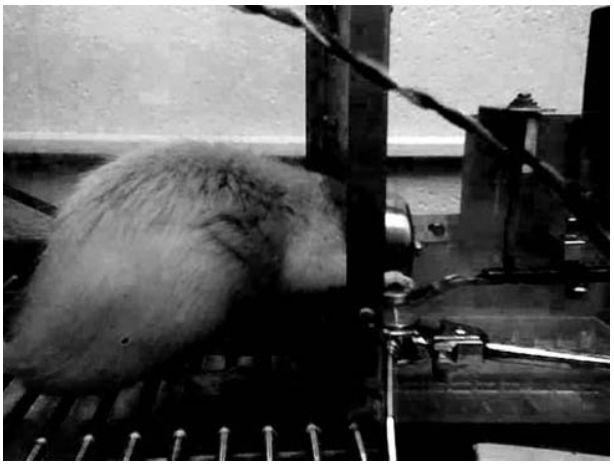

Figure 1 Photograph of a rat performing the press-while-licking task. When the force criterion is exceeded, the solenoid-operated dipper raises, providing access to 0.5 ml water. The dipper remains up as long as a threshold force is maintained. The duration of the press-hold-release bout is determined primarily by the amount of time it takes for the rat to empty the dipper cup. During an 8 min session, a well-trained rat typically produces between 40 and 60 press-hold-release bouts.

Press-While-Licking Method

The press-while-licking task is analogous to isometric force tasks used in human studies. The apparatus consists of an operant chamber enclosed in a sound-attenuating cubicle. The front panel of the chamber has a cylindrical recession that provides access to a 0.5 ml solenoid-operated dipper cup. To the side of the recession is a rectangular opening positioned so that a rat can reach the operandum located outside the chamber using its forelimb (see **Figure 1**). The operandum is an 18-mm diameter disc attached to an isometric force transducer that continuously measures the force exerted on the disc. The spatial arrangement allows a trained rat to press the operandum with a single extended forepaw and drink from the dipper cup at the same time. An interface receives the analog signals from the transducer, converts them to digital form, and routes them to a computer. Signal output is recorded at 100 samples per second with a force resolution of 0.33 g equivalent weights. Contingencies are programmed so that when a rat produces a specified criterion force (we typically use 20 g), the dipper is activated (raised) and the cup is presented through a hole in the cylindrical recession. We usually employ a second, lower force threshold for deactivating the dipper (typically 6.7 g). This inequality results in discrete press-hold-release bouts (see **Figure 2**). Under these conditions, force output peaks early in the first second of the response, and then decreases and plateaus until the disc is released. The duration of a press-hold-release bout is determined primarily by the amount of time it takes the rat to lick the water from the dipper cup. However, durations can also be influenced by drugs, lesions, and age, making duration an interesting dependent variable.

A computer program parses raw force-time data into individual 'response' bouts. We have defined these responses as press and hold bouts that exceed force criteria for at least 4.36 s, with the last 3.36 s used for spectral analysis of tremor (the force variation during the first second of the response precludes its use in spectral analysis). This duration was selected based on sampling requirements (the resulting 336 samples is a compatible sample) and assumptions of a stationary signal for Fourier analysis. Because almost all trained rats produce responses that are longer than this, we discard the remaining portion of the response before ensemble averaging the waveforms. This provides waveforms of equivalent length and without the nonstationary component associated with the release of the operandum. We derive a peak force measure from the first second of the response. The power spectrum and a mean hold force measure are derived from the remaining 3.36 s. Area under the curve of specific portions of the power spectrum is used to quantify tremor and other measures.

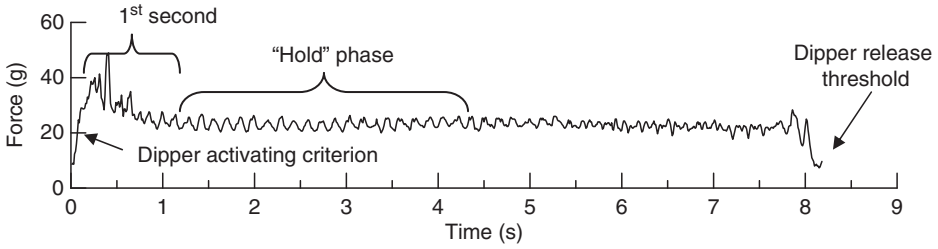

Figure 2 Representative force-time waveform recorded during a behavioral session. The higher dipper-activating criterion results in a peak in the waveform during the first second of the response. Force then decreases and plateaus for the remainder of the bout. Mean force and power spectra are derived from the hold portion of the bout. The prominent oscillations in the hold phase of the waveform are produced by the rat's licking as it is reflected through the forelimb muscles.

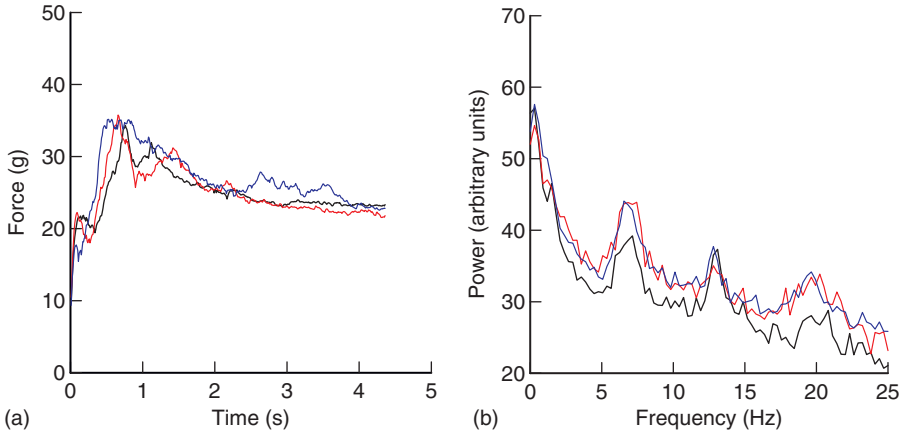

Figure 3 Averaged force-time waveforms and corresponding frequency power spectra from an 18-month-old Sprague-Dawley rat prior to (black lines), and 2 (red lines) and 4 (blue lines) weeks following infusion of 6-hydroxydopamine into the contralateral striatum. This animal sustained a 30% depletion of striatal dopamine. Note that although overall force was not substantially affected by the lesion, isometric force-related tremor was elevated at both the postlesion time points. Note also that because the waveforms were cut off at 4.36 s, the increased response durations are not reflected in this figure.

Research Applications

The press-while-licking task has been used to study the effects of dopamine depletion, drugs, and force training on isometric forelimb force and tremor in rats. Following is a brief synopsis of findings from these studies.

Nigrostriatal Dopamine Depletion

Nigrostriatal dopamine depletion in Parkinson's disease (PD) produces bradykinesia, muscle rigidity, and tremor. Rats with advanced unilateral 6-hydroxydopamine-induced dopamine depletion exhibit severe contralateral forelimb deficits. In order to model early stage PD, we produced a mild (30%) dopamine depletion by injecting 6-hydroxydopamine into the striatum contralateral to the trained forelimb of a rat. The lesion did not affect the overall force output in this rat but did increase isometric tremor (10–25 Hz band) at 2 and 4 weeks postlesion (see **Figure 3**). This may model the enhanced postural tremor observed in patients. The lesion also increased the duration of press-hold-release bouts and power in low frequency portions of the power spectrum. These effects are analogous to deficits in task disengagement and diminished isometric force control observed in clinical studies.

Drug Effects

'Typical' antipsychotic drugs such as haloperidol produce Parkinson's-like motor side effects, including bradykinesia and muscle rigidity. Newer 'atypical' antipsychotic drugs produce fewer motor side effects. Consistent with these clinical phenomena, haloperidol increased isometric force-related tremor in the press-while-licking task. This effect, which was reversed by coadministration of the anticholinergic drug atropine, likely reflects increased muscle rigidity. The atypical antipsychotics clozapine and risperidone attenuate force-related tremor in the task.

We compared the effects of physostigmine and harmaline, two drugs known to produce whole body tremor through different pharmacological mechanisms. Physostigmine increases the amount of acetylcholine in the

synapse, resulting in enhanced muscle contraction. Harmaline, which is used to model essential tremor, activates cells in the inferior olive and induces rhythmic activation of cerebellar Purkinje cells via the climbing fiber pathway. At doses that are too low to produce visually observable tremor, both drugs elevated force-related tremor in the press-while-licking task. The tremor profiles of the two drugs were different, as physostigmine elevated power in a wider portion (10–25 Hz) of the power-frequency spectrum than harmaline (8–12 Hz).

Dantrolene sodium is a skeletal muscle relaxant that inhibits calcium release at the sarcoplasmic reticulum. Because it also possesses neuroprotective potential, we tested dantrolene and found that it attenuates isometric force-related tremor at doses that do not appreciably affect operant responding or force output. This suggests that dantrolene affects neuromuscular function at doses that do not produce muscle weakness (a common side effect of the drug).

Force Training

We subjected rats to a training protocol in which they were required to press and hold with 20 g force, then 40 g, and then 60 g, practicing at each force level for ~2 weeks. Force-related tremor increased with each new force requirement, and force output increased with practice from the beginning to the end of each stage. However, force-related tremor decreased within both the 20 and 40 g stages, reflecting training effects that have been observed in human subjects.

Summary

Although the press-while-licking task involves a substantial amount of operant training, the behavioral control it affords provides advantages over other measurement techniques. Using sensitive isometric load cells, we have measured tremor at doses below those typically required to produce visually observable tremor in rats. We have also measured changes in isometric force that are analogous to those reported using isometric-based force tasks in humans. The press-while-licking task is therefore a valuable tool with translational appeal for preclinical research into motor function.

Primary Orthostatic Tremor

G Deuschl, Universitätsklinikum Schleswig-Hostein, Keil, Germany

Glossary

Orthostatic tremor (OT) – A form of tremor that occurs when the subject stands.

Pathognominic EMG pattern – Pathognomic EMG pattern can be found only for orthostatic tremor (high frequency, 13–18 Hz) and asterixis (pauses of EMG-activity in antagonistic muscles).

Clinical Presentation

Orthostatic tremor (OT) is a unique tremor syndrome characterized by a subjective feeling of unsteadiness during stance, and in severe cases, during gait. Some patients experience sudden falls. By definition, patients do not have problems when sitting and lying. The only clinical finding is visible, more often only palpable fine-amplitude, regular, rippling of leg muscles. Thus, this form of tremor is suspected mainly based on the complaints of the patients rather than clinical findings. The diagnosis can be confirmed with surface electromyography (EMG, e.g., from the quadriceps femoris muscle) while the patient is standing. In OT, pathognomonic 13–18 Hz burst pattern will be detected. All leg, trunk, and even arm muscles will show this pattern, which is in many cases absent during sitting and lying.

OT is a relatively rare condition, and only small case series have been published adding up to <200 cases. Epidemiological data are lacking, but the condition has only been described in patients above 40 years and in one series, the mean age of onset was lower for women (50 years) compared with men (60 years). So far, it is not considered as a hereditary disease, but one familial case has been reported.

OT is considered as an idiopathic condition, but several other movement disorders often occur with it for unknown reasons: Parkinson's disease, vascular Parkinsonism, and Restless Legs Syndrome have all been described in OT, but because OT is so uncommon, none of these conditions appears to be pathophysiologically related to OT. It is of special interest that dopaminergic terminals are significantly reduced in this condition, but clinical trials with L-dopa and dopamine-agonists have been largely unsuccessful.

Arm tremor may occur in roughly half of the patients and is usually more evident during standing up. Because the typical high-frequency EMG tremor pattern is detected in all the muscles of the body. The hypothesis that a bilaterally descending system underlies OT is widely accepted. Such projections presumably originate in the brainstem or cerebellum and not the hemispheres or subcortex. The differential diagnosis is broad, as other idiopathic tremors like essential tremor, and also cerebellar tremors can present with similar complaints. The most important test to separate them is electromyography.

Treatment

OT is responsive to clonazepam and primidone. Valproate and propranolol have been used in single published cases with variable success. Abnormalities of dopaminergic innervation of the striatum have been described, although levodopa has not consistently shown efficiency. Pramipexole, a dopamine agonist, was successful in one case. According to small double-blind studies gabapentine may have an excellent and sustained beneficial effect confirmed by objective measurements. In the author's experience, this is the drug of first choice for OT (1800–2400 mg daily). Surgical therapies were not considered to be helpful until recently. However, one case responded to spinal cord stimulation at thoracic level and three cases have just been reported to respond successfully to deep brain stimulation of the thalamus (Vim).

Summary and New Research Directions

OT is a specific tremor condition that occurs when subjects stand. It has a distinctive pattern that can be detected with surface electromyography. Further research efforts will be aimed at defining its anatomical locus and developing treatments with greater specificity.

Primary Progressive Freezing Gait

Y Balash and N Giladi, Tel-Aviv University, Tel-Aviv, Israel

Primary progressive freezing gait (PPFG) was described, in 1993, in Israel, as a single-sign disorder. From a clinical point of view, PPFG is similar or identical to syndromes of 'gait ignition failure' and 'isolated gait ignition failure,' meaning a marked difficulty in initiation of walking. PPFG can be considered as a higher level gait disorder, most probably associated with pathology involving the frontal lobes and their connections with other cortical regions, basal ganglia, and brain stem. It was described as 'pure akinesia' in Japan as a variant of progressive supranuclear palsy (PSP), where the predominant and initial motor symptom was freezing of gait (FOG). The pathogenesis of FOG remains unknown. It seems to originate from dynamic alteration of the normal cortical (premotor)–basal ganglia-thalamic–cortical (SMA) neuronal network at the level of the basal ganglia or the cortex. We hypothesized that 'unexpected' information reaching the basal ganglia possibly through the frontal–limbic–caudate nucleus network, involved in parkinsonian gait in a hypodopaminergic state, 'jams' the normal locomotion network to cause hyper or dys-synchronization at the level of the basal ganglia outflow. As a result, normal locomotion is no longer possible in the automatic mode, and an alternative but inefficient locomotion network, with an internal rhythm of 4–6 Hz (instead of 1 Hz in the normal gait network) is activated unintentionally. The result of activation of the 'alternative' locomotion network is dys-synchronization and abnormal scaling of leg muscles, which probably causes the feeling of the feet being 'glued' to the ground. The dys-synchronization and abnormal scaling is self-limited in nature but can intentionally be overcome by switching to an 'externally' driven gait (using cues), which bypasses the inefficient gait network.

Epidemiology and risk factors for PPFG are unknown.

Phenomenologically, FOG describes intermittent episodes of inability to initiate or maintain locomotion or to perform a turn that last seconds (rarely exceeding 30 s). Most episodes are associated with a subjective feeling that the feet are 'glued' to the ground. Patients either accept the situation and wait for its spontaneous disappearance or actively try to overcome the block, an effort that frequently causes tremor-like movements of both legs. Typically, most episodes can be overcome by motor, sensory, or mental tricks but habituation has been described. Freezing may occur while walking, passing through tight quarters (entering an elevator), reaching the destination (approaching a chair), or in stressful situations, such as crossing the street ('open space'). Movement during FOG can be divided into three categories: small steps forward, trembling in place, or complete akinesia.

PPFG begins around age 70 years (range 55–85) without gender differences. At early stages of different diseases, PPFG can be the main and, sometimes, the only symptom lasting as such for many years. Ninety percent of PPFG patients first complain about clumsiness, awkwardness of leg movements while walking, initially at sudden changes of a walking pattern, for instance, when suddenly stopping to avoid an obstacle or during a sudden change of walking direction and while turning. About 60% of PPFG patients experience at one stage the typical start or turn hesitations. Nearly one-third of patients experiences bradykinesia at disease onset, usually in the legs. About 20% of patients characterize beginning PPFG as subjectively impaired coordination, retropulsion or festination, gait ataxia, short-step walking, and shuffling though balance usually remains preserved and postural reflexes are normal. No abnormalities in eye movements or apraxia of eyelid opening are usually seen at early

stages of PPFG. Cognitive decline is usually mild and of limited significance at early stages of the disease.

Diagnostic criteria for PPFG, as offered by Factor et al. are: (1) PPFG is the primary feature the disease; (2) No clinical findings consistent with the diagnosis of PD or a known Parkinson plus syndrome; (3) No clinical or laboratory data to suggest other diagnoses such as cerebro-vascular disease; (4) Lack of dyskinesia or motor fluctuations from levodopa therapy. With disease progression, the majority of PPFG patients develop various parkinsonian features such as bradykinesia, micrographia, hypomimia, and mild rigidity, while tremor is less frequent. In the advanced stage of PPFG, the basic complaint is instability of gait and recurrent falls classically with no significant fear of falling.

The main differential diagnosis for PPFG in its early stages is subcortical arteriosclerotic encephalopathy of Binswanger which is classically associated with early falls while falls are less common in the early stages of PPFG. Cerebrovascular disease is frequently associated with basal ganglia and white matter lesions and extrapyramidal features (lower body parkinsonism), in addition to FOG. In most neuroimaging studies, performed to patients with PPFG, using SPECT, MRI, or PET scanning, no striatal abnormalities were observed.

Another important differential diagnostic option is Parkinson's disease (PD), which can be associated with FOG relatively early on. However, most FOGs in earlier stages of PD are short in duration and with limited functional importance as they rarely cause falls. Very significant FOGs in the first years after the onset of motor symptoms are rare in PD and should raise the question of atypical parkinsonism.

Evidence-based information about treatment of the PPFG is nonexistent. Anecdotal case reports have been published describing positive symptomatic effect of rasagiline $1\,mg\,day^{-1}$, and selegiline in greater doses (up to $20\,mg\,day^{-1}$) with reduction of gait blocks and restoration of ambulation. In the USA, the FDA does not recommend the use of selegiline at doses exceeding $10\,mg\,day^{-1}$.

After a mean of 4 years from motor symptom onset, postural instability becomes more prevalent and falling increases in frequency, ultimately leading to a wheelchair-bound state. Time to wheelchair stage ranges from 3 to 10 years after symptom onset.

In conclusion, PPFG is a late onset (60–70 years), slowly progressive syndrome, where FOG is the initial symptom and slowly progresses as years go by. Falling begins, on average, after 2.6 years (range: 1–10 years), retro- and propulsion after 3.2 years (range: 1–10 years) and wheelchair-dependency after a mean of 4.1 years (range: 1–10 years).

Primidone and Movement Disorders

Mitra Habibi

Glossary

Allosteric binding site – A binding site other than the active site.

Cys-loop superfamily – Family of ligand-gated ion channels; examples include: Nicotinic ACh (acetylcholine), 5-HT_3 (5-hydroxytryptamine), glycine, $GABA_A$, and $GABA_C$ receptors.

Enzyme induction – An increase in the synthesis of hepatic metabolizing enzymes causing a decrease in the plasma concentration and elimination half-life of the affected drug.

Half-life – The time required for 50% of a drug to be eliminated from the body.

Metabotropic receptors – G-protein-coupled receptors; examples include: Muscarinic ACh (acetylcholine), $GABA_B$, dopamine, and most of serotonin receptors.
Pyrimidinedione – A chemical compound consisting of a pyrimidine ring substituted with two carboxyl groups.

Introduction

Primidone is an anticonvulsant drug that was first synthesized in 1949. It is the 2-deoxy analogue of phenobarbital and is of the pyrimidinedione class. It is indicated for the treatment of simple and complex partial and secondary and primary generalized tonic–clonic seizures. In addition to epilepsy, it is indicated as the first line of therapy for treatment of essential tremor.

Pharmacokinetics

Primidone is well absorbed and distributed throughout the body. Maximum plasma concentration is reached in about 2 h after administration of a 250 mg tablet. Primidone is metabolized in the liver to active metabolites: phenobarbital and phenylethylmalonic acid (PEMA). Phenobarbital is further metabolized to *p*-hydroxyphenobarbital. Several other minor metabolites of primidone have been identified but there is no evidence that they have a significant therapeutic role. Human studies estimate that on average 24.5% of primidone is converted to phenobarbital. The plasma concentration ratio of primidone to phenobarbital in patients on monotherapy is about 1:1. This ratio is increased to 1:3–5 with the addition of other enzyme inducing medications. Other factors influencing this ratio include age and pregnancy. Primidone and its metabolites are primarily excreted in urine and it has been estimated that about 40–50% of primidone is excreted unchanged. The mean plasma half-life of primidone varies between 6 and 18 h depending on the presence of other enzyme inducing medications. Phenobarbital has a much longer half-life compared to primidone, ranging between 72 and 96 h, while the half-life of PEMA is estimated between 10 and 25 h. It is also important to note that primidone has low protein binding and only about 20% binds to plasma proteins.

Mechanism of Action

Several studies have suggested a synergistic effect of primidone and its two active metabolites. It has been proposed that primidone and its active metabolite, phenobarbital, exert their anticonvulsant activity by enhancing inhibition via the $GABA_A$ receptor. Phenobarbital enhances the activity of $GABA_A$ receptor by increasing the duration of Cl^- channel opening, without affecting the frequency of ion channel opening or its conductance. Phenobarbital can also activate $GABA_A$ receptor in the absence of GABA; this has been linked to its sedative properties.

The antitremor mechanism of primidone is not known; however, there is evidence that GABAergic system and the $GABA_A$ receptors play a major role in regulating motor activity.

GABA Receptors

GABA (γ-aminobutyric acid) is the major inhibitory neurotransmitter and is widely distributed throughout the central nervous system (CNS). GABA receptors are divided into $GABA_A$, $GABA_B$, and $GABA_C$ receptors. $GABA_B$ receptors are metabotropic receptors that couple to K^+ and Ca^{2+} ion channels and activate a second messenger system via G proteins. Like $GABA_A$ receptors, $GABA_C$ receptors are ligand-gated receptors linked to chloride ion channels. However, unlike $GABA_A$ receptors that are composed of variable combinations of different types of subunits, these receptors are only composed of ρ_1–ρ_3 subunits and mostly found in neurons of the retina. The inhibitory effects of GABA are primarily mediated through $GABA_A$ receptors.

$GABA_A$ Receptors

$GABA_A$ receptors are fast ligand-gated chloride ion (Cl^-) channel receptors and are members of the cys-loop superfamily. $GABA_A$ receptors are expressed in most brain neurons. They are transmembrane receptors composed of five subunits. These subunits are identified as α_1–α_6, β_1–β_3, γ_1–γ_3, δ, ε, π, θ, and ρ_1–ρ_3. Each subunit has a large extracellular N-terminal domain, four transmembrane domains (TM_1–TM_4) and a large cytoplasmic loop between TM_3 and TM_4. The Cl^- channel pore is part of TM_2 domain of each subunit. These subunits can be assembled in different compositions to form a large variety of $GABA_A$ receptor subtypes in the brain.

These subunits are wildly distributed in the brain. The α_1 subunit is predominantly found in cerebellum and α_{2-5} subunits are mainly present in the hippocampus. There are intermediate levels of α_{1-4} subunits and low levels of α_5 subunits in the cerebral cortex; α_6 subunit is found in the cerebellar granule cells. The distribution pattern of β_1 and β_3 subunits is as follows: hippocampus > cortex > cerebellum, while the β_2 subunits have the opposite pattern and are mainly found in cerebellum > cortex > hippocampus. In contrast, the mRNA of the γ_1 subunit is mainly found in amygdale and septum. The γ_2 subunit

is found in every part of the brain and γ_3 subunits are distributed mostly in cortex and basal nuclei.

The subunit composition of $GABA_A$ receptors subtypes influences their physiological and pharmacological characteristics. Most common pentameric combinations in the brain consist of two α, two β, and one γ_2 subunits or two α, two γ, and one β subunits. A fully functional $GABA_A$ receptor requires the presence of these three subunits; however, only α and β subunits are considered the essential part of the receptor and $GABA_A$ receptors with less functionality can be formed without the expression of γ subunits. Studies have shown that functional $GABA_A$ receptors were assembled in mice devoid of γ_2 subunits, but they lacked the benzodiazepine receptor binding site. The other subunits, δ, ε, π, θ, are thought to substitute γ in less commonly expressed receptor subtypes.

The GABA binding site is located at the interface of α and β subunits. The binding of GABA results in a conformational change in the receptor, opening the intrinsic Cl^- channel and allowing a rapid flux of Cl^- ions; this causes hyperpolarization and inhibition of the action potential.

$GABA_A$ receptors are pharmacological targets of several important drugs such as anticonvulsants, benzodiazepine, barbiturates, neurosteroids, and general anesthetics. Instead of binding to the GABA binding sites, these drugs exert their action by binding to their allosteric binding sites on the $GABA_A$ receptors.

Physiological Properties

The exact antitremor mechanism of primidone and its two active metabolites is not known; however, the efficacy of primidone in essential tremor has been confirmed in several controlled studies. Its major active metabolite, PEMA does not seem to possess any antitremor properties. In one study, no significant difference in tremor magnitude was noted between patients receiving 400 and 800 mg day^{-1} of PEMA and placebo.

Several studies suggest the involvement of $GABA_A$ receptors in controlling motor functions. In addition, patients with essential tremor show lower concentrations of GABA in their cerebral spinal fluid (CSF). In an animal study, $GABA_A$ receptors with α_1 subunits were deleted. This resulted in the loss of 50% of all $GABA_A$ binding sites throughout the brain, including motor pathways in the brainstem, thalamus, and basal ganglia. Mice with this deletion showed postural and kinetic tremor, characteristics very similar to essential tremor in humans. Drugs used in the treatment of essential tremor, such as primidone, were efficacious in reducing tremor in mice by 45–70%.

In another study, significant reduction in tremor was observed after 2 weeks of therapy and primidone maintained its efficacy for at least 1 year. Several other studies suggest an initial 40–50% reduction in tremor amplitude in about 70% of patients treated with primidone.

In an open-label study, after 4 weeks of therapy with primidone, 82% of patients showed 25% reduction in their tremor. About 63% of these patients maintained the same benefit at 12 months, indicating that some patients develop tolerance to therapy. In these patients, dose of primidone can gradually be increased to see if similar efficacy can be obtained with higher doses.

Tolerability is an important issue with primidone and about 20–30% of patients discontinue therapy because of intolerable adverse effects. The most common CNS side effects are somnolence, ataxia, vertigo, nausea, fatigue, and dizziness. Rare idiosyncratic reactions such as hematological abnormalities, hepatotoxicity, and skin rash have also been reported with primidone.

To minimize the occurrence of initial adverse effects, primidone is usually initiated at a low dose of 25–50 mg day^{-1} and is gradually titrated up based on patient's tolerance and response. The efficacy of 250 versus 750 mg day^{-1} of primidone was compared in patients with essential tremor. The patients receiving 250 mg day^{-1} showed similar or better response, maintained the same efficacy at 12 months and experienced less side effects compared to the higher dose of 750 mg day^{-1}.

Side effects at the initiation of therapy are due to the parent drug, primidone, as they are reported before the active metabolites are formed. However, some of the adverse effects experienced later in therapy may be due to its long lasting active metabolite, phenobarbital. As noted earlier, the concentrations of phenobarbital can be higher than those of primidone and may limit dose increases later in therapy even in those individuals who initially tolerated primidone. There have been reports of less neurotoxicity with PEMA compared to phenobarbital. In one study, patients taking 400 and 800 mg day^{-1} of PEMA reported no side effects. These doses produced plasma steady concentrations expected to be reached by taking 1500 mg day^{-1} of primidone.

Progressive Supranuclear Palsy

D R Williams, Monash University (Alfred Hospital Campus), Melbourne, Australia

Definition and History

Progressive supranuclear palsy (PSP) is the term J. Clifford Richardson first used in 1964 to describe a group of patients he had been studying in Toronto. All of his patients had progressive gait disturbance and falls, ophthalmoplegia, pseudobulbar palsy, and mild dementia, without prominent Parkinsonism. The pathological examination of these patients by John Steele and Jerzy Olszewski confirmed a common underlying pattern of extensive subcortical neurofibrillary degeneration, which was distinct from other known pathologies. This pattern of pathological change has subsequently been observed in a number of other clinical syndromes that expand on Richardson's original observations, and hence the emphasis of this terminology has changed from a clinical to a pathologically defined entity. Accordingly all clinical syndromes associated with pathologically defined PSP will be considered in this article (**Figure 1**).

In 1955, Richardson was visited by a good friend and 52 year old business executive because of clumsiness, trouble in seeing, and mild forgetfulness. During the next 4 years, Richardson was puzzled as his friend progressively developed an unusual constellation of signs that included supranuclear ophthalmoplegia affecting chiefly vertical gaze, pseudobulbar palsy, dysarthria, dystonic rigidity of the neck, and mild dementia.

As he was observing the evolution of this illness, Richardson serendipitously identified similar symptoms in three other middle-aged men. The first was a West Indian laborer, who immigrated to Canada in 1913 and developed unsteady walking in 1954. The second patient was a truck driver who came from England when he was a child and who had been well until his personality changed and he started to fall at the age of 49. The third veteran had come from Ukraine in 1913 and had worked as a laborer until 1956 when he developed difficulty with vision, his speech became slurred, and he had trouble in swallowing. Richardson recognized that despite different presentations, these four patients had the same hitherto unrecognized disorder.

During the next few years, Richardson came across three further patients with what also appeared to be the

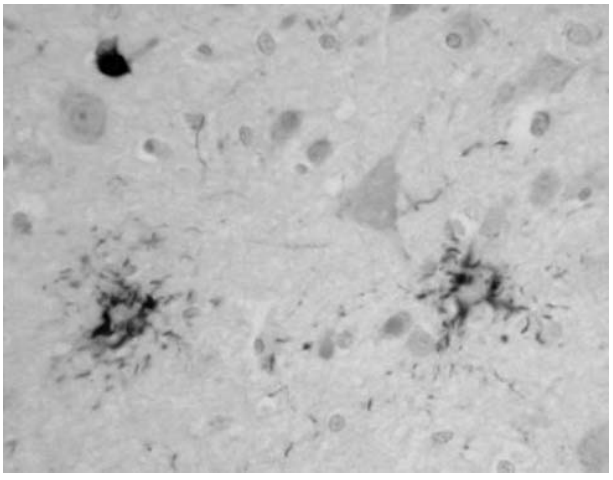

Figure 1 Pathology in the frontal cortex of patient with PSP (Richardson's disease). AT8 positive pathological tau accumulation. Neurofibrillary tangle, tufted astrocytes and neuropil threads (x20 magnification).

same condition. In 1962, he recommended that Dr. John Steele assist Professor Jerzy Olszewski, to thoroughly evaluate the pathology of his cases. In June 1963, at the American Neurological Association meeting in Atlantic City, Richardson presented the first clinical report of eight cases of 'Heterogeneous System Degeneration' with supranuclear ophthalmoplegia, pseudobulbar palsy, nuchal dystonia, and dementia. He observed that this disorder presented in the seventh and eighth decades of life and was relentlessly progressive with death occurring within 9 years.

Olszewski described the anatomy and histopathology of the disease and the detailed localization of the lesions in four cases and presented the findings to the American Association of Neuropathologists in 1963.

The following year, Richardson and Olszewski, together with Steele, published their seminal paper titled 'Progressive supranuclear palsy' (PSP) describing the clinical and pathological features of the disease. The highly specific clinical picture Richardson had observed was, with considerable foresight, dependent on the similar localization of lesions among their cases. Furthermore, they predicted that 'it is possible that further observations may broaden the clinical spectrum of the disease. In other cases, the distribution of pathological changes may be different, and therefore, the clinical picture would be modified.'

In their 1963 reports, Richardson and Olszewski had called the condition heterogeneous system degeneration, a term first used by W. J. C. Verhaart for a similar case he described in 1958. However, as they were not certain that the disease was a primary degeneration or that it was related to other system degenerations, it was agreed that they shouldchoose another term. They briefly considered 'Can't look down disease', and 'Toronto disease.' In the summer of 1963, Richardson proposed that it be called progressive supranuclear palsy, a clinical designation and the name by which the disease is now known, particularly in Europe. Some also refer to it as the Steele–Richardson–Olszewski syndrome, an eponym which was first used by the Montréal neurologist Andre Barbeau in 1965.

Pathophysiology

PSP is considered as one of the primary tauopathies, in which tau dysfunction is regarded as central to its pathogenesis, and neuronal and glial accumulation of abnormal filamentous tau is a characteristic. The postmortem diagnosis of PSP is dependent on the identification of neurofibrillary tangles and neuropil threads in basal ganglia and hindbrain structures. The presence of coiled bodies, and in particular, tufted astrocytes and the predominance of 4-repeat (4R) tau isoforms in both neuronal and glial tau inclusions, are now also recognized as characteristic features of PSP, although they are not included in the current operational diagnostic criteria. Pathological heterogeneity of PSP has been reported and it is as yet unknown whether the pathology in PSP follows a consistent topographical progression or whether a disease 'footprint' of regional susceptibility is established early with subsequent uniform progression of pathology in all affected structures. Serial imaging studies suggest that the brainstem, in particular the midbrain, and frontal lobes bear the brunt of the disease and natural history studies support the notion of a progression of pathology. Different degrees of pathological tau burden have been identified in the different clinical phenotypes. The relatively more benign clinical syndrome of pure akinesia with gait freezing has a less severe and more restricted tau pathology than patients with Richardson's syndrome. Furthermore, patients with corticobasal syndrome or progressive nonfluent aphasia presentations of PSP-tau pathology have a relatively more cortical pathology than patients with Richardson's disease.

A PSP-tau grading system has been proposed to summarize the severity of tau pathology in these cases. The proposed scale uses grade of severity of coiled body and thread lesions in the substantia nigra, caudate, and dentate nucleus. This 12 tiered grading system has been shown to be reliable and repeatable and correlates well with the severity of clinical features throughout life (PSP-tau score: 0 – mild tau pathology, restricted distribution; >8 – severe, widespread tau pathology) and was negatively correlated with disease duration.

Epidemiology

Richardson was surprised that the clinical syndrome he reported had not been reported earlier and in 1963, suggested that 'a good many cases of the same disease will be identified in other areas'. In fact, historical studies had identified reports of the clinical PSP at least 100 years before. It is likely that these patients were considered by physicians of the day to be formes frustes Parkinson's disease, vascular disease, or progressive ophthalmoplegia.

PSP has subsequently been described in most regions around the world, although epidemiological data and clinical reports from Africa are scarce. Geographical clusters of PSP have been reported, in conjunction with high rates of unclassifiable Parkinsonism, motor neuron disease, and dementia, in the Japanese peninsula of Kai, Guam, Guadeloupe, New Caledonia, and East Papua. Pathological studies from some of these regions have identified important pathological differences from PSP, and therefore despite the clinical similarities, currently, these patients are classified separately.

Determining the prevalence of PSP is difficult because of the limitations of clinical diagnostic accuracy. In addition, methods of case finding and population size can result in 20-fold variations in crude prevalence rate estimates.

The best studies of prevalence are community-based, derived from primary care, utilizing sensitive inclusion criteria, personal examination, and validated diagnostic criteria. Two studies in the United Kingdom that satisfy these requirements report a crude prevalence rate of 6.5 per 100 000 and an age-adjusted prevalence of 5.0 per 100 000. Another study using similar methodology estimated crude and age adjusted prevalence in Yonago, Japan to be 5.8 and 5.0 per 100 000 respectively. Studies designed primarily to determine the prevalence of Parkinson's disease (PD) in Northwest Italy and the Faroe Islands estimate the prevalence of PSP to be 3.2 and 4.6 per 100 000 respectively.

These clinical studies used clinical criteria that emphasize Richardson's classic syndrome and therefore probably underestimated the true prevalence of PSP-tau pathology in the community. Overall, however, these rates are similar to prevalence rates reported in motor neurone disease, where disease duration is shorter and more than 25 times less than the rates in PD, where disease duration is almost twice that in PSP.

Table 1 Clinical diagnostic criteria for the diagnosis of PSP

Clinically definite PSP
Gradually progressive disorder
Onset at age 40 or over
Prominent postural instability with falls in the first year of disease onset AND vertical (up or down) supranuclear palsy
Probable PSP
Gradually progressive disorder
Onset at age 40 or over
Vertical (up or down) supranuclear palsy OR
Prominent postural instability with falls in the first year of disease onset AND slowing of vertical saccades
Exclusion criteria
History compatible with encephalitis lethargica
Alien hand syndrome, cortical sensory deficits, focal frontal or temporaparietal atrophy
Hallucinations or delusions unrelated to dopaminergic therapy
Cortical dementia of Alzheimer's type (severe amnesia, aphasia or agnosia)
Prominent cerebellar symptomatology or unexplained dysautonomia (early prominent incontinence, impotence or symptomatic postural hypotension)
Neuroradiologic evidence of relevant structural abnormalities (basal or brainstem infarcts, lobar atrophy)
Whipple's disease, confirmed by polymerase chain reaction, if indicated

Clinical Features and Differential Diagnosis

Richardson's Disease

Richardson's disease is the prototypic clinical manifestation of PSP-tau pathology. The first clinical symptoms usually develop in the seventh decade (median age of onset 63–68), but the age of onset of disease can range from the fifth to the ninth decade.

Richardson's classic description has been validated in different clinicopathological series and is reflected in the operational clinical diagnostic criteria. The NINDS-SPSP criteria for 'possible' PSP require the presence of a gradually progressive disorder with onset at age 40 or later, either vertical supranuclear gaze palsy or both slowing of vertical saccades and prominent postural instability with falls in the first year after onset (**Table 1**). 'Probable' PSP is defined by the presence of vertical supranuclear gaze palsy, prominent postural instability, and falls in the first year of onset, as well as the other features of possible PSP. In many cases, falls or postural instability dominate the early clinical picture. A proportion of patients first present with cognitive and behavioral change or nonspecific visual disturbance.

Falls associated with Richardson's disease (RD) are often seemingly unprovoked and can appear out of context with gait disturbance. Patients often describe their falls as 'if the wind blew' them over. In many cases, gait becomes unsteady and is described by some as a 'drunken' gait. Unlike Parkinson's disease, the initial complaint is rarely of gait slowing, rather a lack of balance and confidence while walking. In almost half of patients, the falls are only backwards, in contrast to Parkinson's disease where falls are more often forwards. Soft tissue injuries and fractures, particularly of the hip, trunk, and head, are a common accompaniment of the postural instability. The median time to first fall in RD is around 12 months. Motor recklessness is another feature, where the patient seems unaware of their imbalance, misinterprets their center of gravity, and attempt to execute movements they are incapable of completing safely. This combination of impulsiveness, apraxia, and bradykinesia contributes to the risk of falling and can be seen in the clinic as the 'rocket sign' where patients sit en bloc, falling back into the chair without appropriate knee and hip flexion.

The diagnostic eye movement abnormalities are the most distinctive clinical feature of Richardson's disease. In 20% of patient's nonspecific visual disturbance are early features, including blurred vision, irritated dry eyes, diplopia, and ocular discomfort or blepharospasm. It is not uncommon for patients to frequently visit their optometrists for new corrective lenses. Patients usually develop subtle slowing of the vertical saccades as the first abnormal eye signs. This slowing can be difficult to measure but may manifest itself as the 'round the houses' sign where horizontal deviations are seen in subtly slow vertical saccades. The saccadic velocities progressively deteriorate and vertical saccadic movements become hypometric and then eventually limitation of the extents of gaze can be seen. Horizontal eye movements are relatively less affected and deteriorate after vertical movements. The gaze paresis can be overcome by activating the vestibulo-ocular reflex using the Doll's head maneuver.

The early cognitive features of RD can be subtle, and the insidious progression often goes unnoticed by patients

Table 2 Clinical pointers (green flags) for the diagnosis of PSP

Early instability with falls
Absent or poor, or waning response to L-dopa
Marked slowing of vertical (up or down) gaze (commonly precedes the limitation of vertical gaze palsy that enables the diagnosis of PSP to be made)
Eyelid abnormalities (e.g. eye lid apraxia)\Severely decreased blink rate
Stuttering or pallilalia as an early feature
Early dysphagia or dysarthria
Axial more than limb rigidity
Retrocollis
Deep inspiratory sighs

Table 3 Non-PSP causes of eye movement abnormalities, postural instability and Parkinsonism

Dementia with Lewy bodies (28)
Multiple system atrophy (29)
Cerebrovascular disease (30)
Aortic surgery and hypoxic damage (31, 32)
FTDP-17 (33)
Ubiquitin positive frontotemporal lobar degeneration (34)
Neuropsyphilis (35)
Motor neuron disease/congophilic angiopathy (36)
Amyotrophic lateral sclerosis (37)
Antiphsopholipid syndrome (38)
Prion disease (39)
Bodig (40)
Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (41)
Whipple's disease (42)
Neimann–Pick type C (43)

and their families. Patients can present with bradyphrenia, frontal type disinhibition, and personality change that can precede the postural instability and other motor manifestations of PSP-tau pathology and dominate the early clinical picture.

In the original descriptions of PSP, Richardson described the absence of Parkinsonism as an important clue to the diagnosis. Although the first symptom was different in all of his patients, they all developed postural instability and falls within the first few years of the disease. The most exceptional clinical feature was the progressive supranuclear gaze palsy that initially affected vertical gaze and progressed to complete ophthalmoplegia in most patients. This characteristic clinical syndrome is helpful in diagnosis, but alternative pathologies should be considered (**Tables 2** and **3**).

Progressive Supranuclear Palsy – Parkinsonism

Richardson stated that none of the patients he described had 'the characteristic Parkinsonian features, and none had tremor'. While hypomimia or hypophonia may be considered as signs of hypokinesia and 'rubbery' rigidity might be thought of as extrapyramidal tone, in isolation, these findings are insufficient to diagnose Parkinson's disease or even vascular Parkinsonism.

Pathological series of PSP have consistently identified a small group of patients who do not fit the classic clinical description and who have 'atypical' clinical features, including normal eye movements, rest tremor a positive-levodopa response, and focal dementia. Clinicopathological studies have consistently identified the classic syndrome described by Richardson as well as a smaller group where Parkinsonism (rigidity, tremor, bradykinesia and L-dopa responsiveness) dominates the early clinical picture. This has provisionally been referred to as PSP-Parkinsonism (PSP-P).

These patients present with bradykinesia, rigidity, and in some cases, tremor to movement disorder clinics and are commonly labeled as Parkinson's disease. Asymmetry of limb signs is more common in this group, and although axial rigidity was often striking early, limb rigidity is more common and severe than in Richardson's syndrome, where muscle tone may be normal. Tremor is included in the mandatory exclusion criteria of some diagnostic guidelines for PSP but jerky postural tremor and even a 4 to 6Hz rest tremor are relatively common in PSP-P. The tremor can diminish over time and may disappear even in the absence of dopaminergic treatment. A 'moderate' or 'good' improvement in bradykinesia and rigidity follows initiation of L-dopa in a proportion of patients with PSP-P, although the response is rarely 'excellent'. In most cases, the beneficial effects wane over a few years although sustained responses have been reported.

The PSP-P phenotype is difficult to differentiate from Parkinson's disease early in the disease. Early helpful pointers may include rapid progression with relatively poor response to L-dopa, and more frontolimbic cognitive deficit and axial symptomatology. Falls and cognitive function occur later in PSP-P than Richardson's syndrome and perhaps as a consequence disease duration is about 3 years longer.

Most patients eventually go on to develop falls and the eye movement abnormalities and cognitive dysfunction characteristic of Richardson's syndrome. In many cases, the transformation from clinical Parkinson's disease to PSP-P occurs five to ten years after disease onset. In a small number of patients, the purely parkinsonian syndrome predominates until death, and eye movement abnormalities or other characteristics of Richardson's disease never appear. A sustained response to L-dopa, drug-induced choreic dyskinesias and a longer disease duration appear to characterize these patients.

Pure Akinesia with Gait Freezing

The syndrome of pure akinesia with gait freezing (PAGF) appears to be highly predictive of PSP-tau pathology and represents a third, clinical presentation. Pure akinesia was

first described in 1974 in two patients, who developed freezing of gait, writing and speech with paradoxical kinesia. At presentation, these patients were cognitively intact, had no eye movement abnormalities, and in many, there was a long disease duration without the development of other parkinsonian features. Clinical diagnostic criteria have recently been proposed for this syndrome and include progressive onset of gait disturbance with start hesitation and subsequent freezing of gait, speech or writing in the absence of rigidity; tremor; dementia or eye movement abnormality during the first 5 years of disease. There is no benefit from L-dopa therapy; and no clinical or radiological evidence of lacunar infarcts of diffuse deep white ischemia.

When these criteria were applied retrospectively to a pathologically diagnosed series of 759 cases with Parkinsonism, seven cases were identified, including 6 with PSP-tau pathology and the other had Lewy body disease. These patients presented gait disturbances and postural instability, for up to 24 months before developing freezing start hesitation and gait initiation failure. Phonation difficulties, facial immobility, and a reduction in the size of handwriting were additional early signs. Axial rigidity with marked neck stiffness in the absence of limb rigidity was a distinctive feature.

A supranuclear downgaze gaze paresis and blepharospasm developed late in the majority of cases, but in contrast to Richardson's syndrome, fronto limbic cognitive deficits and bradyphrenia are not prominent. The median duration of disease is 11 years.

Corticobasal Syndrome

Corticobasal syndrome is characterized by progressive, asymmetric dyspraxia, cortical sensory loss including an alien limb, a jerky dystonia of the limb with rigidity, and bradykinesia unresponsive to levodopa and was first described in patients with corticobasal degeneration (CBD). Pathological series have indicated that only 50% of cases with corticobasal syndrome have CBD pathology, and cerebrovascular disease, Alzheimer's disease, and progressive supranuclear pathology account for the majority of other cases.

Corticobasal syndrome appears to be a rare presentation of PSP-tau pathology, with only 5 cases from a pathological series of 160 patients with progressive supranuclear palsy, identified with asymmetric limb dystonia, apraxia, and alien limb phenomena. Cortical sensory loss and aphasia were seen in some cases. None of these patients developed postural instability or falls within the first year of disease and dysarthria, dysphagia, and axial rigidity were also absent in the early stages. Most patients with PSP-CBS eventually do develop postural instability but it occurs much later than in Richardson's syndrome. An increase in saccadic latency is the most common eye movement abnormality, and typically, it is more marked on the side where the apraxia predominates. The distinction between this and the typical saccadic slowness in Richardson's disease can be difficult early on. In advancing disease, these patients may also develop some mild slowing of saccadic velocity, although never as severe as is seen in Richardson's syndrome.

Progressive Non-Fluent Aphasia

Progressive nonfluent aphasia (PNFA) is a disorder of language characterized by nonfluent spontaneous speech, with hesitancy, agrammatism, and phonemic errors, requiring significant effort in speech production. It fits within the spectrum of frontotemporal dementia syndromes and may be seen with a corticobasal syndrome. There are several components to speech and language difficulties in PNFA, including 'apraxia of speech', which describes errors in timing, coordination, and initiation of speech secondary to disorders of motor command. Clinically, this is evident when patients perform serial repetition, and although it usually accompanies agrammatism, it has been reported as an isolated, early sign of PNFA. Interestingly, in a pathologically diagnosed series, five of seven patients who presented with PNFA and prominent early apraxia of speech were found to have underlying PSP-tau pathology. The other two cases had Pick's disease and CBD diagnosed pathologically. The apparent specificity of prominent early apraxia of speech for tauopathies, and in particular PSP-tau pathology, has lead to the suggestion that this syndrome be considered as a clinical subtype of PSP. Patients who presented in this way were not found to be different at ages of onset or disease duration to patients with Richardson's disease. In other patients, PNFA with a less prominent apraxia of speech was more likely to be due to CBD or frontotemporal lobar degeneration with tau negative and ubiquitin positive inclusions.

Diagnostic Investigations

The diagnosis of PSP relies almost completely on clinical acumen and ancillary tests are only used to exclude other pathologies such as cerebrovascular disease. Some clinical and radiological tools show some promise in differentiating PSP from Parkinson's disease and multiple system atrophy, but differences early in the disease are relatively poorly studied. A therapeutic trial of levodopa typically results in little improvement of clinical symptoms, including the frequency of falls or axial rigidity and can be used as a pointer to non-Lewy body Parkinsonism.

Olfactory testing in small groups of patients with established disease showed a relatively preserved sense of smell among nondemented patients with PSP compared with Parkinson's disease. Although these findings probably apply also to early disease, the sensitivity and specificity for the diagnosis of PSP have not been calculated.

Cardiac metaiodobenzylguanidine (MIBG) scintigraphy measures the postganglionic sympathetic innervation of the cardiac muscle and is abnormal in the majority of patients with idiopathic Parkinson's disease. The test is normal in the majority of patients with PSP and multiple system atrophy, although the results can be difficult to interpret in patients taking certain medications, diabetes, or heart failure.

Electrophysiological studies of the auditory startle response and acoustic blink reflex have shown significant abnormalities in PSP compared with Parkinson's disease. These studies have shown qualitative and quantitative differences in patients with clinically established disease. The findings in patients with early, difficult-to-diagnose disease are uncertain, but in patients with PSP-P and PAGF, the findings are not sufficiently different from those of Parkinson's disease to be diagnostically useful.

Neuroimaging can give clues to the diagnosis of PSP, and typical patterns of regional atrophy can be seen. Midbrain atrophy is most prominent and has been variously described as resembling a hummingbird or penguin on mid-saggital cuts or morning glory flower on axial cuts. The ratio between the area of the midbrain and the pons measured on mid-saggital MRI is decreased in PSP (mean 0.124) compared with MSA (mean 0.266) and controls (0.237), suggesting that quantitative measures may improve diagnostic accuracy (Oba et al., 2005). Atrophy of the superior cerebellar peduncle is severe in PSP and can be identified in the trained observer. Nonspecific T2 hyperintensities or uncertain significance are commonly seen in the brainstem.

Diffusion-weighted MR imaging is a practical and efficient way for changes of PSP to be identified. Regional apparent diffusion coefficient (rADC) is increased in the basal ganglia compared with Parkinson's disease and in the frontal and parietal cortices compared with controls.

Management

The vast majority of neurotransmitter replacement studies in PSP have been negative, and hope of developing a treatment akin to levodopa in Parkinson's disease has gone. More radical breakthroughs in PSP therapeutics will come from a greater understanding of the pathophysiology of the condition and the development of animal models in which to test new disease-modifying treatments. Some symptomatic treatments have beneficial effects in a small proportion of patients, but on the whole, adverse side effects limit there usefulness and randomized placebo-controlled trials have not been done. Amitriptyline appears to be helpful in some patients, particularly in improving speech and swallowing. In a minority of patients, amantadine has improved gait and balance. The hypnotic zolpidem has been reported to be of transient benefit to the motor symptoms of PSP, but often associated with extreme somnolence and confusion. It is recognized that L-dopa is effective in some patients, although the extent of benefit is moderate and transient at best. Coenzyme Q10 has been evaluated in one small pilot study showing mild, nonclinically significant improvement in disease severity associated with significant alterations in cerebral energy metabolism. Botulinum toxin may be effective as a treatment of disabling blepharospasm. Extreme cervical dystonia, and characteristically retrocollis, may also be alleviated with botulinum toxin injection, but the risk of pharyngeal weakness is high. Gastrostomy feeding should be considered when feeding becomes difficult.

Good management of PSP centers on expert palliative care, and charitable support groups are available to support patients and families in North America, Europe, and Australia. Assistance with difficulty in feeding, mobilizing, and self care can be addressed with the help of experienced physiotherapy, speech therapy, and occupational therapy.

Propionic Acidemia

A García-Cazorla, Hospital Sant Joan de Déu, Barcelona, Spain

Glossary

Basal ganglia – Anatomic region located at the base of the brain composed of four clusters of neurons. This area of the brain is involved in body movement and coordination.
Excitotoxicity – Pathological process by which neurons are damaged and killed by glutamate and similar substances. This occurs when receptors for the excitatory neurotransmitter glutamate such as the *N*-methyl *D*-aspartate (NMDA) receptor and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor are overactivated.
Intoxication type neurological distress – Acute or rapidly progressive neurologic symptoms due to the accumulation of toxic compounds proximal to the metabolic block.
Metabolic acidosis – Disruption of the body's acid/base (pH) balance in which the accumulation of a particular acid occurs associated with not enough bicarbonate to effectively neutralize the effects of the acid. It can be due to starvation, gastrointestinal disorders, diabetes, or to those inborn errors of metabolism in which an enzymatic block leads to the accumulation of toxic acids.
Stroke – The sudden death of some brain cells due to a lack of oxygen. The most common cause is a blockage or rupture of a blood vessel to the brain (cerebrovascular accident). 'Metabolic strokes' are present in diverse inborn errors of metabolism and are due to bioenergetic abnormalities that finally lead to a poor oxygen consumption and cell death.

Definition

Propionic acidemia (PA) is a disorder in which a defective enzyme, propionyl-coenzyme A (CoA) carboxylase (PCCA), results in an accumulation of propionic acid. This autosomal recessive disorder is a branched-chain organic aciduria, a class of disease involving the catabolism of the branched-chain amino acids valine and isoleucine (**Figure 1**), and other propiogenic substrates such as methionine, threonine, odd-chain fatty acids, and cholesterol.

Pathophysiology

PCCA, which requires biotin as a cofactor, catalyzes the conversion of propionyl-CoA to methylmalonyl-CoA. Genetic mutations in two subunits of the PCCA gene (PCCA and PCCB) may cause varying levels of PCCA functioning. The A subunit of 72 KD is encoded by the PCCA gene on chromosome 13q32, while the B subunit of 56 KD is encoded by the PCCB gene on chromosome 3q13.3–q22. To date, more than 40 mutations in PCCA and 60 in PCCB have been reported, mostly missense variants.

Defects in the metabolic pathway produce toxic metabolites and it is a cause of the so-called 'intoxication type' neurological distress with acute or rapidly progressive neurologic symptoms due to the accumulation of toxic compounds proximal to the metabolic block. Oxidative stress, mitochondrial dysfunction and excitotoxicity are presumably pathomechanisms related to neurodegeneration in organic acidurias. In the particular case of PA, basal ganglia are especially involved giving rise to abnormal movements. Metabolites of the dysfunctional propionic acid and methylmalonic acid pathways may be selectively toxic to the endothelial cells in the basal ganglia. On the other hand,

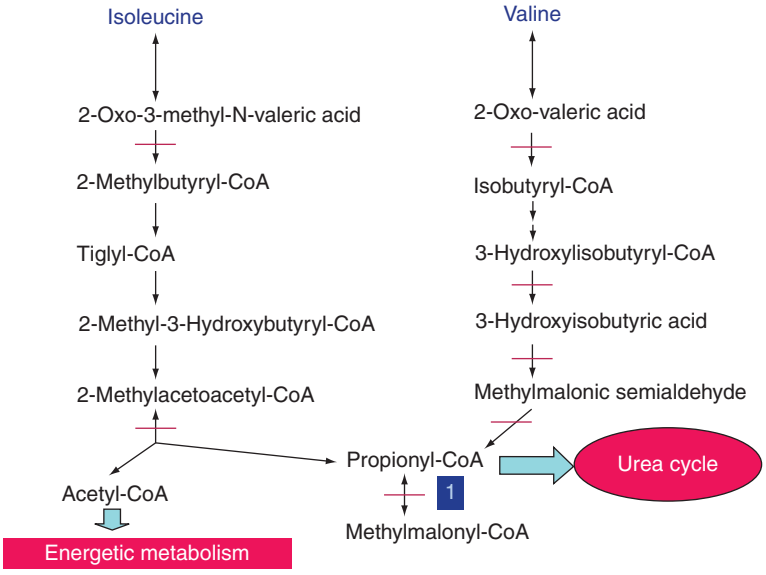

Figure 1 Pathways of the brain chain amino acids, isoleucine and valine. Main metabolic steps are marked by solid red bars. Bar number 1: propionyl-CoA carboxylase. This metabolic pathway is related to urea cycle (the accumulation of propionyl-CoA shown in PA leads to urea cycle inhibition) and energetic metabolism.

mitochondrial dysfunction due to an accumulation of propionic acid apparently results in an abnormal cytochrome *c* oxidase and energetic deficiency. Another hypothesis states that hyperammonemia, which is often associated with PA, leads to an accumulation of glutamine and/or glutamate in astrocytes. This excess glutamate may be excitotoxic to neuronal cells in the basal ganglia. Moreover, free radicals can affect glutamate transporter activity and therefore induce excitotoxicity via increased glutamate concentrations in the synaptic cleft. Probably, a combination of all these intracellular mechanisms produces neuronal damage and the consequent neurological signs.

Epidemiology

The prevalence of PA ranges from 1:165 000 in Italy to 1:277 000 in Germany, and 1: 35 000–75 000 in the United States. Mild forms of the disease due to differences in the mutations of PCCA or PCCB may exist in different parts of the world, and prevalence may be as high as 1 case in 18 000 people. There are no prevalent PCCA alterations in Caucasian patients. Three mutations, namely 922–923insT, 1644–6C > G, and p.Arg399Gln, account for more than 50% of PCCA chromosome in Japanese children. A limited array of PCCB mutations is associated with PA in both Caucasian and Asian populations. It is unclear whether these differences are related to biological factors other than the population specific genetic background. In a study of 65 patients, a slight female predominance was found, with a female-to-male ratio of 1.4:1. Patients present in the neonatal period or during early infancy. Patients with mild forms of the disease may present later in life.

Clinical Features

Patients with PA can be dividend into two subgroups: most of them present in the neonatal period; a less common group has late-onset disease with appearance of symptoms during the first years of life.

1. *Neonatal forms*: The most common clinical picture is a full term baby born after normal pregnancy and delivery, who rapidly deteriorates after an initial symptom-free period (from hours to the first week). Feeding refusal, vomiting, and abdominal distension can be the first signs. Neurological manifestations rapidly appear, including abnormal posturing and movements, hypotonia, lethargy, and seizures, that often present a burst-suppression EEG. Without appropriate treatment, the patient evolves toward brain edema, coma, and death or permanent brain damage.
2. *Late-onset forms*: They have a more variable presentation, including intermittent neurological signs such as ataxia, movement disorders and behavioral abnormalities, recurrent vomiting, and failure to thrive with selective refusal of protein-rich foods. The relapsing episodes are normally triggered by metabolic stressing factors that stimulate catabolism such as infections, fasting, and chirurgical procedures, or can be due to a high-protein intake. Between attacks patients may appear without any symptom. In other cases, the child presents chronic symptoms mainly characterized by psychomotor delay, failure to thrive, and vomiting.

Abnormal Movements

Newborns manifest high-amplitude tremors in the extremities that appear spontaneously or triggered by

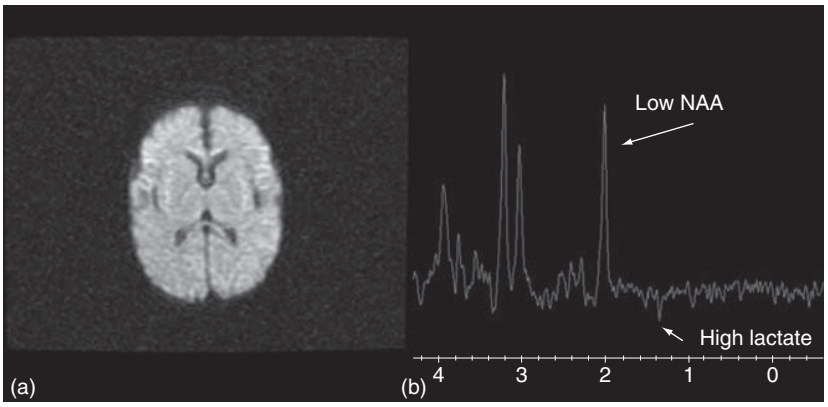

Figure 2 (a) Diffusion brain MRI of a newborn at the onset of the disease showing normal results. (b) Despite normal brain MRI high lactate and low *N*-acetylaspartate (NAA) peaks are pointing toward metabolic decompensation.

stimulation. Nonepileptic multifocal myoclonus is also common. Late-onset forms can present with dystonia, choreoathetosis, and rigidity. Brain MRI may show high-intensity basal ganglia lesions, especially in the globus pallidus. In general, these lesions are localized bilaterally and usually appear during acute episodes of metabolic decompensation or due to long-term poor metabolic control over time. Accumulation of toxic metabolites such as propionyl-CoA can inhibit the mitochondrial respiratory chain and tricarboxylic acid cycle and produce an energetic stroke. Diffusion-weighted images show in the acute phase bilateral pallidus high intensity (putamen and caudate may also be affected). MR spectroscopy may show a decrease of *N*-acetylaspartate (which reflects neuronal loss) and an increase of lactate in decompensation episodes (**Figure 2**). These images may translate basal ganglia infarction. More recently, positron emission tomography has been used to show decreased glucose uptake in the basal ganglia.

Other organs involved are heart (rapidly fatal hypertrophic cardiomyopathy) and pancreas (acute pancreatitis, which is a rare complication).

Differential Diagnosis

In neonatal forms: Sepsis and different causes of metabolic ketoacidosis such as other organic acidurias and some primary hyperlactacidemias (mitochondrial diseases).

In late-onset forms: Different causes of MRI bilateral basal ganglia involvement associated with encephalopathy (mitochondrial cytopathies, organic acidurias, infectious encephalitis, homocystinuria, urea cycle disorders, biotinidase deficiency, creatine deficiency).

Diagnostic Workup

1. *First line laboratory tests*: Metabolic acidosis with ketonuria, haematological abnormalities (leukopenia, thrombocytopenia, anemia), hyperammonemia, and hyperuricemia are the most common routine laboratory findings. They often lead to the wrong diagnosis of sepsis.
2. *Brain MRI*: will provide helpful information especially in late-onset forms with neurological signs.
3. The diagnosis of PA is based on the presence of characteristic compounds detected by gas *chromatography/mass spectrometry* organic acid analysis in urine and blood acylcarnitine profile by tandem mass spectrometry. Methylcitric acid, 3-hydroxypropionate, propionylglycine, tiglylglycine, 3-hydroxy-2-methybutyrate, and 2-methyl-cetoacetate acids are usually elevated. Enzymatic and genetic studies confirm the diagnosis.

Management

Therapeutic approach in acute decompensations must be considered as an emergency and is based on the avoidance of protein intake and the inhibition of endogenous catabolism by providing enough energy (80–120 kcal kg^{-1} day^{-1} in a newborn). Insulin has an anabolic effect and can be added. Acidosis is corrected by rehydration and bicarbonate. Carnitine is used to buffer the intramitochondrial accumulation of propionyl-CoA. In the neonatal period during the refeeding phase, valine intake is progressively increased to 220–250 mg day^{-1} over a period of 5–7 days.

Long-term treatment is based on protein restriction and additional intake of amino acid mixtures free of valine, isoleucine, leucine, methionine, and threonine, to prevent protein deficiency, oral administration of L-carnitine (100 mg kg^{-1} day^{-1}) and metronidazole to reduce the microbial propionate production (10–20 mg kg^{-1} day^{-1} for 10 consecutive days each month).

Prognosis

The use of most accurate and early therapeutic strategies has improved survival over time but has not modified

neurodevelopment. The late-onset forms have a better prognosis compared with the neonatal/early-onset ones. However, neurocognitive deterioration is almost invariably present. Relapsing episodes of acute metabolic decompensation are associated with a high risk of basal ganglia stroke, responsible for severe motor disabilities. Decreased early mortality, less severe symptoms at diagnosis, and more favorable short-term neurodevelopmental outcome were recorded in patients identified through expanded newborn screening.

Propriospinal Myoclonus

S E Lo, F L Pagan, and E A Shamim, Georgetown University Hospital, Washington, DC, USA

Glossary

Myoclonus – Shock-like muscle jerks.
Propriospinal myoclonus (PSM) – A type of spinal myoclonus characterized by involvement of muscles innervated by different segments of the spinal cord.
Spinal myoclonus – A form of myoclonus with origins of the movements in the spinal cord and its pathways.

Clinical Syndrome

Propriospinal myoclonus (PSM) is a type of spinal myoclonus characterized by involvement of muscles innervated by different segments of the spinal cord. The muscles activate sequentially through the propriospinal tract or pathway, which is a spinospinal fiber system interconnecting multiple spinal levels. These fibers are found mainly as a thin shell of small, mostly nonmyelinated fibers surrounding the spinal gray matter. The conduction

speed in the propriospinal tract is ~5–15 m s^{-1}, and is considered to be relatively slow when compared to the corticospinal tract (25–70 m s^{-1}). PSM involves spread of muscle jerks rostrally and caudally along spinal segments from a point of origin, typically in the mid-thoracic region, sometimes referred to as the 'pattern generator.' The timing of muscle activation remains relatively fixed.

PSM primarily involves axial muscles with spread often to proximal limbs, but usually spares cranially-innervated muscles. Clinically, it presents with truncal flexion or extension jerks, with neck, arm, hips, and knee flexion, usually bilateral in distribution. The myoclonus may be rhythmic or irregular, spontaneous, or stimulus-induced. When measured with electrophysiologic testing, the electromyographic (EMG) burst in PSM is longer than in cortical myoclonus, usually ranging from 150 to 300 ms. The electrophysiological characteristics of slow conduction and selective recruitment of truncal and proximal limb muscles can help differentiate PSM from spinal segmental myoclonus or generalized cortical myoclonus. However, it is hard to differentiate PSM from psychogenic/functional movement disorders without the help of electrodiagnostic studies.

PSM was first described in 1988 by Bussel and colleagues, when they reported a patient who developed spontaneous and stimulus-sensitive, rhythmic truncal and lower extremity extension jerks after suffering a complete lower cervical cord transaction from a severe C7 vertebral fracture. They postulated that the myoclonus was due to partial release of a spinal stepping generator. Brown and colleagues did extensive work as well, describing in detail the clinical and electrophysiological characteristics of several patients with predominant abdominal flexion contractions serving as an originating source with spread to neck, arm, and leg muscles. The conduction velocity was quite slow, ~5 m s^{-1}. In the majority of their patients, the myoclonus was stimuli-sensitive, and in several cases, the jerks persisted in sleep and were most prominent when lying supine. Brown and colleagues also suggested that spinal cord damage leads to the release of pattern generators that result in these involuntary movements.

Anatomical Localization

Similar to spinal segmental myoclonus, various spinal cord structural and pathologic processes may cause PSM, including arteriovenous malformations, tumors and cysts, infections, multiple sclerosis plaques, spondylitic myelopathy, cervical disc herniation, inflammatory processes, and trauma. A case report described a patient with new onset PSM following a T11 vertebral fracture, who subsequently experienced an episode of severe myoclonic activity and respiratory arrest. There appear to be idiopathic forms of PSM as well, and in many cases, magnetic resonance imaging of the spinal cord appears normal. Several cases of PSM related to nonstructural pathogenic factors have been reported, including presentation as a paraneoplastic syndrome related to breast cancer, related to ciprofloxacin use, and as the result of an enteropathogenic toxin. One case report described a patient with probable psychogenic PSM, despite having an electrophysiologic profile consistent with PSM. Another study showed that healthy volunteers could simulate PSM clinically and electrodiagnostically but with prolonged EMG burst durations. These two reports appear to indicate that electrodiagnostic studies play an important diagnostic role in PSM but are not full-proof.

Pathophysiology

The pathophysiologic mechanisms for PSM are not fully understood, but in general spinal interneuron dysfunction is thought to be a primary cause, via reduced inhibitory mechanisms. In some cases, dysfunction in motoneurons in the spinal cord has been suggested to be the cause of repetitive muscle jerks. And as postulated by Brown and Bussel, a pattern generator in the spinal cord that is abnormally released may be the initiator for abnormal hyperexcitability in the cord. It is unclear what factors determine whether a structural lesion will lead to segmental involvement only or to caudal–rostral spread via the propriospinal pathway.

Treatment

Treatment of PSM should first be directed at any primary treatable causes if possible. Symptomatic treatments have included clonazepam, which is considered the medication of first choice, as well as diazepam, levetiracetam, valproic acid, tetrabenazine (currently not approved in the United States), baclofen, 5-hydroxytryptophan, and carbamezapine.

Proteasome Function in Movement Disorders

L Stefanis, University of Athens Medical School, Athens, Greece; Biomedical Research Foundation of the Academy of Athens, Athens, Greece

Glossary

Macroautophagy – A process in which double membrane structures engulf cytoplasmic constituents, which are then degraded within lysosomes, following autophagosome–lysosome fusion.
Proteasome – A multicatalytic protein complex that degrades the majority of intracellular proteins.
19S proteasome – A multicatalytic protein complex responsible for recognition of polyubiquitinated proteins, and for threading them into the 20S core.
20S proteasome – A barrel-like structure comprising the enzymatic core of the proteasome.
Ubiquitin – A 76 amino acid protein which is responsible for tagging protein substrates for proteasomal degradation.

Definition and History

Proteasomes, together with lysosomes, are the main systems of intracellular protein degradation. In recent years, dysfunction of the proteasomal pathway of protein degradation has been proposed as a major pathogenetic mechanism underlying Parkinson's disease (PD) and other neurodegenerative conditions. Targets for degradation by the proteasome include rapidly turning over, misfolded, damaged, or oxidatively modified proteins, and, consequently, in many cell types the bulk of total intracellular protein degradation occurs through this system. In most cases, protein substrates are tagged with multiple adducts of a small molecule, ubiquitin, in order to be degraded through the proteasomes, hence the term 'ubiquitin proteasome system' (UPS). Ubiquitination begins with the ATP-dependent activation of ubiquitin by a universal E1 ubiquitin-activating-enzyme. Activated ubiquitin is then transferred to a member of the E2 ubiquitin conjugating enzyme (UBC) family. E2s then transfer ubiquitin to a complex formed between a member of the E3 ligase family and the particular protein substrate, leading to the covalent attachment of ubiquitin to a lysine residue of the substrate, via the catalytic activity of the ligase. The cycle is then repeated to attach further ubiquitin moieties, thus forming a polyubiquitin chain on the substrate. In some cases, E4 enzymes are involved in the stacking of ubiquitin molecules on each other. E2s and, especially, E3s and E4s are specific for a substrate or a group of substrates.

The polyubiquitinated proteins that are formed are subsequently recognized and degraded by the proteasome. Natively unfolded proteins may not need ubiquitin tagging, and thus, ubiquitin-independent proteasomal degradation also occurs. The 26S proteasome contains a core catalytic component, the 20S proteasome, flanked on both sides by a 19S cap, also termed PA700. Polyubiquitinated proteins signaled for degradation are recognized by and bind to components of the 19S cap. Four or more ubiquitin adducts are required for recognition. Following the detachment of the polyubiquitin chain, substrates enter the cylindrical pore formed by the 20S proteasome, which is a barrel-like structure that consists of two identical outer rings of seven α subunits each and two identical inner rings of seven β subunits each. Within the 20S core, substrates are degraded by three sets of enzymes, with chymotrypsin-like, trypsin-like, and peptidylglutamyl-like activity. Proteasomal proteolysis is ATP-dependent and leads to the production of small peptides that are further degraded in the cytosol. The polyubiquitin chains are hydrolyzed to monomeric ubiquitin through the action of de-ubiquitinating enzymes, which include, amongst others, ubiquitin C-terminal hydrolases (UCHs). The released monomeric ubiquitin is reactivated by E1 in order to act on further substrates.

The function of the proteasome is assessed by measuring the three enzymatic activities present within the 20S core by incubating cell lysates or tissue extracts with artificial fluorogenic substrates. Alternatively, the levels or half-lives of particular substrate proteins that are proteasomal targets can be assessed. Such artificial substrates have been created and tagged to fluorescent proteins, so that their accumulation can be monitored in living cells. A method that can be used to assess accumulation of proteasomal targets more globally is Western immunoblotting for ubiquitin. In the case of impairment of the proteasomal system, there is accumulation of polyubiquitinated proteins. However, lysosomal impairment and, in particular, inhibition of macroautophagy may also lead to such accumulation.

Genetic Data Linking the UPS with PD

Genetic data support the idea that defects in the UPS may lead to PD. The product of the *Parkin* gene, which is mutated in early onset autosomal recessive parkinsonism, is an E3 ligase. Mutations in the *Parkin* gene may lead to

diminution or loss of E3 activity, but also to the loss of function through altered stability or solubility. *Parkin* overexpression can ameliorate proteasomal function, and may act as a general facilitator of the degradation of misfolded proteins, in part through binding to the proteasome. Thus, the loss of function of *Parkin*, apart from its effects on the build-up of its specific protein substrates, may lead to more generalized UPS defects. The function of *Parkin*, however, may not be restricted to the UPS, as it may connect to endosomal or lysosomal pathways through monoubiquitination. Furthermore, in seeming contradiction to its facilitatory role in protein degradation as a classical E3 ligase, it may ubiquitinate substrates via the K63 (instead of the classical K48) ubiquitin residue, thus leading to substrate stabilization, instead of degradation. *Parkin* may, thus, have a role in inclusion formation, which may help explain the general lack of inclusions in Parkin-related parkinsonism.

A mutation in UCH-L1, I93M, has been found in one family with autosomal dominant PD, but its pathogenicity is questioned. Whether the S18Y UCH-L1 polymorphism actually offers protection against PD development, as initial studies indicated, is also questionable. UCH-L1 is an abundant neuronal-specific protein, which belongs to the family of UCHs, thus is expected to be a cleaver of ubiquitin, usually monomeric. However, a main function of UCH-L1 is the maintenance of free cellular ubiquitin levels. UCH-L1, similar to Parkin, may also function in a dimeric form, as an aberrant E3 ligase, binding to protein substrates such as α-synuclein and ubiquitinating them via K63, leading to their build-up in the cell. Whether the genetic alterations identified are linked to PD through a loss or gain of function is contested. In sporadic PD, decreased brain levels and oxidative modifications of UCH-L1 have been identified. An unexpected finding from our laboratory has been that the S18Y polymorphism conferred a novel function to UCH-L1, that of a potent antioxidant that prevented oxidative stress-induced ROS generation and death in neuronal cells.

SNCA, the first gene found to be linked to PD encodes for the presynaptic protein α-synuclein, which is also a major component of Lewy bodies (LBs). A number of links between α-synuclein and the proteasome have been proposed. Initial reports suggested that α-synuclein is degraded via the UPS, but we and others have failed to confirm this. Instead, we have found that only very specific soluble α-synuclein oligomeric species, comprising a very small proportion of total α-synuclein, are degraded by the proteasome, and, at the same time, inhibit its function, likely by 'clogging' the 26S proteasome. The A53T mutant appears to have a greater tendency than the WT protein to cause this effect. Certain reports suggest that α-synuclein interacts directly with proteasomal components. It remains to be seen whether the effect of α-synuclein on UPS function represents a significant component of its toxicity.

Studies in Human PD

Ubiquitin within LBs represents polyubiquitinated proteins, and therefore, if there is dysfunction of the UPS in PD, this should be at a level beyond polyubiquitination, at the level of the proteasome. Two groups have reported a decrease of enzymatic proteasomal activity in substantia nigra (SN) of PD patients compared to controls, whereas activities in other CNS regions were unaltered. The specificity of the effect appears to confirm the UPS dysfunction hypothesis in PD, however, a note of caution is needed. The SN is severely depleted of dopaminergic neurons in terminal PD, and therefore, the enzymatic assay is mainly measuring the activity generated from nondopaminergic cells, particularly glia. Furthermore, these studies cannot exclude UPS dysfunction at other levels beyond the 20S proteasome in nonnigral brain regions.

In any case, these studies collectively show that there is a regional impairment of enzymatic activity of the proteasome at the level of the SN in PD (and diffuse Lewy body disease (DLBD)) patients. Studies in incidental Lewy body cases would be needed to establish whether such impairment occurs early in disease pathogenesis, prior to overt nigral cell loss and gliosis.

The accumulation of aberrant soluble oligomeric species of α-synuclein may be the factor leading to proteasomal dysfunction in PD. Alternatively, changes in the levels of select proteasomal subunits, such as the α subunits of the 20S proteasome, have been reported in PD, and other factors such as aging, oxidative, nitrosylative stress, or mitochondrial dysfunction may also be contributory. Application of mitochondrial toxins, in particular, leads to proteasomal impairment in experimental cell and animal models.

Models of UPS Dysfunction in Cell Culture

If UPS dysfunction is a significant factor in PD pathogenesis, proteasomal dysfunction in experimental cell models would be expected to generate a PD-like phenotype. We and others have, therefore, applied relatively selective pharmacological proteasomal inhibitors to cultured neuronal cells, and have detected formation of cytoplasmic ubiquitinated inclusions and neuronal death. Inclusions stain positively for many components of LBs, including for Thioflavin S, which detects fibrillar, β-amyloid-like structures. We have furthermore mapped the pathways involved in these two phenomena, neuronal death and inclusion formation. We have found that proteasomal inhibition may lead to morphologically apoptotic or non-apoptotic neuronal death. In both cases, there is participation of caspases and the apoptotic machinery. Aberrant activation of cell cycle components and p53

nuclear translocation are involved in death, but not the inclusion formation. Formation of inclusions is an active, transcription-dependent process, which also requires ubiquitination. α-synuclein, present within the inclusions in a monomeric and oligomeric conformation, is not required for initial ubiquitinated inclusion formation, but for fibrillar elaboration. Interestingly, the lysosomal pathway of macroautophagy is activated in response to proteasomal inhibition and contributes to the clearance of the inclusions, providing evidence for cross-talk between the two main pathways of intracellular protein degradation. Overall, there is dissociation between inclusion formation and death, suggesting that these phenomena occur in parallel, largely independently of each other.

Although the issue is somewhat controversial, most studies, including our own, have found that cultured nigral dopaminergic neurons are selectively sensitive to death induced by proteasomal inhibition. This could be due to the contribution of oxidative products of dopamine metabolism and the relative lack of a protective HSP70 upregulation response in these neurons.

Models of UPS Dysfunction in vivo

In an attempt to model proteasomal dysfunction in vivo, direct intrastriatal or intranigral injections of pharamacological proteasomal inhibitors in rodents have led to relatively selective nigrostriatal degeneration, with formation of rather ill-defined inclusions in the remaining nigral neurons. McNaught and colleagues applied pharmacological proteasome inhibitors systemically, via the intraperitoneal route, and observed selective neuronal degeneration and ubiquitin/α-synuclein/thioflavin-S-positive inclusions in various brainstem structures, including the SN. Proteasomal function, measured by the enzymatic assay, was only decreased in the nigra and in other affected regions, which may not have the reserve capacity to withstand such insults. They suggested that systemic exposure to the natural proteasomal inhibitors may underlie certain forms of sporadic PD. However, most laboratories have not been successful in replicating this original model.

A very exciting development has been the generation of the first genetic mammalian model of brain proteasomal dysfunction. In this model, regional ablation in the forebrain or in catecholaminergic neurons of Psmc1, a subunit of the 19S proteasome, led to neuronal degeneration and inclusion formation. The inclusions contained α-synuclein and resembled pale bodies identified in PD patients as possible precursors of LBs. Beyond doubt, this model proves that 26S proteasomal dysfunction can lead to a PD-like phenotype in rodents and will be very useful in preclinical studies, if UPS dysfunction turns out to be a major pathogenetic factor in PD.

Huntington's and Related Polyglutamine Repeat Diseases

Mutant huntingtin and other expanded polyglutamine repeat proteins are degraded, at least in part, by the proteasome. Ron Kopito et al., by expressing truncated forms of such proteins in cells carrying a reporter for proteasomal function, made the seminal observation of the link between protein aggregation and UPS dysfunction, which may play a significant role in the pathogenesis of these disorders. Mutant huntingtin has been shown, using reporters of UPS activity targeted specifically to the synapses, to cause UPS impairment both presynaptically and postsynaptically. The UPS normally regulates synaptic function and plasticity, and its dysfunction may underlie the synaptic aberrations that occur in these triplicate repeat disorders and in other neurodegenerative diseases.

However, mutant huntigtin expression in cells does not always cause UPS dysfunction, in part because of compensatory upregulation of proteasomal components or accelerated proteasomal biogenesis, which underlines the dynamic nature of the system. Similarly, it has been controversial whether expression of mutant huntingtin causes UPS impairment in vivo. Using a novel mass-spectrometry-based method, Kopito et al. have shown that there is indeed accumulation of polyubiquitinated proteins in the human disease, as well as in the well characterized R6/2 transgenic and knockin mutant huntingtin mouse models.

Actually, in Huntington's disease (HD) tissues, proteasomal dysfunction is more widespread than expected. Unaffected brain regions and even patient fibroblasts showed impairment of enzymatic proteasomal activity compared to controls. Patients from the very early stage of the disease, with little neuronal loss, also showed proteasomal dysfunction. Therefore, in contrast to the situation in PD, altered cellular composition cannot account for the observed changes. These data suggest that a decrease of proteasomal activity may not be directly toxic, and that issues of selective vulnerability or additional aggravating factors may play a role in determining whether a cell can withstand proteasomal impairment.

Given that no obvious inclusions are present in many of the tissues assessed, the inference is that prefibrillar forms of mutant Huntingtin may be responsible for such proteasomal dysfunction, 'clogging' the system in a similar way to that mentioned for α-synuclein. Alternatively, the large amount of aggregated protein may overwhelm the system by consuming ubiquitin or other elements of the pathway such as proteasomal components themselves, or molecular chaperones. Furthermore, isolated mammalian proteasomes cannot degrade the regions with the polyglutamine repeats, and release them without processing them further. The accumulation of these

super-aggregated species may have further detrimental effects, feeding into a vicious cycle.

There is evidence that some of the polyglutamine repeat proteins, such as Ataxin-3 and -7, may normally serve functions within the UPS pathway. They interact directly with polyubiquitinated proteins, the proteasome, and other UPS components, and may assist in the presentation of polyubiquitinated substrates to the proteasome.

Inhibition of ubiquitination leads to decreased inclusion formation but enhanced toxicity induced by huntingtin or other polyglutamine repeat proteins in cellular and animal models. Therefore, ubiquitination appears necessary for inclusion formation, and inclusions may be protective. Alternatively, there may be something inherently protective in the process of ubiquitination itself, and disrupting that may lead to enhanced toxicity in these conditions. This latter possibility is supported by the recent finding that reduction of free ubiquitin leads to neurodegeneration in vivo.

There is also other indirect evidence for the existence of UPS dysfunction in HD brains. Ubiquitin B (UBB^{+1}) is an aberrant form of ubiquitin caused by molecular misreading at the mRNA level. Under normal circumstances, its protein levels are nondetectable, and they only accumulate in situations of proteolytic stress. Elevated protein levels of UBB^{+1} have been detected in brains of patients with HD or SCA3, suggesting that in these conditions the UPS is impaired. Accumulation of UBB^{+1} can lead to further proteasomal inhibition, and may be a contributing factor to neurotoxicity in these disorders.

Conclusions

Genetic, biochemical, and pathological data suggest that UPS dysfunction may be an important pathogenetic factor in PD, HD, and other movement disorders. More work needs to be done before UPS dysfunction may be considered as a target for therapeutic interventions in these conditions.

Pseudoathetosis

K M Shannon, Rush University Medical Center, Chicago, IL, USA

Glossary

Athetosis – A writhing involuntary movement characterized by inability to maintain the limbs in a posture.

Pseudoathetosis – Writhing involuntary movements caused by severe loss of proprioceptive input to the striatum.

Definition and History

The term 'athetosis' is derived from the Greek word for 'without fixed position.' The description of athetosis is attributed to Hammond: 'Under the name of athetosis I propose to describe an affection which is mainly characterized by an inability to retain the fingers and toes in any position.' The term 'pseudoathetosis' was introduced by Dooling and Adams, and refers to athetotic movements that result from loss of proprioceptive input.

Pathogenesis/Pathophysiology

Pseudoathetosis generally occurs in patients with severe sensory loss in the context of normal motor function. The movements seem to relate to difficulty with integration and control of motor function consequent to loss of proprioceptive input to the striatum.

Epidemiology/Risk Factors

Pseudoathetosis is considered rare, though there are no data on epidemiology or risk factors.

Clinical Features and Diagnostic Criteria

Pseudoathetotic limbs exhibit continuous slow writhing movements that may be worse with posture-holding and action, external stimuli, mental stress, as well as when the eyes are closed. Movements are most prominent in the distal limbs, and are confined to limbs affected by the sensory disturbance. While their onset often coincides with the onset of significant proprioceptive loss, published reports of spinal pseudoathetosis suggest that involuntary movements may first appear after the sensory loss has been present for some time and in association with a painful crisis during the disease course.

There are no validated diagnostic criteria for pseudoathetosis. In 1994, Sharp et al. described seven cases and suggested the following clinical features: (1) the duration of the movement disorder is the same as the duration of the underlying sensory abnormality; (2) the distribution of the movement disorder is the same as the distribution of the sensory loss; (3) if the sensory abnormality resolves, the movement disorder also resolves; (4) lesions at all levels of the sensory pathways may be involved.

Differential Diagnosis

Pseudoathetosis must be distinguished from chorea, athetosis, and dystonia.

Once the movements are correctly identified, the differential diagnosis depends on the localization of the underlying lesion or disease process. Pseudoathetosis can result from a lesion anywhere along the sensory pathways that carry proprioceptive information. The differential diagnosis is broad and includes: peripheral nerve diseases such as neuropathy and leprosy; disease of the dorsal root ganglion such as that associated with diabetes mellitus; spinal cord pathology such as multiple sclerosis, subacute combined degeneration associated with Vitamin B12 deficiency, myelitis, infarct, trauma, tumor, syringomyelia; and brainstem disease such as central pontine myelinolysis, thalamic damage due to tumor or stroke, and motor cortex diseases.

Diagnostic Work-up/Tests

The diagnostic work-up depends on clinical localization of the underlying lesion and may include nerve conduction velocity studies and electromyography, somatosensory-evoked potentials, neuroimaging studies of the spinal cord or brain, and cerebrospinal studies.

Management

The primary focus is on treating the underlying etiology of the illness. There is no proven treatment for the movements themselves.

Prognosis

Prognosis is generally linked to that of the underlying lesion or disease process.

Pseudobulbar Symptoms

R B Schiffer, Texas Tech University Health Sciences Center, Lubbock, TX, USA

Background and Clinical Features

Sudden outbursts of involuntary, difficult-to-control, exaggerated laughter and/or crying have long been known to occur in patients with neurological disorders. In a 1924 paper, Kinnier Wilson described the core features of the "pseudobulbar affect" (PBA) syndrome and its association with focal and diffuse brain pathology across widely distributed networks. He noted that patients' emotional displays were often disproportionate to the stimuli that evoked them, inappropriate to the context in which they occurred, and out of synchrony with their subjective feelings. Wilson hypothesized that the anatomical basis for this syndrome was the loss of voluntary, cortical inhibition from brainstem centers that produce the faciorespiratory functions associated with laughing and crying.

PBA occurs on a spectrum of severity and can significantly impair social and occupational function. PBA may be associated with aspiration risks and contribute to medical morbidity.

Several different terms have been used for the clinical syndromes related to PBA. Clinicians have also used terms such as pathological laughing and weeping, emotional lability, emotional incontinence, pathologic emotionality or affect, and emotionalism to refer to these disorders. PBA has been reported in association with stroke, brain trauma, motor neuron disease, multiple sclerosis, and other neurodegenerative disease.

Measurement Instruments

Standardized scales exist, which may be used to screen for PBA, or to follow the severity of PBA over time. Two such scales are available.

Robinson and colleagues developed the Pathological Laughter and Crying Scale (PLACS), an interviewer-rated instrument, which is both valid and reliable in quantitatively assessing the severity of PBA symptoms in stroke patients. The PLACS rates sixteen items to quantify the aspects of laughter and crying, and scores the severity of each symptom on a 0–3 point scale. Scores on all items are totaled to obtain an overall score. A score of 13 or higher was reported to distinguish those with PBA.

Moore and colleagues developed and validated the Center for Neurologic Study-Lability Scale (CNS-LS), a self-report measure of "affective lability" in patients with amyotrophic lateral sclerosis (ALS). The CNS-LS quantifies perceived aspects of PBA, including frequency, intensity, lability, degree of voluntary control, and inappropriateness to context. It consists of two subscales: one for laughter (4 items) and one for tearfulness (3 items). Each item asks respondents to indicate on a five-point scale (where 1 = applies never and 5 = applies most of the time) how often they experience symptoms of PBA. A score of 13 on the CNS-LS, as on the PLACS, is thought to be the threshold for significant PBA.

Neural Substrates of the Disorder

The PBA syndrome occurs in patients with some structural disease of the central nervous system, capable of disturbing the functional neural networks of emotional display. These networks are distributed through prefrontal, temporal-amygdala, brainstem, and cerebellar systems. The neurochemistry of these systems is also complex, involving various receptor networks mediated by serotonin, dopamine, acetylcholine, histamine, γ-amino butyric acid, glutamate, *N*-methyl-D-aspartate, and opioids. The central neurophysiologic concept concerning the neurobiology of PBA is that there occurs an interruption of one or more inhibitory neural networks related to brainstem nuclei that affect the complex physiologies of laughter and weeping. No single anatomic site seems necessary or sufficient for the expression of the PBA syndrome. Lesions may occur in subfrontal systems, connector systems in the brainstem, or in the cerebellum.

Treatment

There are clinical reports of therapeutic benefit for the PBA syndrome from both antidepressants and dopaminergic agents. Comparative trials, case series, and individual reports suggest that tricyclic antidepressants (TCA) and selective serotonin reuptake inhibitor (SSRI) antidepressants have efficacy. Dopaminergic agents have also been reported to benefit the PBA syndrome. Psychotherapy is not considered helpful in the treatment of PBA. A novel therapeutic option is under investigation for the treatment of the PBA syndrome, consisting of a fixed combination of dextromethorphan and quinidine. Dextromethorphan is a well-known antitussive agent with pharmacological activity as a potent sigma-1 agonist and as a noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist. Rapid metabolism of dextromethorphan is blocked by quinidine, a cytochrome P450 2D6 inhibitor, resulting in an increased availability of dextromethorphan. This product was proved effective and safe for PBA in two multicenter, controlled trials, one in amyotrophic lateral sclerosis patients and one in multiple sclerosis. Since dextromethorphan has agonist action on sigma receptors in brainstem and cerebellar neural networks, these efficacy studies suggest the possibility that there may be a selective neurochemistry to the PBA syndrome and to its treatment.

Psychogenic Movement Disorders

V K Hinson, Medical University of South Carolina, Charleston, SC, USA

Definition and History

Psychogenic movement disorders (PMDs) are physical manifestations of an underlying psychiatric illness or malingering and cannot be attributed to any known structural or neurochemical diseases. Clinically, PMD often present with complex movements of various phenomenology. Symptoms can mimic the full spectrum of organic abnormal involuntary movements, affect gait and speech, or present as bizarre undifferentiated movements. From a psychiatric perspective, most PMD fulfill criteria for somatoform disorders, and more specifically, conversion disorders of the motor subtype. The first descriptions of somatoform disorders, found in the medical literature of ancient Egypt, date back to 2000 BC. Hippocrates first introduced the term 'hysteria' (Greek for uterus)

into the medical literature. Hysteria was looked at as a disorder of the uterus, until Galen first described it in men and attributed its cause to sexual abstinence. In the nineteenth century, the French neurologist Jean-Marie Charcot took a major interest in the study of hysteria and described the clinical features in detail in his lectures and manuscripts. The modern concept of a psychiatric origin of hysteria and psychotherapy as a treatment modality were finally introduced in 1893 by the Austrian physicians Josef Breuer and Sigmund Freud.

Pathophysiology

The pathophysiology of PMD and other somatoform disorders remains unclear, but initial steps to understand the underlying mechanisms have been undertaken with the use of functional neuroimaging. Spence et al. used positron emission tomography (PET) to investigate the pathophysiology of psychogenic paralysis. They studied two men with psychogenic left-arm weakness, two healthy individuals feigning arm weakness, and six normal controls. Measurements of regional cerebral blood flow showed a relative hypoactivity of the left dorsolateral prefrontal cortex when attempting to move the affected right limb in subjects with psychogenic paralysis compared with feigners and normal controls. Marshall and colleagues evaluated a patient with left-sided psychogenic paralysis, using PET scanning and found failed activation of the right primary motor cortex and overactivation of the right orbitofrontal and anterior cingulate cortex. A study by Vuilleumier and colleagues aimed at differentiating imaging findings secondary to the somatoform disorder itself from findings attributable to coexisting psychiatric disorders such as depression and anxiety. The investigators compared Tc-99m single-photon emission computerized tomography (SPECT) imaging data from patients with psychogenic sensorimotor paralysis before and after recovery by measuring cerebral blood flow at rest and with an activation procedure of passive vibratory stimulation of both hands. There was a decreased regional cerebral blood flow in the thalamus and basal ganglia contralateral to the deficit in each subject. Importantly, these abnormalities resolved with clinical recovery, suggesting that conversion disorders may entail functional disorders in striatothalamocortical circuits controlling sensorimotor function and voluntary motor behavior.

Epidemiology/Risk Factors

PMD account for approximately 2–3% of cases seen in movement disorders clinics. Estimates for the prevalence of psychogenic disorders in the general neurology population vary, but range between 1% and 9%, depending on the applied definitions and methods for case ascertainment. The mean age of onset of PMD ranges between 37 and 50 years and women are predominantly affected. There are no data in the literature on racial distribution, but a transcultural comparison between PMD subjects in Spain and the United States found essentially similar demographic and clinical characteristics. Risk factors for PMD include major emotional stressors such as divorce or death of a family member, history of sexual abuse or rape, previous surgery, or other physical trauma.

Clinical Features and Diagnostic Criteria

Typical characteristics of PMD are abrupt onset, history of a precipitating event, rather fast progression to maximal symptom severity, distractibility, and variability of the movement disorder. The movement phenomenology can mimic the whole spectrum of movements seen in movement disorders of organic origin (tremor, dystonia, chorea, bradykinesia, myoclonus, tics, athetosis, ballism, cerebellar incoordination), and also affect speech and gait. Tremor and dystonia are most common, whereas parkinsonism is only rarely seen. When evaluating patients for psychogenic tremor, the presence or absence of entrainment and coactivation are useful clinical indicators. Entrainment is tested by having the patient execute voluntary movements at a given frequency with the extremity contralateral to the side under evaluation. The psychogenic movement will assume the frequency of the contralateral voluntary movement if entrainment is present. Coactivation refers to an increased muscle tone in the tremulous extremity affected by PMD that is inconsistent during the examination and can be overcome with passive movement. Typical features of psychogenic dystonia include fixed dystonic postures, excessive pain, or unusual distribution of symptoms such as limb dystonia in an adult.

Patients with PMD often exhibit multiple movement phenomena, have bizarre undifferentiated movements, or present with dysfunction of gait and speech in addition to other PMD symptoms. Psychogenic gait disorders often present with exaggerated effort and slowness, bizarre uneconomic postures, convulsive shaking episodes, sudden knee buckling, and near falling. Psychogenic speech disturbances can present with excessive slowness of speech output, stuttering, or even mutism. Symptoms may fluctuate drastically and sometimes resolve completely when the patient is unaware of being observed. The movement disorder is often accompanied by other psychogenic neurological symptoms such as false weakness, excessive pain and tenderness, or coexisting psychiatric illnesses.

Based on these clinical features, Fahn and Williams have defined four diagnostic categories of PMD:

1. *Documented PMD:* Movements relieved by psychotherapy, suggestion, or placebo, or spontaneous symptom resolution when the patient feels unobserved.

2. *Clinically established PMD:* Movements incongruent with organic disease or inconsistent symptoms, in addition to the presence of other false neurological signs, multiple somatizations, or a documented psychiatric illness.
3. *Probable PMD:* Movements are incongruent with organic disease or inconsistent, but no other supportive features are present.
4. *Possible PMD:* Suspicion for PMD, based on the patient's obvious emotional disturbance alone.

According to the DSM IV, there are three pertinent diagnostic categories for the psychiatric classification of PMD: somatoform disorders, factitious disorders, and malingering. Somatoform disorders encompass conversion disorders (physical symptoms that are brought on by psychological stressors), as well as somatization disorders (a multitude of physical, nonorganic symptoms). Factitious disorders refer to symptoms that are intentionally produced with the purpose of achieving some psychological gain, whereas malingering is the intentional symptom production for a material (e.g., financial) gain. The most commonly encountered psychiatric diagnosis of PMD is conversion disorder, followed by somatization disorder, factitious disorder, and malingering. PMD are commonly associated with other axis I psychiatric disorders; most commonly depression and anxiety.

Differential Diagnosis

The differential diagnosis of PMD consists of ruling out the organic counterpart of the type of PMD in question. By means of careful history taking, detailed physical examination and ancillary testing, clues to organic disorders will be elicited. A slowly progressive course without a precipitating event, associated organic abnormalities such as pathological reflexes, and electrophysiological findings suggestive of organic disease will make a diagnosis of PMD unlikely. Organic dystonia as well as paroxysmal dyskinesias are organic movement disorders that are quite often mistaken for PMD, highlighting the importance for expert evaluation.

Diagnostic Workup/Tests

Ancillary testing in the form of neuroimaging and spinal fluid examination is often undertaken to exclude organic diseases. In addition, there are several neurophysiological tests that positively reinforce the diagnosis of PMD. In cases of psychogenic tremor, electromyography (EMG)-based tremor analysis can demonstrate entrainment, an increase of tremor amplitude and frequency with weight loading of the tremulous extremity, variability in tremor frequency, and coactivation of antagonist muscles. EMG evaluation of psychogenic myoclonus is used to demonstrate an abnormally long and variable latency between stimulus and the myoclonic response, variable patterns of muscle recruitment within each jerk, and prolonged duration of myoclonic bursts, as well as significant habituation with repeated stimulation. In difficult-to-diagnose cases of psychogenic parkinsonism, functional neuroimaging with [^{123} I]β-CIT SPECT or [^{18}F]DOPA-PET has been used, confirming the absence of striatonigral degeneration in PMD.

Management

The management of PMD contains three important steps: (1) Clear and sensible delivery of the diagnosis by the neurologist, (2) avoidance of iatrogenic harm from unnecessary tests and medications, and (3) treatment by a psychiatrist, often in conjunction with a psychologist and physical therapist.

It is important for the treatment success that the patient understands the diagnosis of PMD. The specific movement disorder based on the primary movement phenomenology (e.g., tremor, dystonia, myoclonus) should be disclosed, and the underlying etiology (PMD) clearly discussed in layman's terms. Some physicians prefer the term 'functional movement disorder' as the term 'psychogenic' might be perceived as pejorative by the patient. On the other hand, 'psychogenic' seems to be more meaningful and easier to grasp, and 'functional' might be somewhat artificial and abstract. In any case, the concept of physical expression of emotional problems should be explained, as well as the potential for better outcome of PMD compared with organic neurodegenerative diseases. A referral to a psychiatrist will be made who will first establish the pertinent diagnostic category for PMD (somatoform disorder, factitious disorder, or malingering) and define secondary psychiatric illnesses. Treatment of the psychiatric comorbidities, most often depression or anxiety, can improve physical symptoms. Clear guidance as to the best psychiatric treatment modality specific to PMD is lacking, but a combination of psychodynamic psychotherapy and antidepressants or anxiolytics is often used, sometimes in conjunction with a rehabilitative physical or occupational therapy program. Cognitive behavioral therapy aimed at the reduction of perceived stress and disability and limiting the inappropriate use of medical care has also been shown to be of value in the management of functional somatic symptoms.

Prognosis

The outcome of patients with PMD is highly variable and mostly dependant on the duration of symptoms by the time of diagnosis. If left untreated, PMD are often chronic and disabling, persisting in 65–95% of patients. A treatable comorbid psychiatric condition such as depression or

anxiety has been found to be a positive prognostic factor. Negative prognostic value has been associated with long-standing symptoms, insidious onset of movements, and primary psychiatric diagnosis of hypochondriasis, factitious disorder, or malingering. Other commonly encountered obstacles to treatment are patient resistance toward the diagnosis of psychogenicity, and lack of willingness to engage in psychiatric treatment. If PMD are recognized early and appropriate psychiatric treatment is administered, functional status could be completely restored.

Psychosis in Parkinsonism

L B Zahodne, University of Florida, Gainesville, FL, USA
H H Fernandez, University of Florida/McKnight Brain Institute, Gainesville, FL, USA

Glossary

Acetylcholinesterase inhibitors – Pharmacological agents that inhibit the acetylcholinesterase enzyme from breaking down the neurotransmitter acetylcholine.

Atypical antipyschotics – Heterogeneous group of pharmacological agents used to treat psychiatric conditions that differ from traditional antipsychotics in chemical composition and/or side effect profile.

Delirium – A transient mental state characterized by confusion and disorientation, sometimes associated with psychotic phenomena.

Delusion – A false belief often firmly held in light of evidence to the contrary that is not explained by cultural or religious doctrine.

Hallucination – A disturbance in the perception of reality consisting of a sensory experience without an external percept. Can manifest in a variety of modalities (i.e., visual, auditory, olfactory, tactile, gustatory).

Illusion – A sensory distortion resulting from incorrectly perceiving or misinterpreting an external percept.

Psychosis – A mental disorder characterized by a compromised ability to recognize reality consisting of hallucinations and/or delusions.

Definition and History

Psychosis in PD is characterized by hallucinations that are primarily visual, delusions, and 'minor' sensory disturbances such as illusions, 'passage,' and 'sense of presence' hallucinations. The understanding of psychosis in PD has expanded markedly from an initial interpretation of symptoms as dopaminergic drug side effects to the current view of a complex interplay of extrinsic and disease-related factors.

Dopaminergic medication use was the first risk factor implicated in PD psychosis. However, hallucinations in PD patients were reported prior to the introduction of levodopa. Evidence that dopaminergic medications are neither necessary nor sufficient to account for psychotic symptomatology is accumulating, and the underlying pathophysiology of psychosis is a rich area of research.

Pathophysiology

The Role of Dopaminergic Medications

All PD medications have been implicated in the appearance of psychotic features, and these features often remit after drug therapy has been reduced or eliminated. Dopaminergic agonists (e.g., cocaine and amphetamine) can induce psychotic symptoms. Conversely, the mechanism of action of atypical antipsychotics (AAs) used to reduce the occurrence of these symptoms is thought to involve dopamine (D2) receptor occupancy. A prominent theory for the mechanism by which PD drugs increase susceptibility to psychosis involves hypersensitization of dopamine receptors following chronic stimulation, which may lead to dysfunction of limbic structures that assign emotional and hedonic significance to sensory input. This dysfunction may result in misattributions of internal stimuli as having originated from the external sensory world.

However, studies have failed to find a clear relationship between medication dosage and the occurrence or severity of psychosis in PD. Psychotic symptoms have also been found to be associated with nondopaminergic agents, such as anticholinergics and amantadine. Intrinsic, disease-related processes combine with anti-PD medications to contribute to the emergence of PD psychosis. Recent research implicates visual processing abnormalities, sleep dysfunctions, and structural and neurochemical changes.

Visual Processing Abnormalities

PD patients who experience visual hallucinations may also suffer from deficits in visual processing. Compared with nonhallucinating PD patients, hallucinators exhibit a lower visual acuity, deficits in color and contrast recognition, and a greater ocular pathology, including cataracts, retinal disease, and glaucoma. Disease-related dopamine deficiency at the level of the retina has been linked to the occurrence of visual hallucinations in both PD and dementia with Lewy bodies (DLB). These deficits may facilitate the onset of visual hallucinations.

While structural MRI studies of hallucinating PD patients have not revealed specific occipital lobe or deep white matter lesions, studies using fMRI have identified functional abnormalities in visual processing. Hallucinating PD patients appear to exhibit a more frontal (i.e., BA 44, 6), visual association cortex (i.e., BA 19), and subcortical (i.e., caudate nucleus) activation coupled with a less occipital activation than do nonhallucinating PD patients. Hallucinators exhibit deficient reality monitoring in that they are more likely to believe that mental images represent real external stimuli. Such findings may indicate disinhibition of 'top-down' processing and the subsequent release of internally generated images into areas that normally represent externally generated percepts, perhaps resulting from the weakening of retinal–striatal–cortical signals.

Sleep Dysfunction

Psychosis in Parkinson's has also been linked to sleep disturbances. Although the 'continuum hypothesis,' which asserts that sleep disturbances in PD lead to altered dream phenomena and then to frank daytime hallucinations and delusions, has not been fully supported, these phenomena do appear to overlap. A prominent view of the relationship between sleep disturbances and PD psychosis involves disruption in rapid eye movement (REM) sleep. Polysomnographic studies of Parkinson patients have found a relationship between visual hallucinations and short, fragmented REM sleep. Specifically, patients experiencing hallucinations evidenced lower sleep efficiency and reduced total REM sleep time and percentage, compared with nonhallucinating patients. Some purport that visual hallucinations in PD represent a narcolepsy-like phenomenon in which REM dream imagery intrudes into the waking state, perhaps due to a reduction in acetylcholine. Moreover, sedating antipsychotic drugs such as quetiapine and clozapine have shown a greater efficacy in controlling psychosis than nonsedating agents such as olanzapine.

Neurochemical Abnormalities

Of the brain's neurotransmitters, dopamine is most consistently linked to psychosis in PD as described earlier. However, serotonin, acetylcholine, and the interaction between these and dopaminergic systems may also play a role in psychosis emergence. Several pharmacological agents (including nonpsychotropic medications) that reduce serotonergic activity improve psychotic symptoms. PD involves a cholinergic deficit, which is even more apparent in cognitively impaired and demented

PD patients who are at higher risk for psychosis. A cholinergic deficit has been linked to psychosis in DLB. Anticholinergic drugs used to treat motor symptoms can lead to the emergence of psychotic symptoms, while cholinesterase inhibitors may represent an alternative to AAs to treat PD psychosis. Overall, it appears that PD psychosis involves the dysregulation of a combination of neurotransmitter systems.

Structural Abnormalities

Lewy body deposition is associated with dementia in PD, which is a risk factor for PD psychosis. Researchers have documented strong correlations between the distribution of Lewy bodies in the temporal lobe, specifically in the amygdala and parahippocampus, and well-formed visual hallucinations in Lewy Body diseases such as DLB and PD dementia. These Lewy bodies may also be associated with an earlier onset of hallucinations.

Epidemiology and Risk Factors

It has been estimated that psychotic symptoms occur in 20–40% of PD patients, and they typically occur later in the disease (i.e., 10 or more years after initial diagnosis). While all anti-PD medications have been associated with psychosis, it appears that dopamine agonists in particular and the use of multiple drugs put patients at highest risk. While drug therapy is a risk factor for psychosis, neither duration nor dose has been found to be. Multiple other risk factors have now been identified, including cognitive impairment and dementia, increased age, disease duration and severity, depression, and various sleep disturbances.

Clinical Features and Diagnostic Criteria

Psychosis in PD comprises a specific constellation of clinical features that are different from those typical of other psychotic disorders such as schizophrenia. Psychosis in PD usually takes the form of visual hallucinations, which most commonly start in the evening hours during periods of low stimulation, although they can eventually occur at any time of the day. The content of visual hallucinations typically involves people or animals but may also feature inanimate objects. Visual hallucinations last seconds to minutes at a time and tend to be chronic, occurring at least once a week, often much more frequently. Unlike schizophrenia, auditory hallucinations occur less commonly in PD, and they typically cooccur with visual hallucinations. They consist more often of whispers or music, as opposed to the threatening voices reported in schizophrenia; however, some cases of threatening auditory hallucinations have been documented in PD. Tactile, olfactory, and gustatory hallucinations have also been reported in PD psychosis, but they are not common and tend to cooccur with visual hallucinations.

'Minor' phenomena such as illusions, 'passage,' and 'sense of presence' hallucinations have been included in the literature on PD psychosis. Illusions are disturbances in perceptual experience, such as mistaking a plant for a person. 'Sense of presence' refers to the feeling that a person or animal is in close physical proximity to the patient. A typical 'passage' hallucination is described as seeing shadows or quick fleeting objects (e.g., cockroach) passing through the peripheral visual field. As these features are less likely to disrupt patients' daily lives, they are less likely to be spontaneously reported.

Delusions and disorganized thinking may also emerge, although they are not as common as visual hallucinations. Paranoid thoughts (e.g., spousal infidelity) are a common theme, although, rarely, grandiose, somatic, persecutory, and religious delusions have also been reported.

While there are no standardized diagnostic criteria for PD psychosis, the NINDS and the NIMH recently gathered a work group to promote discourse on provisional diagnostic criteria forming an inclusive constellation of clinical features, not shared by other psychotic syndromes. PD psychosis was conceptualized as involving at least one psychotic symptom (i.e., illusions, false sense of presence, hallucinations, or delusions) that emerges *after* the onset of PD (defined by UK brain bank criteria) that lasts at least 1 month and cannot be better accounted for by another cause. In addition, associated features, such as the presence or absence of insight, dementia, and pharmacological treatment, should be noted.

Differential Diagnosis

The differential diagnosis of psychosis in PD first involves excluding delirium as the cause of symptoms. Psychotic symptoms may emerge as part of a delirium caused by infection, toxins, metabolic disturbance, or acute drug intoxication from sudden changes in antiparkinsonian drug doses and newly prescribed narcotics. Other neurodegenerative disorders involving parkinsonism may also produce psychotic features, such as progressive supranuclear palsy, corticobasal degeneration, DLB, and various psychiatric disorders (e.g., schizophrenia, psychotic depression, brief psychotic disorder).

The main distinction between DLB, which is defined as a progressive cognitive decline with at least two additional features (i.e., fluctuating cognition, recurrent, well-formed visual hallucinations, and spontaneous parkinsonism), and PD psychosis with dementia lies in the temporal course of symptoms. If dementia occurs within the year before or concurrently with parkinsonism, then a diagnosis of DLB is more appropriate.

Psychosis related to PD can be distinguished from that due to a primary psychiatric disorder by considering the history of symptoms. If symptoms arise very early (i.e., first 3 months) in the course of PD, involve fear and/or prominent paranoia with nonvisual hallucinations, and do not fluctuate during the course of a day, the psychosis may be due to a psychiatric disorder. Psychosis onset in late adolescence and early adulthood, a progressive clinical course, signs of grossly disorganized speech, and the presence of negative symptoms are highly suggestive of schizophrenia. While some negative symptoms (e.g., apathy, affective flattening) are common among PD patients, they may fluctuate with medication. Psychosis lasting more than 1 month, which is characteristic of PD psychosis, is, by definition, not considered as a brief psychotic disorder. If psychosis appears in the context of prominent affective symptoms and manifests in mood congruent symptoms such as delusions of guilt or worthlessness, it may result from a mood disorder. The average age of onset of delusional disorder is middle or late life, and unlike those seen in schizophrenia, delusions are typically not bizarre or accompanied by hallucinations. If present, hallucinations are more often olfactory or tactile in mood disorders with psychotic features, in contrast to prominent visual hallucinations characteristic of PD psychosis.

Assessment Instruments

Psychosis in PD can be assessed with a variety of instruments, most of which were originally designed for use in non-PD populations. Scales vary in information source (patient, caregiver, or clinician), necessity for trained raters, inclusion of psychiatric symptoms other than psychosis, and original validation population. The most commonly used instruments include the Neuropsychiatric Inventory (NPI) and the Brief Psychiatric Rating Scale (BPRS). The NPI is a caregiver-based interview comprising 12 queries aimed at characterizing psychopathology in patients with dementia. While this instrument assesses hallucinations and delusions, it may not be very sensitive to change in PD populations. The BPRS was specifically designed to measure clinical change in schizophrenia and is the most commonly used rating scale in clinical trials of antipsychotic agents in patients with PD despite lacking a formal validation study in this population. The BPRS comprises 18 items scored on a 7-point Likert-type scale. Six items are scored based on clinical judgment, and the remaining 12 are scored based on the content of a patient interview. This instrument appears to be sensitive to change in PD psychosis; however, it requires well-trained raters. Other recommended scales include the Positive and Negative Syndrome Scale (PANSS) and the Schedule for Assessment of Positive Symptoms (SAPS).

Several scales have been developed specifically to assess psychotic symptoms in PD, including the Parkinson Psychosis Rating Scale (PPRS), the Parkinson Psychosis Questionnaire (PPQ), and item two from the Mood, Mentation, and Behavior section (Part I) of the Unified Parkinson Disease Rating Scale (UPDRS). The PPRS comprises seven total items rated on a 4-point Likert-type scale and includes a global assessment item based on family report. While this scale was specifically developed in PD, it may not capture the heterogeneity of symptoms seen in the disease, and applicability appears limited. The PPQ was developed as a screening measure and consists of initial probes followed by detailed questions and separate frequency and severity ratings. This scale may not assess the range of PD hallucinatory phenomena and may overemphasize a link between sleep phenomena and psychotic symptoms. The single 'thought disorders' item (item 2) from the UPDRS, which combines dream phenomena, hallucinations, and delusions, constitutes a screen rather than a measure of psychosis severity and is scored on a 5-point Likert-type scale. This item assumes a continuum from dream phenomena to frank psychosis and may exhibit floor effects. The Movement Disorder Unified PD Rating Scale, a revision of the original UPDRS, has one question on hallucinations and psychosis with reference to other scales in its Appendix.

Management

Reduction/Simplification of PD Medications

General consensus and clinical practice support a reduction in anti-PD medications as the most appropriate first-line treatment for PD psychosis. If a patient is on multiple medications, most authorities would recommend the gradual removal of anti-PD medications in the following order: anticholinergics, amantadine, MAO-B inhibitors, dopamine agonists, catechol-O-methyltransferase (COMT) inhibitors, and lastly, levodopa. Furthermore, the short-acting formulation of levodopa, compared with the continued-release version, may mitigate the accumulation of adverse side effects. Aside from these medications, polypharmacy has been identified as an independent risk factor for psychosis in PD. It should be noted that various commonly prescribed agents (e.g., narcotics, hypnotics, antidepressants, anxiolytics) can lead to psychotic symptoms.

Due to adverse side effects, the addition of an antipsychotic agent should be considered only if medication reduction to the lowest tolerated dosages causes significant motor worsening or does not improve psychosis. Since reducing medications will likely lead to a reemergence of motor deficits, the clinician and patient are faced with a difficult challenge (see **Table 1**).

Table 1 Summary of pharmacological treatment of psychosis in Parkinson's disease

Agent	*Class*	*Dosages reported (mg day^{-1})*	*Empirical support*	*Extrapyramidal side effects*	*Other considerations*
Clozapine	Atypical antipsychotic	24.7–36	+++	Minimal	Monitoring for agranulocytosis required
Risperidone	Atypical antipsychotic	0.7–1.9	−	Significant	Prolactin elevation
Olanzapine	Atypical antipsychotic	4.1–6.5	−	Moderate	
Quetiapine	Atypical antipsychotic	54–200	++	Mild	
Aripiprazole	Atypical antipsychotic	1–12	−	Variable	
Ziprasidone	Atypical antipsychotic	N/A	−	Moderate	Effects on electrical cycle of the heart
Tacrine	Cholinesterase inhibitor	40–60	+	Variable	Hepatic toxicity
Donepezil	Cholinesterase inhibitor	5–10	+	Minimal	
Galantamine	Cholinesterase inhibitor	4–8	+	Unclear	
Rivastigmine	Cholinesterase inhibitor	1.5–8.9	++	Minimal	
Ondansetron	Antiemetic	12–24	−	Minimal	Cost

+++, Fully recommended; ++, Moderate support, further trials warranted; +, Minimal support; −. Little to no support.

Atypical Antipsychotics

After simplifying a patient's medication regimen, prescribing an AA represents the most common clinical response to PD psychosis. Since differences between the six AAs currently marketed in the US lie in their relative tendencies to lead to motor dysfunction, the choice of an agent is based largely on its distinct side effect profile.

Clozapine is the only AA fully recommended for the treatment of PD psychosis, according to a 2007 meta-analysis. In addition to two well-designed, randomized, controlled and numerous open-label trials that demonstrated acute efficacy and tolerability of clozapine in PD populations, longitudinal studies have shown it to be well-tolerated and effective long term. Despite these results, clozapine is often avoided by clinicians because of the requirement of cumbersome monitoring for agranulocytosis, which has been shown to occur in only 0.38% of a sample of over 99 000 US patients with schizophrenia. WBC count monitoring is required weekly during the first 6 months and bi-weekly thereafter. Other adverse side effects (e.g., sedation, orthostatic hypotension, sialorrhea) may also occur. Therefore, research is moving toward identifying more practical agents.

Although released in the United States as an AA, risperidone may more closely resemble 'typical' neuroleptics due to the dose-dependent incidence of extrapyramidal side effects and prolactin elevation. While most studies in PD demonstrate significant improvements in psychosis, the majority are open-label, which may partly contribute to the variability in reports of motor side effects. Due to numerous reports of motor worsening and the agent's documented 'typical' antipsychotic behavior, it is often avoided by clinicians combating PD psychosis.

Olanzapine is estimated to lead to motor worsening in about 40% of PD patients and is generally considered to be a poor choice for treating PD psychosis.

Among the AAs, quetiapine is most chemically similar to clozapine, but it does not show a risk of agranulocytosis. Despite results from numerous open-label studies involving more than 400 patients in which it was well-tolerated and efficacious in the treatment of PD psychosis, two double-blind trials reported no significant improvements in psychosis. A third, in which 40 patients were randomized to either quetiapine or clozapine, did show quetiapine efficacy in treating psychosis. The discrepancy between open label and double-blind studies is puzzling, but quetiapine remains a commonly prescribed AA in patients with PD and hallucinations.

The use of ziprasidone has been limited due to its effects on the heart's electrical cycle (i.e., prolongation of the QT interval), but there have been no reported cases of *torsades de pointes*. Case reports and series suggest that ziprasidone may be a relatively safe treatment for psychosis in PD, especially when other AAs have proved ineffective or caused intolerable side effects. However, after reviewing data on ziprasidone for the treatment of schizophrenia, a panel of expert psychiatrists concluded that its extrapyramidal side effects profile is 'better than risperidone, the same as olanzapine, but not quite as good as quetiapine or clozapine.'

Unlike other AAs, aripiprazole is a 'partial agonist' at both D_2 and 5-HT_1 receptors and is believed to carry a relatively low risk of extrapyramidal side effects. Data from case reports and two open-label trials in PD suggest that its efficacy and tolerability in PD patients are variable. While aripiprazole may be efficacious for some patients, it carries a considerable risk of adverse effects, and there is a need for further controlled trials of aripiprazole in the PD population.

While AAs continue to be the most commonly prescribed pharmacological agents in the treatment of PD psychosis, the US Food and Drug Administration (FDA)

has mandated that all manufacturers provide a boxed warning on product labels stating that AAs have been found to be associated with a higher risk of mortality when used in elderly patients with dementia. This finding is particularly relevant to the management of PD psychosis due to the age and frailty of the late-stage PD patients who typically exhibit psychosis. Since the mechanism by which AAs cause increased mortality is not well understood, they will likely continue to be used in the treatment of PD psychosis, especially when the consequences of inaction are considered. However, studies involving alternative therapies such as cholinesterase inhibitors are ongoing.

Cholinesterase Inhibitors

The first published report of a cholinesterase inhibitor in PD was an open-label trial of tacrine in which psychotic symptoms completely resolved in five out of seven demented patients and improved in the remaining two. Despite a previous account of exacerbated parkinsonism in one patient treated with tacrine, no motor worsening was reported in this trial. Today, tacrine is rarely used for the treatment of PD psychosis due to its tendency to cause hepatic toxicity.

While many open-label studies using donepezil in PD patients have shown improvements in psychosis, motor side effects have been variable. In addition, placebo-controlled trials published to date have shown nonsignificant improvements in psychosis, perhaps as a consequence of small sample sizes and/or low baseline symptom severity.

Unlike other cholinesterase inhibitors, galantamine also acts on nicotinic receptors, activity at which may prevent the downregulation of acetylcholine that accompanies treatment with cholinesterase inhibitors. In the striatum, increasing activity at nicotinic receptors on presynaptic dopamine neuron terminals may facilitate the release of dopamine, thereby improving motor symptoms. Only one study using galantamine in PD psychosis has been published, and it reported that three out of nine patients experienced a complete resolution of hallucinations, and four additional patients reported an improvement. While parkinsonism improved in six of the patients, the remaining three experienced a worsening of tremor. Further studies are necessary to determine the utility and safety of galantamine in treating PD psychosis.

Rivastigmine, the only one in its class now FDA approved for the treatment of PD dementia, is unique among cholinesterase inhibitors in that it inhibits not only acetyl, but also butyryl cholinesterase. One open-label trial showed that caregiver distress, Mini-Mental State Exam scores, and scores on the NPI hallucinations and sleep disturbances subscales improved. Also, rivastigmine was well-tolerated, and motor symptom severity remained stable. A large, double-blind, placebo-controlled trial using rivastigmine to treat patients with PD and dementia showed that it better alleviated symptoms in the subset of hallucinating patients. A significant improvement in both total NPI score and the agitation/aggression item was noted. Additional double-blind, controlled trials using this promising agent for the treatment of visual hallucinations in PD are warranted and are underway.

Ondansetron

Ondansetron, an antiemetic, was tested in schizophrenia because of its antagonism of 5-HT_3 receptors, but it has not been found to be efficacious for this purpose. However, several early reports suggested that it may be efficacious in the treatment of psychosis in PD without worsening motor symptoms, presumably due to its high selectivity. Two open-label trials conducted by one group reported improvements in psychosis with limited side effects; however, these positive results have not been reproduced by others. Furthermore, the cost of the drug has kept it from being tested further in the PD population.

Prognosis

Once hallucinations appear, they tend to become a chronic and progressive condition. While treatment with AAs has been shown to provide some degree of symptom relief, data regarding long-term treatment effects have been variable. Some studies document no long-term outcome differences between patients who received treatment and those who did not, and many treated patients still experience psychotic symptoms. Other reports suggest that many patients receiving antipsychotic treatment experience continued efficacy, especially those who responded to medication early on.

After patients initiate antipsychotic therapy, continued treatment may be necessary to maintain symptom control and avoid psychosis exacerbation. One study that attempted to wean psychosis-free PD patients off their antipsychotic medications was aborted because five of the six subjects experienced 'rebound psychosis.' Furthermore, three of these five patients experienced an exacerbation (compared with the original psychotic episode that prompted antipsychotic use) in the form of paranoid delusions or threatening auditory hallucinations. Additional research is needed to confirm the utility and necessity of continued antipsychotic treatment.

Psychotic features may be prognostic of additional complications such as cognitive impairment and weight loss, as well as negative outcome variables such as caregiver distress, nursing home placement, and mortality. Data appear to support the clinical observation that PD patients who present with visual hallucinations are more likely to develop cognitive impairments later on.

Psychosis and cognitive decline often cooccur, and both have been related to the development of the other. When psychosis and dementia coexist in PD, it is perhaps the greatest limiting factor for the optimal treatment of motor symptoms. These symptoms severely impact on caregiver burden and patients' quality of life and may partly explain these patients' increased risk of nursing home placement and related mortality. A case-control study controlling for motor and cognitive impairment identified hallucinosis as the primary factor differentiating PD patients who were placed in a nursing home from those who were not. The finding that hallucinations and other psychotic phenomena are predictive of negative outcome has been well-replicated and underscores the importance of treating PD psychosis.

Glossary

Dopamine dysregulation syndrome (DDS) – A troublesome condition, close to addiction, consisting of motor and behavioral disturbances caused by an intake of DRT at doses well beyond those required to control motor symptoms of Parkinson's disease (PD). It is also reported as hedonistic-homeostatic dysregulation syndrome (HHDS).

Dopamine-related compulsions (DRCs) – A group of motivational disorders related to abnormal activation of the reward mechanisms, caused by DRT. Some authors include in this group: DDS, ICDs, and punding behaviors.

Dopaminergic replacement therapy (DRT) – A therapeutic category that includes levodopa and dopaminomimetics and that represents the cornerstone of pharmacotherapy in PD.

Impulse control disorders (ICDs) – A set of psychiatric disorders including intermittent explosive disorder (hot-headedness), kleptomania (stealing), pathological gambling, pyromania, trichotillomania (pulling one's hair out),

dermatillomania (skin picking), and compulsive shopping. Impulsivity, the key feature of these disorders, can be thought of as seeking a small, short-term gain at the expense of a large, long-term loss. ICDs may be caused by DRT: among the DRT-induced ICDs, some authors include DDS and hypersexuality.

LEDD – The acronymic of 'levodopa equivalent daily dose' that means all the pharmacologic therapy taken in 1 day (24 h) for PD converted in levodopa, as follows: levodopa (100 mg) = 130 mg controlled-release levodopa = 70 mg levodopa + COMT inhibitor = 1 mg of pergolide = 1 mg of lisuride = 1 mg of pramipexole = 5 mg of ropinirole = 10 mg of bromocriptine = 10 mg of apomorphine = 20 mg of dihydroergocriptine.

Obsessive–compulsive disorder (OCD) – The essential feature is recurrent obsessional thoughts or compulsive acts. Obsessional thoughts are ideas, images, or impulses that enter the patient's mind again and again in a stereotyped form. They are almost invariably distressing, and the patient often tries, unsuccessfully, to resist them. They are, however, recognized as his or her own thoughts, even though they are involuntary and often repugnant. Compulsive acts or rituals are stereotyped behaviors that are repeated again and again. They are not inherently enjoyable, nor do they result in the completion of inherently useful tasks. Their function is to prevent some objectively unlikely event, often involving harm to or caused by the patient, which he or she fears might otherwise occur. Usually, this behavior is recognized by the patient as pointless or ineffectual, and repeated attempts are made to resist. Anxiety is almost invariably present. If compulsive acts are resisted the anxiety gets worse.

Punding behaviors – Punding is a complex, prolonged, purposeless, stereotyped behavior (such as collecting or arranging objects) observed in drug addicted individuals and in patients treated with dopaminergic drugs.

Definition and History

Punding refers to a complex, stereotypical behavior characterized by an intense fascination with repetitive and purposeless activities. The term originates from Swedish slang ('block-head'), and was first used to define a stereotyped behavior in amphetamine and cocaine addicts in California and in Denmark. Since the first description in the 1970s, this phenomenon came to the attention of neurologists when punding was reported in a patient with Parkinson's disease (PD), triggered by dopaminergic replacement therapy in 1994.

Epidemiology

Punding is probably underreported and underestimated for several reasons, one being that repetitive behaviors have been reported under the label of 'obsessive–compulsive behavior' or 'hypomania.' Prevalence data from the medical literature are conflicting, as it was observed in only 1.4% of 291 PD patients by Miyasaki, while Evans and colleagues reported that 14% of 123 unselected PD were punders, and that the percentage increased to 30% in patients treated with large doses of dopaminergic drugs (>800 levodopa equivalent daily dose – LEDD).

Clinical Presentation

Punding is a peculiar stereotyped behavior characterized by an intense fascination with a complex, excessive, nongoal oriented, repetitive activity such as manipulation of technical equipment, handling, examining, or sorting through common objects, grooming, hoarding, and engagement in extended monologues devoid of content. Men tend to repetitively tinker with technical equipment such as radio sets, clocks, watches, and car engines, the parts of which may be analyzed, arranged, sorted, and catalogued but rarely put back together. Women, by contrast, incessantly sort through their handbags, tidy continuously, brush their hair, or polish their nails. The behavior is reported as soothing/calming and associated with an intense curiosity; while involved in their chosen activity, punders withdraw into themselves, become tacit and unresponsive, and give the impression of absent-mindedness, becoming irritable when distracted from their tasks. Punders are normally aware of the inapposite obtuse nature of the behavior, and recognize that time and money spent on their behaviors are excessive and inappropriate; despite the consequent self-injury, they do not abort such behavior. Therefore, they can have devastating psychosocial consequences.

Nosology and Psychiatric Comorbidity

In the last decade, a set of complex behaviors related to excessive or aberrant dopaminergic stimulation have been recognized in PD patients. These include pathological gambling, hypersexuality, compulsive shopping, compulsive eating, hobbyism, punding, and compulsive medication use. These disorders have been classified within

overlapping psychiatric categories focusing on phenomenology, particularly among the impulse control disorders (ICDs). In a recent review, Voons and Fox used the term 'repetitive behaviors' to avoid any reference to possible underlying pathophysiological mechanisms. In another comprehensive review on ICDs, Ferrara and Stacy categorized these behaviors among motivational disorders, inversely related to the severity of motor symptoms, and aggravated by dopamine replacement therapy (DRT). They include three categories among dopamine related compulsions (DRCs): (1) reward-seeking behaviors (or ICDs) such as pathological gambling; (2) punding behaviors such as sorting collections; and (3) hedonistic–homeostatic dysregulation syndrome (HHDS), a maladaptive pattern of DRT overuse close to drug addiction.

Punding is a senseless repetitive behavior not described anywhere. The only mention of the disorder in *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision* (DSM-IV-TR) is 'stereotypical and repetitive behaviors' in amphetamine intoxication. Hence, the classification of repetitive behavior disorders is debated, and the current nosology may be inadequate. Punding shares some similarities with obsessive–compulsive disorder (OCD) as it may be considered a form of compulsion: behaviors are complex, repetitive, and result in isolation from or conflict with other people. In contrast with OCD; however, punding is not driven by anxiety or obsessions (such as religious, checking, symmetry, ordering, counting, or contamination), and is compulsive in the sense that the person could be distracted from the intrusive behavior but would become irritable if prevented from resuming.

Even though there is no study specifically addressing this issue, depression or anxiety was reported in ~10% of cases, a proportion to be expected considering the high prevalence of these disorders among PD patients. Therefore, punding does not correlate with mood or anxiety disorders; punders feel anxious only when they are forced to stop or if prevented from resuming.

Punders frequently present with agitation, disinhibition, irritability, and sleep disturbance, all features of mania. However, disinhibition is neither stereotyped nor universal; moreover, punders do not report typical features of mania like racing thoughts, feeling of grandiosity, or distractibility.

Among PD punders reported so far, one or more ICDs were reported in 13 out of 22 cases (59.1%), a prevalence much higher than reported in other PD series, where 2–8% is the estimated value. Although the role of dopaminergic stimulation in the development of punding is confirmed by several lines of evidence, not all patients taking dopaminergic drugs develop this behavior; moreover, there has been a report of punding following introduction of the atypical neuroleptic quetiapine. On the other hand, most punders improve with neuroleptics, or reduction of dopaminergic stimulation.

Risk Factors and Pathophysiological Considerations

In a recent survey of 141 PD cases it was found that higher impulsivity and younger age of disease onset were independent predictors of higher Punding Scale scores. Others found that, besides younger age, punding was associated with male gender and reduced night time sleep. In PD punders, a history of psychosis is common; this may either reflect a common predisposing condition or the high doses of dopaminergic drugs usually taken by these patients or both. Punding has not been systematically assessed for association with medication subtypes; however, an association with a high LEDD, and overuse of rescue doses (especially during night) have been reported. Even though some punders are on levodopa monotherapy, the majority of punders take a combination of levodopa and dopamine-agonists.

Experimental and clinical evidence suggest that punding is a phenomenon triggered by stimulation of D1 and D2 receptors. Although the pathophysiology of punding is yet to be clarified, its similarity with drug-induced stereotypies in animals, the frequent association with dopamine dysregulation syndrome (DDS) and dyskinesias in PD suggest that it may be related to plastic changes in the ventral and dorsal striatal structures including the nucleus accumbens, and linked to psychomotor stimulation and reward mechanisms.

The role of the frontal corticostriatal circuitry in inhibiting the dopamine (DA)-dependent induction of stereotypic behavior has been established in experimental models. Accordingly, in humans the inability to modulate automatic routines is likely due to impaired frontal lobe function. Large frontal lesions are associated with highly stereotyped behaviors, including forced collectionism ('hoarding'). In addition, homologies of clinical features and epidemiological considerations aside, the role of D1 and D2 receptors, which is already well established for the other conditions, support the view of a common pathophysiologic process shared by addiction, dyskinesias, and stereotypies.

It has been proposed that the basal ganglia store and select specific competing motor programs under the control of frontal cortex and that a dysfunction of this process may underlie conditions involving the abnormal expression of stereotyped motor behaviors such as compulsions. Analogously, punding may be considered a kind of *on* complication like dyskinesias and, accordingly, it has been included among the 'motor complication' of DRT. In favor of this hypothesis, it was recently reported that amantadine can reverse punding.

Management of Punding

Since punding, as well as the other DRCs, presents or increases following the DRT introduction or escalation,

DRT tapering (especially of DA receptor agonists) will be helpful in most patients. Besides DRT reduction, patient and caregiver information and education are important: patient must be discouraged from taking frequent rescue doses, especially during the night. As psychiatric comorbidity is frequent, a psychiatric assessment and follow-up is advisable. If DRT lowering induces worsening of PD symptoms, one strategy (especially when punding coexists with ICDs) is to shift to levodopa monotherapy, as DA agonists seem to be, as a class, more likely to induce ICDs, low dose quetiapine or clozapine can be added. Risperidone should be avoided as it worsens PD symptoms. The role of amantadine and of medications anecdotically reported to help patients with hypersexuality (valproate, lithium, donepezil) need to be assessed. Antidepressants that enhance dopaminergic transmission should be avoided, as they could worsen DRCs. Deep brain stimulation (DBS) in combination with a reduction of DRT has been reported to be effective in controlling DDS. On the other hand, some patients have been reported to develop hypersexuality, mania, and pathological gambling after DBS of subthalamic nucleus.

Q

Quinolinic Acid

J L McBride, Oregon Health and Sciences University, Beaverton, OR, USA
S Ramaswamy and J H Kordower, Rush University Medical Center, Chicago, IL, USA

Glossary

Excitotoxicity – The biological process whereby neurons undergo cell death upon excess stimulation by glutamate and glutamate-like substances.
GABA (γ-aminobutyric acid) – An inhibitory neurotransmitter found throughout the brain that binds to and inhibits postsynaptic neurons harboring GABA receptors.
Glutamate – An excitatory neurotransmitter found throughout the brain that binds to and excites postsynaptic neurons harboring NMDA receptors.
Huntington's disease (HD) – A genetic, neurodegenerative disease characterized by a mutation in the gene that encodes the protein, huntingtin. Symptoms of HD include a hyperkinetic movement disorder, cognitive decline, and personality changes.
Neurodegeneration – The global phenomenon to describe a loss of neurons in the central and/or peripheral nervous systems.
Striatum – A structure in the forebrain composed of the caudate nucleus and putamen. The striatum receives excitatory input from the cortex and sends inhibitory projections to the globus pallidus and substantia nigra. This brain nucleus is involved in the planning and fine-tuning of motor programs as well as certain cognitive processes.

Description and Mechanism of Pathogenesis

Quinolinic acid (QA) is a 2,3-pyridine dicarboxylic acid ($C_7H_5NO_4$). QA is produced following the metabolic breakdown of the amino acid tryptophan, via the kynurenine pathway. Tryptophan is able to cross the blood–brain barrier (BBB), and upon entering the brain, is taken up by astrocytes, macrophages, microglia, and dendtritic cells and converted into kynurenine. In the presence of the enzyme 3-hydroxyanthranilic acid, kynurenine is converted into QA through a series of enzymatic reactions. QA is normally present in extremely low, nanomolar concentrations in the brain and in cerebrospinal fluid and does not cause damage to the surrounding cells. However, it has been recently demonstrated that increased levels of QA can be produced by activated macrophages and microglia in the brain. Accumulation of endogenous QA has recently been implicated in the etiology of certain neurodegenerative diseases, especially those with a strong inflammatory component, such as Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), Huntington's disease (HD), Alzheimer's disease (AD), stroke, multiple sclerosis (MS), and epilepsy.

QA exerts its biological effects by binding to and potentiating Mg^{2+}-sensitive *N*-methyl-D-aspartate (NMDA) receptors, which normally bind the neurotransmitter, glutamate. As such, QA acts as a glutamate agonist and can potentiate NMDA receptors to the point of excitotoxicity. Specifically, overstimulating this receptor subtype allows high levels of calcium ions (Ca^{2+}) to enter the cell, activating enzymes such as endonucleases, phospholipases, and proteases. These enzymes can then go on to damage cellular structures such as components of the cytoskeleton, membrane, and DNA and ultimately cause cell death. QA administration induces both apoptotic and necrotic types of neurodegeneration. In addition to a loss of neurons, QA administration also leads to a robust increase in the number of astrocytes (astrocytosis) and reactive microglia (microgliosis) in the region of the lesion.

Animal Models

The exogenous administration of QA to specific areas of the brain harboring NMDA receptors has been associated

with robust cellular dysfunction and cell death. While QA has been used as an excitotoxin to induce neurodegeneration in animal models of various movement disorders such as dystonia (injection into the striatum), stroke (injection into various regions of the cortex or hippocampus), and PD (injections into the substantia nigra pars compacta and/or the striatum), by far, its most widespread application in the past several decades has been in animal models of HD. While HD is strictly a genetic disease caused by a trinucleotide repeat (CAG) in the HD gene on chromosome 4, the most prominent anatomical and behavioral manifestations of the disease (cell loss in the striatum, a movement disorder characterized by hyperkinesia and cognitive decline) can also be seen following injection of QA into animals. Unlike its precursor, tryptophan, QA is incapable of crossing the blood–brain barrier and must be injected directly into the brain region of interest to elicit its neurotoxic effects. In animal models of HD, QA is typically injected into the striatum via stereotaxic injection and has been shown to cause cell death in several species, including mice, rats, and nonhuman primates.

QA Administration in Rodent Models of HD

In both mice and rats, the injection of QA into the striatum leads to a rapid (most cell death occurs within 3 days) and extensive degeneration of medium-sized, spiny, striatal projection neurons that use the neurotransmitter γ-aminobutyric acid (GABA). These cells harbor NMDA receptors and normally receive glutamatergic projections from the cortex and the thalamus, rendering them highly susceptible to QA-induced excitotoxicity. The cell death seen in the striatum following QA administration involves similar degeneration of both enkephalin-positive and substance P-positive GABA-ergic neurons (two subpopulations of striatal projection neurons that are part of the indirect and direct basal ganglia circuits, respectively). QA injection into the rodent striatum also leads to the variable death of cholinergic interneuons (depending on the dose). In rats, a single, 1 μl, unilateral injection of QA into the striatum at a dose of 200 nmol produces almost a complete loss of neurons, as evidenced by immunohistochemical staining of neurons with an anti-NeuN antibody (see photomicrograph, scale bar = 1.2 mm). QA is usually administered unilaterally in rodents, as bilateral injections at doses that induce robust cell death render the animal unable to ambulate and sustain itself with food and water.

Striatal neurons that degenerate following QA administration are an integral component of the basal ganglia and project to the internal and external segments of the globus pallidus, as well as the substantia nigra pars reticulata. Therefore, perturbation of the striatum and the rest of the basal ganglia leads to severe behavioral and cognitive consequences that mimic some of the behavioral manifestations seen in humans with HD. Unilateral QA lesions lead to difficulty in using the contralateral forepaw and digits, as evidenced by the reduced performance of the affected paw in the cylinder and staircase tests. Additionally, unilaterally QA-lesioned rats exhibit apomorphine-induced rotational asymmetry (rotations in the direction ipsilateral to the lesioned hemisphere) and spontaneous dyskinesias at higher doses. Rodents that receive striatal injections of QA also have difficulty performing on certain cognitive tests, and display deficits in the Morris Water Maze and the T-Maze, which examine both long-term and working memory, respectively.

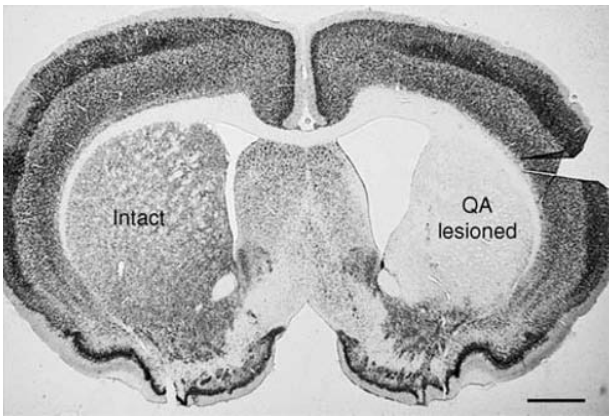

Figure 1 Coronal section of a rat brain stained for the neuronal marker, NeuN. Note the robust loss of NeuN-immunoreactive neurons in the striatum which received a single, 1 μl injection of QA (200 nmol). Scale bar = 1.2 mm.

QA Administration in Primate Models of HD

Injection of QA into the nonhuman primate striatum (composed of the caudate nucleus and putamen) causes a similar type of cell death seen upon administration to rodents a robust loss of medium-sized spiny projection neurons with variable death of cholinergic interneurons. However, because of their much larger brain size and similar anatomical organization of the striatum to humans, primates injected with QA offer the advantage of a much more extensive, measurable behavioral repertoire that more accurately mimics human HD. For example, the cardinal motor deficit seen in HD patients, chorea (involuntary, hyperkinetic movements of the limbs, head, and neck), is not replicated following administration to either the mouse or rat striatum. Conversely, upon bilateral QA injection into the nonhuman primate striatum, animals exhibit an apomorphine-induced choreic phenotype, as well as limb dystonia and orofacial dyskinesias. Monkeys also have a significant difficulty with specific memory tasks, such as the object retrieval-detour task (ORDT), which requires them to coordinate a reaching movement while performing a procedural memory task to retrieve a fruit treat.

This particular test requires intact frontal-striatal circuitry, which is disrupted following QA injections into the caudate and putamen.

R

Rabbit Syndrome

B J Robottom, L M Shulman, and W J Weiner, University of Maryland School of Medicine, Baltimore, MD, USA

Definition and History

Rabbit syndrome (RS) is an unusual iatrogenic movement disorder named after the characteristic appearance of the movement. It is said to resemble the chewing of a rabbit and consists solely of vertical motion. There is no involvement of the tongue. RS was first described in 1972 by Villeneuve as an iatrogenic movement disorder secondary to exposure to typical antipsychotics. More recently, it has been described after exposure to atypical antipsychotics and other classes of medication.

Pathophysiology

As the majority of cases of RS occur after exposure to antipsychotics, it is presumed that the pathophysiology involves a disturbance in the dopaminergic function of the basal ganglia. One hypothesis is that RS may be due to hypersensitive dopamine D_2 receptors as a result of chronic antipsychotic use. Others have speculated that RS is due to a hypercholinergic state, thus explaining the beneficial results of anticholinergics for treatment. Since RS improves upon withdrawal of the offending agent, it is possible that the syndrome is a direct result of dopamine receptor blockage rather than a result of receptor adaptation to dopaminergic blockade. This last hypothesis is consistent with the idea that RS is a type of drug-induced parkinsonism.

Epidemiology

Most cases of RS are iatrogenic and involve antipsychotic administration. The prevalence of RS after exposure to typical antipsychotics is 1.5–4.4%. It occurs predominantly in middle-aged and elderly populations, and women appear to be at increased risk. Of the reported cases, 66% are women. Prevalence after exposure to atypical antipsychotics is unknown, but the syndrome is documented to occur after exposure to aripiprazole, clozapine, olanzapine, and risperidone. The majority of the case reports (8/11) involve risperidone. RS has also been reported in two patients receiving citalopram or escitalopram. The authors of these cases note that, although rare, selective serotonin reuptake inhibitors are thought to cause other extrapyramidal symptoms (EPS). Additional medications implicated in the development of RS include methylphenidate and imipramine. Isolated case reports of RS citing phenol ingestion, multiple system atrophy, or idiopathic oromandibular tremor as alternative causes of RS exist.

Clinical Features and Differential Diagnosis

RS is a rhythmic movement involving the mouth with a highly recognizable appearance that consists of vertical movements of the mouth and lips, which spare the tongue. The movements are rhythmic with a frequency of ~5 Hz. There can be an associated popping sound produced by the opening and closing of the lips. Not surprisingly, patients may have findings of parkinsonism, including rigidity, bradykinesia, and tremor. In contrast to tardive dyskinesia, the movements of RS continue during stage I sleep. Fatigue and anxiety can worsen the movements of RS. The worsening of the movements can occur during tasks of attention or concentration. Timing of the onset of RS after exposure to antipsychotics is variable, with RS starting in as little as a week after initiation of drug to years after start of therapy.

The most common misdiagnosis of RS is oral tardive dyskinesia. One key to differentiating the syndromes is to examine the tongue. The tongue is uninvolved in RS and displays no abnormal movements. An additional clue to the diagnosis of RS is that unlike oral tardive dyskinesia, the lip movements are restricted to the vertical plane in RS. The speed and rhythmicity of the movements may help to distinguish the two, as RS is faster and more

rhythmic than the movements of oral tardive dyskinesia. Tardive dyskinesia with oral movements resembles chewing and smacking of the lips, whereas RS is a perioral tremor typical of parkinsonism. Unlike oral tardive dyskinesia, RS cannot be suppressed voluntarily. The jaw tremor of Parkinson's disease (which some authors refer to also as RS) and oral stereotypes seen in the elderly and edentulous should be included in the differential diagnosis.

Management and Prognosis

Since RS is secondary to exposure to antipsychotics, treatment involves reducing or replacing the offending agent. RS often responds within days to a reduction in the dose of the antipsychotic drug. If it is not possible to lower the dose of the antipsychotic, then adding an anticholinergic or changing to an atypical antipsychotic are other options. Anticholinergic medications effectively suppress the movements of RS; however, if they are stopped, the movements of RS can reappear. The most commonly used anticholinergics for RS include trihexyphenidyl, procyclidine, and benzatropine. Successful treatment has also been described by switching from a typical antipsychotic to the atypical antipsychotics olanzapine, quetiapine, and clozapine.

Unsuccessful approaches to the treatment of RS include the addition of dopaminergic medications. Dopamine agonists and amantadine have been tried without success, and levodopa was reported to worsen symptoms in one patient. The knowledge of the use of benzodiazepines is limited, but there appears to be no benefit to their use. The antiepileptic phenytoin has also been utilized unsuccessfully.

Conclusion

RS is an unusual iatrogenic movement disorder primarily associated with exposure to antipsychotics. It is readily recognized by the presence of a perioral tremor of the lip and mouth that spares the tongue. It is important to distinguish RS from tardive dyskinesia, as prompt recognition of this unique syndrome will facilitate treatment, which can be effective.

Ramisectomy

T Taira, Tokyo Women's Medical University, Tokyo, Japan

The word 'ramisectomy' is a combination of words 'ramus' and 'sectioning.' Ramus can refer to a branch and used like 'A nerve ramus such as the dorsal ramus of spinal nerve.' In the management of movement disorders, the term 'ramisectomy' generally means the surgical section of the peripheral branches of the cervical spinal nerves for the treatment of spasmodic torticollis or cervical dystonia (selective peripheral ramisectomy). This surgical procedure is also called 'selective peripheral denervation.'

The spinal nerves have dorsal and ventral rami, and the majority of dorsal rami of the cervical spinal nerves innervate the posterior neck muscles such as the splenius

muscle and the semispinalis muscle. These muscles act to rotate the head horizontally to the ipsilateral direction. By sectioning the dorsal rami from C1 to C6 spinal nerves, the posterior neck muscles are inactivated resulting in symptomatic relief of involuntary horizontal rotation of the neck in patients with spasmodic torticollis or cervical dystonia. This operation is usually combined with sectioning of the contralateral peripheral branches of the accessory nerve that innervate the sternocleidomastoid muscle. A Canadian neurosurgeon, Claude Bertrand (1917), established this procedure in the 1980s. Selective peripheral ramisectomy is called Bertrand's procedure and now accepted as a mode of surgical treatment that can improve symptoms in certain types of cervical dystonia. Clear distinction should be made between Foerster-Dandy intradural rhizotomy and Bertrand's procedure. Foerster-Dandy intradural rhizotomy had been widely performed until the 1980s in which intradural ventral spinal roots are sectioned from C1 to C3 or C4 level. This operation inactivates not only muscles innervated from dorsal rami but also muscles from the ventral rami, which may induce neck instability and swallowing problems. To avoid denervation of the phrenic nerve and nerves to the shoulder and arm, intradural rhizotomy is limited down to C4 on one side and to C3 on the opposite side. This is inadequate to denervate the posterior neck muscles completely. In selective peripheral ramisectomy (Bertrand's procedure), the posterior neck muscles are totally denervated without involvement in the territories of ventral rami of the spinal nerves.

In the original method of selective peripheral ramisectomy of Bertrand, a large hockey-stick-shaped skin incision is made in the posterior neck and occipital area, which results in numbness, sometimes tingling sensation, in the occipital region due to sectioning of the peripheral part of the great occipital nerve. Even if a linear skin incision is used, the sensory component of the C2 is sacrificed at the proximal part of the C2 nerve, because the motor and sensory components are difficult to differentiate during surgery. In order to avoid such a complication, Taira et al. modified Bertrand's ramisectomy by combining both intradural and extradural procedures. In this modified method, the intradural C1 and C2 ventral roots are sectioned after C1 hemilaminectomy, and ramisectomy from C3 to C6 is performed as in Bertrand's procedure.

The sternocleidomastoid muscle (SCM) contralateral to the involved posterior neck muscles is generally active in patients with cervical dystonia with predominant head turn in the horizontal axis, and this muscle is usually denervated simultaneously during the operation. SCM has a nerve supply from the accessory nerve. In the original Bertrand's technique, the peripheral main trunk of XIth nerve is completely exposed by sectioning the SCM with a large skin incision along the direction of XIth nerve. This makes it easier to identify all the motor nerves going to SCM. For cosmetic reasons, a smaller skin incision along the posterior border of SCM may be used. The branch to the trapezius muscle should be preserved, because weakness of this muscle results in marked disabilities such as difficulty in raising the arm and shoulder joint problems.

In some patients with cervical dystonia, the levator scapulae muscle may be responsible for laterocollis symptoms. This muscle is not affected by the traditional selective peripheral denervation, because the levator scapulae muscle is innervated from the anterior rami of the C3/4 peripheral nerves. When this muscle should be denervated, there are two surgical routes: through the posterior cervical triangle and through the same incision as the Bertrand procedure.

When the symptom of CD is retrocollis, and bilateral posterior neck muscles are involved, bilateral peripheral ramisectomy can be carried out. However, bilateral extensive denervation may result in 'head-drop' (inability to raise head), and therefore bilateral denervation should be limited to C1–C5.

After selective peripheral denervation or ramisectomy for cervical dystonia, patients should be well informed of the importance of physiotherapy. It is very important that patients do posture exercises to regain a sense of midline and to improve the range of movement.

Recently, the National Institute of Clinical Excellence of the United Kingdom (http://www.nice.org.uk/) launched a guideline for Selective peripheral denervation (ramisectomy) for cervical dystonia. It mentions as follows.

Current evidence on the safety and efficacy of selective peripheral denervation for cervical dystonia appears adequate to support the use of this procedure provided that the normal arrangements are in place or consent, audit and clinical governance. The procedure should be performed by a multidisciplinary team in a specialist neurosurgical unit. Patient selection for this procedure is important. Patients should be offered the procedure only when their disease has become refractory to best medical treatment.

Standard treatment for cervical dystonia includes physiotherapy, drugs to reduce spasm, injections of botulinum toxin, and brain surgery. Selective peripheral denervation may be an alternative, especially for people who have not responded to other treatments.

Selective peripheral denervation is a surgical procedure that varies according to the muscle groups affected. It is performed under general anaesthetic and involves cutting, through a skin incision, the nerves that supply the affected muscles. Sometimes the muscles themselves may be divided.

The evidence was limited to one systematic review and several case series studies. The review found no controlled studies and no reliable evidence to compare the procedure with other treatments. Two of the larger case series studies found 'very good to excellent' results in 88% (228/260 and 182/207) of patients at follow-up. However, the time to follow-up and how these outcomes were

assessed were not specified in either of these two studies. The largest case series study identified reported the following complications: occasional tic-like pain (1%, 3/260); tonsillar abscess (0.4%, 1/260); transient swelling of the neck in a few patients (number not specified); and pins and needles or sensation of tightness or fullness in a few patients (number not specified). For more details, refer to the Sources of evidence (see right).

The Specialist Advisors have listed potential adverse events as difficulty in swallowing, as well as the usual potential complications of surgery, such as infection and hemorrhage.

Selective peripheral ramisectomy is generally indicated in patients with cervical dystonia who do not achieve adequate response with medical treatment or repeated injections of botulinum toxin. This is a safe procedure with infrequent and minimal side effects. Since this procedure requires a specialized expertise with the understanding of detailed anatomy of cervical peripheral nerves, it is not widely available.

Rating Scales in Movement Disorders

P Martinez-Martin and C Rodríguez Blázquez, National Center of Epidemiology and Consortium for Biomedical Research in Neurodegenerative Diseases (Centro de Investigación Biomédica en Red Enfermedades Neurodegenerativas – CIBERNED) Carlos III Institute of Health, Madrid, Spain
M João Forjaz, National School of Public Health, Carlos III Institute of Health, Madrid, Spain

Principles of Measurement

Measurement is an intrinsic attribute of science and forms an indispensable part of neurological diagnosis and severity assessment of impairment and disability. Measurement allows for the sharing of information concerning individuals or groups, aids in therapeutic decisions, and facilitates the evaluation of outcomes of clinical practices, research, and health policy.

In neurology, measures can be either objective (biological assays, functional tests, and physical structure) or subjective (rating scales and questionnaires). Both the modalities are applied to the evaluation of patients with movement disorders (MD). Objective methods are usually complex and expensive, with demanding requirements in terms of staff, equipment, and application conditions. Such methods furnish true measures, in real numbers, though limited in time and site. Subjective methods are

simple and relatively quick. Their application furnishes data susceptible to the influence of individual factors, yet they nevertheless provide global information on the patient's status. Due to these characteristics (simplicity, global information, and low cost), these methods are widely used in clinical research and practice.

To rate something is to estimate its worth or value. In a clinical setting and in operational terms, rating can be defined as 'the assignment to a situation or event of its corresponding quantitative level, according to rules' and is equivalent to measuring (determining the quantity of something by comparison with a given unit). Many attributes or phenomena lack such a unit, belong instead to the conceptual realm, and are thus not directly observable. These abstract concepts or 'constructs' (such as intelligence, pain, or well being) can be indirectly evaluated by means of indicators which are related to them and susceptible to valuation. Such indicators are incorporated as the components (items and domains) of rating scales, which should be tested by using complex methodology to determine the quality of their psychometric attributes.

In MD, severity ratings are applied to assess impairment (objective limitation) or disability (functional loss). Some scales combine both.

In line with the sentiments expressed by the World Health Organization in the International Classification of Functioning, Disability and Health (2001), more comprehensive evaluations that take personal and environmental factors into account, are currently being developed.

The science of rating scale evaluation and development is a dynamic and extensive field, and this discussion will focus on the most widely known scales used to assess MD.

Design and Validation of a Rating Scale

The design of a rating scale should comply with the following principles: (1) inclusion of the most relevant areas for the objective being targeted; (2) integration of relevant components specifically linked to those areas; (3) generation of scores that represent the real situation of the construct being measured; (4) susceptibility of such scores to statistical analysis; and (5) simplicity and brevity.

The steps to be followed when designing a rating scale are, in brief, specifying and/or identifying the (1) objectives (construct and target population); (2) purpose, that is, whether the intention is to obtain a discriminative (for establishing differences among groups), evaluative (for assessing changes) or predictive instrument (for predicting situations or results); (3) format and mode of application (e.g., examination, interview, computer-based, etc.); (4) potential components (items, subscales); (5) type and number of questions and answers; (6) time frame to be considered; (7) score range and definition of each answer option, where applicable (special attention to wording); (8) instructions for application and scoring; as well as, (9) undertaking a pilot study to check the scale's feasibility and identify any ambiguities, redundancies, etc.; and (10) validating the definitive version.

Scale validation entails checking its properties as a measuring tool according to a rigorous methodology based on scientific theories of health measurement, including Classical Test Theory and Item Response Theory. Validation studies are conducted on a representative sample of the target population, with demographic and historical data as well as scores being obtained, not only from the scale being tested, but also from other measures that are applied simultaneously. These data undergo statistical analysis, and the results are then compared against standard values and rules so as to establish the scale's quality. Validation of a scale is a dynamic process because each modification or new application setting means that its properties must be retested.

The fundamental psychometric attributes of a rating scale are:

1. *Acceptability*: This refers to the extent to which the measure is applicable in the envisaged context, and explores the completeness and distribution of the scores in the sample.
2. *Scaling assumptions*: Referring to the correct clustering of items in the scales and the extent to which their direct sum is suitable for generating a total score representative of the construct.
3. *Reliability*: This refers to the extent to which the scale is free of random error, and includes the measure's internal consistency and stability (inter-rater, test–retest).
4. *Validity*: This attribute determines whether or not an instrument really measures what it was designed to measure. Validity assumes various forms, but content and construct validity are the most frequent types. Content validity indicates the extent to which the scale's components are deemed suitable with respect to the construct to be measured. Construct validity refers to the evidence that supports a given interpretation of the scores, based on their theoretical relationship with the construct. It mainly includes: (i) convergent (concurrent) validity, which refers to the correlation with other measures used to evaluate the same or related constructs; (ii) divergent (discriminant) validity, which refers to the relationship with measures that assess different constructs; and, (iii) discriminative (known groups) validity, which indicates the scale's ability to detect differences among groups.
5. *Precision*: The measure's capacity to detect small differences, which in turn depends on the number of distinctions that such a measure is able to make.
6. *Responsiveness*: The instrument's capacity to detect change (across time or after a therapeutic intervention),

explores the association that exists between detected and real change. This property is linked to reliability and precision.
7. *Interpretability*: The assignment of a comprehensible meaning to scores and score changes.
8. *Other aspects of scale validation*: Administrative and respondent burden concern the time, effort, and other demands involved in the instrument's application. When a scale is to be used in a sociocultural context other than that in which it was initially developed and validated (e.g., in a country on another continent), cross-cultural adaptation may be required. This process consists of the following two phases: (i) translation, in order to obtain a version equivalent to the original in conceptual content and linguistic terms and (ii) a check of the psychometric attributes in the new setting.

Rating Scales for Movement Disorders

There now follows a list of the respective MD in alphabetical order. Shown against the corresponding heading are the rating scales for assessment of the specific disorders, including brief comments about the features and psychometric attributes of the most frequently used instruments.

Akathisia

- *Barnes Akathisia Rating Scale* (*BAS, BARS*) 4-item scale assessing the presence and severity of drug-induced akathisia. It includes both objective and subjective items, rated from 0 to 3, leading to a total sum score. Its reliability, validity and sensitivity are adequate. It is the most widely used scale for akathisia.

Ataxia

- *International Cooperative Ataxia Rating Scale* (*ICARS*): Semiquantitative assessment of cerebellar symptoms and impairment. It consists of the following four subscales: posture and gait disturbances (7 items, maximum 34 points), kinetic functions (7 items, 52 points), speech disorders (2 items, 8 points), and oculomotor disorders (3 items, 6 points). Inter-rater and test–retest reliability and internal consistency are satisfactory, but factorial analysis has not confirmed the scale structure, and several items were redundant and overlapping. The scale has been tested in focal cerebellar lesions, Machado–Joseph disease, multiple system atrophy, and Parkinson's disease (PD) patients, with adequate results despite its limitations.
- *Scale for the Assessment and Rating of Ataxia* (*SARA*): It measures the severity of ataxia via 8 items (maximum total score: 40 points). These are gait (scored from 0 to 8), stance (0–6), sitting (0–4), speech disturbance (0–6), finger chase (0–4), nose–finger test (0–4), alternating hand movements (0–4), heel–shin slide (0–4). Scale psychometric properties have been established for both spinocerebellar and nonspinocerebellar ataxia patients, with satisfactory results.
- *Other scales*:
  - *Cerebellar Ataxia Scale.*
  - *Nobile-Orazio Ataxia scale.*

Chorea

Huntington's disease

- *Shoulson and Fahn Functional Disability Scale for Huntington's Disease*: This scale assesses occupation, handling financial affairs, activities of daily living (ADL), managing domestic responsibilities, and required care. The first three items are scored from 0 to 3, the last two from 0 to 2, and they can be converted into a five-stage disease classification. It has still to be formally validated.
- *Huntington's Disease Activities of Daily Living Scale* (*HD-ADL*): 17-item scale for assessment of patient's adaptive functioning, based on an informant's report. Each item is scored from 0 to 3, with 51 points being the maximum possible score. Internal consistency, test–retest reliability, and convergent validity proved satisfactory in the original study.
- *Unified Huntington's Disease Rating Scale* (*UHDRS*): It is a complex scale that assesses clinical and functional manifestations in four domains, namely: motor function (15 items, scored from 0 to 4); cognitive function (including a phonetic verbal fluency test, the Symbol Digit Modalities Test, and the Stroop Interference Test); behavioral abnormalities (rating frequency and severity of symptoms from 0 to 4); and functional capacity (including the Huntington's disease (HD) functional capacity scale, scored on a 0- to 2- or 3-point scale; the Independence scale, scored from 10 to 100; and a checklist of common daily tasks, rated by means of yes/no response options). The UHDRS has shown satisfactory responsiveness in follow-up studies and clinical trials. Although its psychometric properties were adequate, its length and administrative load were criticized, and so a shortened version of the motor section of the UHDRS (15 items) was subsequently developed and validated.
- *Behavior Observation Scale Huntington* (*BOSH*): Description of the manifestations of HD in the final stages. Administered by nursing staff, it contains 32 items in the following three subscales: activities of daily living (ADL), social-cognitive functioning, and mental rigidity and aggression. Inter-rater and internal consistency are adequate and the scale discerns behavioral patterns as the disease progresses.

Sydenham's chorea

- *UFMG Sydenham's Chorea Rating Scale* (*USCRS*): The USCRS comprises 27 items, scored from 0 (no symptom or sign) to 4 (severe disability), and designed to assess ADL, behavioral problems and motor functioning in Sydenham's Chorea patients. Test–retest and inter-rater reliability have proved satisfactory.

Drug-Induced Movement Disorders

- *Extrapyramidal Symptom Rating Scale* (*ESRS*): 12-item instrument assessing four types of drug-induced MD: parkinsonism, akathisia, dystonia, and tardive dystonia. Using a 7-point response option for each item, it rates both frequency and movement amplitude. The ESRS has a 6-factor structure, which has shown satisfactory inter-rater reliability, convergent validity and sensitivity to change.
- *Simpson–Angus Scale* (*SAS*): 10-item scale, with item scores ranging from 1 to 5, designed to assess the presence and severity of rigidity and bradykinesia. It is the most widely used scale for extrapyramidal symptoms in clinical assays. Thanks to its fast and easy mode of administration, it is also suitable for clinical practice. There are 1- and 4-item short versions.
- *Abnormal Involuntary Movement Scale* (*AIMS*): This assesses MD (dyskinesia, akathisia, and chorea) associated with psychotropic medication. The AIMS is made up of 12 items scored from 1 to 5. Widely used in clinical assays as an outcome measure, this instrument registers good inter-rater and test–retest reliability, and convergent validity.

Dystonia

Generalized dystonia

- *Fahn–Marsden Dystonia Rating Scale* (*F–M Scale*): The F–M Scale assesses the severity of generalized dystonia, and consists of two parts, that is, movement (motor examination of nine body regions) and disability (patient's perspective on ADL, rated from 0 to 4). The movement scale includes severity, provocative maneuvers, and weighting factors. The F–M scale is the standard instrument for assessing dystonia, though its psychometric properties were only recently established. Internal consistency, inter-rater (except for some body regions) and test–retest reliability, and convergent validity are satisfactory. Its responsiveness is still to be tested.
- *Barry–Albright Dystonia* (*BAD*) *Scale*: 5-point ordinal severity scale for secondary dystonia in children. Inter-rater and test–retest reliability and responsiveness were found satisfactory. The scale has been used to measure treatment efficacy. Training is recommended before using this scale.
- *Unified Dystonia Rating Scale* (*UDRS*): Developed to overcome the limitations of the F–M Scale, it includes a more detailed rating of body regions and a dystonia duration factor, and eliminates patients' perception and the weighting factor. Severity and duration are scored from 0 to 4. It has a better internal consistency than the F–M scale, and satisfactory inter-rater reliability. The UDRS has been used as a measure of efficacy following surgical interventions but responsiveness has not been tested.
- *Global Dystonia Severity Rating Scale* (*GDS*): It rates dystonia severity in the same regions described for the UDRS, with a scale scored from 0 (no dystonia) to 10 (severe). There are no modifying or weighting factors. Internal consistency, inter-rater reliability, and convergent validity are excellent. It has been found to be easier to administer than the F–M and the UDRS.

Focal dystonia

Blepharospasm

- *Blepharospasm Rating Scale* (Lindeboom et al., 1995): This scale is divided into two sections, namely: a movement scale (including severity of eyelid closure, frequency, location, and influencing factors of involuntary movements) and a disability scale. The disability section has been validated, and has displayed adequate internal consistency, convergent and discriminative validity, and responsiveness. Lindeboom et al. recommend removing two weak or redundant items from the first version (sunglasses and watching movies) to improve the scale's reliability.

Cervical dystonia

- *Spasmodic Torticollis Rating Scale* (Tsui et al., 1986): Specifically designed to measure cervical dystonia severity in clinical trials, this has four subscales, that is, amplitude, duration of movement, shoulder elevation, and tremor. Only inter-rater reliability has been tested, with satisfactory results.
- *Torticollis Rating Scale*: This scale evaluates both movement (direction of muscle pulling, influencing factors, severity of the deformity and pain, and presence of jerking movements, with heterogeneous item scoring) and disability (impact on ADL, scored on a scale from 1 to 2, 3, or 5 points; maximum score, 27). It has not yet been validated.
- *Toronto Western Spasmodic Torticollis Rating Scale* (*TWSTRS*): Despite its complexity, the TWSTRS is the most widely used scale for assessing cervical dystonia in clinical practice and research. It consists of the following three subscales: motor severity (10 items assessing severity, range of motion and duration, scored heterogeneously, maximum score: 35); disability (6 items assessing difficulties in several activities, scored from 0 to 5, maximum score: 30); and pain (severity and duration, and

disability due to pain, maximum score: 20). The total maximum scale score is 85. A teaching video-tape has been developed for the motor section. Inter-rater reliability and convergent validity of the motor subscale are satisfactory. Several studies suggest that the TWSTRS may not be sensitive enough to detect clinically significant changes.

- *Cervical Dystonia Severity Scale* (*CDSS*): Objective measurement of head position in 5-degree intervals, using a wall chart and protractor. The head rotation deviation, laterocollis, and anterocollis/retrocollis scores can be transformed into a severity scale. Good inter-rater and test–retest reliability has been found in the original study, but validity and sensitivity studies are still required.

Limb dystonia

- *Arm Dystonia Disability Scale* (*ADDS*): The ADDS evaluates functional impairment of the dystonic hand, on a 7-item scale, scored from 0 to 3. It has been used as a treatment efficacy measure. Moreover, it shows adequate convergent validity with the Frequency of Abnormal Movements (FAM) Scale.
- *Leg Dystonia Disability Scale*: Assessment of functional impairment caused by the dystonic leg in walking, standing, and other activities. It consists of 7 items, with the final total score expressed as a percentage. It has not been validated to date.
- *Writer's Cramp Rating Scale* (*WCRS*): Objective clinical assessment of writing movement (3 items) and speed (1 item). Item scores range from 0 (no) to 2 (marked/severe). This scale has been mainly used to assess treatment efficacy, with good results. Inter-rater reliability was also satisfactory, though correlation with other writer's cramp measures (ADDS, kinematic patterns analysis) was low, as the latter assess different aspects of motor impairment.
- *Frequency of Abnormal Movements* (*FAM*) *Scale*: It was purpose-developed to assess musician's dystonia. Internal consistency, test–retest and inter-rater reliability, convergent validity, and sensitivity are satisfactory.

Oromandibular dystonia

- *Oromandibular Dystonia Rating Scale*: Includes a severity (severity, frequency, location, and influencing factors) and a disability scale for oromandibular dystonia. It has not been validated.

Hemifacial Spasm

- *Martí and Tolosa Scale*: Assessment of treatment efficacy in hemifacial spasm. It rates: severity, on a scale from 0 (no spasm) to 4 (severe); frequency, from 0 (absent) to 5 (>75% of the time); and functional impairment, with 7 items scored from 0 (no impairment) to 3 (severe). Test–retest and inter-rater reliability have been analyzed, with good results.

Myoclonus

- *Unified Myoclonus Rating Scale* (*UMRS*): The UMRS assesses myoclonus severity, characteristics, and disability. It is made up of 73 items, grouped into 5 sections, namely: patient's questionnaire (12 items, scored from 1 to 5); myoclonus at rest (8 items, scored from 0 to 4, rating frequency and amplitude); stimulus sensitivity (17 items, dichotomous); myoclonus with action (10 items, scored for frequency and amplitude on a 5-point scale); and functional tests (5 items, scored from 0 to 4). There are also 3 items evaluating global disability on a scale from 0 (normal) to 4 (severe disability, invalid), negative myoclonus presence (yes/no) and severity (from 0, not present, to 3, severe). The UMRS displays good internal and inter-rater consistency, as well as adequate sensitivity to change.
- *Other scales:*
  - *Myoclonus Evaluation Scale*: Aimed at quantifying the severity of myoclonus, it consists of two sections that evaluate this MD in upright posture, and dynamic function. Although not validated, it has been used to assess clinical trial outcomes.
  - *Opsoclonus Myoclonus Syndrome Evaluation Scale*: It assesses opsoclonus myoclonus syndrome severity via 12 items rated on a scale from 0 to 3 (normal to severe). A clinical study established inter-rater reliability.

Parkinsonisms

Parkinson's disease (PD)

Multidimensional scales

- *Unified Parkinson's Disease Rating Scale* (*UPDRS*): The UPDRS is made up of 42 items grouped into four subscales: Section I – mentation, behavior and mood; Section II – ADL (scored for 'on' and 'off'); Section III – motor examination; and Section IV – complications. Items from Sections I–III are scored on a 4-point scale. Section IV contains dichotomous items and items scored on a 4-point scale for duration or severity. The UPDRS battery includes also the Hoehn and Yahr, and the Schwab and England scales. Psychometric attributes have been widely analyzed. The scale displays adequate internal consistency. Its factorial structure is stable across studies. Section II displays a higher inter-rater reliability than Section III. Test–retest reliability is also acceptable, except for some Section III items. The UPDRS shows good convergent validity with other PD scales and satisfactory discriminative validity with PD severity levels. Not only is it sensitive to change and the most widely used PD scale, but it is also the reference measure for regulatory agencies (European Medicines Agency, and the US Food and Drug Administration). A revised version (Movement Disorder Society-UPDRS) has been

developed to overcome some problems identified in the previous version. The new scale also is made up of four sections, with a part to be used as a patient's self-assessment. First analyses demonstrate it is a reliable and valid measure.

- *The Short Parkinson's Evaluation Scale* (*SPES*): Inspired by the UPDRS, the SPES is made up of 24 items, scored from 0 to 3, forming four sections and showing adequate sensitivity to change.
- *Scales for Outcomes in Parkinson's Disease – Motor* (*SCOPA–Motor*): This seeks to assess motor signs, functional ability and motor complications in PD. Derived from the Short Parkinson's Evaluation Scale (SPES), it is composed of 21 items grouped in the following three sections: motor examination, ADL, and complications. Each item is scored on a 3-point scale. The three subscales display adequate internal consistency, as well as good test–retest reliability and adequate inter-rater reliability. Convergent validity with PD-related measures is excellent. The SCOPA–Motor shows satisfactory discriminative validity according to PD severity level.
- *Intermediate Scale for Assessment of Parkinson's Disease* (*ISAPD*): This is a short scale for use in clinical practice and in research, composed of a 13-item section that assesses functional aspects, and a 4-item section that assesses dyskinesias and fluctuations, with all items being scored from 0 to 3.

Functional scales

- *Schwab and England Scale*: This measures patients' global functioning and dependency via only 1 item scored on an 11-point scale (0%, completely independent, to 100%, vegetative). The main advantages of this scale are its simplicity and wide use, despite its lack of standardization. It forms part of the UPDRS battery and possesses satisfactory acceptability and construct validity. It displays precision and sensitivity to change comparable to other functional scales (those embedded in the multidimensional scales, for instance).
- *Columbia University Rating Scale* (*CURS*): Made up of 13 items, each scored from 0 to 4, the CURS measures impairment. It was frequently used before the introduction of the UPDRS. Indeed, the UPDRS-Section III (motor examination) was derived from the CURS, as was the Sidney Scale (Hely et al., 1993).

Dyskinesia

- *Parkinson Disease Dyskinesia Scale* (*PDYS-26*): This scale aims at quantifying the impact of dyskinesias on patient functioning, according to the patient's perspective. It comprises 26 items, rated on a 4-point scale, which yield a total score. The scale was developed using Rasch analysis, and then standard psychometric methods were applied. Both methods support the scale's unidimensionality. It displays high internal consistency and good construct validity.
- *Obeso Dyskinesia Scale*: It assesses the intensity and duration of dyskinesia by combining historical and motor examination data. This scale has not yet been validated.
- *Rush Dyskinesia Rating Scale*: An objective evaluation of dyskinesia and its impact on functional state, this scale assesses the three activities of: walking, putting on a coat and buttoning it, and lifting a cup to the lips for drinking. Severity of dyskinesias is scored from 0 to 4. The Rush scale shows good inter- and intra-rater reliability.
- *Clinical Dyskinesia Rating Scale* (*CDRS*): This consists of independent evaluations for hyperkinesia and dystonic posture in seven body parts. Items are scored from 0 to 4, and the maximum possible score is 28 for hyperkinesias as well as for dystonia. This scale does not evaluate disability. It displays good inter- and intra-rater reliability.

Wearing-off

- *Wearing-off Questionnaire*: There are three versions of the wearing-off questionnaire. The original, with 32 items, is referred to as the 32-item Wearing-off Questionnaire (WOQ-32) or as the Patient Questionnaire. Based on the WOQ-32 and validated independently, the 19-item version was developed retrospectively as a more practical tool for clinical practice and research. This 19-item version is referred to as the Wearing-off Questionnaire, the Patient Card Questionnaire, or the Quick Questionnaire. Finally, there is a shorter version, the 9-item Wearing-off Questionnaire (WOQ-9). Both the 9- and 19-item versions are made up of items contained in the WOQ-32. The 19-item version captures wearing-off symptoms more frequently than do other methods, including the original 32-item scale, and a cut-off value of two symptoms results in high specificity and sensitivity. The 9-item version displays high sensitivity and moderate specificity.

Fluctuations and dyskinesia

Home diaries: They are useful tools for obtaining valuable information on PD motor complications. A diversity of diaries exists but, in essence, they capture the patient's situation throughout the day, at scheduled intervals, with regard to the following situations: 'on' and 'off,' with or without dyskinesias, and functional impact of the 'off' period and abnormal movement. Diaries allow to distinguish between good or bad time in 'on with dyskinesia,' an important point for treatment and clinical trials.

Gait evaluation

- *Rating Scale for Gait Evaluation* (*RSGE*), *second version*: This is formed of 21 items, scored from 0 to 3 and grouped

in 4 sections, that is, socioeconomic, functional, examination, and complications. It displays good convergent validity, high internal consistency, and fair inter-rater reliability. The first version of the RSGE was never validated.

- *Clinical Gait and Balance Scale, GABS*: A battery of tests that measures gait-dependent functional activity through historical information and examination. Some items are scored from 0 to 4, and others from 0 to 1, or 0 to 2, with 0 being normal. It displays high intra-rater test–retest reliability and adequate concurrent validity with computerized gait-related measures.
- *Other scales:*
  - *Hoehn and Yahr Staging Scale*: This scale collapses the evolutionary course of PD into five stages. It is mainly used to stratify patients for research purposes and to furnish a global severity assessment. It is reviewed in a separate section of this volume (see Section MS34).
  - *Clinical Impression of Severity Index for Parkinson's Disease* (*CISI-PD*): A 4-item global impression scale that summarizes clinician ratings of motor signs, disability, motor complications and cognitive impairment. Items are scored on a 0- to 6-point rating scale, that then yields a total sum score. It is a fast, valid, and reliable measure.

Multiple system atrophy

- *Unified Multiple System Atrophy Rating Scale* (*UMSARS*): This scale assesses functional deficit, as well as autonomic and urogenital dysfunction. It comprises the following four subscales: historical review, motor examination scale, autonomic examination, and global disability scale. For the UMSARS-I and UMSARS-II, item scores range from 0 to 4, and the maximum possible score for each subscale is 48 and 56, respectively. The UMSARS-III consists of cardiovascular parameters relating to blood pressure and heart rate, and the UMSARS-IV rates overall disability on a 5-point scale. The first two subscales display high internal consistency. Inter-rater reliability of parts I and II is substantial to excellent. The UMSARS also shows adequate internal and discriminative validity. It is used as an outcome measure in therapeutic trials.

Progressive supranuclear palsy

- *Progressive Supranuclear Palsy Rating Scale* (*PSPRS*): The PSPRS is a comprehensive disability rating scale for progressive supranuclear palsy, formed by 28 items grouped into six dimensions, namely, daily activities, behavior, bulbar, ocular motor, limb motor, and gait/midline examinations. Items are rated on a 0–2 or 0–4 scale, thereby providing a total score of 0–100. This scale registers good inter-rater reliability, with a satisfactory independent predictor value of survival.

Psychogenic Movement Disorders

- *Rating Scale for Psychogenic Movement Disorders*: This rates 10 phenomena (rest tremor, action tremor, dystonia, chorea, bradykinesia, myoclonus, tics, athetosis, ballism, and cerebellar ataxia), 2 functions (gait, speech) and 14 body regions. Items are scored for severity (from 0, none, to 4, severe), duration (from 0, none, to 4,>75% of the time) and incapacitation (from 0, none, to 4 severe). A total phenomenology and a total function score are produced, and summed to obtain the total scale score. Inter-rater reliability, construct validity and responsiveness have all been studied, with satisfactory results.

Restless Legs Syndrome (RLS)

- *International Restless Legs Syndrome Study Group* (*IRLS*) *Rating Scale*: This is a 10-item self-administered scale to measure severity and impact of RLS. Items are scored from 0 (none) to 4 (very severe). The scale's psychometric properties have been extensively analyzed, using both classical and item-response methods. Good levels of internal consistency, test–retest and inter-rater reliability, and convergent and criterion validity have been observed. Factor analysis has revealed two factors, namely, symptoms and symptom impact. The IRLS scale has been widely used in clinical trials and epidemiologic studies.
- *Johns Hopkins Restless Legs Syndrome Severity Scale* (*JHRLSS*): The JHRLSS assesses symptom severity based upon the patient's response (from 0, none, to 4, severe) to a single question on the usual time of the day that symptoms start. This scale correlates well with other RLS and sleep measures, and shows good inter-rater reliability. A telephone-based interview has been derived from the JHRLSS (telephone diagnostic interview, TDI), with good psychometric properties.
- *Other scales*:
  - *RLS-6 Severity Scales*
  - *Augmentation Severity Rating Scale* (*ASRS*)

Spasticity

- *Ashworth Scale*: This scale evaluates muscle resistance to passive stretching. It includes 5 grades, ranging from 0 (no increase in tone) to 4 (limb rigid in flexion or extension). The Modified Ashworth Scale (Bohannon, 1987), more frequently used now, increases the sensitivity of low values by adding a grade, 1+, and more descriptive grade information. It displays low inter-rater reliability.

- *Other scales*:
  - *Modified Tardieu Scale*: Based on the Tardieu Scale, it measures passive range of movement at three different velocities.
  - *Resistance to Passive Movement Scale (REPAS)* (Platz et al., 2008): A summary rating scale for REPAS.

Tics and Tourette's disorder

- *Tourette Syndrome Global Scale* (*TSGS*): A multidimensional scale that includes symptoms (4 dimensions, scored for frequency from 0 to 5, and degree of disruption, from 1 to 5) and social functioning (3 dimensions, rated on a continuous scale from 0, no impairment, to 25, severe impairment). These two part scores are transformed into a global score, though they can also be used separately. The TSGS has been used as a primary outcome variable in clinical trials, and has shown good inter-rater reliability. It lacks further validation studies and has been criticized for its underweighting of social dimension (failing to assess tic types) and complexity.
- *Shapiro Tourette Syndrome Severity Scale* (*STSSS*): Composite clinician rating of Tourette syndrome severity, based on the following 5 items: degree to which tics are noticeable to others; whether they elicit comments of curiosity; whether other individuals consider the patient odd or bizarre; whether tics interfere with functioning; and whether the patient is incapacitated, homebound or hospitalized. The sum score affords a global severity index. It has been used to measure treatment results and is simple to use, valid, and highly reliable (inter-rater reliability). It does not include assessment of a wide range of tic characteristics, as it primarily focuses on social disability associated with Tourette syndrome.
- *Yale Global Tic Severity Scale* (*YGTSS*): A semistructured interview for evaluation of motor and phonic symptom severity. The YGTSS includes a tic inventory, as well as items on the number, frequency, intensity, complexity, interference of motor and phonic tics, scored from 0 (none/absent) to 5 (severe/always). It yields total motor and phonic scores, an overall impairment rating, and a global severity score (the sum of motor, phonic, and impairment scores). The scale has been tested primarily in clinical settings, with satisfactory results in terms of internal consistency, stability, and validity, for children and adults alike. It is also suitable for measuring treatment efficacy. The YGTSS is a complex and comprehensive scale, requiring a highly experienced rater, as the final score reflects the clinician's overall impression of the symptoms.
- *Other scales*:
  - *Rush Videotape Rating Scale*
  - *Hopkins Motor and Vocal Tic Scale* (*HMVTS*)
  - *The Tourette's Disorder Scale* (*TODS*)
  - *Tourette Syndrome Symptom List* (*TSSL*)
  - *Tourette Syndrome Questionnaire* (*TSQ*)
  - *Motor tic, Obsessions and compulsions, Vocal tic Evaluation Survey* (*MOVES*)

Tremor

- *Washington Heights-Inwood Genetic Study of Essential Tremor Rating Scale* (*WHIGET*): This aims at assessing the following aspects of essential tremor: intensity, amplitude, oscillation prevalence, and persistence. Rest, kinetic and postural tremor are evaluated separately. The scale is made up of 26 items that assess actions or tasks where essential tremor may occur. Items are scored on a scale from 0 to 3. A revised version adds a score of 4 to the kinetic tremor section, which improves the scale's sensitivity in clinical trials. There is a teaching videotape to improve inter-rated reliability. The scale displays good test–retest and inter-rater reliability, as well as convergent validity with related clinical, functional and computerized measures.
- *Other scales*:
  - *Bain Findley Tremor Scale*: A functional assessment of the effects of tremor on different body parts.
  - *Fahn–Tolosa–Marin Tremor Rating Scale* (*TRS*): A functional evaluation of rest, postural and kinetic tremor.
  - *Essential Tremor Screening Questionnaire*: A shortened version of another screening procedure for essential tremor, consisting of seven yes/no questions and a spiral drawing.

Conclusions

Use of rating scales for assessment of patients with MD is necessary for sharing information, quantifying health status, and outcomes research. A wide variety of scales is available for many MD. Selection of suitable measures should be guided by knowledge of their characteristics, psychometric attributes, and appropriateness for the designated study objectives. Validation of a rating scale is a complex process that follows a rigorous methodology and must precede any clinical or research application.

Reaction Time

T L Davis and J Y Fang, Vanderbilt University, Nashville, TN, USA

Glossary

Choice reaction time – A reaction time that involves multiple stimuli and differing responses for each stimulus.

Reaction time – The time between a stimulus and a response.

Simple reaction time – A reaction time that involves a single stimulus and a single response.

Definition and History

Reaction time may simply be defined as the time between a stimulus and a response. Three basic reaction time paradigms have been described: (1) simple reaction time involves a single stimulus and a single response, (2) recognition reaction time involves the selection of a specific stimulus after the presentation of different multiple stimuli, and (3) choice reaction time involves multiple stimuli and differing responses for each stimulus. Serial reaction time is a combination of recognition and choice reaction time, where the stimulus is a repeating sequence that the subject must learn to predict and then to respond in a prescribed fashion.

Reaction times are usually recorded as a mean of several trials following a practice period (cueing) to minimize practice effects and to reduce variability of the response. Reaction times are very situation specific, and can vary according to choice of device, stimulus, or response. In designing a paradigm for measuring the reaction time, it is important to select the test instrument carefully and to compare trends between studies rather than absolute times if different devices are used. In general, simple reaction times are faster than recognition reaction times and recognition reaction times are faster than choice reaction times. Multiple factors, including age, gender, IQ, handedness, fatigue, sleep deprivation, and medications, may influence the reaction time and it is important for studies to control for these variables. Many reaction time instruments filter results to eliminate responses that are shorter than physiologic (anticipated) or uncharacteristically long (distraction).

Reaction Time in Animal Models of Parkinson's Disease

Reaction time measures can be useful in the study of animal models of disease assuming the animal is able to learn the reaction time task. Rodents subjected to bilateral 6-hydroxydopamine lesions of the nigrostriatal dopamine system perform poorly on a reaction time task while asymmetric lesions have little effect on reaction time performance. High-frequency stimulation of the subthalamic nucleus in hemiparkinsonian rats more dramatically improved basic motor function than choice reaction time.

Reaction Time in Parkinson's Disease

Several studies have investigated reaction time paradigms in Parkinson's disease. The search for specific patterns of impaired reaction time in Parkinson's disease has yielded conflicting results. In general, patients with Parkinson's disease separate from control subjects most dramatically with tasks that have a shorter reaction time. More elaborate tasks require a greater cognitive component and are less specific measure of loss of motor control.

Reaction time in Parkinson's disease tends to correlate with measures of global cognitive capacity and frontal-lobe function, as well as motor disability. Some studies have demonstrated that treatment with dopaminergics had no effect on simple reaction time or choice reaction time, despite clinical benefit on overall motor performance. This suggests that these processes are not substantially dopamine-dependent but may be served by nondopaminergic neurotransmission. Other studies have shown improvement in reaction time measures by either dopaminergics or by deep-brain stimulation. There is also the observation that practice improves reaction times more in normal individuals than in patients with Parkinson's disease. These findings suggest that the frontal lobes are implicated in the slowed response speed in Parkinson's disease. The inability to control for the heterogeneity of frontal and cerebellar deficits seen in individual patients with Parkinson's disease may explain the apparent inconsistent results across studies.

Reaction Time in Other Movement Disorders

Electromyography has been used to devise reaction time tasks for the study of the ability to relax muscles in dystonia. These studies suggest that muscle relaxation is abnormal in patients with focal (multifocal or segmental) dystonia. They demonstrate the difficulty in interpreting the results of reaction time data from a motor-impaired body part. Studies comparing reaction times in patients with Parkinson's disease, Huntington's disease, and cerebellar disorders have been performed. These demonstrated that the patients with Huntington's disease had a significantly longer simple reaction time than those with Parkinson's disease. None of the other group differences in uncued and unwarned simple reaction time and choice reaction time were significant. Generally, the results are similar between the groups suggesting a nonspecific slowness having diverse central mechanisms. In a model examining the speed of wrist flexion in 10 patients with moderate to severe disability from essential tremor, the mean reaction time and movement time of the patients did not differ from the mean values of controls.

Summary

The neurochemical basis of reaction time deficits in Parkinson's disease and other movement disorders remains unclear. Movement disorders, even within a single disease, represent a highly diverse phenotype, and many variables including nonmotor features (depression, cognitive impairment, and sleep disorders), medications, and inherent incongruity of the disease must be considered when designing and interpreting the studies of reaction time in movement disorders.

Recessive Hereditary Methemoglobinemia Type II

E Roze, M Vidailhet, and C Ewenczyk, Federation de Neurologie, Hôpital Salpêtrière, Paris, France

Glossary

Athetosis – Involuntary slow continuous distal writhing movements.
Chorea – Irregular, unpredictable, brief involuntary movements that flow from one part of the body to another in nonstereotyped fashion.
Cytochrome b5 reductase – An enzyme involved in erythrocytic methemoglobin reduction and in fatty acid desaturation; its possible role in neural development and function is unknown.
Dystonia – Movement disorder characterized by involuntary twisting movement or abnormal postures resulting from simultaneous contraction of agonist and antagonist muscles.
Methemoglobin – Oxidized form of hemoglobin that does not carry oxygen and is reduced to hemoglobin by the soluble erythrocytic cytb5r isoform.
Protein isoforms – Different forms of a protein produced by related genes or arising from the same gene by alternative splicing.

Definition and History

Recessive hereditary methemoglobinemia (RHM) is an autosomal recessive metabolic disorder due to NADH-cytochrome b5 reductase (cytb5r) deficiency. The gene that encodes this enzyme is located on chromosome arm 22q13-qter.

This enzyme exists as soluble and membrane-bound isoforms, both of which are ubiquitously expressed. The soluble erythrocytic cytb5r isoenzyme is involved in methemoglobin reduction, while the biological role of the soluble nonerythrocytic cytb5r isoenzyme is unclear (**Figure 1**). The membrane-bound microsomal enzyme plays a role in fatty acid desaturation and in drug metabolism.

Two types of RHM have been delineated. Type I RHM is characterized by cytb5r deficiency restricted to erythrocytes, resulting in benign chronic cyanosis. In 1845, François reported the first patient with long-standing congenital cyanosis despite no obvious cardiac or pulmonary disorders. In 1948, Gibson et al. found that the disease was related to a deficiency in an erythrocytic enzyme that was later identified as soluble cytb5r. Type II RHM is characterized by a profound deficiency of both the soluble and membrane-bound cytb5r isoforms in all tissues. Permanent cyanosis is associated with severe neurological manifestations. The first case was reported in 1948 by Sacerdotti-Favini, and the disease was shown to be due to generalized cb5r deficiency by Leroux et al. in 1975.

Genotype–Phenotype Correlation and Pathophysiology

More than 40 mutations have been identified in the cytb5r gene, some of which are common to both types of RHM.

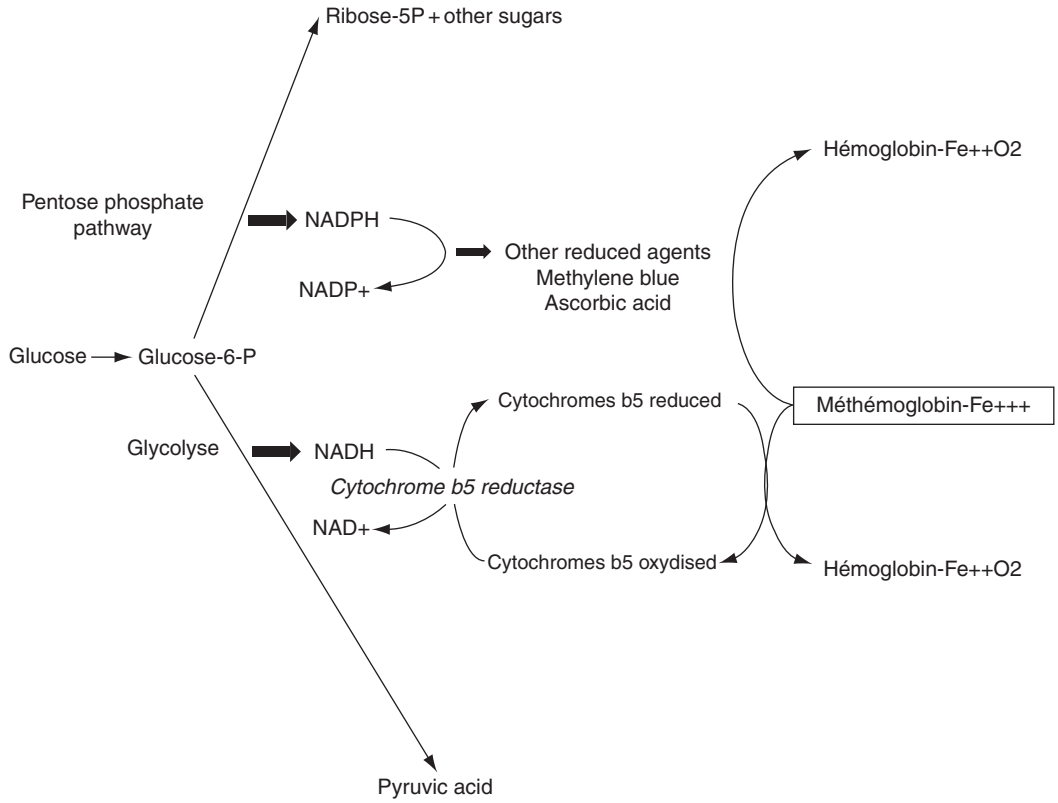

Figure 1 Methemoglobin reduction in erythrocytes. Cytochrome b5 reductase catalyses electron transfer from NADH (produced by the glycolysis pathway) to cytochrome b5. Reduced cytochrome b5 in turn reduces the oxidized ferric ion of hemoglobin. When cytochrome b5 reductase activity is deficient, reduction of methemoglobin uses NADPH from the pentose phosphate pathway, and other electron donors such as methylene blue or ascorbic acid.

Missense mutations are commonly present in type I RHM. They result in amino acid substitutions and diminished enzyme stability. In cells possessing the protein-synthesizing machinery the unstable enzyme is replaced in both its soluble and membrane-bound forms. By contrast, mature erythrocytes cannot synthesize proteins, and the lack of the soluble enzyme results in elevated methemoglobin levels, linked to continuous oxidative stress and nitrite exposure. Mutations associated with type II RHM lead to altered splicing, disruption of the enzyme's active site, or premature truncation of the protein. The enzyme is thus inactive in both its soluble and membrane-bound forms in all cell types.

Although the genotype–phenotype correlation in RHM is becoming clearer, the pathophysiology of the neurological disorder in type II RHM is still completely unknown. Type II RHM is characterized by generalized cytb5 reductase deficiency. The membrane-associated enzyme plays a fundamental role in the microsomal electron transport system and participates in fatty acid elongation and desaturation, as well as in fatty acid synthesis and drug metabolism. In contrast, its role in central nervous system development and function is unknown. Only two autopsy cases have been published. One patient had a hypoplastic brain, a thin cerebral cortex, and delayed myelination. The basal ganglia were normal but the cerebellum showed marked degeneration. The fatty acid composition of tissues (myelin, white matter and gray matter, adipose tissue, liver) was found altered in the second autopsied patient, suggesting that subnormal unsaturated fatty acid production is involved in type II RHM, possibly leading to central nervous system dysmyelination and encephalopathy.

Epidemiology

51 cases of type II RHM have been published since 1948. The disorder seems to occur worldwide but is mainly reported in the Mediterranean basin and Europe. It is probably underdiagnosed, especially in African subjects in whom cyanosis is more difficult to detect.

Clinical Features

During the first 2 months of life, half the patients have normal neurological findings. The full clinical phenotype

emerges at about 9 months of life. The neurological features are fairly uniform. Fixed encephalopathy is always present and extremely severe. Psychomotor skills are always inferior to those of a 1-year-old child. At best, these patients can sit, grip objects in a dystonic palmar manner, react and smile at familiar faces, and utter sounds. All the patients have generalized dystonia that can result in dystonic storms. Dystonia is often associated with axial hypotonia and diffuse choreoathetoid movements. With aging, the axial hypotonia tends to improve, abnormal movements decrease, and the dystonia becomes more fixed. Microcephaly is always present, and progressive growth retardation and converging strabismus are frequent. Refractory epilepsy has been reported in three patients, including a patient with West's syndrome. Behavioral abnormalities, such as screaming and agitation, are reported in the first years of life. The few patients who survive beyond 10 years of age have severe skeletal deformations such as scoliosis, and musculotendinous retractions owing to chronic dystonia.

Cyanosis is the key to diagnosis but may be difficult to detect. The blood has a chocolate-brown color due to the chronically high erythrocytic methemoglobin level. The complexion has been described as pale or 'grayish-blue.' Cyanosis can only be seen on the labial mucosa and nails of dark-skinned patients, and this may explain the lack of reported African cases. Cyanosis is accentuated during stressful events such as infections, but it may remain unnoticed for years. It is the most helpful sign, however, and failure to detect it may delay the diagnosis.

Rare atypical cases in five families (four Japanese and one Cuban) have been reported. These patients appeared to have a milder form of the disease, with prolonged survival and milder psychomotor retardation.

Diagnostic Work-up

MRI shows non specific cortico-subcortical atrophy and delayed myelination. The methemoglobin level is always elevated (over 1%) and usually ranges from 10% to 40% in type II RHM. Methemoglobinemia is suggested by abnormal pulse oxymetry (85–95%), incompatible with normal blood saturation (pO_2 assay). Methemoglobinemia is confirmed by measuring the methemoglobin level in arterial blood by cooximetry.

To confirm the diagnosis, generalized cytb5r deficiency must be established. In type I RHM, the activity of the soluble form of cytb5r is only diminished in erythrocytes. In type II RHM, cytb5r activity is diminished (<30% of normal) in both erythrocytes and leukocytes. Molecular genetic testing can be performed as a basis for reliable genetic counseling and prenatal diagnosis for future pregnancy.

Management and Prenatal Diagnosis

While cyanosis can be treated with methylene blue, riboflavin, or ascorbic acid, there is currently no way of preventing or even slowing the neurological deterioration associated with type II RHM. Patients may benefit from symptomatic treatment of their movement disorders with anticholinergics, benzodiazepines, or tetrabenazine physiotherapy and swallowing rehabilitation are also important part of the management.

Prenatal diagnosis should be proposed to affected families, as each subsequent sibling has about a 25% risk of being affected and there is no effective treatment. Prenatal diagnosis is based on cytb5r assay in fetal amniotic cells, or on the detection of previously identified mutations in trophoblast biopsy specimens.

Prognosis

In the first reports, the life expectancy of patients with typical type II RHM did not exceed 10 years of age. However, a few older patients (up to 24 years) with the typical severe form have now been reported, and they appear to have no particular life-threatening disorders. Survival is likely to depend on swallowing function (risk of respiratory infections and failure to thrive), and overall management, especially prevention of decubitus complications.

Refsum Disease- a Disorder of Peroxisomal Alpha-oxidation

A S Wierzbicki, St. Thomas' Hospital, London, UK; Chelsea and Westminster Hospital, London, UK

Glossary

α-Oxidation – Oxidative metabolism of methyl group at the α position next to the carboxylic acid group of a fatty acid.
β-Oxidation – Oxidative metabolism of fatty acids at the β position after complexing with coenzyme A by removal of two carbon acetyl-CoA units.
ω-Oxidation – Metabolic process with an initial oxidation of the end methyl-group of a fatty acid to produce a double carboxylic fatty acid followed by β-oxidation from either end.
Apheresis – Physical removal of plasma lipoproteins in a process analogous to dialysis.
Peroxisome – Cellular organelle containing enzymes for synthesis of complex long chain fatty acids, first stages of cholesterol as well as enzymes to perform α-oxidation of 3-methyl-fatty acids, and β-oxidation of polyunsaturated or complex fatty acids.
Phytanic acid – (3*R*,*S*, 7*R*, 11*R*, 15-Tetramethylhexadecanoic acid) a bacterial oxidative product of chlorophyll side-chain which accumulates in Refsum's disease.
Plasmalogen – Plasmalogen is an ether lipid where the first position of glycerol binds a vinyl residue (from a vinyl alcohol) with the double bond next to the ether bond, the second carbon is occupied by an ester-linked fatty acid, and the third has a phospholipid group like choline or ethanolamine.
Plasmapheresis – Physical removal of lipoproteins and other plasma proteins in a process analogous to dialysis.

Definition and History

Adult Refsum's disease (ARD) (OMIM 266510), also called *heredopathia atactica polyneuritiformis* and hereditary sensory motor neuropathy type IV, actually first described in 1947, was recognized by Refsum in 1962. Its key features are retinitis pigmentosa and anosmia, but it can present acutely with weakness, ataxia, and sensorimotor neuropathy.

Pathogenesis/Pathophysiology

Clinical Enzymology

Phytanic acid (3*R*,*S*, 7*R*, 11*R*, 15-tetramethylhexadecanoic acid) (PA) is an isoprenoid lipid derived from the phytol side-chain of chlorophyll. PA is preferentially taken up by the liver and may account for up to 50% of the free fatty acid pool in hepatocytes, and can be acutely mobilized secondary to illness or drastic weight loss. Adipose tissue and neurons accumulate PA because of its hydrophobicity. The elimination half-life of total body PA is usually 40 months.

Alpha-Oxidation of PA

Fatty acids are generally metabolized by the β-oxidation pathways in peroxisomes and mitochondria. PA cannot be metabolized by this route because of the presence of a β-methyl group. Instead, PA is metabolized either by α-oxidation to remove the carbonyl group and produce pristanic acid, or by ω-oxidation from the other end of the molecule. Most of the metabolism occurs in the liver, though skin fibroblasts are used for clinical diagnostic purposes. PA enters the peroxisome in association with the sterol carrier protein-2 (SCP2) and is metabolized by a four step α-oxidation pathway. Later cycles of β-oxidation generate the shorter derivatives and release acetyl-CoA or propionyl-coA, which are exported to the mitochondria.

Molecular Genetics

ARD is classically a single peroxisomal enzyme deficiency in contrast to infantile Refsum's disease (IRD) (OMIM 266500) – a mild clinical variant of the peroxisomal biogenesis disorder. The phytanoyl coA-hydroxylase (*PhyH*) gene codes for a 338 amino acid protein, including the N-terminal 30 amino acid 'PTS-2 signal' domain. *PhyH* is imported into peroxisomes by the protein transporter peroxin 7 (*Pex* 7). Deficiency in this transporter is responsible for rhizomelic chondrodysplasia punctata type 1 (RCDP). There seems to be little phenotype–genotype correlation in ARD, though truncation mutations generate a more severe phenotype with leukodystrophy and mental retardation.

A second form of ARD, phenotypically identical to those with PhyH mutations, occurs with some mutations in peroxin-7. These patients also have slight deficiencies of other PTS-2-dependent enzyme functions (plasmalogen

synthesis) consistent with mild variants of RCDP. Though mostly presenting with a sensorimotor neuropathy, α-methylacyl-CoA racemase (AMACR) deficiency (OMIM 604489) can clinically mimic ARD except with gross pristanic acidaemia.

Molecular Toxicology of Refsum's Disease

The exact mechanism of the toxicity of PA to neuronal, cardiac, and bone tissue is gradually being clarified. PA is a direct toxin to mitochondria with a rotenone-like action. This may explain why neuronal or allied retinal pigment tissues rich in mitochondria are the prime tissues affected in ARD.

Clinical Features and Diagnostic Criteria

ARD usually presents in late childhood with progressive deterioration of night vision, the occurrence of progressive retinitis pigmentosa and anosmia (**Figure 1**). Anosmia is a constant feature of ARD. After 10–15 years, cataracts, deafness, ataxia, polyneuropathy, ichthyosis, and cardiac arrhythmias may occur. The severe cases often present with acute weakness allied with ataxia and often deterioration in vision following an episode of illness or starvation. Premature death can occur in acute cases from cardiac arrhythmias.

Osteological abnormalities, including short metacarpals or metatarsals, are found in ~30% of patients. Rare findings include acute psychiatric disturbance and proteinuria. Unlike in RCDP or the peroxisomal biogenesis disorders, no intellectual defects are usually seen and bone abnormalities are mild.

The pathognomic biochemical finding of ARD is a raised plasma PA level ($>200\,\mu mol\,l^{-1}$; normal $<30\,\mu mol\,l^{-1}$), in contrast to other peroxisomal disorders where levels are usually lower. Other metabolic abnormalities of α-oxidation are also present, including decreased levels of pristanic acid and a mild nonspecific elevation in pipecolic acid levels as seen in many peroxisomal disorders. Urine 3-methyl adipic acid levels are raised secondary to induction of ω-oxidation.

Differential Diagnosis

The differential diagnoses of the neuropathic disorders, and relevant signs and investigations are shown in **Table 1**.

Diagnostic Work-up/Tests

The key investigations in the case of neuropathic ARD are the measurement of PA for ARD and pristanic acid for AMACR. These are the diagnostic for these disorders. Other common findings are pipecolic acidaemia and 3-methyl adipic aciduria.

For clinical staging purposes, electroretinograms are often performed, but often show flat responses characteristic of well-established retinitis pigmentosa (RP). Visual fields should be assessed regularly as functional diplopia is a long-term complication of ARD, and slit lamp examination for cataracts is also indicated as these can be treated. Ideally, retinal photography should be performed so that

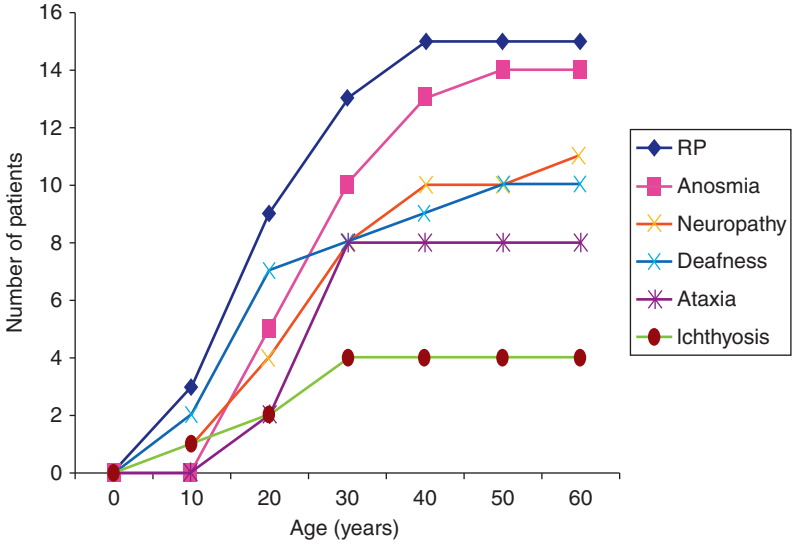

Figure 1 Cumulative incidence of clinical features on presentation of 15 patients with Refsum's disease. RP, retinitis pigmentosa. Reproduced from Wierzbicki AS, et al. (2002) Refsum's disease: A peroxisomal disorder afeecting phytanic acid α-oxidation. *Journal of Neurochemistry* 80(5): 727–735.

Table 1 Differential diagnosis of other adult neuropathies caused by inborn errors of metabolism

Disease	*Age of onset*	*Neuropathy*	*Signs*	*Chemistry*	*Treatment*	*Screening*
Mitochondrial myopathy	15–50	All	Retinitis pigmentosa, epilepsy, ataxia	CSF/plasma lactate	None	Lactate, muscle biopsy
Metachromatic leukodystrophy	15–50	Demyelination sensorimotor	Psychiatry, ataxia	Aryl-sulfatase A	None/bone marrow transplant	Aryl-sulfatase A
Krabbe's disease	15–50	Demyelination sensorimotor	Spastic paraparesis	WBC galacto–cerebrosidase	None/bone marrow transplant	WBC galacto–cerebrosidase
GM_2 gangliosidosis	15–50	All	Psychiatry; ataxia,	Hexosaminidase	None	WBC hexosaminidase
AMACR	10–50	Demyelination sensorimotor	Retinitis pigmentosa, ataxia, anosmia, IQ	Pristanic acid, D/THCA	Low phytanic acid diet (?)	Pristanic acid
Abetalipoproteinaemia	5–20	A,S /S + M	Ataxia, movement disorder, retinitis pigmentosa, acanthocytes	Low cholesterol, low apolipoprotein B, vitamins A and E	Vitamin A and E	Apolipoprotein B
Vitamin E deficiency	10–20	Axonal, demyelination sensorimotor	Ataxia, movement disorder, retinitis pigmentosa, acanthocytes	Vitamin E	Vitamin E	Vitamin E
Homocysteine metabolism (CblC)	15–50	Axonal, motorneurone disease sensorimotor	Psychiatric, stroke, leukoencephalopathy; macrocytosis	Homocysteine; methylmalonic acid	Folate, vitamin B_{12}, B_6, betaine	Homocysteine
X-linked adrenoleukodystrophy	15–50	Axonal, demyelination sensorimotor	Neuropsychiatric leukoencephalopathy; adrenal failure	Very long chain fatty acids	?Lorenzo's oil	Very long chain fatty acids

WBC, White blood cell.

Source: Sedel F et al. (2007) Peripheral neuropathy and inborn errors of metabolism in adults. *Journal of Inherited Metabolic Disease* 30(5): 642–653.

the extent and progression of RP can be monitored. Anosmia is best quantified by the University of Pennsylvania smell identification test (UPSIT), as other tests are neither quantitative nor sufficiently sensitive. Auditory function should be assessed by auditory evoked potentials. Peripheral neuropathy should be investigated using somatosensory potentials, nerve conduction studies, and electromyography. A nonspecific demyelinating pattern is typical of ARD. Osteo- or chondrodysplasia is best identified by a radiological survey of hands and feet for short metatarsals and knee radiology for signs of current or previous chondrodysplasia.

Subtler signs that may accompany these definitive tests include an electrolyte profile showing mild hypokalaemia, and a Fanconi-like amino aciduria can occur in ARD. Liver function tests should be performed, and if bilirubin is raised or AMACR suspected, a detailed bile acid profile should be performed by mass spectrometric methods. As the differential diagnoses include vitamin deficiencies, vitamin A and E levels should be measured to exclude retinol-deficient retinopathy and tocopherol-deficient ataxia. Vitamin B_{12} levels and folate levels are used to exclude cobalamin/folate deficient neuropathy. Though cerebrospinal fluid (CSF) protein is raised in ARD, this investigation is outdated.

To differentiate PhyH from Pex 7 ARD, it is necessary to measure plasma for very long chain fatty acids and plasmalogens. However, often the deficiencies are subtle, and these investigations are superficially normal. For a definitive diagnosis, a skin biopsy should be taken, fibroblasts grown, and detailed enzyme and immunofluorescence profiles examined in a specialist peroxisomal laboratory.

Criteria for Diagnosis

The pathognomic finding of ARD is a plasma PA level ($>200\,\mu mol\,l^{-1}$; normal $<30\,\mu mol\,l^{-1}$), in contrast to other peroxisomal disorders where levels are usually lower. Unlike in RCDP or the peroxisomal biogenesis disorders, no intellectual defects are seen, bone abnormalities are mild (if at all present), and there is no defect in plasmalogen synthesis. In AMACR neuropathy, the pathognomic findings are raised levels of pristanic acid ($>100\,\mu mol\,l^{-1}$) allied with increases in di- and trihydroxy cholestanoic acids (DHCA and THCA). A secondary elevation of PA may be seen, but levels are usually $50–100\,\mu mol\,l^{-1}$.

Management

ARD is one of the few inherited disorders of metabolism with an exogenous precipitating cause. The disease is treated acutely by its removal from plasma using plasmapheresis or apheresis, and chronically by restriction of dietary PA intake. Foods particularly rich in PA include herbivore meat (beef, mutton), dairy products, and top carnivore fish (cod, tuna), while low PA foods include pork and poultry. These regimes reduce plasma PA levels by 50–70%, to values typically $\sim 100–300\,\mu mol\,l^{-1}$ and can eliminate PA completely from fat stores in 35% of patients. Treatment successfully resolves symptoms of ichthyosis, sensory neuropathy, and ataxia in approximately that order.

Prognosis

The prognosis in ARD depends on the degree of reduction of PA achieved. In untreated ARD, presentation is with progressive weakness and neuropathy usually following an acute infective illness, which leads to anorexia and acute hepatic PA release exacerbating the condition. If left untreated, cardiomyopathy and sudden death can occur. If PA levels are reduced by plasmapheresis, adequate parenteral nutrition and then a low-PA diet prognosis is good. If PA levels can be normalized, then ophthalmological changes will be slow. The principal problems in chronic therapy are increasing loss of visual field overlap with subsequent diplopia and progressive cataract formation. Auditory function generally remains good unless PA levels are substantially raised, in which case, cochlear implants are required. Though acute myopathy resolves, patients may suffer from muscle spasms or contractures. Splints and surgical correction of osteopathy may be required. These patients seem to have a normal life expectancy.

Conclusion

The story of PA and α-oxidation started with the discovery of an unusual fatty acid in sheep milk. Only later was this linked to a human neuroophthalmological disease (Refsum's disease), and it took 40 years to clarify the pathways and organelles involved in its metabolism. As an easily identifiable and treatable form of neuroophthalmic disease, ARD should form part of the differential diagnosis of any patient with retinitis pigmentosa and any neurological signs.

REM-behavior Disorder

M Park, Rush University Medical Center, Chicago, IL, USA

Glossary

Electroencephalogram (EEG) – The measurement of electrical activity produced by the brain as recorded by electrodes placed over the scalp.
Electromyogram (EMG) – Used during PSG, EMG channels are usually placed on the chin and limbs to assess for the degree of muscle tone and to record muscle movements and during sleep.
Nonrapid eye movement (NREM) sleep – Consists of three stages of sleep, N1–3, which do not include rapid eye movements, are not accompanied by muscle atonia and have parasympathetic dominance.
Polysomnography (PSG) – A test used to study sleep.
Rapid eye movement (REM) sleep – A stage of sleep characterized by REM, muscle atonia, and desynchronized EEG patterns.

Definition/History

Parasomnias are unusual behaviors that occur during sleep and are categorized according to whether they occur during nonrapid eye movement (NREM) or rapid eye movement (REM) sleep. REM sleep behavior disorder (RBD) is a parasomnia characterized by loss of voluntary muscle atonia that normally occurs during REM sleep. Atonia during REM sleep is thought to be a

protective mechanism, enabling relative paralysis against motor activity in response to dreaming. Loss of REM atonia allows for excess motor activity to occur in association with dreaming, leading to potentially significant injuries for both patient and bed partner.

Experimental animal models in the 1960s described brainstem lesions that enabled behaviors during REM sleep to occur. Differentiation between wake and REM events was made by other features of REM sleep that are not seen during wakefulness, such as loss of thermoregulation, blunted response to stimuli, and specific autonomic activity. Subsequently, human behaviors equivalent to animal models were described, associated with dream content, and described as 'stage 1-REM sleep with tonic electromyogram.' RBD was recognized as a distinct sleep disorder in 1986. RBD may occur as an idiopathic disorder or may be associated with neurological diseases such as parkinsonism.

Pathogenesis/Pathophysiology

Polysomnographic criteria of REM sleep consist of three components: REMs, desynchronized electroencephalogram (EEG), and muscle atonia. During REM sleep, the pedunculopontine nucleus and laterodorsal tegmental area within the pons, also termed the perilocus coeruleus, send signals to the thalamus and activate the cortex, causing desynchronized EEG rhythms similar to wake states. The perilocus coeruleus also sends excitatory projections to the medial medulla, which then sends inhibitory signals to motor neurons, resulting in the skeletal muscle atonia characteristic of REM sleep.

Brief muscle twitches commonly observed during REM sleep are thought to be transient interruptions to muscle atonia by excitatory inputs from brainstem to cortex, which generally occur in conjunction with REMs. However, continuous phasic motor activity is actively suppressed by inhibition of muscle tone during REM sleep, perhaps facilitated by descending inhibition to brainstem areas. Activity during REM sleep is thus prevented directly by activating inhibitory mechanisms to spinal motor neurons, and indirectly by inactivating facilitory systems from brainstem to cortex, allowing maintenance of muscle atonia and suppression of prolonged phasic activity.

Structural Pathology of RBD

Prior animal studies demonstrated persistent absence of REM atonia with bilateral lesions at the pontine tegmentum. However, lesions in other brainstem areas also caused RBD, with differing complexity of behaviors depending on specific lesion sites. These studies suggest that RBD can manifest by disrupting specific mechanisms within brainstem centers that establish muscle atonia (i.e., descending from brainstem to spinal neurons) or via interference of phasic suppression of muscle activity (i.e., interrupting inactivation of ascending signals from brainstem to cortex) during REM sleep.

Although RBD in animals generally occurs due to the disruption of brainstem structures, human RBD is not as structurally simplistic. Although RBD manifests with disorders affecting the brainstem including vascular insults, neoplastic diseases, infections, and congenital malformations, RBD is also reported in pathological processes that compromise descending inhibition from higher cortical centers to the brainstem. For example, magnetic resonance imaging (MRI) SPECT studies demonstrate decreased blood flow in frontal, occipital, and pontine regions in some idiopathic RBD cases, with impaired cortical activation as shown by EEG spectral analysis. As such, RBD may not be due to the disruption of one particular structural center but rather by any mechanism that potentially causes imbalance between atonia maintenance and locomotor drive suppression during REM sleep.

Neuropharmacology of RBD

Neuroimaging primarily implicates abnormalities of dopaminergic transmission in RBD. Single photon emission computed tomography (SPECT) studies demonstrate reduction of striatal dopamine transporter binding in some idiopathic RBD cases. Similarly, positron emission tomography (PET) studies show reduction of striatal dopaminergic terminal binding in RBD associated with neurodegenerative disorders. Theories regarding dopaminergic impairment in RBD are further supported by the relationship between RBD and disorders of α-synuclein, such as Parkinson's disease (PD), multiple systems atrophy (MSA), and dementia with Lewy bodies (DLB).

Despite the growing evidence of dopamine's role in RBD, it is unlikely that RBD is caused by dopaminergic dysfunction alone. RBD is also reported in Alzheimer's disease and other neurodegenerative diseases that do not primarily affect dopaminergic pathways. Reports of RBD secondary to antidepressant and cholinergic agents also suggest serotonin and acetylcholine pathway disturbances. Anecdotal reports of RBD induction with beta blockers, monoamine oxidase inhibitors (MAOI), and α-adrenoreceptor antagonists implicate norepinephrine involvement as well. As such, RBD neuropharmacology remains unclear but likely involves an imbalance of several neurotransmitters that influence sleep architecture.

Epidemiology/Risk Factors

RBD has a reported prevalence of 0.38% in the general population and 0.5% in the elderly, the vast majority being older men. However, the prevalence rate of RBD may be higher in neurodegenerative disorders. RBD is clinically present in 25% or more in patients with PD and

in up to 95% of patients with DLB. Up to 90% of MSA patients meet polysomnographic criteria for REM sleep without atonia (RWA), and the presence of RBD may be an early differentiating factor between MSA and pure autonomic failure. Further, RBD may precede motor manifestations of these diseases by 10 years or more.

Racial differences in RBD incidence or prevalence are not reported, and frequency does not vary internationally. Although no deaths have been reported, patients and bed partners experience significant morbidity including minor contusions, assaults to the bed partner, and subdural hematomas. The risk of RBD increases after the sixth decade, although it can occur at any age. Comorbid neurological diseases such as PD, MSA, DLB, narcolepsy, amyotrophic lateral sclerosis, and dementia increase the risk of RBD, although spectral analysis and quantitative evaluation of muscle tone during REM sleep differ across disease states. There are likely genetic factors as well, as demonstrated by familial predisposition in RBD.

Certain medications can cause clinical RBD to manifest in previously asymptomatic cases. Because of suspected dopaminergic dysfunction in both idiopathic and neurodegenerative-associated RBD, dopaminergic agents were initially thought to be potential treatment options. Although some studies do report a therapeutic effect of dopamine agonists and levodopa, others paradoxically report increases in both REM phasic and tonic electromyogram (EMG) activity. This paradoxical effect may be due to the subtle dopamine receptor sensitivities among different patients, particularly those who may have existing neurological diseases. Similar discrepancies have been reported with tricyclic antidepressants (TCAs) and serotonin-specific reuptake inhibitors (SSRIs), with some studies reporting RBD induction while others report RBD suppression. However, the bulk of evidence suggests that SSRIs and TCAs likely induce RBD by increasing EMG tonic activity during REM sleep, particularly in cases with comorbid psychiatric and neurological disorders. Although these discrepancies suggest an imbalance of dopamine and serotonin as the cause for RBD, they do not explain the reports of RBD secondary to other agents such as β blockers and α-adrenoreceptor antagonists that do not primarily affect dopaminergic or serotonergic pathways. Finally, abrupt withdrawal from alcohol and sedatives, treatment with meprobamate, use of pentazocine, and even excess ingestion of caffeine have anecdotally induced RBD, which may be due to REM rebound phenomena after sleep deprivation.

Clinical Features and Diagnostic Criteria

Clinical Features

RBD consists of dream-enacted behaviors that occur more often in the latter half of nocturnal sleep and can range from simple to complex. Simple behaviors include talking, laughing, shouting, and limb jerking. Complex behaviors consist of swearing, gesturing, reaching, grabbing, punching, kicking, sitting up, getting out of bed, and running. While simple movements are not necessarily violent, complex behaviors are generally aggressive and injurious, leading to ecchymoses, lacerations, and fractures to both patient and bed partner. If the patient awakens during an episode, dream content is usually recalled. Aside from dream-related injuries, sleep disruption is generally not reported unless accompanied by sleep disorders such as sleep-related breathing disorders, narcolepsy, and periodic limb movement disorder (PLMD). It is important to note that personality traits do not indicate predisposition to development of RBD, as many studies have found that individuals with RBD tend to be calm and friendly during wake states.

RBD may also occur as a side effect of medications, including MAOIs, cholinergic agents, tricyclic antidepressants (TCAs), and serotonin-specific reuptake inhibitors (SSRIs), implicating dopaminergic nigrostriatal neurons, the locus coeruleus, and cholinergic innervated areas. RBD is also associated with toxic-metabolic states such as alcohol withdrawal, untreated obstructive sleep apnea (OSA), and narcolepsy.

Diagnostic Criteria

Because of the injurious nature of RBD, and the availability of effective treatment, accurate and timely diagnosis is essential. Diagnostic criteria are based on the clinical history and polysomnography (PSG) defined factors, as outlined by the second edition of the International Classification of Sleep Disorders (ICSD): (1) presence of REM sleep without atonia (RWA): the EMG finding of excessive amounts of sustained or intermittent elevation of submental EMG tone or excessive phasic submental or (upper or lower) limb EMG twitching; (2) at least one of the following is present: (2a) sleep related injurious, potentially injurious, or disruptive behaviors by history, (2b) abnormal sleep behaviors documented during polysomnographic monitoring; (3) absence of EEG epileptiform activity during REM sleep unless RBD can be clearly distinguished from any concurrent REM sleep related seizure disorder; (4) the sleep disturbance is not better explained by another sleep disorder, medical or neurological disorder, mental disorder, medication use, or substance use disorder.

PSG in RBD shows excess amounts of sustained EMG activity, excessive phasic limb activity, or intermittent loss of REM atonia during PSG. In contrast to disorders of arousal, autonomic hyperactivity is uncommon. Excess periodic limb movements (PLMs) are commonly observed, but normal sleep architecture is otherwise preserved. Time-synchronized video recording is recommended for establishing diagnosis.

Patients who have PSG evidence of RBD without clinical history have 'REM without atonia' (RWA), which is generally considered a subclinical or preclinical state of RBD. At least 25% of cases with RWA eventually display clinical features of RBD.

Differential Diagnosis

Several disorders can manifest as unusual, complex, or injurious behaviors during sleep. Common examples include NREM parasomnias and nocturnal seizures.

Sleepwalking and sleep terrors are NREM parasomnias which primarily affect children and younger adults, although persistence into adulthood is not uncommon. Unlike RBD, NREM parasomnias generally occur within the first 2 h of sleep onset. Arousing the individual during the event is difficult, and dream content is generally absent. NREM parasomnias are associated with autonomic signs of arousal although this is variable from case to case. PSG is the best diagnostic tool, distinguishing whether the events occur during REM sleep or NREM slow wave sleep (SWS). NREM parasomnias typically have normal muscle atonia during REM sleep, but if RWA or RBD is also present, the parasomnia is diagnosed as parasomnia overlap disorder. Like RBD, PSG is also helpful in evaluating nocturnal sleep disorders that may be fragmenting nocturnal sleep, in which case identification and treatment of those disorders help resolve the parasomnia.

Nocturnal seizures can also cause unusual and sometimes violent behaviors. In particular, nocturnal frontal lobe epilepsy is commonly diagnosed in the sleep laboratory, as daytime EEG is often negative for epileptiform activity even when performed during drowsy and sleep states. Nocturnal seizures tend to be stereotypic and are not associated with dream content. Unlike other seizures, altered mental status is not commonly observed after nocturnal events occur. EEG channels on traditional PSG studies may not reveal epileptiform activity, as nocturnal seizures are often deep within the frontal lobe and therefore difficult to detect from standard scalp electrodes. However, atonia during REM sleep is preserved during PSG.

Diagnostic Work-up/Tests

Although the clinical history of dream enactment behaviors is suggestive, PSG is essential in establishing the correct diagnosis of RBD. Clinical evaluation should include a history of sleep deprivation, toxic-metabolic causes, and possible medication effects as exacerbating factors. If underlying structural causes are suspected, MRI of the brain and EEG may be clinically useful. Routine laboratory tests are needed only as indicated from the history and physical examination.

Management

Safety measures such as removal of sharp objects from bedside, placing mattresses on the floor, and separate bedrooms for the bed partner should be discussed with the patient and bed partner. When RBD symptoms are clinically significant, pharmacologic treatment should be considered. Clonazepam is the primary agent prescribed for RBD, although its mechanism of action is not well understood and no controlled studies have been done. Clonazepam may enhance serotonergic pathways that influence RBD events, making it unique amongst benzodiazepine receptor agonists. Clonazepam may be more effective in suppressing phasic motor activity and altering dream content than in restoring REM atonia. Clonazepam is effective for most cases and rarely leads to abuse or tolerance. Initial dose of clonazepam is typically 0.5 mg at bedtime with gradual dose titration up to 1–2 mg if necessary. Although breakthrough simple behaviors may occur during treatment, complex and injurious behaviors tend to be well-controlled. The major side effect of clonazepam is daytime sedation, which tends to be dose-dependent and possibly managed by taking the medication earlier in the evening. Clonazepam may worsen underlying sleep-disordered breathing and contribute to nocturnal confusion, particularly in neurodegenerative disorders. Sudden discontinuation may lead to rebound worsening of RBD.

Melatonin may also be useful in treating RBD. Melatonin is secreted by the pineal gland and helps synchronize the sleep–wake cycle. Its mechanism of action in RBD may involve restoring presumed dysregulation between the underlying circadian rhythm and REM sleep, although this has not been adequately studied. Melatonin seems to partially reestablish REM atonia rather than suppress phasic activity. Melatonin can be discontinued abruptly although RBD events generally recur weeks to months later. Doses between 3 and 12 mg per night are reported to be effective, with response within 1 week. However, there are no placebo-controlled trials evaluating melatonin, and it is not regulated by the Food and Drug Administration. Although a melatonin agonist (ramelteon) is available by prescription, it has not been studied in RBD. Adverse side effects of melatonin can include hallucinations, next-day somnolence, and rare interaction with warfarin.

Pramipexole, a dopamine agonist, is reportedly effective in idiopathic RBD. However, pramipexole is not shown to be effective in controlling RBD in neurodegenerative disorders. It is unknown whether this disparity is due to possible differences in pathophysiology between idiopathic RBD and RBD associated with neurodegenerative disorders.

Medications known to cause or worsen RBD, including antidepressants with serotonergic activity and antihistamines, should be evaluated and changed to an alternative

medication if possible. It is also important to actively treat the underlying medical and sleep disorders that can mimic RBD and cause RWA.

Prognosis

Treatment for RBD is generally effective. RBD may be a harbinger for future neurological disorders. Patients should be regularly evaluated for both neurological and psychiatric disorders. Education about RBD, particularly its association with neurodegenerative disorders, should accompany clinical evaluations. Safety behaviors, avoidance of sleep deprivation and toxic-metabolic conditions, and treatment of comorbid medical and sleep disorders should also be routinely discussed and evaluated.

Rest Tremor

M M Nashatizadeh, K E Lyons, and R Pahwa, University of Kansas Medical Center, Kansas, KS, USA

Glossary

Deep brain stimulation – The surgical implantation of electrodes to specific targets deep within the brain as a treatment for various brain disorders.
MPTP – The chemical 1-methyl 4-phenyl 1,2,3,6-tetrahydropyridine.
Positron emission tomography – A computerized radiographic technique used to examine metabolic activity in various tissues.
Psychogenic tremor – Tremor most often resulting from underlying stress that can display variable frequency, amplitude, and direction with distractibility.
Rubral tremor – Irregular low-frequency rest tremor due to lesions in (the vicinity) of the red nucleus.

Definition and History

The Greek physician Galen (AD 129–200) wrote numerous works regarding disorders of motor function and distinguished between different forms of limb shaking based on appearance specifically identifying rest tremor among the aged. The tenth century Muslim physician Avicenna (ibn Sina) studied various motor disturbances and advised bathing in mineral salts and ingesting herbal treatments including rue and scolopendrium to relieve rest tremor.

The term *rest tremor* describes a rhythmic involuntary contraction of alternating agonist and antagonist muscles in an affected body part at rest. Because involved muscles are not actively contracting, they must be supported against gravity such as when the hands rest in the lap or when the entire body is supine on a surface.

Pathophysiology

Most evidence suggests that rest tremor develops from multiple oscillators as a result of abnormal processing of circuits between the thalamus, basal ganglia, and cortex. Synchronization of actively firing neurons within the basal ganglia may also contribute to rest tremor pathophysiology. Experimental models of rest tremor include anatomical lesions within nigrostriatal projections and cerebellar outflow areas mostly in dentatorubrothalamic connections although damage to only one system alone may be insufficient to generate tremor. Some have suggested that subtle variation in tremor frequency can be attributed to spinal reflex or other mechanical mechanisms although the lack of reliable change in rest tremor frequency with weight bearing on an affected limb does not support this theory.

Clinical Features

Stress can increase striatal acetylcholine levels, leading to greater imbalance against striatal dopamine levels and resulting in increased rest tremor amplitude. This relationship explains why anticholinergic medications can improve rest tremor in Parkinson's disease (PD) more so than bradykinesia or rigidity. Walking may also increase rest tremor amplitude in many patients.

Differential Diagnosis

Parkinson's Disease

PD is the most common cause of rest tremor. Low-frequency rest tremor is one of the cardinal features of PD that presents in 80–90% of patients. The typical presentation of distal limb rest tremor involves flexion-extension movements at the elbow, pronation–supination movements of the forearm, and/or pill-rolling movements of the finger and thumb. Various clinical rating scales that quantify PD severity (such as the Unified Parkinson's Disease Rating Scale) consistently demonstrate that rest tremor asymmetrically favors one side of the body. Tremor frequency within a given PD patient often appears to be quite similar in different muscles. Studies of various muscle groups show lack of coherence in rest tremor frequency even on the same side of the body. These findings suggest that rest tremor in PD is generated by not one but multiple oscillatory circuits operating at similar frequencies.

People with tremor-predominant PD tend to have slower progression of disease than those with predominant bradykinesia and rigidity in the absence of tremor. Neuropathologic studies show evidence that retrobulbar area (A8) is more severely affected in tremor-predominant PD. Reemergent tremor in PD is noted in the postural position but develops only after prolonged latency and shares the same average frequency (5.5 Hz) and amplitude of rest tremor suggesting a shared pathophysiology. The same neural mechanisms involved in rest tremor in PD likely remain active with postural change.

In one study of 11 patients with rest tremor, more than 50% reduction in putaminal fluorodopa (^{18}F) levels was noted on positron emission tomography. Unlike rigidity and bradykinesia, rest tremor severity does not correlate with the magnitude of striatal dopaminergic deficit. Performing certain tasks such as counting backwards from 100 or tapping the contralateral foot usually increases rest tremor amplitude within 2–3 min.

Secondary Parkinsonism

Vascular parkinsonism rarely presents with rest tremor unless one or more isolated stroke lesions disrupt key anatomic regions such as the substantia nigra, red nucleus, or other thalamic midbrain connections. Patients with hydrocephalus frequently demonstrate bradykinesia and rigidity but are less likely to display tremor. Although rest tremor is an atypical finding in progressive supranuclear palsy (PSP), 2 of 12 individuals with pathologically confirmed PSP in one study had mild rest tremor. Less than 10% of patients with multiple system atrophy (MSA) have rest tremor.

Drug-Induced Rest Tremor

Rest tremor that develops with acute or subacute use of neuroleptic medications often presents like classic PD although bradykinesia often occurs earlier. Unlike PD, drug-induced parkinsonism may present with bilateral symmetric involvement. Up to 90% of patients with drug-induced rest tremor may develop symptoms within three months of starting the offending drug. Newer atypical neuroleptics may be less likely to result in rest tremor than older drugs although antidepressants can also lead to extrapyramidal syndromes.

Essential Tremor (ET)

Rest tremor of the hands can be seen among some elderly patients with ET although the presence of this symptom is more commonly due to coexistent PD. More commonly, postural tremor involving incompletely relaxed muscles simulates rest tremor but is really postural tremor in ET. The presence of accompanying rest tremor in ET is associated with longer disease duration, higher amplitude postural and kinetic tremor and greater likelihood of head tremor.

Rubral Tremor

Irregular low-frequency rest tremor can be seen in the 'wing-beating' rubral or midbrain tremor (also called

Holmes tremor) in combination with intention and postural tremor. Rubral tremor occurs due to lesion in the red nucleus.

Supratentorial Mass Lesions

Many supratentorial tumors that spare the basal ganglia can disrupt thalamocortical connections resulting in rest tremor that may or may not resolve after tumor debulking or complete surgical excision. These masses include meningiomas, epidermoid cysts, fibrillary astrocytomas, anaplastic oligodendrogliomas, and glioblastomas.

Pineal Gland Mass Lesions

Various pineal gland cysts and tumors have been reported to cause unilateral rest tremor in the absence of other parkinsonian findings. Although the presence of hydrocephalus related to compression of the posterior thalamus and upper midbrain could explain the bradykinesia and rigidity frequently seen in these lesions, another possible theory involves congestion of the deep venous system draining nigrostriatal projections.

Toxic Exposures

Many people exposed to 1-methyl -4-phenyl -1,2,3,6-tetrahydropyridine (MPTP) as a result of illicit drug use can develop acute-onset rest tremor indistinguishable from classic PD. Organophosphate poisoning can frequently present with dystonia, rest tremor and rigidity most likely due to inhibition of striatal acetylcholinesterase (AChE).

Psychogenic Tremor

Rest tremor can be seen in stress-induced or psychogenic tremor along with other types of tremor. The presentation usually involves tremor of variable frequency, amplitude, direction and/or location that is often distractible or entrainable by performing complex volitional movements in the contralateral hand or foot. Rest tremor may also be coupled with classic features of *la belle indifference*, convergence spasm, and/or somatization in the presence of underlying depression or cumulative psychosocial stressors.

Treatment

Pharmacologic Treatments

The primary treatment for drug-induced tremor due to neuroleptic medications such as antipsychotics or metoclopramide is to discontinue the provoking medication after careful consideration of risks and benefits. Whenever possible, the offending drug should be switched to a different class of medication. Anticholinergics are also useful in treating drug-induced tremor.

The standard treatment of rest tremor in PD over the past 40 years is levodopa. Oral dopamine agonists such as pramipexole and ropinirole are also approved for the treatment of PD and are frequently useful in treating rest tremor particularly in the early stages. Monoamine oxidase B (MAO-B) inhibitors, anticholinergics, and amantadine are also used to treat rest tremor.

Deep Brain Stimulation

Deep brain stimulation (DBS) of the subthalamic nucleus (STN), globus pallidus, and thalamus are safe and effective therapies for PD, although rest tremor by itself is rarely disabling enough to warrant surgical intervention. DBS may be more effective than dopaminergic medications alone in reducing rest tremor severity. DBS of the STN is the preferred target for rest tremor as it is generally thought to be more effective in treating accompanying bradykinesia and rigidity in PD whereas DBS of the ventral intermediate nucleus (VIM) usually only improves rest tremor alone. DBS of the globus pallidus interna (GP_i) is less effective in treating rest tremor and is generally not favored for rest tremor. Several reports suggest that midbrain tremor has been successfully treated with DBS although more information is needed to determine long-term outcomes in these patients.

Restless Legs Syndrome

P Hamilton-Stubbs, Sleep Clinic for Children and Adults, Richmond, VA, USA
A S Walters, Vanderbilt University School of Medicine, Nashville, TN, USA

Glossary

A11 region – A cluster of dopamine containing cells located in the diencephalon with projections to the spinal cord.
BTBD9 – The symbol for (Broad-Complex-Tram-Track-Bric-A-Brac Domain 9) and is a gene encoding a BTB (Poz) domain on Chromosome 6p.
DMT1 – The abbreviation for divalent metal transporter 1. DMT 1 removes iron from endosomes and makes iron available to the intracellular labile iron pool.
LBXCOR1 – The code name for ladybird homeobox 1 homolog (*Drosophila*) corepressor 1 and is located near MAP2K5 on chromosome 15q.
MAP2K5 – The symbol for Mitogen-activated protein kinase 5 and is located on Chromosome 15q.
MEIS1 – The symbol for Meis homeobox 1. MEIS1 is linked to embryonic proximal–distal limb formation. MEIS1 is located on chromosome 2p.
MPT1 – The abbreviation for metal transporter 1 (ferroprotein) and is thought to be involved in cellular iron efflux.
Periodic limb movements in sleep (PLMS) – Repetitive stereotypic leg movements that reoccur throughout the night during sleep. Scoring criteria for PLMS include four movements in a row, 0.5–10 s duration, spaced 0.5–90 s apart, and at least 8 μV elevation above the baseline EMG.
Restless legs syndrome (RLS) – It is a sensorimotor disorder with four essential diagnostic criteria: (1) An urge to move the legs usually accompanied or caused by uncomfortable and unpleasant sensations in the legs. (2) The urge to move or the unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting. (3) The urge to move or unpleasant sensations are partially or totally relieved by movement such as walking or stretching, at least as long as the activity continues. (4) The urge to move or unpleasant sensations are worse in the evening or night than during the day or only occur in the evening or night.

Definition and History

Restless legs syndrome (RLS) is a neurogical disorder associated with sensory and motor symptoms. Sir Thomas Willis published the original description of RLS in 1672. During the nineteenth century, RLS was considered a form of hysteria or neurasthenia. Theodor Wittmaack,

a German physician, called the condition 'anxietas tibiarum.' RLS was not recognized as a neurological disorder until 1923 when H. Oppenheim described it as a genetic neurological disorder. In 1943, F. Gerard Allison described a phenomenon 'leg jitters' as a common minor ailment characterized by unpleasant, unlocalized restlessness in one or both legs associated with voluntary and involuntary limb jerks and sleep disturbance. Leg jitters, according to Allison, were sometimes relieved by 'getting up and walking.'

In 1944, based on eight cases, Karl-Axel Ekbom, a Swedish neurologist, published a description of a new syndrome, Asthenia Curum Paraethetica (Irritable legs). From 1943 to 1944, Ebkom screened 4259 patients for irritable legs and identified 20 patients with moderate to severe symptoms. Thinking that people with mild symptoms did not seek medical treatment, Ekbom screened 503 patients from an outpatient neurological service and an additional 503 healthy people. Of the 1006 people screened, 65 people had mild RLS symptoms: 39 patients from the outpatient clinic and 26 healthy people.

In addition, Ekbom believed that there was an association between pregnancy and irritable legs. Ekbom questioned 486 postpartum women. Fifty-five of the women described leg paresthenias during pregnancy. In 1945, based on 169 cases and his extensive study, Ekbom published a comprehensive description of the disorder. Ekbom classified symptoms as predominantly sensory or painful and renamed the disorder RLS but noted that symptoms could occur in the arms.

Ekbom and his contemporary, Dr. Nil Brage Nordlander, lectured extensively on RLS. Ekbom described the disease as 'so common that every practicing physician meets it.' We now know that RLS affects 7–15% of the general population and almost 2% of children. The essential symptoms of RLS as described more recently by the International Restless Legs Syndrome Study Group (IRLSSG) are as following:

1. an urge to move the legs usually accompanied or caused by uncomfortable and unpleasant sensations in the legs,
2. the urge to move or the unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting,
3. the urge to move or unpleasant sensations are partially or totally relieved by movement such as walking or stretching, at least as long as the activity continues,
4. the urge to move or unpleasant sensations is worse in the evening or night than during the day or only occur in the evening or night.

Types of RLS

RLS is classified as primary or secondary. Primary RLS is not associated with an underlying medical or neurological abnormality or caused by a drug. Although RLS can be genetic or sporadic, most primary RLS, especially with young onset and a positive family history, are genetic.

Secondary RLS is diagnosed when a precipitating illness, medical condition or causative drug can be identified. Secondary RLS is frequently associated with uremia, diabetes, neuropathy, gastric surgery, and conditions associated with iron deficiency such as pregnancy and frequent blood donations. There is also an association with fibromyalgia, rheumatoid arthritis, and multiple sclerosis. More recently hypertension and heart disease have also been linked to RLS.

Periodic Limb Movements and RLS

Periodic limb movements in sleep (PLMS) are repetitive highly stereotyped movements that occur involuntarily at predictable intervals. Polygraphic recordings done by Coccagna and Lugaresi et al. in 1962 documented that PLMS occurred in patients with RLS. Coccagna called these movements 'nocturnal myoclonus.' Approximately 80% of people with RLS have PLMS. Periodic limb movements also occur in wakefulness in RLS as determined by the Suggested Immobilization Test (SIT). Although the European discovery of the BTBD9 gene was driven by RLS, the simultaneous discovery of the same gene was driven by PLMS in the Icelandic population.

PLMS occur commonly with other sleep disorders such as narcolepsy and REM sleep behavior disorder (RBD) as well as in isolation as an incidental finding on polysomnography.

The current polysomnographic scoring criteria for PLMS include four movements in a row, 0.5–10 s duration, and spaced 5–90 s apart, at least 8 μV elevation above the baseline EMG.

Development of Diagnostic Criteria and Classification

In 1979 and 1990, The Diagnostic Classification Steering Committee of the American Association of Sleep Medicine developed RLS diagnostic criteria, which were published in The International Classification of Sleep Disorders: Diagnostic and Coding Manual (ICSD). In the early 1990s, physicians and scientists dedicated to research on restless legs/periodic limb movements in sleep formed the International Restless Legs Syndrome Study Group (IRLSSG). The IRLSSG felt that the 1990 definition did not include all the essential features of RLS and mistakenly included some nonessential features as well. The IRLSSG currently consists of more than 130 physicians and scientists from 17 countries. In 1995, the IRLSSG published the original consensus definition of RLS. For better clarity, the IRLSSG updated the definition and diagnostic criteria for RLS. The IRLSSG published the updated definition in 2003.

This new definition was incorporated into the new International Classification of Sleep Disorders (ICSD-2) in 2005. This definition now stands as the universal definition of RLS in 2008.

The consensus definition of RLS published by the IRLSSG and the International RLS Severity Scale were instrumental in subsequent RLS research leading to FDA approved medications.

Pathogenesis/Pathophysiology

The pathogenesis of RLS is unknown but appears to involve iron metabolism within the central nervous system, the neurotransmitter dopamine and genetic factors.

Iron is closely linked to secondary forms of RLS. Many of the illnesses that precipitate secondary RLS are characterized by decreased iron levels: renal failure, pregnancy, frequent blood donations. Patients with RLS and low ferritin levels improve with iron therapy. Researchers have found that severity of RLS symptoms increases inversely when serum ferritin levels are decreased below $50\,\mu g\,l^{-1}$.

Ferritin is the major storage protein for iron and has two parts L-ferritin and H-ferritin. Transferrin is the primary iron transport protein. Transferrin is manufactured primarily in the liver and does not cross the blood brain barrier. Cerebral transferrin is manufactured within the brain. When researchers compared the cerebral spinal fluid (CSF) levels and the serum levels of ferritin, iron, and transferrin in RLS patients compared to normal controls, they found that RLS patients with normal or elevated serum iron levels had lower CSF ferritin levels and higher CSF transferrin levels than controls, suggesting a selective reduction of CSF iron. Similarly, histological and immunohistochemical studies have reported reduced brain iron. Likewise, brain magnetic resonance imaging (MRI) studies demonstrate a reduction in iron in the substantia nigra and to a lesser degree the putamen of people with RLS.

Iron is intricately related to dopamine. The D2 dopamine receptor is a protein that contains iron and iron is a cofactor for tyrosine hydroxylase, an enzyme that controls the rate-limiting step in the conversion of tyrosine to levodopa, a precursor to dopamine. Although patients with RLS respond to dopamine, it is possible that dopamine is deficient due to defective acquisition or utilization of iron by brain cells.

The role of dopamine in RLS is substantiated by the remarkable benefit of dopamine drugs for RLS symptoms, and the exacerbation of symptoms associated with dopamine receptor antagonists. Similarly, opioid agents can improve symptoms and opioid antagonists can exacerbate symptoms in RLS patients treated with opioids. Thus both the endogenous dopamine and opioid systems are implicated in the pathogenesis of RLS. Further studies suggest that it is the dopaminergic system that is primarily involved, and that this is modulated by opioids. Some researchers have hypothesized that decreased dopamine-D2 receptor stimulation is responsible for RLS symptoms.

Dopaminergic PET scan studies have shown modest and variable pre and postsynaptic deficits in the nigrostriatal pathways in many studies. However, it does not appear that the predominant abnormality is in the nigrostriatal dopamine pathway, the pathway involved in Parkinson's disease. Rather, it is thought that the dopaminergic neurons in the A11 region of the hypothalamus are involved. The A11 neurons that project to the neocortex and dorsal raphe have local connections within the hypothalamus and descend to the spinal cord as the sole source of spinal dopamine. Diencephalospinal neurons terminate predominately in the dorsal horns of the spinal cord in areas that have sensory afferent input, interneurons, somatic motor neurons and the intermediolateral nucleus (IML).

Preliminary autopsy evidence also suggests that the endogenous opioids Beta endorphin and Met enkephalin are decreased in the thalamus of patients with RLS.

Genetics and RLS

The first chromosome linkage study suggested an autosomal recessive inheritance pattern (RLS1). Subsequent studies of other possible loci suggest an autosomal dominant inheritance pattern (RLS 2, RLS 3, RLS 4, and RLS 5).

Two genome-wide association studies were published based on data from Europe and Iceland. The European researchers studied people with a familial pattern and sporadic forms of RLS. The Icelandic researchers studied people with RLS and periodic limb movements. Both groups identified a common variant in an intron of BTBD9 on chromosome 6p. Additionally, the European researchers identified a MEIS1 gene on chromosome 2p and genes encoding mitogen-activated protein kinase MAP2K5 and the transcription factor LBXCOR1 on chromosome 15q. The MEIS1 gene is thought to be associated with limb development.

Epidemiology/Risk Factors

RLS affects 7–15% of the general adult population and almost 2% of children. Forty to 65% of people with RLS report a positive family history of RLS. A first-degree relative of a person with RLS has a 3–6 times greater risk of developing RLS.

RLS affects both genders and all ethnic groups. Caucasians and women have a higher incidence. Research suggests a lower incidence of RLS among persons from the Indian subcontinent and other Asian countries.

Clinical features and Diagnostic Criteria

Essential Criteria

Restless Legs Syndrome is diagnosed primarily by the patient's description of clinical symptoms. Adults with RLS must have four essential clinical symptoms: (1) An urge to move the legs usually accompanied or caused by uncomfortable and unpleasant sensations in the legs. (2) The urge to move or the unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting. (3) The urge to move or unpleasant sensations are partially or totally relieved by movement such as walking or stretching, at least as long as the activity continues. (4) The urge to move or unpleasant sensations are worse in the evening or night than during the day or only occur in the evening or night. Supportive and associated symptoms help confirm the diagnosis. Supportive and associated features are often present but are not essential to the diagnosis. These include a positive family history of RLS, improvement of symptoms with dopaminergic therapy, and the presence periodic limb movements during sleep or wakefulness. RLS almost invariably occurs in the legs but can involve the arms, torso, or face. Symptoms may be unilateral or bilateral.

Children diagnosed with RLS must have the four essential clinical features described above and be able to describe leg sensations in their own words. Alternatively, a child who cannot describe the leg sensations in their own words must meet all four essential clinical features and in addition meet two of the following: (1) sleep disturbance greater than expected for age, (2) a parent or sibling with definite RLS, (3) periodic limb movements that occur during sleep at a frequency greater than five movements per hour.

Differential Diagnosis

RLS must be differentiated from legs cramps, positional discomfort, neuroleptic-induced akathisia, and painful legs and moving toes syndrome.

In children RLS must be differentiated from motor tics, attention deficit hyperactivity disorder, muscle pains, leg cramps, Osgood–Schlatter's disease, arthralgia and akathisia. Growing pains are thought to be the onset of RLS in some cases.

Diagnostic Work-up/tests

The diagnosis of RLS is based on the clinical history. Serum iron, ferritin levels and iron-binding capacity are essential to obtain in order to evaluate whether iron deficiency may play a role. Some researchers recommend checking vitamin B12, folate and magnesium levels, although there is less evidence for these as associated conditions. A polysomnogram is not indicated for diagnosis of RLS, but may be useful if assessment for periodic limb movements or other sleep disorder is suspected. All patients should undergo a physical and neurological examination. If suspected, peripheral neuropathy or radiculopathy can be documented by electromyography (EMG) and nerve conduction studies. Additional testing may be necessary to differentiate primary RLS from secondary RLS. The diagnostic tests recommended depend upon the suspected precipitating condition.

When the diagnosis of RLS is unclear a trial of dopaminergic medication may help confirm the diagnosis. Almost all patients with RLS will respond to dopaminergic agents.

The frequency and severity of symptoms should be documented and the patient classified as having intermittent RLS, daily RLS or refractory RLS.

Management

Nonpharmacologic Therapy

Nonpharmacologic therapies that benefit people with RLS include: (1) mental distraction and mental alerting activities. There are case reports that mental distractions, such as playing the piano, can decrease symptoms. The mechanism is unknown but it is thought that mental distraction activates parts of the brain that block the perception of RLS symptoms. (2) Eliminating dietary triggers such as caffeine, alcohol, and tobacco; (3) hot or cold soaks; (4) massaging the legs; (5) adjusting the bedtime so that the patient goes to bed after symptoms stop; (6) if possible discontinue drugs known to exacerbate RLS symptoms: tricyclic antidepressants, SSRIs, H1 antihistamines, calcium channel blockers and dopamine antagonists; (7) walking or exercising the legs; (8) avoiding excessive exercise.

Pharmacologic Therapy

All medications used to treat RLS should be started at the lowest dose and increased slowly to an effective dose. Because medication half-life is different from peak effect, one recommendation is that medication should be dosed every three hours during the symptomatic period. The number of doses per day depends on the number of symptomatic hours per day.

Replace iron in patients with serum ferritin levels below $50\,\mu g\,l^{-1}$. Recommended dosing is 325 mg of ferrous sulfate three times a day with supplemental vitamin C 500 mg with each dose of ferrous sulfate. Reevaluate the serum ferritin level after 3 months of therapy. There is no indication to treat patients with iron who do not have a low ferritin, and iron overload may occur. Additionally, in patients with iron deficiency, an evaluation for the underlying cause of the deficiency should be undertaken.

In 1982, Akpinar reported that dopamine agonists improved RLS. In 2005 ropinirole, a nonergot dopamine

agonist became the first Federal Drug Administration (FDA) approved medication for RLS. Since 2005 the FDA approved another dopamine agonist, pramipexole. Dopaminergic agonists drugs are regarded as the first line pharmacologic therapy for RLS. There are two types of dopaminergic drugs: ergot preparations and nonergot preparations. Bromocriptine, pergolide, and cabergoline are all ergot dopamine preparations. Prolonged use of ergot preparations is associated with cardiac valvular fibrosis and pulmonary fibrosis. Therefore ergot preparations are used with caution and monitoring for these side effects. Pergolide is no longer available for use in the United States.

Nonergot dopaminergic agents are the only FDA approved medications for RLS in the United States. The two that are approved include pramipexole (Mirapex®) and ropinirole (Requip®). The therapeutic dose of ropinirole ranges from 0.25 to 4 mg day^{-1}. Ropinirole should be started at 0.25 mg given 30 min before the onset of symptoms or 90–120 min before bedtime. The dose is increased by 0.5 mg weekly until alleviation of symptoms. The maximum dose is 4–6 mg day^{-1}.

Pramipexole is available in multiple dosage strengths and should be started at 0.125 mg, the lowest dose available. Medication is increased by 0.125 mg every 4–7 days as needed. The average dose prescribed is 0.5 mg day^{-1}. Some physicians increase pramipexole to a maximum dose of 2 mg day^{-1}.

Levodopa/carbidopa is an older dopaminergic agent with a short half-life. Levodopa/carbidopa is used when symptoms occur intermittently or in preparation for sitting for prolonged times. Because of a tendency to cause more marked augmentation, daily use at higher dosages is not recommended.

Cabergoline is a long acting ergot dopaminergic agonist effective against RLS symptoms but seldom used to treat RLS in the United States due to cost and potential associated side effects.

Side effects of the dopaminergic drugs include nausea, light-headedness, daytime drowsiness, orthostatic hypotension and sleep attacks. Chorea and hallucinations are common side effects of dopamine agonist in Parkinson's disease but are not reported in RLS. Compulsive gambling and compulsive shopping have been reported.

The most troubling side effects of dopaminergic agents in RLS are rebound and augmentation. Rebound occurs when symptoms increase at a time compatible with the half-life of the medication. Augmentation is a more common side effect and is particularly prominent with the use of levodopa. Augmentation is the earlier occurrence of RLS symptoms in the evening, requiring an earlier administration of medication. Furthermore, the symptoms are usually worse and may spread to other body areas besides the legs. The management of RLS augmentation includes avoiding chronic treatment with levodopa, use of longer acting dopamine agonists, earlier doses of the dopamine agonists if mild augmentation occurs, and a reevaluation for iron stores as a low ferritin has been associated with augmentation. For severe or recurrent augmentation, the dose of the dopamine agonist should be lowered or the dopamine agonist discontinued. Alternate therapy can then be chosen.

Other treatment options include the opioids, gabapentin, and benzodiazepines.

For severe RLS, opioids (codeine, propoxyphene, hydrocodone, methadone, oxycodone, or tramadol) are sometimes prescribed. There is little addiction or tolerance to opioids when used to treat RLS. Constipation, dizziness, nausea, and vomiting are side effects associated with opioids. Patients treated with opioids should be monitored for the development or exacerbation of sleep apnea.

Gabapentin (Neurontin) is an anticonvulsant frequently prescribed for painful RLS, daily RLS, and refractory RLS. The starting dose is 100–300 mg. The average dose is 300–1200 mg day^{-1}. The therapeutic range is 300–2700 mg day^{-1}. Side effects associated with gabapentin include ataxia and drowsiness.

Benzodiazepines, clonazepam (Klonopin®), temazepam (Restoril®), and triazolam (Halcion®), may reduce leg discomfort, decrease the urge to move and help patients sleep through periodic limb movements. High doses of benzodiazepines cause carry-over effects such as morning drowsiness and decreased cognition. Benzodiazepines are not recommended in patients with untreated or inadequately treated sleep apnea because benzodiazepines may increase apnea. Addiction and tolerance to benzodiazepines rarely occurs in patients without a previous history of addiction.

Nonbenzodiazepine hypnotics (eszopiclone, zolpidem) are sometimes prescribed to help patients sleep but have not been shown to reduce RLS symptoms or periodic limb movements.

In 2004, the Medical Advisory Board of the RLS Foundation established treatment recommendations for RLS. This approach separates patients into one of three categories: intermittent symptoms, daily symptoms and refractory symptoms. Treatment is based on frequency and severity of symptoms.

Intermittent symptoms are treated with nonpharmacologic therapies alone or in combination with medications. Medications used to treat intermittent RLS include benzodiazepines, levodopa, low potency opioids (tramadol, propoxyphene, codeine), and dopamine agonists.

Dopamine agonists are the drugs of choice for treating daily RLS. Combination therapy is also used. Gabapentin and low potency opioids are also used for daily RLS. Nonpharmacologic therapies may also be helpful.

Refractory RLS is difficult to treat. Treatment may require a change in therapy to gabapentin or another dopamine agonist. Alternatively, refractory RLS can be treated by adding a benzodiazepine, opioids, or gabapentin.

Refractory RLS may require high potency opioids. Combination therapy is also used.

Most medications prescribed to treat RLS are not recommended for pregnant women. Pregnant women should be evaluated for iron deficiency. Iron deficiency should be treated and the use of nonpharmacologic therapies encouraged. There is some evidence that folate, B12 and magnesium are helpful in pregnancy. When pharmacologic therapy is necessary, opioids are used with caution.

Children with RLS should be evaluated for iron deficiency anemia and treated as needed. Children who are not iron deficient or in whom symptoms are not controlled by iron therapy should be first treated with nonpharmacologic therapy. When medication is needed, nonergot dopaminergic agents are recommended. There is anecdotal evidence that gabapentin, benzodiazepines, or clonidine are also helpful.

Prognosis

Primary RLS is an idiopathic or genetic disorder with a familial pattern. When symptoms develop at an early age, progression of symptoms develops slowly and may not occur daily for many years. Although 15% of patients with RLS experience a remission in symptoms for a month or more, primary RLS is considered to be a chronic progressive disorder.

Secondary RLS remits when the precipitating condition resolves. Although some women who develop RLS during pregnancy will continue to have symptoms postpartum, most will be symptom free after pregnancy. There is anecdotal evidence that women who develop RLS during pregnancy have a higher incidence of RLS in later life.

Symptoms of primary and secondary RLS can usually be controlled by medication and nonpharmacologic therapies (**Table 1**).

Table 1 Guide to videotape

Motor restlessness during wakefulness
1. Tossing/turning in bed (patient 1)

Rett Syndrome

Yoshiko Nomura, Segawa Neurological Clinic for Children, Tokyo, Japan

Definition and History

Rett syndrome (RS, RTT; MIM 312750) is a neurodevelopmental disorder caused by a mutation in the gene methyl-CpG-binding protein 2 gene (*MECP2*) encoding for methyl-CpG-binding protein2 (MeCP2).

Since the first clinical delineation, substantial progress has been achieved in the clinical understanding of RS, which has been further fortified by the finding of the causative gene.

Its clinical features consist of autistic symptomatology, mental retardation, stereotyped movements mainly involving hands and mouth, dystonia, scoliosis, epilepsy, abnormal respiratory patterns, acquired microcephalus, and female preponderance.

In RS, particular signs and symptoms appear in an age-dependent fashion and this is considered to be due to abnormal synaptogenesis at certain stages of the course of development caused by the *MECP2* mutation. The exploration of the role of *MECP2* in RS is helpful in understanding not only other developmental disorders but also normal brain development.

In 1966, Andreas Rett, a pediatrician in Vienna Austria, described a disorder with the specific symptoms occurring only in females as 'Über ein eigenertiges hirnatrophisches Syndriome bei Hyperammonämie' in German. In 1977, Rett wrote a chapter in the Handbook of Clinical Neurology entitled 'Cerebral Atrophy associated with hyperammonaemia'. Because his initial paper was written in German and his initial English paper was under the misleading heading of hyperammonemia, his original contribution had remained unknown outside of Austria and Germany. The clinical characteristics of the disorder were described as 'hyperammonaemia, hypomimia or amimia, alalia, stereotyped movement patterns in arms and hands, enhanced reflex activity, spastic increase in tone, gait apraxia, tendency to cerebral convulsive attacks, high grade of mental retardation, gynecotrophy (only females), and progressive course'. In 1972, this disorder was first described as 'Rett Syndrom' by Leiber in a syndrome textbook 'Die klinischen Syndrom' known in German-speaking area. In 1978, Ishikawa et al. wrote a short case report with identical symptoms and signs to the cases reported in the article by Rett; however, this report by Ishikawa was not noticed either. In 1983, the paper by Bengt Hagberg et al. in Annals of Neurlogy brought the disorder into medical nosology. We proposed for the first time, in 1984, that this disorder is a developmental disorder involving monoamine systems. In April 8, 1983, Rett organized the first meeting on this disorder in Vienna. It was only then that the international collaboration on the research of the disorder began intensively.

In 1999, the causative gene *MECP2* was identified by Amir et al., and the new era started on the clinical–biological–molecular correlation, and basic research of *MECP2* and its role in the development of brain began.

Pathogenesis/Pathophysiology

RS is associated with characteristic and complex phenotypes. The natural course of RS consists of a unique age-dependent appearance of the specific clinical symptoms and signs. The age-dependent presentation of the features of the disorder is important in considering its pathophysiology, because it reflects the changes taking place along the maturation of the responsible neurons or neuronal systems.

The onset of the disorder is in early infancy, although the initial symptoms and signs are very subtle. The early motor signs of RS are hypotonia with failure of crawling, abnormal pattern of walking, and disturbance in skillful hand manipulation. Clinical evaluation has revealed that the former results from postural hypotonia, with failure in locomotion. Additionally, neurophysiological examination has showed this to be due to hypofunction of the aminergic neurons of the brainstem. The latter signs are considered to indicate dysfunction of the corticospinal tract at higher levels.

Early psychobehavioral characteristics are a poor response to environmental stimulation, a poor formation of circadian rhythm, and more sleep during daytime, which are the earliest features of autistic tendency and can be speculated as being due to hypofunction of braistem serotonergic and noradrenergic systems.

Along with these features, the deceleration of head growth begins to appear in late infancy. This is speculated to be due to the dysfunction of noradrenergic neurons, which is involved in the cerebral cortical synaptogenesis.

The pathognomonic stereotyped hand movements appear in early childhood after the loss of purposeful hand use. These occur on the background of dystonic posturing and fixed position of the hands. With age, rigid hypertonia appears and later, fixed dystonic posture.

The frequency of the repetitive hand movements has been found to be minimally affected by environmental manipulations, suggesting that the movements are driven by automatic reinforcement or neurochemical processes.

The pathophysiology of the stereotyped hand movements with the loss of purposeful hand use and appearance of dystonic posturing are thought to be induced by the dysfunction of the basal ganglia-premotor and supplementary motor area with dopaminergic receptor supersensitivity. Scoliosis, which manifests itself in early childhood and shows progression with time, is also considered to be part of the dystonia.

The psychobehavioral characteristics of the disease include autistic features, and sudden episodes of screaming, laughing, or crying. Abnormal sleep–wake rhythms are present from early infancy.

With regard to the abnormal respiratory patterns and suggested abnormal cardiorespiratory centers in the brainstem, the involvement of the brainstem serotonergic system has been proposed. It is also suggested from experimental observations in mice that decreased substance P and other neuromodulators in the brainstem are the cause of the abnormal respiration.

The cause of sudden death in RS is not fully understood, but alteration of brainstem cardiorespiratory center can be an attributing factor.

Neurochemical studies in the cerebrospinal fluid and brain tissues revealed the involvement of most systems of transmitters, their receptors, and trophic factors, including acetylcholine, dopamine, serotonin, glutamate, substance P, and the nerve growth factor. It is important to note their roles as neurotrophins in brain development and their later role in the normal function of mature brain.

Neuroimaging studies have revealed altered volume of specific areas of the cerebral cortex, such as the prefrontal, posterior frontal, and anterior temporal regions, and relative preservation of posterior temporal and posterior occipital regions.

A neuropathological report by Armstrong showed decreased brain weight to the level of a 1-year-old and decreased pigmentation of the substantia nigra pars compacta. The weight loss does not progress with age, indicating that it is not degeneration. No degenerative, demyelinating, or gross malformative process is recognized. The neuronal size is decreased and increased neuronal packing density is observed in the cortex and subcortical areas. Significant decrease of dendritic territories in the frontal, motor, and subcortical cortices was shown by Golgi technique. In the midbrain and substantia nigra, the large neurons of pars compacta have less melanin and tyrosine hydroxylase staining than controls. Limited studies of the brainstem suggest abnormalities in serotonin receptors and in the substance P content. These neuropathological findings suggest a failure of development. General autopsies show that all organs except the adrenal gland are small for age but not for height.

Studies using receptor autoradiography demonstrate abnormalities in the density of excitatory glutamate and inhibitory gamma-aminobutyric acid (GABA) synaptic receptors in postmortem brain tissue, supporting the hypothesis that RS is a genetic disorder of synapic development, especially that of the synapses that use glutamate and GABA as transmitters.

RS is a genetic disorder affecting mostly girls and is primarily a sporadic disorder with few familial cases.

Mutations in *MECP2*, X-linked gene encoding methyl-CpG-binding protein 2 (MeCP 2), in exons 1 to 4 or DNA deletions, represent the genetic cause of more than 90% of typical cases of RS.

The phenotype–genotype correlation has revealed that MECP2 correlates with clinical severity and characteristics. The *MECP2* mutation is also found in the case of some phenotypes of Angelman syndrome and autism.

The mutation can also be found in normal females or females with mild learning disability. The mutation type, pattern of X chromosome inactivation, or other unknown factors seem to play a role in these phenotypical variations.

The mutation is also found in males, and the phenotypes in males vary from fatal infantile encephalopathy to familial X-linked mental retardation. Classical RS can occur in males with somatic mosaicism or with Kleinfelter syndrome.

MECP2 mediates transcriptional silencing through its methyl-CpG-binding domain (MBD) and transcriptional repression domain (TRD), and modifies gene expression of its target genes. This epigenetic function seems to be significant in the genetic control in brain development.

In normal early embryonic life, MeCP2 is expressed in two developmentally important regions, that is, the medulla and the thalamus. In normal brain development, the neurons of the medulla express monoamines (noradrenaline and serotonin), which act as the critical trophic roles, and send nonspecific afferents to the developing cortex, where they influence migration and organization of neuronal systems. MeCP2 is also a marker of a maturing neuron, being increasingly expressed in neurons as they evolve. The increase in MeCp2 expression in the brain after the prenatal period suggests that MeCP2 might also be required for neuronal maintenance and function.

The abnormalities, observed in the features of clinical symptoms and signs as well as the chemical and anatomical findings, suggest that MeCP2 is essential for neuronal maturation of the specific systems. The signal for the initial expression of MECP2 in a neuronal precursor cell can be regulated by a cell-autonomous mechanism. Its increasing expression in fully matured neurons can then be regulated in part by external factors, such as

synaptic input. Thus, MECP2 appears to be required for both the structural and the functional maturity of the neurons.

The establishment of the *MECP2*-deficient mice displaying phenotypic features mimicking some symptoms of RS as well as the understanding of the function of *MECP2* at the cellular and molecular levels is developing.

Epidemiology/Risk Factors

Cases of RS have been reported worldwide among all ethnic backgrounds. The classical form of RS was reported to have a prevalence of about 1 in 10 000–15 000 girls.

The frequency may increase with the addition of atypical cases, variants, or formes fruste cases. Particularly, the discovery of the causative gene may increase the prevalence by clarifying the genetic bases of atypical, variants, or formes fruste cases. There are some geographical areas where the prevalence is higher.

There are no known risk factors for the occurrence of the disorder.

Clinical Features and Diagnostic Criteria

The clinical presentation of RS is characterized by the specific psychomotor developmental delay, and pathognomonic symptoms and signs, which appear in an age-dependent fashion.

The onset of the disorder was initially late infancy to early childhood after a seemingly normal development. However, placidity and mild muscle hypotonia are present from early infancy, and the onset of RS is believed to be in early infancy. Sleep–wake rhythm is abnormal with increased sleep during the day, starting from early infancy. These earliest clinical features are subtle in most of the cases and are often overlooked.

These clinical features are similar to the ones observed in autism, showing delayed development of the circadian sleep–wake rhythm and poor response to environmental stimulation.

In late infancy, failure to crawl, delayed development of voluntary hand use, and the deceleration of head growth are observed. From late infancy to early childhood, psychomotor regression and social withdrawal appear. This social withdrawal seen in this period and the aforementioned characteristics seen in early infancy comprise the autistic features of RS.

The most striking and pathognomonic symptom of RS is the stereotyped movements of the hands associated with the loss of purposeful hand use appearing at this period. The typical hand stereotypies are characterized by repetitive squeezing, flapping, clapping, wringing, or bizarre hand automatisms. These movements occur mostly in the midline and virtually continue during wakefulness.

Before these stereotypies manifest themselves, habit-like behaviors involving the hands are present, and excessive clapping may be present.

Stereotyped movement of the tongue and mouth and licking and teeth grinding are also characteristics.

These stereotypies are observed during wakefulness, and increase when the child gets excited or becomes anxious.

Age-dependent changes are also observed in the hand stereotypies, evolving from simple to complex and fast, then to slow and simple with age.

In early childhood, dystonic posture appears. Hand stereotypies are obscured by dystonic rigidity. Because of the dystonia, the stereotyped movements of the hands become fixed and this does not change through the rest of the course of the disease.

The pes varus or vulgus, dystonic posture of all extremities progresses after childhood. Kyphosis and scoliosis, which are the postural dystonia involving trunk, progress after childhood to adulthood in some patients.

The deceleration of the growth of the head begins in late infancy, and patients often become microcephalic after early childhood.

The characteristic gait was initially described as apraxic by Rett. However, both failure of crawling and gait dysfunction are due to failure of locomotion.

Epilepsy may be seen, but the severity is variable among individual cases.

Abnormal sleep–wake rhythm and inappropriate laughing or crying during wakefulness or sleep are also seen often.

Breathing abnormalities, such as hyperventilation, breath holding, air swallowing, and bloating are striking features seen in some RS. Heart rate variability, difficulty in swallowing, and constipation suggest autonomic impairment. Cold and small feet are also consistent with dysfunction of the autonomic nervous system.

Height, weight, and hand and foot sizes also decline later. Overweight or emaciation may be seen in some patients.

The age-dependent appearance of the clinical features has led to the proposal of staging the disease.

Because of the difficulty in understanding the complex clinical features, the efforts of constructing the diagnostic criteria were set in 1984 and in 1988. With the increase of reported cases and advances of the understanding of the pathophysiology of the disorder, some components of these diagnostic criteria need to be changed or deleted.

Differential Diagnosis

The diagnosis of RS is not difficult with careful history taking of characteristic symptoms and signs, and noting the age-dependent appearance of these symptoms and signs.

However, there are disorders that need to be differentiated from RS. They include for example autism and Angelman syndrome. Some female cases with autism, particularly the cases with regression during the course, may later prove to be RS. Infantile neuronal ceroid lipofuscinosis may show temporarily similar features to RS. Finally, some neurodevelopmental disorders may present with similar features with RS. Therefore, in these cases, some symptoms or some periods of the course may overlap with the features of RS.

X-linked-cyclin-dependent kinase-like 5 (CDKL5/STK9) has been proposed as another causative gene for RS, particularly early seizure cases with severe mental retardation.

Diagnostic Workup/Tests

The clinical features and their evolution at specific ages are typical of RS. Careful history taking and neurological examination leads to the correct diagnosis in most cases.

There are no pathognomonic laboratory, neurophysiological, or neuroradiological tests.

The finding of mutation of *MECP2* is the best test to clarify the diagnosis; however, it is important to keep in mind that there are cases even with typical clinical features that do not carry the *MECP2* mutation.

Management

Therapeutic approaches are still symptomatic, and unfortunately, no crucial treatments have been established. Rehabilitation, including physical and occupational therapy, and enhancement of communication with music therapy have been tried with limited results. Trials of theoretically attractive treatments in these areas have been reported. Medications directed to possible correction of the underlying pathomechanisms have failed to produce appreciative and sustained effects.

Seizure is one of the common symptoms of RS that appears in early childhood. In such cases, administration of a suitable anticonvulsant(s) is essential. However, there is no antiepileptics specifically recommended for RS, and some cases can be drug resistant.

The effort to control the abnormal respiratory patterns is another challenge. Each abnormal respiratory pattern requires unique and special intervention. Some of the phenotypes can partly respond to pharmacological intervention, but others do not.

When physical therapy and orthopedic management of scoliosis fail, surgical treatments are indicated.

With some patients, management of nutrition becomes necessary, including gastrostomy.

General health care and prompt appropriate management for the undercurrent or acute illnesses is also important. All necessary managements for better quality of life need to be considered.

Prognosis

Initially, RS was thought to be progressive, but the clinical course is basically one of a developmental disorder.

As for the life-expectancy, relatively healthy patients survive into the fourth and fifth decades, although there is an increased incidence of sudden death in adolescent years. Cases surviving into their seventieth have been reported.

Rhizotomy

T Taira, Tokyo Women's Medical University, Tokyo, Japan

Definition and History

In 1913, Otfrid Foerster, a German neurosurgeon, introduced a technique to relieve severe spasticity mainly due to cerebral palsy by a complete division of the lumbosacral dorsal spinal roots with preservation of the motor roots. As he sectioned almost all the posterior roots, the result was unsatisfactory and this procedure was abandoned. Gros reported modification of Foerster's procedure in 1979 by partially sectioning dorsal spinal roots in an attempt to preserve some sensory function and afferent signals from the muscles. Further refinements to these techniques were made by Fasano and Peacock in the late 1970s. They used electrophysiological evaluation during the operation to determine which roots should be cut. After the introduction of intraoperative neurophysiologic monitoring, the effect of dorsal rhizotomy became satisfactory and complications such as sensory disturbance and too much hypotonicity decreased. In 1980s, selective dorsal rhizotomy (SDR) became a standard neurosurgical procedure for control of harmful spasticity in cerebral palsy children.

SDR (or selective posterior rhizotomy; SPR) is now a well-established treatment for spasticity in children with mainly cerebral palsy when the spasticity has proved unresponsive to less invasive procedures such as oral medications, local drug injections (botox, phenol), or orthopedic surgeries. After a rhizotomy, a patient who had suffered from severe muscle spasticity will be significantly less tight, have more range of motion and more fluidity in motion, and will never have to worry about the same muscles tightening up again as they may have before the procedure.

There have been many reports showing the efficacy of SDR and several reports with evidence-based assessment that showed long-term benefit of SDR. The following issues are scientifically proven:

- decrease of spasticity and improvement of range of motion;
- increase of gait speed;
- improvement of sitting ability;
- improvement of transfer motion;
- improvement of self care and ADL;
- secondary improvement of upper limb function;
- no sensory deficit in children;
- effects probably last longer than 20 years;
- positive effects on higher cognitive function.

General Course After SDR

After the surgery, all patients who were walking independently before surgery regain independent walk within a few weeks. Patients maintain independent walking for the long term; when some have more difficulty in walking independently, they may eventually need an assistive device – however, in nearly all cases spasticity can be eliminated and the quality of independent walking improves. Orthopedic surgery is rarely required after SDR.

In children who are 2–7 years old and walk with a walker or crutches before SDR, independent walking after the procedure is possible. Once they have achieved independent walking, they can maintain it. In children who are older than 7 years and walk with crutches, independent walking is also possible. If they walk with a walker at this age, they will most likely walk with a walker or crutches after the procedure, although it improves the quality of assisted walking and transition movements and alleviates deformities of the legs. Many of these patients will need orthopedic surgeries after SDR.

Indication

Not all patients with spastic cerebral palsy benefit from rhizotomy. SDR should be considered for those younger than 12 years. If a patient is older than 13 years, an intrathecal baclofen pump should be considered, because postoperative dysesthetic pain may become a problem as the age increases. Suitable candidates should fulfill the following conditions:

- at least 2 years of age;
- diagnosis of spastic diplegia, spastic quadriplegia, or spastic hemiplegia;
- some form of independent mobility; for example, crawling or walking with or without an assistive device;
- no severe damage to the basal ganglia on MRI examination;
- potential for improvement in functional skills;
- exclusion of severe dystonia or athetosis;
- motivation to attend intensive physical therapy and perform home exercise program.

Surgical Procedure

The SDR is generally performed by experienced pediatric neurosurgeons. General anesthesia without muscle

relaxant is necessary. With the patient in the prone position, a midline linear skin incision is made in the thoracolumbar region. There are two major approaches in SDR. The traditional and most common approach is through laminectomy from Th12 to S1–2, and all the dorsal roots are exposed at the distal part in the intradural space (Peacock's operation technique). The advantage of this is that the level of spinal roots is easily identified and that the surgeon can easily separate S2 or S3 roots from others to avoid complications regarding bowel and urinary functions. The disadvantage is related to the multilevel wide laminectomy: more invasiveness, postoperative pain, and long-term deformity of the spine. Another approach is through a limited laminotomy of only L1 and L2 (Park's technique). This eliminates the problems of multilevel laminectomy, but differentiation of the level of the roots may become difficult. In both procedures, an operative microscope should be used, although some neurosurgeons still use only magnifying glasses.

Intraoperative electrophysiological assessment is very important to determine which rootlets should be cut. Multichannel evoked electromyography (EMG) is recorded from the muscles in the leg. The dorsal roots are dissected to smaller rootlets, and every rootlet is stimulated with electrical current. If the evoked EMG pattern is "abnormal" with a certain rootlet stimulation, this rootlet should be cut. There are several abnormal patterns: prolonged response, extra-segmental spread, bilateral response, and so on. Some neurosurgeons also use urogenital sensory mapping to avoid urinary and bowel complications. Approximately 50–60% of rootlets from L2 to S1 or S2 have to be cut to achieve satisfactory functional improvement.

Postoperative pain may be severe, a pain related to both the surgical exposure and the nerve root manipulation. Various pain management strategies for children undergoing SDR have been reported. The majority of centers use continuous infusions of opioids, with an intravenous, epidural, or intrathecal approach.

Other Types of 'Rhizotomy'

Foerster-Dandy's rhizotomy had been widely performed for the treatment of spasmodic torticollis or cervical dystonia until the 1980s. In this procedure, intradural ventral spinal roots are sectioned from C1 to C3 or C4 level. This operation inactivates not only muscles innervated from dorsal rami but also muscles from the ventral rami, which may induce neck instability and swallowing problems. To avoid denervation of the phrenic nerve and nerves to the shoulder and arm, intradural rhizotomy is limited down to C4 in one side and to C3 in the opposite side. This is inadequate to denervate the posterior neck muscles completely. Because of such possible complications and the limitations of clinical benefit, this procedure is no longer performed, and it is replaced by selective peripheral ramisectomy (Bertrand's procedure).

Posterior rhizotomy (section of posterior spinal roots) used to be a treatment of choice for the management of intractable pain of malignant origin. However, such kind of procedure is no longer performed for the management of pain, because more effective and less invasive treatment modalities have been introduced.

Rigidity

O S Gershanik, Favaloro Foundation University Hospital, Buenos Aires, Argentina

Glossary

Bradykinesia – Slowness of movement.
Dystonic posture – Abnormal posturing of a limb with a torsion component.
Myoclonic jerks – Brief muscle jerks causing displacement of a body segment.
Parkinsonism – Any disorder presenting with the combination of bradykinesia, rigidity, and/or tremor.
Rhizotomy – Surgical sectioning of the nerve roots.

Definition and History

Having been derived from the Latin word 'rigor' meaning stiffness, rigidity refers to the presence of an increased muscle tone detected through passive displacement of a body segment. Hypertonicity or hypertonus is a general denomination for any type of increased muscle tone, including rigidity. Aside from resistance to passive displacement, increased muscle consistency, decreased flexibility, and passivity are additional features usually found in the examination of patients with hypertonicity, irrespective of the nature of the disorder. Paratonia, spasticity, and stiffness (as seen in the Stiff Person syndrome or in any situation where continuous muscular activity is present) are different forms of hypertonia, each having particular clinical features and differing pathophysiology. Rigidity is one of the distinguishing clinical features of the Parkinsonian Syndrome or Parkinsonisms in general (also designated 'akinetic-rigid syndrome'). The term 'rigid' or 'rigidity' is frequently used outside the field of movement disorders, for example, decerebrate rigidity, rigid spine, etc.

In James Parkinson's original monograph, there is no specific mention of rigidity as one of the main features of 'Paralysis Agitans.' It was Charcot, who, in the second half of the nineteenth century, clearly recognized rigidity to be part of the clinical features of this disorder. It was not until the beginning of the twentieth century that the cogwheel phenomenon was first mentioned by Camillo Negro in Italy and Harold N. Moyer in the United States. Apparently, a Spanish neurologist, Robert Novoa Santos, had made the same observation almost simultaneously. A further and significant contribution to the understanding of rigidity was made by another prominent French neurologist, Jules Froment, who extensively studied this motor phenomenon both clinically and with physiological recordings using a myograph. He was the first to discover the presence of 'enhanced resistance to passive movements of a limb about a joint that can be detected specifically when there is a voluntary action of a contralateral body part.' This accentuation of rigidity with voluntary activation of another body part has become known as the 'Froment's maneuver' and is the basis of the activation or facilitation test. Froment also demonstrated that variations in the amount of rigidity depend on changes in posture, increasing during the Romberg test, gaze deviation, and oriented attention. His hypothesis proposed that 'maintenance stabilization' was impaired in PD, whereas 'reactive stabilization' and 'rigidification' were compensatory changes against gravitational forces.

Pathophysiology

The pathophysiological basis of rigidity is not as well understood as that of bradykinesia. Afferent impulses are thought to play a role, as sectioning of the dorsal roots or application of local anaesthetic in the epidural or subarachnoid space decreases rigidity. Several theories have attempted to explain rigidity, through both hyperactivity and hyperxcitability of long-loop reflex pathways or disruption of function of the spinal interneurons due to abnormal afferent input from suprasegmental centers, including the reticular nuclei, via descending tracts. From a biomechanical perspective, these disturbances may cause that the forces generated by lengthening a given muscle during passive movement be offset by activation of the antagonist, that is, 'shortening reaction.' Changes intrinsic to the muscle have also been proposed.

Clinical Features and Diagnostic Criteria

Features that distinguish rigidity from other forms of hypertonicity are the presence of uniform resistance to passive displacement usually referred to as the 'lead pipe phenomenon,' as many perceive this uniform resistance as being similar to what is experienced when bending a soft lead pipe, and the 'cogwheel phenomenon.' Rigidity can occasionally have a ratchety quality, referred to as 'cogwheeling,' whereby the muscle resists and gives way in small, ratchety, step-like movements as if it were being controlled by a cog-wheel. The hypertonicity is regularly interrupted by the cogwheel mechanism at a 6–9-Hz

frequency, which is higher than the frequency of resting tremor (4–5 Hz) and postural tremor (5–6 Hz) frequency. Cogwheeling is not always present or necessary to diagnose rigidity. Cogwheeling appears to be present only when tremor is associated with rigidity. Uniformity of resistance to passive movement is indeed the distinguishing clinical feature of rigidity. The degree of resistance remains fairly constant through the entire range of motion, both flexion and extension, and is not greatly influenced by the stretch velocity or force with which the movement is performed. It persists as long as the stretch is maintained.

Rigidity is one of the cardinal symptoms of the Parkinsonian Syndrome, together with bradykinesia, rest tremor, and postural disturbances. Parkinsonism, and therefore rigidity, is present in a variety of disorders, including primary parkinsonism (Parkinson's disease (PD) both sporadic and genetic), the atypical parkinsonisms (multiple system atrophy, progressive supranuclear palsy, and the corticobasal syndrome), and parkinsonism associated with other heredodegenerative disorders (Juvenile Huntington's disease, Spinocerebellar ataxias, Pantothenate Kinase associated neurodegeneration, Neuroacanthocytosis, Wilson's Disease, etc.). Rigidity also occurs in secondary or symptomatic parkinsonisms (drug-induced, infectious, metabolic, structural, or toxic). The topographic distribution, presentation, and clinical course of rigidity differ from one syndrome to another. In PD, rigidity may be initially restricted to one limb (as often PD starts asymmetrically, involving just the upper or the lower extremity; with progression of the disease, involvement of the contralateral limbs and axial muscles is generally the rule. In progressive supranuclear palsy, the pattern of distribution of rigidity differs from that of PD, preferentially affecting the axial muscles (neck) more than the limbs. The corticobasal syndrome may present initially with rigidity localized to either one of the upper or lower extremities, but it is usually associated with apraxia (and other signs of cortical involvement such as agnosia), myoclonic jerks, and dystonic posturing of the affected limb. In the remaining conditions in which rigidity may be present, the pattern of topographical distribution is not in any way different from that observed in PD, but the presence of other neurological signs that are atypical for PD frequently lead to a correct diagnosis.

The contribution of rigidity to the motor impairment observed in these conditions is controversial, or at least uncertain. It is quite difficult to dissociate rigidity from bradykinesia in most of the cases. However, in clinical experience, it is frequently observed that patients may have very little or no rigidity but nonetheless are significantly impaired by the presence of bradykinesia; or just the opposite: despite the presence of significant rigidity, there is no obvious motor impairment. In the case of PD and other parkinsonisms, it may contribute to the generation of pain in the affected body segment, which is often relieved by the medications that improve rigidity.

Differential Diagnosis

Spasticity, contrary to what is observed in rigidity, exhibits a gradual variation in resistance, depending on the velocity and range of the movement whereby the examiner experiences a phenomenon comparable to the sudden closure of a clasp-knife. Spasticity is also more pronounced in extension than in flexion during clinical examination, contrary to what is usually found in rigidity. However, a recently published biomechanical study has found that, contrary to common belief, rigidity is more readily elicited in the antigravity muscles, although this distinction is not evident in clinical practice. The presence of weakness and additional signs of pyramidal tract involvement (increased deep tendon reflexes, Hoffmann and Babinski signs) helps in differentiating spasticity from rigidity.

Paratonia or gegenhalten, usually observed in cortical or subcortical frontal dysfunction, can also be distinguished from rigidity by the paradoxical and intermittent nature of the response to passive movement, presenting an increase in opposition depending on the degree of force applied. The finding of other signs of frontal involvement (cognitive deterioration of the frontal type, a positive grasp reflex, imitation and utilization behavior, frontal dysequilibrium) also helps in differentiating this type of hypertonia from rigidity.

Stiffness as seen in the 'Stiff-person syndrome' is described as 'board like' increase in muscle tone; it involves preferentially the paraspinal muscles, causing hyperlordosis, and is often accompanied by superimposed muscle spasms. The presence of continuous muscle activity through electromyography helps in confirming the nature of the increased muscle tone in this condition.

Diagnostic Work-up/Tests

In routine clinical practice, rigidity is explored through manual examination of the patient by passively moving the neck and the extremities and estimating subjectively the amount of resistance encountered. Although the evaluation of the consistency of the muscles through palpation, or the passivity with which a body segment is displaced around a joint (e.g., elbow, wrist, knee, ankle) by shaking the affected limb may also give an indication of the presence of rigidity, these are maneuvers that are not routinely used at present. In fact, in the Motor Examination part of the Unified Parkinson's Disease Rating Scale (UPDRS, Part III), which is the standard scale used in the evaluation of the severity of rigidity in PD and other parkinsonisms, only the passive displacement of a body segment around a joint is considered. In the UPDRS, the severity of rigidity is given a score from 0 to 4; 0 means the absence of rigidity; 1 indicates that rigidity

is present only by activation maneuvers (closing and opening the hand repetitively, while the examiner evaluates the presence of rigidity in a given body segment; this is known as the Froment maneuver); score 2 is given when, despite the presence of an increased muscle tone or resistance to passive movement, the whole range of motion can be achieved; a score of 3 is applied when there is limitation in the range of movement; and finally a score of 4 is used whenever there is complete limitation of movement. In the revised version of this scale, the MDS-UPDRS, the most severe level of complete limitation of movement captured in the earlier version is not an option, based on the rare applicability of this score in typical PD.

There have been many attempts at designing objective tests for the evaluation of rigidity by means of mechanical or electrophysiological devices; however, none of these tests has become part of the routine examination of this phenomenon.

Management

There are very few specific measures that can be applied to the treatment or management of rigidity. In PD, levodopa and other dopaminergic medications significantly improve rigidity, almost in parallel with bradykinesia. Some of the other parkinsonisms may also show some degree of response to antiparkinsonian medications, such as Multiple System Atrophy (short lived) and Progressive Supranuclear Palsy (rarely). In the majority of the remaining conditions, there is no significant improvement of rigidity with standard antiparkinsonian drugs. In drug-induced Parkinsonism, the removal of the causative drug, usually an antipsychotic or other dopaminergic receptor antagonist, may lead to progressive improvement of rigidity. In some cases of severe drug-induced parkinsonism, short-term antiparkinsonian medications are reported to accelerate the recovery.

Functional stereotactic surgery is also effective in reducing or improving rigidity. Both the pallidum and the subthalamic nucleus are effective targets for the relief of rigidity either by ablative surgery or by deep brain stimulation. Some of the earliest attempts to relieve rigidity in PD by surgical means involved the sectioning of the dorsal roots (dorsal rhizotomy), which leads to disastrous functional outcomes but provided evidence of the afferent component of this phenomenon.

In severe cases in which rigidity is associated with postural deformity and pain, which is often observed in the Corticobasal syndrome, the use of botulinum toxin may be helpful.

Stretching exercises and passive and active movements in the context of physical therapy may also help in relieving some of the discomfort attributed to rigidity.

Prognosis

Rigidity being a sign among a constellation of other signs and symptoms that are present in the conditions that were discussed in this article, there are no specific considerations to be made regarding prognosis. Rigidity is only one of the contributing factors leading to disability in these disorders. As mentioned previously, it is quite difficult to establish the major contributing factors leading to the progressive functional decline and immobility in such diverse and complex conditions in which rigidity is present.

RNA Interference

P Gonzalez-Alegre, University of Iowa, Iowa City, IA, USA

Glossary

MicroRNA pathway – Posttranscriptional gene silencing process triggered by endogenous miRNAs that bind the target mRNA leading to translational suppression.

Posttranscriptional gene silencing – Process by which expression of a specific gene is suppressed by small, double-stranded RNAs after transcription of the gene into mRNA but before translation of this message into protein.

RISC (RNA-induced silencing complex) – Enzymatic multiprotein complex assembled once the complementary (guide) strand of the dsRNA pairs with the targeted mRNA to mediate the cleavage of the mRNA (siRNA) or to translational repression (miRNA).

RNA interference (RNAi) – Posttranscriptional gene silencing process triggered by exogenous dsRNA in which perfect pairing with the target mRNA leads to its cleavage.

Short hairpin RNA (shRNA) – Short paired strands of RNA joined by a loop to form a hairpin that, after cytoplasmic processing and cleavage of the loop, forms a double-stranded siRNA. shRNAs are usually delivered to cells in the form of a DNA template.

Small interfering RNA (siRNA) – Short, double-stranded RNA formed by two perfectly paired strands of ~21 nucleotides which triggers the assembly of the silencing complex in the RNAi pathway.

Definition and History

The discovery of the process known as RNA interference (RNAi) has been one of the most important advances in biomedical research in recent decades. RNAi is a natural process by which cells use short, double-stranded RNAs (dsRNAs) to recognize messenger RNAs (mRNAs) with exquisite specificity, leading to their enzymatic destruction and preventing their translation into a protein. Therefore, they inhibit gene function. For the exogenous manipulation of this pathway, dsRNA can be introduced into cells in different forms. The two approaches most commonly used to silence a given gene in the laboratory through RNAi are (1) the introduction into cells of in vitro synthesized small interfering RNA (siRNA) or (2) the use of DNA templates known as short hairpin RNA (shRNA) that host cells will use to generate the siRNAs. One way or the other, these techniques allow researchers to block, or silence, expression of a given gene with a wide variety of goals, including therapeutic development.

The Process of RNAi

Scientists are able to use RNAi technology in mammalian cells because they express a highly organized machinery that mediates an endogenous process of posttranscriptional gene silencing, known as the microRNA (miRNA) pathway (**Figure 1**). miRNAs are generated by transcription of noncoding genes in mammalian cells, undergoing enzymatic processing of the transcript in the nucleus before being actively transported to the cytoplasm by exportin 5. In the cytoplasm they undergo additional processing to be converted into mature miRNA. miRNAs recognize their target mRNA, triggering the assembly of RISC (RNA-induced silencing complex) and usually lead to translational repression. The miRNA and RNAi pathways follow a similar process but with some differences. For instance, miRNAs differ structurally from siRNAs, usually pair with untranslated regions of the target

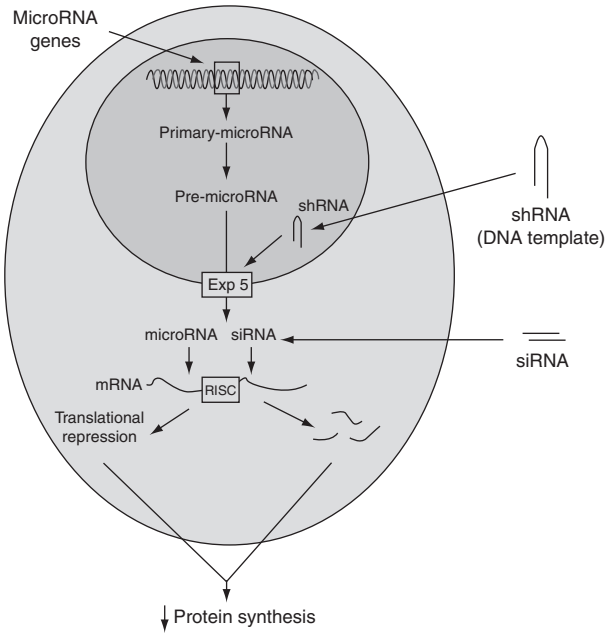

Figure 1 MicroRNA and RNAi pathways.

through imperfect base pairing and do not mediate cleavage of the mRNA. On the other hand, exogenous siRNAs usually pair with coding regions of the target through perfect pairing and direct the enzymatic cleavage of the target. Nevertheless, both ultimately result in the decreased synthesis of a specific protein.

The different constructs used in the laboratory to silence genes through RNAi also exhibit important differences between them. For instance, whereas shRNA incorporate into this pathway as DNA templates in the nucleus to be transcribed, siRNAs enter the cytoplasm ready to identify their targets, thus bypassing nuclear export and cytoplasmic processing (**Figure 1**).

Applications of RNAi

The possibility of manipulating the expression of any given gene through RNAi has facilitated investigations into the cause and treatment of several movement disorders. For instance, RNAi may be used in the laboratory as a molecular tool to understand the pathobiology of these disorders or to generate animal models of diseases caused by loss of gene function. However, the therapeutic use of RNAi is perhaps its most promising application.

The principle of therapeutic RNAi lies in silencing expression of genes that are key to the pathogenic process. In general, diseases considered for the development of therapeutic RNAi are those in which targets amenable to traditional pharmacological approaches are lacking, but our knowledge of disease pathogenesis allows us to identify molecular targets for therapeutic RNAi silencing. In this case, valid targets will be genes that, if eliminated would halt or slow down the pathogenic process without causing significant adverse effects. For instance, many dominantly inherited movement disorders, such as Huntington disease or the spinocerebellar ataxias, are caused by expansion in polyglutamine tracts that, through a toxic gain of function, lead to neuronal dysfunction and death. Although many of the investigational treatments for these diseases act downstream the pathogenic cascade, silencing expression of the mutated gene through RNAi would directly eliminate their cause. In recessive diseases caused by loss of gene function, although silencing the mutated gene would not be helpful, suppressing expression of specific molecular components of the pathogenic cascade could be beneficial. A similar scenario is encountered in the more common sporadic disease, when the molecular etiology remains unknown. For example, there is increasing evidence of a crucial role for α-synuclein in the pathogenesis of Parkinson's disease (PD), whether inherited or sporadic. Consequently, silencing α-synuclein expression in nigral neurons could be a reasonable therapeutic approach for PD. A similar scenario could be found in several diseases in which the aggregation of phosphorylated tau is important in their pathogenesis. In summary, several dominant, recessive, and sporadic diseases may be candidates for the development of therapeutic RNAi.

Once a target gene is identified, the next question is how to deliver the effector complex to the target cells. For the nervous system, most preclinical trials in animal models have used viral delivery of shRNAs, although significant advances in the use of nonviral delivery methods are very promising. If valid animal models are available, preclinical trials can then be performed. Therapeutic trials have been completed, with promising success, in different mouse models of Huntington disease, SOD1-linked amyotrophic lateral sclerosis, spinocerebellar ataxia type 1, Creutzfeldt–Jacob disease, PD, and Alzheimer disease. These trials support the potential of this therapeutic modality, and additional studies are being performed to answer other experimental questions required before planning therapeutic trials in humans.

However, there are potential obstacles faced in the development of therapeutic RNAi. In addition to demonstrating therapeutic efficacy, the completion of animal studies has raised important concerns about the safety of this therapeutic approach. Potential adverse effects include, for instance, the activation of inflammatory responses, sequence-specific silencing of nontargeted genes or the saturation of the endogenous miRNA machinery. In experiments performed by administering shRNA to mice with molecular targets in liver cells, it was found that high expression of these effector complexes saturated the nuclear export pathway, leading to the accumulation of unprocessed endogenous pre-miRNA in the nucleus of hepatocytes, causing cell death and animal demise. Toxicity induced by shRNA was also reported in a mouse model of Huntington disease. However, modifying these shRNAs to mimic endogenous pre-miRNAs, or the use of siRNA, which do not enter the nucleus, prevent the development toxicity. Overall, it seems that manipulation of the RNAi pathway with therapeutic goals may potentially impact neurodegenerative diseases within the next decade.

Rotation, Drug-induced

Y Luo, B J Hoffer, and Y Wang, National Institute on Drug Abuse, Baltimore, MD, USA

Glossary

6-Hydroxydopamine or 6-OHDA – A neurotoxin selective for dopaminergic and noradrenergic neurons.
Hemiparkinsonism – Parkinsonism affecting only one side of the body and often induced by lesion confined to the unilateral substantia nigra or nigrostriatal pathway.
Rotation – A circular locomotor movement.
Substantia nigra – A nucleus in the midbrain containing dopaminergic neurons that degenerate in Parkinson's disease.

Drug-induced rotation was first used by Profs. U. Ungerstedt and Nils-Eric Anden in Sweden more than 40 years ago. It is still a commonly used tool to evaluate the degree of neurodegeneration after lesioning and regeneration after treatment in a rodent model of Parkinson's disease.

Stereotaxic unilateral destruction of nigrostriatal dopaminergic systems in brain is often achieved by the injection of the catecholaminergic neurotoxin 6-hydroxydopamine (6-OHDA). Depending on the site of injection, 6-OHDA can lead to a partial or complete lesion of the mesencephalic dopamine system in one hemisphere. The injection of 6-OHDA into the striatum or substantia nigra of the animal results in a partial lesion of the nigrostriatal dopaminergic system. A near-complete lesion can be achieved by the administration of 6-OHDA to the axonal projection pathway of the nigrostriatal system, also called the medial forebrain bundle lesion. In this model, 6-OHDA is injected in the ascending nigrostriatal bundle and results in a complete destruction of A9 (substantia nigra, SN) dopamine (DA) neurons and their projection in striatum. This loss does not take place immediately and there is a variable time for the loss of phenotype preceeding neuronal death.

The injection of 6-OHDA causes degeneration of dopaminergic neurons in the A9 and their terminals in basal ganglia ipislateral to the injection side, while leaving the contralateral striatum and nigra relatively intact. The destruction of unilateral nigrostriatal dopaminergic pathway also leads to dopamine receptor supersensitivity in the lesioned striatum.

Two classes of chemicals are commonly used to evaluate denervation and receptor supersensitivity after unilateral 6-OHDA lesioning. (1) Amphetamine analogs, such as amphetamine or methamphetamine, cause ipislateral rotations due to differential increase of dopaminergic activity on the intact side, (**Figure 1**). The molecular mechanisms for amphetamines to increase synaptic levels

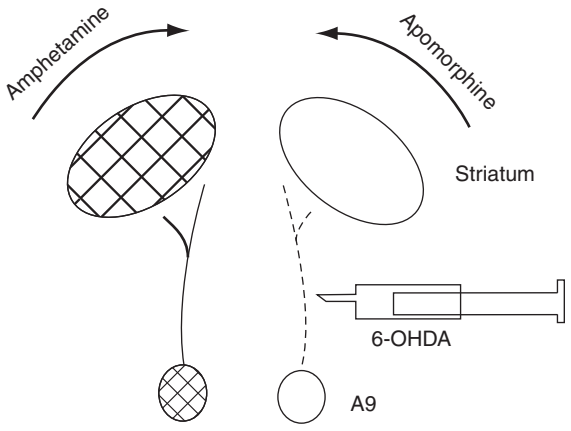

Figure 1 Schematic diagram of drug-induced rotation in unilaterally 6-OHDA lesioned animals. Injection of 6-OHDA to the medial forebrain bundle induces lesioning of DA neurons in A9 and striatum. Administration of amphetamine or apomorphine induces ipislateral or contralateral rotation, respectively.

of dopamine in the intact terminals include redistribution of catecholamines from synaptic vesicles to the cytosol, the reverse transport of neurotransmitter through plasma membrane transporters, blocking the activity of monoamine transporters, and inhibiting the activity of monoamine oxidase. (2) Dopamine receptor agonists in contrast, such as apomorphine, stimulate dopamine receptors directly, preferentially on the supersensitive denervated side and result in contralateral turning (**Figure 1**).

Typical doses that induce rotation are 1–5 mg kg^{-1} for amphetamine, 2.5–5 mg kg^{-1} for methamphetamine, and 0.05–0.2 mg kg^{-1} for apomorphine. These apomorphine doses maximize the differential sensitivity of the denervated DA receptors. Turning behavior can be quantified by various tools, such as infrared systems, mechanical rotomotors, or computerized video systems. Time course for measuring the rotation often lasts from 1 up to 4 h after drug injection.

There is a correlation between the loss of DA in the nigrostriatal system and drug-induced rotation. Significant correlation has been found between amphetamine (5 mg kg^{-1}, s.c.) induced ipislateral rotation or apomorphine (0.05 mg kg^{-1}, s.c.) induced contralateral rotation and the depletion of dopamine in the nigra. Maximal (>90%) lesions of the striatum and substantia nigra are required to generate rotations demonstrable with low-dose (0.05 mg kg^{-1}, s.c.) apomorphine. Partially lesioned (75–90% depleted) rats can still respond to amphetamine. Little correlation has been found between the depletion of dopamine in ventral tegmental area and the rotational behavior induced by apomorphine or amphetamine at these doses.

The number of rotations can also be used to predict the degree of lesioning in the striatum. Animals rotating over 300 turns per hour after 0.05 mg kg^{-1} apomorphine injection have maximal (≥90%) depletion of dopamine content in the striatum. It is less accurate to predict maximal lesioning using D-amphetamine at 5 mg kg^{-1}. It has also been reported that no turning could be elicited in markedly lesioned animals and that nonlesioned rats may rotate extensively on amphetamine. It has also been shown that the early phase of rotation, over the first 5–10 min, may be a behavioral conditioning phenomenon rather than a drug effect.

There are several other precautions for interpreting data, using drug-induced rotation. For example, apomorphine-induced rotation relies on the supersensitivity of dopamine receptors in the lesioned striatum. Further lesions of the denervated striatum can reduce dopamine receptor numbers and can result in the attenuation of apomorphine-induced rotation. Amphetamine can induce sensitization and the repeated administration of amphetamine may thus enhance rotation.

Amphetamine and apomorphine-induced rotation are commonly used to evaluate the protective or regenerative functions in 6-OHDA-lesioned rats after various treatments. For example, administration of glial cell line derived neurotrophic factor (GDNF) protein, transplantation of fetal substantia nigra or mesencephalic progenitor cells, or injection of viral vectors encoding GDNF have been found to reduce apomorphine or amphetamine-induced rotation in hemiparkinsonian rats.

Drug-induced rotation has also been used in nonhuman primates. The administration of apomorphine (0.05–0.5 mg kg^{-1}) or amphetamine (0.5 mg kg^{-1}) increases contralateral or ipislateral rotation in unilaterally 6-OHDA-lesioned marmoset monkeys. At the highest dose of apomorphine, animals vomited and were slow to start rotating.

Drug-induced rotation has sometimes been used in other animal models with unilateral striatal lesions. For example, in a rodent model of Huntington's disease, the administration of high doses of apomorphine (1 mg kg^{-1}, s.c.) induces ipislateral rotation at month 1 after the unilateral intrastriatal injection of quinolinic acid. Similarly, in stroke rats, amphetamine (1 mg kg^{-1}) significantly increases ipislateral rotation, toward the lesion side, at months 1–3 after unilateral middle cerebral artery occlusion (MCAo). However, there is no significant correlation between the rotational behavior and the size of lesion.

Roussy–Levy Disease

V Planté-Bordeneuve, AP-HP CHU Henri Mondor, Paris, France
G Said, AP-HP CHU Pitié-Salpétrière, Paris, France

Glossary

Amyotrophy – Muscle atrophy.
Charcot–Marie Tooth diseases – Group of hereditary sensorimotor neuropathies characterized by distal atrophy of the legs, deformation of the feet ('pes cavus'), and a predominantly distal motor deficit that is slowly progressive. This group of disease is genetically heterogeneous.
Demyelination – Abnormal process leading to degeneration and ultimately to loss of the myelin sheath of the nerves.
Pes cavus – Deformation of the foot with high plantar arches and clawing of the toes related to a slowly progressive atrophy of the foot muscles.
Schwann cells – Satellite cells of the peripheral nerves associated with myelinated and with unmyelinated axons. In myelinated axons, myelin sheath is formed by the compaction of layers of the Schwann cell surface membrane.
Tomacula – 'Sausage' aspect of myelin fibers seen in teased fiber preparation. This appearance is caused by redundant myelin loops.

Definition and History

In 1926, Gustave Roussy and Gabrielle Levy reported on seven members of a large kindred, who presented with a dominantly inherited disorder over four generations. An unsteady gait of early childhood with pes cavus and generalized areflexia were the prominent features of the disease. The patients eventually developed distal amyotrophy and weakness, clumsiness, postural tremor, and limb ataxia. Sensory modalities were preserved in virtually all cases. Overall, the course of the disease seemed benign. With the report of similar familial cases, the eponym of Roussy–Levy syndrome was subsequently used to designate this pattern of dominantly transmitted hereditary ataxia with tremor.

Roussy–Levy syndrome was considered by some as a forme fruste of Friedreich ataxia, but the absence of pyramidal tract involvement and the autosomal dominant inheritance were not compatible with this diagnosis. Furthermore, reduced nerve conduction velocity and the hypertrophic and demyelinating lesions found in the nerve biopsy of two patients of the original family, and, later on, at autopsy of one case also of the original family led Roussy–Levy syndrome to be considered as a variant of demyelinating Charcot–Marie-Tooth disease (CMT-1).

We have had the opportunity to follow several members of the original family over decades, and were able to perform nerve biopsy and postmortem studies of members of this family and ultimately DNA analysis of one of them. In this review, we will try to summarize our findings, which go together with the progression of our knowledge in clinical, electrophysiological, pathological, and genetic aspects of peripheral nerve disorders.

Clinical Features

As emphasized by Roussy and Levy, the clinical features of the syndrome differed from the classical CMT disease since they had an early onset with prominent ataxia, and they lacked the characteristic distal atrophy and weakness. The main distinctive features of Roussy–Levy Syndrome include: an early onset with pes cavus but with little disability, and delayed milestones. When seen after age 60 years, arched feet with hammer toes were present in all patients.

Kyphoscoliosis, subtle motor deficits with little progression over time, diffuse areflexia, slight or absent sensory impairment, balance problems with difficulty to stand still, and ataxia without cerebellar manifestations were common to all. A postural or kinetic tremor was frequently observed. Although considered a hallmark of the Roussy–Levy syndrome, postural tremor was found in four out of five patients of the original family. Whether postural tremor and the neuropathy represent a combination of two inherited disorders or whether postural tremor is a nonspecific manifestation of minimal weakness and impairment of type 1a afferent fibers, remains unsettled. Nerve conduction velocity was below $20\,m\,s^{-1}$ in the upper limbs, and often nonmeasurable in the lower extremities due to the gradual axon loss that occurs over the years. The progression of symptoms was remarkably slow since four out of five patients survived past the age of 80, and walked independently or with one stick at 70 years of age.

Morphological Findings

From a pathological point of view, the main findings were severe loss of myelinated axons associated with conspicuous irregularity of the myelin sheath. Extensive demyelination, thinly remyelinated internodes, and focal hyperplasia of the myelin sheath were present. Some surviving axons were surrounded by an abnormally thick and hyperfolded myelin sheath, while others were either thinly remyelinated or demyelinated. On teased fiber preparations, all myelinated fibers showed conspicuous abnormalities of the myelin sheath including demyelination, thinly remyelinated short internodes, hyperplastic myelin and accumulation of Schwann cell nuclei dispersed along single fibers. In some places, the thickened myelin sheath had a tomaculous (sausage-like) appearance. These pseudotomacula were so prominent that they mimicked the myelin changes seen in Wallerian degeneration in 20% of the fibers isolated in patient III-1 specimen. On cross sections, these abnormalities of the myelin sheath are comparable to those reported in patients with a mutation located in the extracellular domain of the myelin protein zero (MPZ) and in the MPZ deficient mice. It is worth noting that onion bulb formations were absent in two of the three patients whose nerve was studied morphologically (**Figures 1–3**).

Molecular Genetics

The molecular genetic study performed in four members of the family identified a previously unknown missense mutation in the third exon predicting an Arg131Lys substitution in the extracellular domain of the myelin protein MPZ that segregated with the disease. These findings indicate that the Roussy–Levy family falls into the CMT1b subgroup the group of hereditary demyelinating neuropathies.

Progress in molecular genetics demonstrated the role of the peripheral myelin proteins PMP_{22} and P_0 genes in such neuropathies termed CMT1a and CMT1b. Approximately 70% of the CMT-1 cases carry a segmental duplication of the 17p11.2-12.1 region that encompasses the PMP_{22} gene. Other patients have a point mutation of the PMP_{22} or the P_0 genes. The phenotypes associated with the chromosome 17p11.2-12.1 duplication range from the CMT to the 'Roussy–Levy' pattern. In addition to the historical aspect, the identification of a new MPZ gene mutation in the original Roussy–Levy family illustrates the limits of phenotype–genotype correlations in hereditary neuropathies.

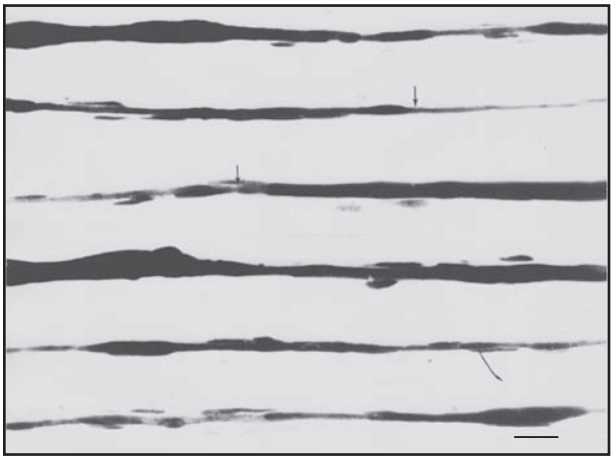

Figure 1 Consecutive segments of a teased fiber after osmication showing conspicuous irregularity of the myelin sheath (arrows) with long segments demyelinated or thinly remyelinated. Myelin sheath changes were so marked that most nodes of Ranvier were impossible to localize. Bar: 10 μm.

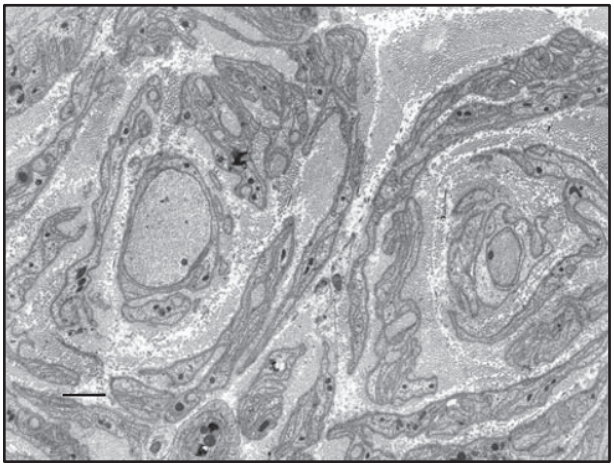

Figure 2 Electron micrograph of the same specimen (III-1) showing conspicuous onion bulb formations due to proliferation of Schwann cells (S) around demyelinated axons (A). Bar: 2 μm.

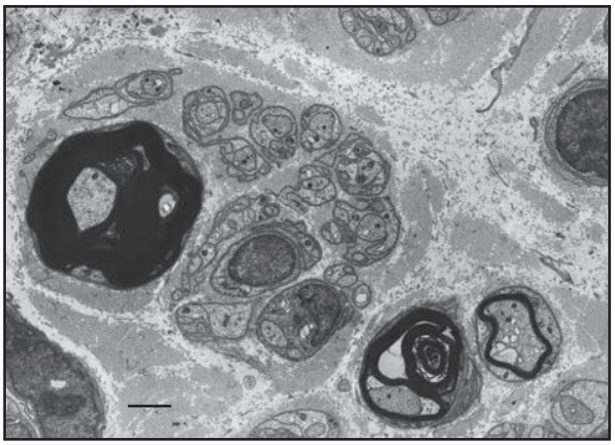

Figure 3 Electron micrograph of a nerve biopsy specimen showing a fiber with an abnormally thick and redundant myelin sheath (A) and preservation of unmyelinated fibers. Bar: 2 μm.

Summary

The Roussy–Levy disease deserves its eponym since it combines original clinical, pathological, and genetic features. Clinically, its early onset with pes cavus and predominant ataxia, tremor associated with very slow nerve conduction are different from the common patterns of CMT syndromes. Pathologically, the irregularity of the myelin sheath with extensive demyelination seems also very peculiar. The identification of a specific missense mutation in the third exon predicting an Arg131Lys substitution in the extracellular domain of the myelin protein MPZ underlines the originality of the disease. The Roussy–Levy kindred, which is clearly individualized morphologically and genetically, illustrates the overlaps between the phenotypes associated with the P_0 and PMP_{22} peripheral myelin protein disorders.

Hence, Roussy–Levy disease represents an original variant of hereditary neuropathy with a combination of characteristic clinical, pathological, and genetic features.

rTMS

K Udupa and R Chen, University of Toronto, Toronto, ON, Canada; Toronto Western Reasearch Institute, Toronto, ON, Canada

Definition and History

Repetitive transcranial magnetic stimulation (rTMS) refers to the application of recurring TMS pulses to a brain region. The first physiological effects of rTMS on speech and counting were reported by Pascual-Leone et al. in 1991. rTMS may work by modulating the cortical excitability. rTMS has been broadly classified as high (>1 Hz) and low (1 Hz or lower) frequency. High frequency stimulation may increase cortical excitability, whereas low frequency rTMS may transiently depress cortical excitability.

rTMS has been studied as a potential noninvasive treatment in several neurological and psychiatric disorders. In movement disorders, rTMS has been evaluated as an adjunctive treatment. Compared to medications, it has the theoretical advantage of modulating specific neural circuits. The neuromodulatory effects depend on the stimulation parameters such as cortical target, frequency, intensity, duration, number of sessions, and patient factors such as disease state, individual symptoms, and state of medication treatment.

Effects of rTMS in Movement Disorders

Parkinson's Disease (PD)

In normal subjects, 10 Hz rTMS of the prefrontal cortex induces dopamine release in the caudate measured by raclopride binding, whereas motor cortex stimulation causes dopamine release in the putamen. In PD, rTMS of the more affected motor cortex caused reduced dopamine release from the putamen compared to the less affected hemisphere.

High frequency rTMS may modulate underactive brain regions in PD patients and produce clinically significant motor improvement. It has been reported that 5 Hz rTMS to the motor cortex improved reaction time and performance in a grooved pegboard test during the stimulation, but a subsequent study did not confirm the results. Some studies also reported improved motor performance after 5 Hz rTMS in PD patients, but other studies reported no effect. The normal increase in motor evoked potential (MEP) size from 5 Hz rTMS was absent in PD patients and was partially restored with dopaminergic medications. High frequency stimulation of the supplementary motor area was found to worsen motor performance in one study. Some of these differences may be due to variations in the stimulus parameters and the brain area being stimulated. More recent studies suggested that repeated sessions of rTMS may lead to improvement in the motor symptoms, and the effects may last for 1 month. Several randomized controlled trials used rTMS to treat the PD motor symptoms. These results are promising, and further studies with larger number of patients and adequate controls are needed to evaluate rTMS as a potential treatment for PD.

Low-frequency rTMS to the motor cortex has also been reported to improve motor symptoms in PD. However, some studies used very low intensity of TMS (20% resting motor threshold) and others used very low frequency of stimulation (0.2 Hz). In these studies, control conditions such as sham stimulation were not performed or may not have been adequate. One study found no effect of 1 Hz stimulation. A relatively large study involving 85 PD patients and a realistic sham control found no significant effect of 0.2 Hz rTMS although there was a significant placebo effect. Thus, low-frequency rTMS appears to have no significant effect on parkinsonian motor signs. However, low-frequency rTMS is a potential treatment for levodopa-induced dyskinesia.

Dystonia

Neuroimaging studies in patients with focal dystonia demonstrated reduced activation of the primary motor cortex and hyperactivity in frontal nonprimary motor areas during writing. Therefore, measures designed to decrease the activities of nonprimary motor areas such as the premotor cortex and the supplementary motor area might improve the dystonic symptoms. In addition, TMS studies have found reduced cortical inhibition in the motor cortex in dystonia. Low-frequency (1 Hz) rTMS over both the premotor and motor cortices was found to reduce motor cortex excitability in normal subjects. Thus, treatment strategies in focal dystonia have involved application of rTMS over the primary motor cortex or the premotor cortex, with the goal of decreasing motor cortex excitability.

In patients with focal dystonia, 1 Hz rTMS for 30 min over the dorsal premotor cortex led to a greater decrease in regional cerebral blood flow (rCBF) in the lateral and medial premotor areas, putamen, and thalamus, and a larger increase in cerebellar rCBF than in controls. These widespread changes in regional synaptic activity of the motor system, observed at rest and during movement, may represent a physiological trait that characterizes patients with focal arm dystonia.

In writer's cramp patients, suprathreshold 1 Hz rTMS over the left primary motor hand area was found to increase the area of rest MEPs, which is different from the effects observed in normal subjects. Subthreshold 1 Hz rTMS also normalized short interval intracortical inhibition and prolonged the silent period, without affecting the stimulus–response curve in writer's cramp patients. In addition, there was temporary improvement in writing with reduced writing pressure.

Tremor

In a double-blind, crossover, placebo-controlled study, low-frequency suprathreshold rTMS of the cerebellum induced short-lasting ($<$1 h) improvement of essential tremor evaluated with both clinical and accelerometric measures. However, some of the effects could be mediated by activation of the peripheral nerve fibers. On the other hand, rTMS of the motor cortex may induce a cerebellar-like and postural tremor during stimulation in normal subjects, possibly by interfering with cerebellar afferent inflow to the motor cortex. The frequency of rTMS-induced tremor is independent of stimulus parameters. Another study showed that rTMS over the premotor

cortex but not to the primary motor cortex led to a decrease in the postural tremor, and 1 Hz rTMS over premotor cortex was reported to improve cortical tremor.

Myoclonus

Low-frequency (~1 Hz) inhibitory rTMS may be able to improve myoclonus by restoring intracortical inhibition. A few reported cases illustrated the potential efficacy of low-frequency rTMS to alleviate myoclonus. Thus, in cortical myoclonus with loss of cortical inhibition, low-frequency rTMS may be a therapeutic option.

Chorea

One study found that MEP size following rTMS trains of 10 stimuli at 5 Hz was unchanged in Huntington's disease (HD), in contrast to increased MEP amplitude in healthy volunteers. The excitability of facilitatory intracortical interneurons may be decreased in HD.

The above studies showed that rTMS can help to understand the pathophysiology of movement disorders and is a promising treatment for some movement disorders. Further investigations are needed to establish its therapeutic efficacy and role in the management of patients with movement disorders.

Glossary

aCGH (array-comparative genomic hybridization) – A microarray-based comparative genomic hybridization that detects genomic copy number variations with resolution higher than that of whole chromosomes.
ASO (allele-specific oligonucleotide) – A short molecule of synthetic DNA complementary to the sequence of a variable target DNA, acting as a probe for the presence of the target.
Contiguous gene syndrome – A disorder due to deletion of multiple gene loci that are adjacent to one another; characterized by multiple, apparently unrelated, clinical features caused by deletion of the multiple adjacent genes. Each of the individual genes within a contiguous region, when mutated, gives rise to a specific feature.
EST (expressed sequence tag) – A short piece of transcribed cDNA sequence.
Founder effect – The loss of genetic variation occuring when a new population is established by a reduced number of individuals from a larger population.
Ubiquitin–proteasome system – A cellular quality control system that tags misfolded proteins for refolding or degradation.

Definition and History

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) was first described in 1978 as an early-onset familial disease with prominent retinal striations. Over 300 patients have been identified, and most of their families originated in the Charlevoix-Saguenay region of northeastern Quebec in Canada. The frequency of several recessive diseases in these Canadian regions increased because of a founder effect caused by the settlement patterns of the late seventeenth to the mid-nineteenth centuries. The gene carrier prevalence was estimated to be 1 out of 22.

Disease presents in early childhood with ataxia and spasticity and progresses in the second and third decades. Retinal striations due to prominent myelinated nerve fibers have been variably reported in the kindreds but in the Quebec families they are always present. Deep tendon reflexes are increased. Distal weakness and atrophy and decreased sensation may occur. Some patients lack spasticity. Patients may become wheelchair-bound by their fifth decade, although this is variable. Sensory nerve conduction potentials are absent, and there is a high incidence of distal axonal neuropathy with slow onset and progression. Brain magnetic resonance imaging (MRI) shows vermian atrophy of the cerebellum as well as extensive cerebral cortical atrophy associated with secondary callosal attrition after the third decade. ARSACS patients show little cognitive impairment; they remain autonomous for all daily living tasks until the very late stages of evolution, despite their motor problems. The principal neuropathological signs are atrophy of the upper vermis and loss of Purkinje cells in the cerebellum.

SACS Locus and Its Evolution

The ARSACS (*SACS*) locus was mapped using Quebec samples to chromosome 13q11 by noting increased homozygosity for locus *D13S787*. Initially, the *SACS* gene was reported as a single, gigantic exon spanning 12.8 kb with an 11.5 kb open reading frame (ORF). Two *SACS* mutations were identified in Charlevoix-Saguenay ARSACS families, both predicted to cause the premature termination of the sacsin protein. An allele-specific oligonucleotide (ASO) based test is now used for ARSACS diagnosis or gene carrier detection for Quebec families at-risk. The human genome assembly revealed 5′ expressed sequence tags

(ESTs) with homology to *SACS*. Now, the gene has 9 exons with an ORF of 13.7 kb. It has a protein coding capacity of 4,759 amino acids, yielding a protein with an estimated molecular weight >520 kDa.

More recently, patients with diseases compatible with ARSACS have been widely recognized outside of Quebec. Although Quebec patients show a homogeneous phenotype, the disease in non-Quebec patients is often more heterogeneous. It is associated with a lower incidence of retinal hypermyelination, a juvenile or early adult onset, and slower disease evolution. A lack of spasticity and an association with intellectual impairment are also seen. To date, over 40 mutations have been found in patients from France, Holland, Belgium, Italy, Japan, Spain, Tunisia, and Turkey. All classes of mutations are represented: in addition to nonsense and missense, splice site mutations and small deletions have also been identified. Generally, the mutations are private (i.e., occurring only in a particular family or small population), but the occurrence of a founder effect for *SACS* mutation, originally useful in mapping and mutation identification in Quebec, is also observed in Dutch patients. The mutation mechanism resulting in ARSACS recently has further expanded. In a Belgian patient, a clinical condition compatible with ARSACS is caused by a heterozygous microdeletion on chromosome 13q12.12 was detected using aCHG. There is a de novo 1.54 Mb deletion encompassing SACS on one allele, while the other carries a novel missense mutation in the giant ninth exon. This microdeletion is thought to have occurred because of nonallelic homologous recombination between segmental duplications at the breakpoint-containing region. Two unrelated Italian patients also have been described with similar microdeletions that include *SACS* combined with private mutations on their other alleles. In addition to the *SACS* region deletion, these three cases also share moderate hearing impairment, the causes of which remain elusive. A recent publication suggests that ARSACS could also be a part of a contiguous gene syndrome, as both ARSACS and limb-girdle muscular dystrophy type 2C were seen in a patient because of a homozygous 584 kb deletion that contains both *SACS* and the immediate upstream gene, γ-sarcoglycan. Thus, worldwide, sacsinopathy is increasingly considered in the differential diagnosis of early-onset cerebellar ataxia with spasticity and peripheral neuropathy combined with other clinical signs.

The Sacsin Protein: Domain Structure and Function

While the initial sequence comparisons, based on the 11.5-kb ORF failed to detect extensive similarity of sacsin to known proteins, a 'DnaJ' motif was detected in the C-terminal. Both human and mouse proteins have three large segments with sequence similarity to each other, of which two show some similarity to the N-terminal domain of the Hsp90 class of heat-shock proteins. It was also noted that sacsin had similarity to the predicted product of an ORF in *Arabidopsis*. The impact of other analyses of the domain structure of sacsin has yet to be fully understood. Sacsin contains a C-terminal HEPN (higher eukaryotes and prokaryotes nucleotide-binding) domain. Although HEPN is present in many bacterial and archeabacterial species, sacsin is currently the only higher vertebrate protein known to contain it. Studies of the crystal structure of the HEPN domain from the bacterium *Thermotoga maritima* show that the domain belongs to a family of kanamycin nucleotidyl transferases. Another publication showed that sacsin has a domain with 35% sequence identity to hHR23 (human homolog of yeast Rad23); hHR23 is an interaction partner of XP-C (xeroderma pigmentosum) group C proteins, involved in global genome repair. Sacsin is the only protein outside the RAd23 family to have domain homology.

Sacsin is an apparent binding partner of a form of LDL receptor related protein (LRP1b), a protein often deleted in tumors. The same study also identified several other protein fragments with chaperone type functions as binding to LRP1B.

Once the final size of the predicted protein became unequivocal, important advances have been achieved in the understanding of sacsin function. A key publication was the elegant demonstration, using yeast two hybrid screens, that the protein is part of an ataxia and Purkinje cell degeneration network and that it shares interaction partners with other ataxia-causing proteins. The most recent and significant advance in understanding sacsin function was a publication that shows sacsin as a functional co-chaperone in the ataxin-1 pathway. When *SACS* mRNA function was inhibited by siRNA in cells that express polyglutamine (polyQ) expanded ataxin-1, this inhibition increased the cellular toxicity of the polyQ ataxin-1, suggesting that normal sacsin function is protective against the toxicity of PolyQ ataxin-1. This publication confirmed that the sacsin protein has a molecular weight of 520 kDa and that its expression is mainly neuronal. In rat brain, it is localized to the cytoplasm of neuronal cell bodies and to dendrites and axons. When the cerebellum was examined, the expression of both *SACS* mRNA and sacsin protein was highest in the Purkinje cells. The bioinformatic analysis of the N-terminal portion showed a ubiquitin-like domain (UbL) that is functional and interacts with components of the 20S proteasomal alpha subunit C8. In fact, the previously described homology to DNA repair protein Rad23 has been attributed to this UbL. Also demonstrated was that the sacsin 'DnaJ' domain can function in an in vitro assay of the Hsp70 chaperone system.

The current hypothesis of sacsin function is that it may act as a molecular scaffold for the assembly of a specific

protein complex and that the regulation of this complex requires the integration of molecular chaperone machinery and the ubiquitin–proteasome system. This hypothesis now opens new avenues of investigation to determine the specific molecular mechanism for each of the clinical signs observed, with the overall aim of developing treatments.

SCA1

D A Hall, University of Colorado, Denver, CO, USA

Glossary

Contiguous – Multiple gene loci or nucleotides that are adjacent to one another.
Gain-of-function – A mutation that confers new or enhanced activity on a protein.
Mosaicism – The condition in which an organism has two or more cell populations that differ in genetic makeup.
Polymorphic – Normal variation in a sequence of genetic information.
Transmission – The transfer of genetic information from genes to another generation, or from one location in a cell to another. For example, maternal transmission is inheritance from the mother.

Definition and History

Spinocerebellar ataxia type 1 (SCA1) is a progressive autosomal dominant disorder with cerebellar, pyramidal, and bulbar symptoms caused by a CAG expansion in the *SCA1* gene. In 1974, Yakura reported linkage of a form of autosomal dominant cerebellar ataxia with the Human Leukocyte Antigen (HLA) locus, and Jackson, in 1977, confirmed that the locus was linked to chromosome 6. In 1991, both the Orr and Zoghbi groups determined that the disease was tightly linked to genetic marker D6S89. A unique 20 year collaborative arrangement between the Orr and Zoghbi groups led to the discovery of a repeated CAG trinucleotide on the short arm of chromosome 6. With positional cloning, the *SCA1* gene was mapped, and the groups have gone on to create mouse models and elucidate much of the pathogenesis of this disease.

Pathogenesis/Pathophysiology

SCA1 is caused by a repeat expansion in the *SCA1* gene, which has two coding exons, and is located at 6p23. Normal individuals contain 6–44 CAG repeats, while affected individuals have 39–82 CAG repeats. Expansion of the repeat size depends on transmission, with 63% of paternal transmissions resulting in an increased repeat number and 68% of maternal transmissions resulting in no change or a decrease of repeat number. The CAG repeat is interrupted with a CAT in 98% of normal individuals. When this interruption is missing, the contiguous CAG repeat is more unstable and tends to expand. In the intermediate range, individuals with 39 uninterrupted repeats develop the SCA1 phenotype, but individuals with 39 interrupted repeats do not. Thus, the molecular diagnosis of SCA1 depends not just on repeat size, but on the presence of CAT interruptions as well.

The size of the CAG repeat correlates with age of onset, with the largest allele sizes seen in juvenile cases. Variation in severity and duration of disease also correlate with CAG repeat size. Offspring of an affected father trend toward having a shorter disease course and earlier age of death than offspring of affected mothers. In addition, for the same number of repeats, disease onset is earlier in men than it is in women. Disease penetrance in affected women appears to be incomplete.

The CAG repeat does not exhibit somatic mosaicism like other repeat expansions, such as muscular dystrophy or fragile X syndrome. The *SCA1* gene codes for the ataxin-1 protein. This protein, an RNA binding protein, is predominantly nuclear in neuronal brain cells, but both neuronal and cytoplasmic in Purkinje cells. In the setting of a CAG expansion in the *SCA1* gene, nuclear aggregates containing the polyglutamine protein accumulate in patient neurons, especially in the pons and substantia nigra. Mutant ataxin-1 may disrupt the function of nuclear matrix-associated complexes involved in nuclear RNA metabolism. A dominant toxic gain-of-function model has been proposed for pathogenesis, but it is unclear how the function of ataxin-1 would support this model.

Pathology shows marked loss of Purkinje cells with Bergmann's gliosis and torpedo-like formation of axons. There is severe degeneration in the olivocerebellar and dentatorubral pathways and severe atrophy of cranial nerve III and XII nuclei, with atrophy occurring at the base of the pons and in the middle cerebellar peduncles. Loss of neurons in the dorsal nucleus of raphe and depigmentation of the substantia nigra also occurs. There is extensive loss of motor neurons in the anterior horns and Clarke's nucleus. In addition, there is a loss of dendrites, reduced dendritic arbors, decreased formation of proximal spines, and abnormal accumulation of neurofilaments in affected patients. Despite a lack of parkinsonian features in the disorder, there is a marked reduction of dopamine and tyrosine hydroxylase in autopsied putamen of affected patients, with moderate to severe depopulation of pigmented dopaminergic cell bodies.

Epidemiology/Risk Factors

Unlike many of the other spinocerebellar ataxias, SCA1 has been reported widely around the world in various populations, with varying prevalence rates (**Table 1**).

Clinical Features and Diagnostic Criteria

The mean age of onset of SCA1 is $\sim 34 \pm 9$ years and duration of disease averages 14 ± 7 years. The disorder is characterized by ataxia, bulbar signs, and pyramidal involvement. In the first couple of years of illness, the typical symptoms

Table 1 Selected prevalence studies in SCA1

Population	*Movement disorder*	*Number of patients*	*Prevalence of SCA1*	*Author*
American	ADCA, ARCA, sporadic, unknown	361 families	10/361 (5.6%)	Moseley
Dutch	ADCA families	145 famiies, 391 patients	14/145 (9.6%)	van de Warrenburg
Italian	ADCA	116 families, 248 patients	28/117 (24%)	Filla
British	SCA	146	2/146 (1.4%)	Leggo

ADCA, Autosomal dominant cerebellar ataxia; ARCA, Autosomal recessive cerebellar ataxia; SCA, spinocerebellar ataxia.

include impaired tandem gait, mild limb ataxia, hypotonia, hyperreflexia, paresis of upward or lateral gaze, and nystagmus. In the next 5 years, patients develop worsening limb ataxia, truncal ataxia, dysarthria, and ophthalmoplegia. Amyotrophy (or pes cavus) can be seen in 57%, and dysphagia in 71% at this stage of disease. Ten years and later into the illness, dysphagia and dysphonia become more pronounced. Spasticity with hypertonia and babinski signs is present. Tongue paresis, atrophy with fasciculations, and muscular wasting can occur. Some patients develop intellectual deterioration, with prominent executive dysfunction. Late in the disease, affected patients may have euphoria, emotional lability, crying, irritability, or aggressiveness.

A large affected population with 225 SCA1 ataxic individuals showed that progressive cerebellar deficiency was present in all patients, but that associated signs (dysphagia, tongue atrophy, ophthalmoparesis, and diffuse muscular atrophy) were more likely with higher repeat numbers. Lower motor neuron involvement was seen in 15 of 22 patients with repeat sizes greater than 52. In at risk individuals, symptoms may include occasional unsteadiness, tremor, slight ataxia, or dysarthria. Juvenile onset cases (less than 18 years), that are seen in some kindreds, have larger repeat sizes and manifest typical SCA1 symptoms.

Differential Diagnosis

The two most similar spinocerebellar ataxias to SCA1 are SCA2 and SCA3. However, SCA2 tends to have earlier onset and a prominent sensorimotor neuropathy. SCA3 has many of the cerebellar and bulbar features of SCA1, but in addition, individuals have more oculomotor signs (reduction in the vestibulo-ocular reflex, bulging eyes, etc.) and may have dopamine-responsive dystonia. The other SCAs are less likely, with severe sensory disturbances common in SCA4; SCA5, SCA11, and SCA16 being more pure cerebellar syndromes; SCA10 having an association with epilepsy; and SCA13 and SCA14 having very slow progression. Tremor is seen in SCA8 and is pronounced in SCA12. Nonspinocerebellar ataxia diseases that may mimic some features of SCA1 include Huntington disease and spinal and bulbar muscular atrophy. However, both of these disorders have characteristically fewer cerebellar signs.

Diagnostic Work-up/Tests

EMG can show a mild decrease in motor and sensory nerve conduction velocities, in addition to fibrillation potentials. MRI shows early midline atrophy of the cerebellum. Later in the disease, severe cerebellar atrophy with brainstem involvement is common. Morphometry shows decreased size of the pons, cerebellar hemispheres, middle cerebellar peduncle, and medulla; with an increase in fourth ventricle size Single Photon Emission Computed Tomography (SPECT) shows a profound decrease in the *N*-acetylaspartate/Creatine (NAA/Cr) ratio in clinically affected carriers in the pons and cerebellum, which may reflect loss of neuronal variability in that region.

Management

A potential cure for SCA1 may involve altering the misfolding or nuclear transport of mutant ataxin-1. Recently published, lentivector mediated expression of Collapsin Response Associated GTpase (CRAG), a new guanosine triphosphate, in Purkinje cells of SCA mice cleared polyglutamine aggregates and rescued the mice from ataxia. A study in SCA1 transgenic mice showed that a creatine supplemented diet resulted in maintanence of Purkinje cell numbers, but did not improve or delay the development of ataxia. SCA1 knock-in mice receiving lithium had improved motor coordination, learning and memory, and neuropathologically, lithium treatment attenuated the reduction of dendritic branching in mutant hippocampal pyramidal neurons. Symptomatic treatment for gait ataxia may include medications that modify monoamine transmission, such as amantadine and buspirone, or physical therapy for gait training. Recently, case reports in three patients with ataxia show that varenicline, a partial agonist selective for $\alpha_4\beta_2$ nicotinic acetylcholine receptors and prescribed for tobacco cessation, may be helpful for gait ataxia. Dysphagia is best managed by dietary modifications.

Prognosis

Life expectancy is shortened in SCA1, with average age at death reported to be between 43.2 and 54.1 years. With repeat sizes greater than 52, individuals are more likely to have motor neuron involvement leading to progressive respiratory failure.

SCA2

S Furtado, University of Calgary, Calgary, AB, Canada

Glossary

CAG repeat – Genetic mutation characterizing the trinucleotide repeat disorders whereby abnormal numbers of CAG repeats produce the clinical syndrome.
Cerebellar ataxia – Syndrome of cerebellar and often associated brainstem dysfunction with progressive dysarthria, oculomotor abnormalities, and gait and limb ataxia.
Parkinsonism – Syndrome similar to idiopathic Parkinson's disease, characterized by some shared features such as bradykinesia, rigidity, and possibly resting tremor; may or may not respond to antiparkinsonian medications.
SCA2 – Spinocerebellar ataxia type 2; inherited autosomal dominant neurodegenerative movement disorder usually presenting as a progressive cerebellar syndrome with CAG repeat expansion on chromosome 12.

Definition and History

Spinocerebellar ataxia type 2 (SCA2) is an inherited neurodegenerative disorder; patients with this disorder typically demonstrate cerebellar dysfunction. The disorder is characterized by a CAG repeat expansion on chromosome 12, genetically identified in 1996. The spinocerebellar ataxias are a group of autosomal dominant inherited cerebellar ataxias. SCA types 1, 2, 3, 6, 7, and 17 are characterized by a CAG repeat expansion in the coding region of the gene. Prior to the discovery of the genetics, these dominantly inherited ataxias fell under the autosomal dominant cerebellar ataxias (ADCAs) classification, types 1–4; later on, in the absence of a family history, the multiple systems atrophy (MSAc) rubric might have been used. However, as Anita Harding suggested of the ADCAs, it is very difficult to separate these disorders on clinical grounds and the discovery of the genetics of the spinocerebellar ataxias (CAG repeat expansions and other genetic mutations) led to a new clinical classification. It should be noted that there are many other inherited

spinocerebellar ataxias (e.g., SCA12-nonconding CAG expansion; Friedreich's ataxia-GAA repeat expansion), episodic ataxias (e.g., channelopathies), or cerebellar syndromes of other causes (e.g., Marinesco–Sjogren syndrome).

Pathology/Pathophysiology/Genetics

The diagnosis of SCA2 is made by detection of a CAG repeat expansion, greater than 34 repeats, on chromosome 12q24.1. The CAG repeat is unstable, resulting in an earlier age of onset with successive generations (i.e., anticipation). The CAG repeat expansion in the coding region of the gene results in a polyglutamine expansion.

The parkinsonian syndrome associated with SCA2 tends to be characterized by a CAG repeat interrupted by CAA insertions, while the cerebellar syndrome of SCA2 is not associated with CAA interruptions. These CAA/CAG interruptions in the parkinsonian variant of SCA2 are thought to contribute to the relative stability of the repeat over generations, and in general, the parkinsonian variant is associated with a smaller number of repeats than the cerebellar variant. However, anticipation is associated with both variants, suggesting that anticipation may be due to factors other than the expansion of the repeat. The CAG repeat produces a polyglutamine expansion resulting in the expression of the protein ataxin-2.

The pathology of the cerebellar variant of SCA2 shows degeneration of the cerebellum and brainstem, but also the involvement of other areas of the brain, including substantia nigra, striatum, thalamus, and frontal cortex. The degeneration of the cerebellum is reflected in the loss of Purkinje cells in the cerebellar vermis and hemispheres. Ataxin-2 is infrequently detected in neuronal inclusions in comparison to other triplet repeat diseases ataxin-2 is not restricted to cerebellum but is also found in other areas of the brain. The role of ataxin-2 has not been fully defined, but the protein may play a role in RNA metabolism and the plasma membrane.

Epidemiology

In general, the spinocerebellar ataxias are relatively rare neurologic disorders. However, the frequency of each SCA varies with different ethnic populations. SCA2 has a higher prevalence in Caucasian than in Japanese populations; the prevalence of SCA2 is even higher in Cuban and southern Italian populations. In Canada and the United States, the most common (and diagnosable) SCAs are 1, 2, and 3. In the Finnish population, SCA3 is relatively uncommon, while SCA8 is more common. The prevalence of the parkinsonian variant is difficult to estimate, due in part, to underdiagnosis, but probably ranges from 1.5% to 8% of cases of inherited parkinsonism.

Clinical Features and Diagnostic Criteria

The typical cerebellar presentation of SCA2 involves the gradual onset of a cerebellar disorder involving impairment of eye movements, cerebellar dysarthria, limb and gait ataxia, and other neurologic signs mentioned previously. Other neurologic features associated with SCA2 include early slowed saccades, amyotrophy, peripheral neuropathy, dystonia, and myoclonus. A small subgroup of SCA2 patients has a predominantly parkinsonian presentation. The disease has a variable age of onset, dependent on the size of the CAG repeat expansion; the age of onset can range from childhood to late adulthood and is inversely associated with the size of the triplet repeat. The disease is inexorably progressive and results in significant disability, with the affected patient confined to a wheelchair in the later stages of the illness.

Differential Diagnosis and Diagnostic Workup

The diagnosis of SCA2 rests upon the identification of a CAG repeat expansion on chromosome 12. However, there is a differential diagnosis to be considered. A patient presenting with a cerebellar disorder should have a careful history taken regarding the onset and the rate of clinical progression. A rapid rate of progression might suggest a paraneoplastic disorder or prion disease. Family history of balance or gait disturbances as well as a family history of neurologic disorders especially parkinsonism should be reviewed. Documentation of alcohol consumption is often overlooked. The past medical history should also include any inflammatory or autoimmune disorders and a current list of medications. Workup for the ataxias may include neuroimaging (MRI) of the brain and spine, available genetic testing for cerebellar disorders, vitamin E level, testing for celiac disease, and vitamin B12 level; testing for paraneoplastic syndromes should be guided by the rate of clinical progression.

The clinical exam will also further guide the clinician in the diagnostic workup: in addition to cerebellar signs, early slowing of saccades is suggestive of SCA2; systemic signs of neoplasm would point toward a paraneoplastic syndrome; associated rapid cognitive decline may be indicative of a prion disease; and a primary midline ataxia referable to the vermis may point to excessive alcohol consumption.

A patient presenting with levodopa-responsive parkinsonism or parkinsonism with a family history of the same may be tested for SCA2 and SCA3; testing for α-synuclein, parkin, and LRRK2 may be considered, although typically not widely available. Drug-induced parkinsonism should be ruled out.

Management

At present, there are no meaningful pharmacologic treatments for the cerebellar variant of SCA2; treatment of the illness is primarily supportive, involving assessment and treatment of swallowing, balance issues, and bladder issues. Swallowing difficulties, bladder continence issues, and autonomic difficulties are present in later stages of the illness.

Those patients presenting as levodopa-responsive parkinsonism without other signs, or parkinsonism associated with other features, including restless leg syndrome, dystonia, cerebellar signs, or postural tremor. These patients can respond to use of traditional antiparkinsonian medications, including levodopa, dopaminergic agonists, and botulinum toxin. The relatively small numbers of identified parkinsonian SCA2 patients makes a general clinical prognosis difficult. Positron emission tomography in these patients shows a profile identical to that of Parkinson's disease. It has become clear that the clinical profile of SCA2 is much wider than previously thought and that patients with a familial history of parkinsonism should be tested for SCA2.

In patients with an identified SCA2 mutation, genetic counseling and testing should be offered to adult children who are at 50% risk of inheriting the disorder.

SCA3, Machado–Joseph Disease

G Stevanin, A Durr, and A Brice, CR-ICM UMR_S975 (formerly U679), Groupe Hospitalier Pitié-Salpêtrière, Paris, France

Glossary

ADCA – Autosomal dominant cerebellar ataxia is a heterogeneous group of inherited neurodegenerative diseases.
CAG – Cytosine–adenosine–guanosine trinucleotide encoding glutamine at the protein level.
MJD – Machado–Joseph disease designates a clinical and genetic entity of ADCA.
SCA3 – Spinocerebellar ataxia 3 designates the locus on chromosome 14 and the disease, which is also commonly called Machado–Joseph disease.

Definition and History

Autosomal dominant cerebellar ataxias (ADCA) comprise a wide spectrum of diseases with different clinical and neuropathological profiles. Machado–Joseph disease (MJD) or spinocerebellar ataxia 3 (SCA3) is the most frequent form of these diseases worldwide. MJD was initially described in patients of Portuguese-Azorean ancestry variably associating pyramidal, peripheral nerve and extrapyramidal signs, ophthalmoplegia, and dysphagia. Its locus was mapped to chromosome 14q in Japanese families with possible Portuguese origin (MJD locus) and subsequently to the same region in French families with similar clinical

presentation (SCA3 locus). Despite the absence of Portuguese ancestry in the French families and several clinical differences attributed to ethnic background, the mapping results suggested a mutation in the same gene in both clinical entities. This hypothesis was confirmed when the mutation, a CAG repeat expansion in the *MJD1* gene, was found in both groups of families and in large series of patients from various countries.

Pathogenesis/Pathophysiology

Molecular Bases

Because of the nature of the mutations, SCA3/MJD is one of the polyglutamine-coding $(CAG)_n$ repeat expansion diseases that shares common properties: (1) onset mostly in adulthood; (2) progressive, unremitting, and usually fatal disease course; (3) clinical symptoms appearing above a threshold number of CAG repeats (SCA3/MJD: >52 units, normal repeat size: 12–44 repeats, incomplete penetrance for 45–51 repeats); (4) strong inverse correlation between the number of CAG repeats and the age at onset; (5) instability of the repeat sequence that increases in size during transmission resulting in genetic anticipation; (6) ubiquitous expression of the protein; and (7) aggregation of the pathological protein into ubiquitinated neuronal intranuclear inclusions in several affected as well as in nonaffected brain structures.

Pathophysiology

Animal and cellular models have been very useful for exploring the pathophysiology. Directed expression of a human cDNA encoding the *SCA3* gene with expanded CAG repeats causes Purkinje cell degeneration and ataxia in transgenic mice and neuronal degeneration in flies. That expansion alters the conformation of polyglutamine tracts in the product of the gene, ataxin-3, which could explain the formation of insoluble intranuclear aggregates that have also been detected in the brains of patients and models, and appear to constitute a common signature of polyglutamine disorders. However, these aggregates are also present in nonaffected neuronal and nonneuronal tissues in various models, indicating that their presence is not sufficient to cause cell death and/or the phenotype. Despite these unifying features of polyglutamine diseases, clinical symptoms are diverse, suggesting that protein sequences outside the polyglutamine tract contribute to the pathogenesis, and that normal functions of ataxin-3 might be partially involved in the specificity of the degenerative process. It has been suggested that ataxin-3 could be involved in the ubiquitin proteasome system with characteristics of an ubiquitin protease and in transcription regulation as a transcriptional repressor via interaction with the major histone acetyltransferase CREB-binding protein and histone deacetylase 3. Indeed, these functions have been found to be altered in models.

Promising therapeutic avenues that have been successfully applied to SCA3 models include RNA interference and increased autophagy.

Epidemiology/Risk Factors

Although in most countries SCA3/MJD is the major locus for autosomal dominant forms of cerebellar ataxia (~30%), its relative frequency varies widely according to the geographical origin; SCA3/MJD represents 80% of affected families in Portugal (SCA3/MJD prevalence reaches 1 out of 4000 in the Azores Islands) and is also frequent in Germany (49%), Japan (39%), and France (30%), but has only exceptionally been detected in Italy. These differences are the result of regional founder effects and migrations with a major lineage that may have occurred more than 5000 years ago in Asia and were transmitted by Portuguese sailors to Europe and then to the Americas.

De novo mutations from the expansion of large normal alleles are rare in ADCA and have only been reported in SCA7 patients. Even if never observed in SCA3, this is also likely the case since pathological flanking haplotypes are also found associated with large normal alleles of over 33 repeats.

Clinical Features and Differential Diagnosis

Clinical Presentation in Patients

Onset mainly occurs during the fourth and fifth decades but is known to manifest as early as 5 years and also as late as 70 years of age. However, compared to other forms of ADCA, cases with onset before age 20 are exceptional. No single clinical sign is specifically associated with SCA3/MJD compared to other SCAs (see **Table 1**). However, characteristic combinations of several signs in affected family members characterize the phenotype of SCA3/MJD: cerebellar ataxia associated with pyramidal signs, some dystonic postures, and axonal neuropathy. SCA3/MJD patients, such as SCA6 patients, frequently present with cerebellar oculomotor signs such as saccadic smooth pursuit, gaze-evoked nystagmus, and diplopia. Myokymia and bulging eyes are not specific for SCA3/MJD and can be found in SCA1 and 2 in equal frequencies. Interestingly, some patients present with a parkinsonian syndrome responding well to levodopa treatment and showing treatment complications such as fluctuations and dyskinesias, reminiscent of typical Parkinson's disease. This can be associated with orthostatic hypotension as seen in multiple system atrophy.

Table 1 Frequency of neurological signs associated with SCA3/MJD mutations (based on the authors' observations)

Cerebellar syndrome	+++
Cerebellar dysarthria	+++
Extensor plantar reflexes	++
Brisk reflexes	++
Diminished or abolished reflexes	++
Spasticity in lower limbs	++
Wasting	++
Extrapyramidal syndrome/dystonia	+
Myoclonus	±
Gaze evoked nystagmus	+++
Supranuclear ophthalmoplegia	++
Decreased saccade velocity	+
Decreased visual acuity	0
Bulging eyes	+
Myokymia	+
Decreased vibration sense at ankles	+
Dysphagia	++
Sphincter disturbances	++
Cognitive difficulties	+
Tremor	±
Axonal neuropathy	++
Decreased hearing acuity	0

Frequency: 0 = absent; ± = rare; + = 5–24%; ++ = 25–74%; +++ = 75–100%.

Brain Imaging and Neuropathological Lesions

Cerebral magnetic resonance imaging of SCA3/MJD cases is characterized by severe pontine and spinal cord atrophy with moderate cerebellar vermian atrophy.

At autopsy, lesions of the basal ganglia, intermediolateral column, and Clarke's column are severe compared to other SCAs, but the Purkinje cells, inferior olives, and posterior column are spared. This profile varies as a function of CAG repeat size.

Factors Influencing Intrafamilial Clinical Variability

The major factors that influence phenotype are the size of the repeat expansion and disease duration at the time of examination:

1. the frequency of clinical signs such as dysphagia or sphincter disturbances increase with disease duration.
2. CAG repeat size influences the age of onset and clinical profile. There is an inverse correlation between the age of onset and CAG repeat length in SCA3, with a correlation coefficient varying from −0.67 to −0.92. The repeat length only partially explains the variability in age of onset and other factors, including normal allele size and homozygosity, that influence clinical onset. In addition, the frequency of pyramidal signs increases with the size of the expanded repeat, whereas the frequency of altered vibration sense decreases. Late onset SCA3 patients often present with peripheral neuropathy (areflexia and wasting) and have small CAG expansions. Some patients with small SCA3/MJD expansions can present with late onset DOPA-responsive parkinsonism. The presence of mild axonal neuropathy helps to distinguish these patients from patients with idiopathic Parkinson's disease. On the other hand, SCA3 patients with large expansions usually suffer from dystonic postures.

Management

Molecular analysis permits routine diagnostic testing of affected individuals. DNA testing is offered to asymptomatic at-risk individuals in specialized centers with multidisciplinary teams including a geneticist, psychologist, and neurologist. Therapy is symptomatic, mainly targeting the most involved systems: physiotherapy for gait and balance, exercises for cerebellar involvement, levodopa therapy for parkinsonism, botulinum toxin injections for dystonia, and spasticity. Depression is frequent in SCA3/MJD and should be treated, and psychological support should be proposed to the patient and the family. The number of CAG repeats on the expanded allele is a major factor, but given individual variations, age of onset cannot be precisely predicted from the number of CAG repeats.

SCA4

D A Hall, University of Colorado, Denver, CO, USA

Glossary

Allelic – Allelic of or relating to alleles. An allele is one member of a pair or series of genes that occupy a specific position on a specific chromosome.
Anticipation – The phenotype of the mutant allele increases in severity as it is passed down the generations.
Polyglutamine – CAG, which is a trinucleotide, codes for an amino acid called glutamine. When CAG repeats are expanded pathologically in the human genome, these repeat disorders are collectively known as polyglutamine diseases.

Definition and History

Spinocerebellar ataxia type 4 (SCA4) is an autosomal dominant disorder characterized by a prominent sensory axonal neuropathy, cerebellar, and pyramidal tract signs. A large family with the disorder in Utah and Wyoming led to one of the first major descriptions of SCA4 from the Flanigan group. Subsequent work in SCA4 has also been done in a large affected family from Germany, with multiple studies reported by Hellenbroich. In 1954, Biemond described six patients in a family with severe sensory loss and ataxia, with degeneration of the posterior columns on pathology. He termed the disorder 'ataxie héréditaire des cordons posterieurs.' Two siblings were then reported in 1997 with a similar phenotype, but it is not clear that these cases or the Biemond cases are SCA4 due to the lack of linkage studies in these cases.

Pathogenesis/Pathophysiology

SCA4 has been localized to a 3.69 cM interval on chromosome 16q24. A study investigating 34 candidate genes in this region involved in protein degradation or correlated with neuronal inclusions did not result in detection of the causative mutation for SCA4. Once the original descriptions of the linkage to 16q were reported, a number of Japanese groups reported a pure cerebellar syndrome also linked to this region. The causal mutation was discovered

in 2005 for this Japanese syndrome and was a heterozygous C-to-G single nucleotide substitution in the *puratrophin*-1 gene in the 16q region. Due to the lack of sensory neuropathy in the Japanese ataxia families, it is likely that that the Japanese ataxia and SCA4 are not allelic.

Anticipation can be seen in some individual pedigree branches, but is not universally present. The five generation German family did show some anticipation with the average age of onset of 53.3 ± 6.7 years in the first generation, average age of onset of 37.4 ± 11.7 in the fourth generation, and average age of onset of 25.3 ± 3.3 in the fifth generation. Pathology of one of the affected German SCA4 individuals showed widespread cerebellar and brainstem neurodegeneration. There was marked neuronal loss in the substantia nigra, ventral tegmental area, multiple cranial nuclei, the nucleus raphe interpositus, dorsal column nuclei, and the inferior olive. In addition, there was severe neuronal loss in the Purkinje cell layer of the cerebellum and in the cerebellar fastigial nucleus. Pathology of two Italian patients with possible SCA4 showed similar findings, with abnormalities primarily in the cerebellar Purkinje cell layer, dorsal root ganglia, and posterior columns.

The antipolyglutamine antibody 1C2 failed to detect any polyglutamine-related immunoreactivity in the abnormal central nervous system regions. This may suggest that the disease is not related to a CAG or glutamine expansion or that the expansion is located in a nontranscribed region of the gene.

Epidemiology/Risk Factors

The prevalence for SCA4 has not yet been well determined in ataxia populations as the gene causing the disorder has not been discovered. The disorder is likely to be rare due to its description in only a couple of families to date.

Clinical Features and Diagnostic Criteria

The median disease onset is 39.3 years with a range of 19–59 years. The earliest noted symptom in affected individuals is gait disturbance, but a subclinical neuropathy may be the first true sign of disease. Subsequently, difficulty with fine motor tasks and dysarthria occur and eventually patients develop gait ataxia severe enough to lead to wheelchair dependence. All individuals with SCA4 have sensory findings, with 100% having decreased sensation and vibration and loss of ankle jerks. The majority (95%) of patients also have decreased pinprick, with a smaller percentage having complete areflexia (25%), extensor plantar responses (20%), and distal weakness (20%). Gait ataxia is a characteristic feature in 95%, with the majority of patients having limb dysmetria as well. Oculomotor signs are less frequent, with slight saccadic pursuits occurring in 15%.

In two Italian patients with possible SCA4, decreased pinprick and light touch was seen in the distribution of the trigeminal nerve, with one patient having sensory loss on the anterior chest and abdomen. Vertical gaze evoked rotatory nystagmus was seen in one patient. Detailed descriptions of the five generation German family confirmed previous reports of clinical features with 100% of the affected individuals having ataxia, dysmetria, dysarthria, absent sural sensory nerve action potentials, and cerebellar atrophy on MRI/CT. Less frequently seen were saccadic pursuits in 57%, reduced compound motor action potentials in 38%, and extensor plantar response in 7%.

Differential Diagnosis

Other diseases that may present similarly to SCA4 include Friedreich ataxia (FA) due to the fact that both diseases share areflexia and dorsal column involvement. Ataxia with isolated vitamin E deficiency (AVED) may also present similarly and can be evaluated by serum vitamin E levels. A family history may help to determine inheritance pattern, with an autosomal recessive pattern seen in both FA and AVED. SCA 1–3, 7–8, and dentatorubropallidal luysian atrophy do not typically have severe sensory disturbances. SCA 5–6 and 11 are pure cerebellar disorders, making them less likely. Individuals with SCA12 and the fragile X-associated tremor/ataxia syndrome have kinetic tremor. SCA10 is associated with epilepsy, SCA13 with mental retardation, SCA16 with axial myoclonus, and SCA17 with dementia.

Diagnostic Work-up/Tests

Nerve conduction tests are abnormal in most affected individuals, with most having absent sural sensory nerve action potentials and a smaller percentage lacking radial sensory nerve action potentials. In an Italian man with possible SCA4, median and tibial nerve sensory evoked potentials were not elicitable and sural nerve biopsy showed markedly reduced myelinated axons. MRI shows mild dilatation of the sulci and ventricles and mild atrophy of the cerebellar folia in earlier stages of the disease. Diagnostic testing for SCA4 is not yet available as the causal gene mutation has not yet been identified.

Management

It is unknown whether SCA4 represents a polyglutamine disorder and therapies directed to the pathophysiology are likely to be lacking until the gene is discovered. Symptomatic treatment for gait ataxia may include

medications that modify monoamine transmission, such as amantadine and buspirone. However, studies with these medications have been small, with one being open label. Recently, case reports in three patients with ataxia show that varenicline, a partial agonist selective for $\alpha4\beta2$ nicotinic acetylcholine receptors and prescribed for tobacco cessation, may be helpful for gait ataxia. Despite sensory symptoms in the disorder, most patients do not complain of pain. Dysphagia is best managed by dietary modifications and individuals with nystagmus may respond to a variety of medications reported effective in case reports.

Prognosis

Prognosis for the disorder has not been well described due to the small sample size of affected individuals, but wheelchair dependence later in the disease is common.

SCA5

G Stevanin and A Durr, Groupe Hospitalier Pitié-Salpêtrière, Paris, France

Glossary

ADCA – Autosomal dominant cerebellar ataxia is a heterogeneous group of inherited neurodegenerative diseases.

CAG – Cytosine–adenosine–guanosine trinucleotide encoding glutamine at the protein level.

SCA5 – Spinocerebellar ataxia 5 designates the locus on chromosome 11, and the disease.

β-III Spectrin – Protein component of the cellular cytoskeleton, encoded by the spectrin β nonerythrocytic 2 (*SPTBN2*) gene.

Definition and History

Spinocerebellar ataxia type 5 (SCA5) is a rare form of autosomal dominant cerebellar ataxia (ADCA), a clinically and neuropathologically heterogeneous group of diseases for which different genes have been identified. Polyglutamine-coding $(CAG)_n$ repeat expansions have been identified as responsible for the disease in six of the most frequent causative genes, while, more recently, conventional mutations have been reported in six other genes, including *SPTBN2*, responsible for SCA5.

The SCA5 locus was assigned in 1994 to the centromeric region of chromosome 11 in a single large American

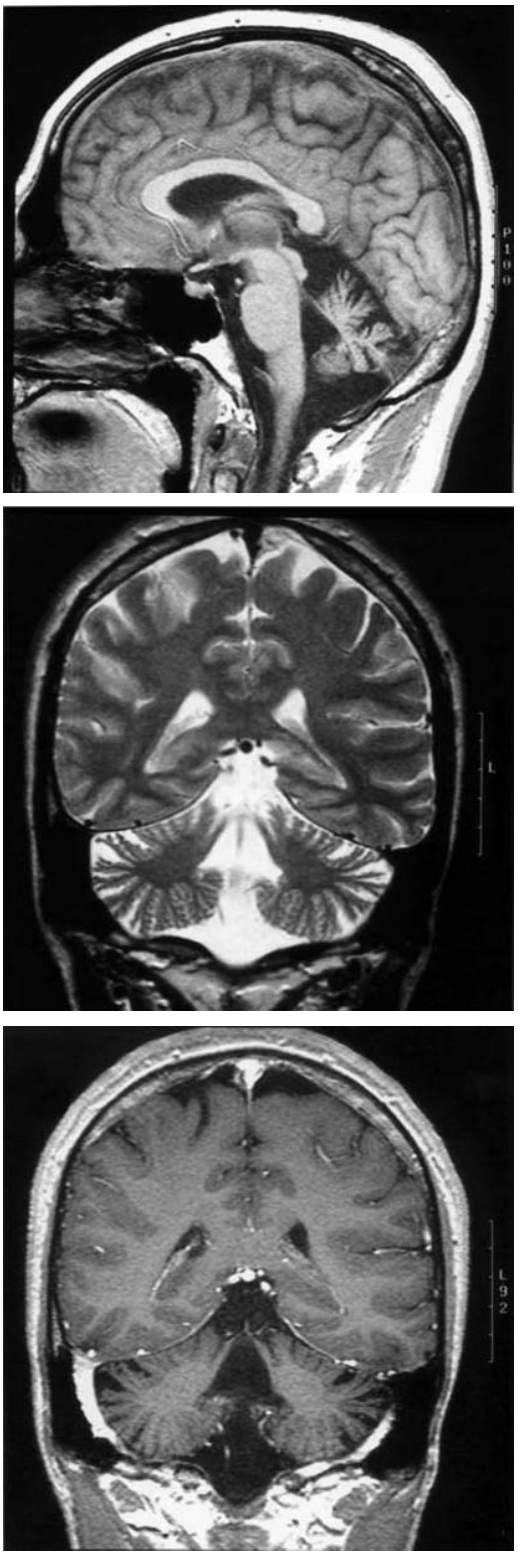

Figure 1 Sagittal T1-(top) and coronal T2- and T1-(middle, bottom, respectively) weighted magnetic resonance scans of a SCA5 patient with 4 years of disease duration showing severe atrophy of the vermis and hemispheres with sparing of the brainstem. Reproduced from Stevanin et al. (1999) Clinical and MRI findings in spinocerebellar ataxia type 5. *Neurology* 53: 1355–1357, with permission from Wolters Klumer Health (http://lww.com).

family descending from the grandparents of President Lincoln, which suggested that his gait and coordination signs were in fact early stages of SCA. Two additional families with European ancestry were subsequently reported in France and Germany, which helped narrow the disease locus to a 5.15 Mb interval in 11q13. Following a decade of positional cloning efforts, three different mutations in the *SPTBN2* gene, encoding β-III spectrin, were identified in these three large families, which highlight the defect of the cellular cytoskeleton as a new mechanism leading to cerebellar degeneration.

Pathogenesis/Pathophysiology

Three different SPTBN2 mutations have been identified in affected members of the three SCA5 families: (1) a 39-bp deletion in exon 12, leading to an in-frame deletion in one of the spectrin repeat domains (p.E532_M544del) in the American kindred, (2) an in-frame 15-bp deletion in exon 14 in the same spectrin repeat, in the French family (p.L629_R634delinsW), and (3) the c.758T > C transition in exon 7, leading to a missense mutation (p.L253P) in the calponin homology domain, in German patients.

The mechanisms linking these mutations to the ataxic phenotype in patients are not fully understood. However, β-III spectrin is highly expressed in Purkinje cells and may be involved in organelle transport and in stabilization of membrane proteins. Indeed, synaptosomal localization and stabilization at the plasma membrane of the excitatory-amino-acid-transporter-4 (EAAT4), a Purkinje cell-specific glutamate transporter, are disrupted compared to the wild-type protein by overexpression of the American mutation in vitro. It should be noted that antisense knockdown of EAAT4 is known to produce a progressive ataxia in rats, and that this gene is downregulated in the SCA1 mouse model. It remains to be determined if the two other SPTBN2 mutations, particularly the different mutation found in the German kindred, similarly affect the function of the β-III spectrin. This is the first spectrin, component of the cytoskeleton, connected to cerebellar ataxia.

Epidemiology/Risk factors

Inherited forms of cerebellar ataxia account for 1–5 out of 100 000 people. SCA5 is likely a rare form of ataxia for three reasons: (1) the three mutations identified were not found in a large series of 310 dominant and sporadic ataxia patients of German ancestry, (2) no new mutations were found by direct sequencing of 22 unrelated German patients, (3) linkage to the SCA5 locus was excluded in seven French kindreds with a similar phenotype. The relative frequency of SCA5, however, is yet to

be determined in large series of patients, using a large-scale mutation screening, but the size of the gene precludes its analysis on a routine basis.

Clinical Features and Differential Diagnosis

The increasing number of genetically defined subtypes of SCAs reported in the past two decades has shown that there is a broad overlap of phenotypes. There are, however, clinical features that point toward some specific SCA types: gaze-evoked nystagmus in SCA3, retinal degeneration in SCA7, slow eye movements in SCA2, and pyramidal signs in SCA1. Pure forms of ADCA, which include SCA5, are defined by the fact that after 10 years of disease duration, there are no additional neurological signs associated with the cerebellar syndrome. Compared to other types, age of onset of SCA5 is usually older and disease progression is relatively slower.

The three SCA5 families reported are Caucasian. Overall, although SCA5 is disabling, the clinical picture is milder than in many other forms of ataxia, in that patients have a very slow disease progression, reminiscent of SCA6.

The mean age of onset and its range are similar in the three families (ranges 10–68, 14–40, and 15–50 years in the American, French, and German patients, respectively) and are discordant with the late onset that was thought to characterize pure cerebellar ataxias. Clinical anticipation affecting the age of onset is also suggested in these families, but although the mutations have been identified, the underlying mechanisms remain unknown.

Patients present with a pure cerebellar syndrome with gaze-evoked nystagmus sometimes occurring prior to the development of other features. Facial myokymia, tremor at rest as well as postural and action tremor, writer's cramp, and decreased vibration sense are also occasionally observed and reflect secondary lesions of structures other than the cerebellum or its pathways. These signs are also observed in other SCAs; however, they do not represent specific features of this genetic subform.

On brain imaging, SCA5 primarily affects, even after short disease duration (**Figure 1**), both the cerebellar vermis and hemispheres, and spares regions of the brainstem and the cerebrum. Cerebellar atrophy is usually global and severe and is strikingly similar to that observed in SCA6 patients.

Management

Confirmatory diagnostic testing and presymptomatic/prenatal diagnosis are possible, with a detection rate close to 100% in the SCA5 families.

There is no specific drug therapy for this neurodegenerative disorder. Therapy remains purely symptomatic (physiotherapy for gait and balance disturbances).

SCA6

B L Fogel and J C Jen, UCLA David Geffen School of Medicine, Los Angeles, CA, USA

Glossary

Ataxia – Impairment of balance and coordination.
Calcium channel – A large class of physiologically important multi-subunit membrane proteins which are voltage-gated, allowing the passage of calcium ions into a cell upon membrane depolarization.
Cerebellum – Structure located behind the brainstem involved in the coordination of movement; cerebellar connections include the primary motor cortex, the spinal cord, the thalamus, and the vestibular nuclei.
Nystagmus – Biphasic involuntary movements of the eye, named for the direction of the fast phase, which may occur spontaneously or be evoked by gaze or positional changes; commonly resulting from damage to the cerebellar and/or vestibular systems.
Spinocerebellar ataxia – An extensive class of hereditary neurodegenerative disorders characterized primarily by degeneration of the cerebellum and its pathways and manifesting clinically as a progressive dysfunction of balance and coordination.

Definition and History

The spinocerebellar ataxias (SCAs) make up a large diverse group of hereditary disorders which can be generally defined as autosomal dominant neurodegenerative conditions involving dysfunction of primarily the cerebellum and its pathways, resulting in progressive impairment of balance and coordination. Many of the disorders grouped under this heading (and discussed in other entries) may also involve additional brain regions and include features such as peripheral neuropathy, pyramidal or extrapyramidal features, cognitive or psychiatric disturbances, or epilepsy. Spinocerebellar ataxia type 6 (SCA6) is often considered a pure cerebellar ataxia with minimal associated features and can be considered as a prototypical spinocerebellar ataxia for illustrative purposes when discussing the class.

In 1997, following the molecular identification of polyglutamine-encoding CAG repeat expansions in a number of neurodegenerative diseases, Zhuchenko et al. examined the role of such repeats in novel genes potentially involved in neurodegeneration. They identified a specific human α_{1A}-calcium channel as a candidate gene due to the presence of polymorphic CAG trinucleotide repeats encoding a C-terminal polyglutamine tract in several isoforms. A screening of patients with late-onset progressive ataxia identified eight unrelated patients whose disease was associated with expansion of these repeats. Four of these patients had similarly affected relatives, and the repeat expansions segregated with the disease in an autosomal dominant manner. This hereditary ataxia was termed spinocerebellar ataxia type 6 (SCA6).

Pathogenesis/Pathophysiology

The human α_{1A}-calcium channel gene associated with SCA6 is now commonly known as the *CACNA1A* gene. This gene, located on chromosome 19p13, encodes the neuronal P/Q-type voltage-gated calcium channel α_1-subunit, $Ca_v2.1$, which forms the voltage-sensitive ion pore. The $Ca_v2.1$ calcium channel is found throughout the human brain, but is particularly concentrated in the cerebellum, including Purkinje cells, granule cells, and cells of the molecular layer, where it is thought to be involved in synaptic transmission. The C-terminus of the protein contains the CAG repeat region expanded in SCA6 (**Figure 1**). Missense and nonsense mutations elsewhere in the *CACNA1A* gene have been reported to disrupt its function and cause other neurological disorders, including familial hemiplegic migraine type 1 (FHM1) and episodic ataxia type 2 (EA2), variably associated with progressive cerebellar ataxia.

The trinucleotide repeat region is located in the C-terminus of the protein and appears to be quite stable with limited intergenerational expansion. The pathological number of repeats is also not marked, with a range that would be considered normal for most of the other SCAs. The normal number of CAG repeats in the *CACNA1A* gene varies from 4 to 18, with 19–20 repeats being intermediate and often nonpathogenic, and repeat numbers of 21 or greater resulting in the SCA6 phenotype. The age of onset appears to inversely correlate with the number of repeats. Of note, extensive alternative splicing generates a variety of *CACNA1A* isoforms where the C-terminus is either coding or noncoding. When part of the coding region, a string of polyglutamine residues is expressed, similarly to most other SCAs.

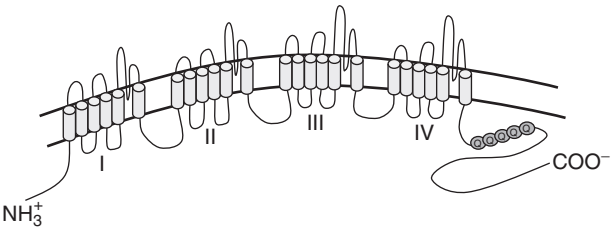

Figure 1 Structure of $Ca_v2.1$, the human P/Q-type α_1-subunit of the neuronal voltage-gated calcium channel associated with SCA6. The protein is depicted within a cell membrane. The four domains which contribute to the formation of the voltage-sensitive ion pore are indicated. The location of the intracellular polyglutamine (Q) repeat region expanded in SCA6 is shown.

The pathogenesis of SCA6 is not yet fully established and may involve contributions both from channel disruption and from polyglutamine toxicity. Studies of channel properties have been inconsistent, showing either gain or loss of function depending on the study and the experimental system utilized. Pathologically there is a loss of Purkinje cell neurons, and cytoplasmic and nuclear polyglutamine aggregates have been detected in cerebellar Purkinje cells. More recent studies have shown that the C-terminus of $Ca_v2.1$ is cleaved and transported to the nucleus both in vivo and in vitro and that the expanded polyglutamine repeats seen in SCA6 are toxic to cultured cells in vitro. This mechanism of action is most consistent with other polyglutamine disorders. This is also consistent with data from a transgenic SCA6 animal model where the murine *Cacna1a* gene was replaced with the human version and no significant differences were detected in the properties of either the normal or expanded CAG repeat mutant channels when expressed in cerebellar Purkinje cells. However, given that symptoms of ataxia are seen with non-CAG mutations in *CACNA1A* and that episodic vertigo and ataxia in some SCA6 patients may be clinically indistinguishable from EA2, impairment of channel function likely contributes to the pathogenesis to some degree. Further study is necessary to determine the precise molecular pathogenesis of SCA6.

Epidemiology

SCA6 is found worldwide but appears to be most prevalent in the countries of Japan and Germany. Interestingly, it is relatively rare in certain populous countries such as China, India, Italy, or Brazil. In the United States, SCA6 is one of the most prevalent SCAs, estimated to account for 15% of adult-onset dominant ataxia, on par with SCA2 (15%) and SCA3 (20%).

Clinical Features and Diagnostic Criteria

SCA6 is clinically characterized primarily as a progressive cerebellar ataxia, leading to it often being referred to as a pure cerebellar ataxia. Patients present with appendicular and gait ataxia, dysarthria, gaze-evoked nystagmus (both horizontal and vertical), cerebellar eye movements, and neurootological dysfunction, including positional vertigo and downbeat positional nystagmus, which can precede progressive ataxia by decades. In some cases, patients may exhibit exacerbation of symptoms with physical or emotional stress. A key physical finding seen in SCA6 is downbeat nystagmus that can be present in primary position or accentuated on horizontal gaze. It is important to note, however, that features such as pyramidal or extrapyramidal signs, peripheral neuropathy, or cognitive impairment may also be observed, albeit less frequently. Average onset is near 50 years of age.

Differential Diagnosis

The evaluation of a patient presenting with a late-onset ataxia can be quite extensive as multiple acquired etiologies cause such symptoms in addition to hereditary and sporadic conditions. The details of such screening is too extensive to be discussed here (see Further Reading) but should include a detailed medical history particularly concerning the family history, magnetic resonance imaging (MRI) of the brain and possibly the spinal cord, as well as additional testing for autoimmune, metabolic, nutritional, infectious, and neoplastic conditions among others. Once acquired causes are excluded, a detailed evaluation of hereditary disorders can be initiated. Based upon historical, clinical, and phenotypic characteristics, genetic testing may then be performed if indicated.

A key historical feature aiding in the diagnosis of SCA6 is that the average age of onset is ~50 years compared to ~30 years for other SCAs. Because the onset is often quite late and the condition can progress slowly, symptoms may be attributed to other medical conditions and patients may not be recognized as having an ataxic syndrome. Therefore, when mild, the disorder can often be overlooked within a family and patients seen in initial evaluation may report negative family histories. Consequently, it is important to rule out SCA6 in all patients presenting with a familial or sporadic ataxia with onset of symptoms after age 40.

Diagnostic Work-up/Tests

There are no common laboratory tests diagnostic or suggestive of SCA6. MRI of the brain will typically show

isolated cerebellar atrophy without brainstem or spinal cord involvement. Neurootologic testing shows abnormal oculomotor findings with impaired suppression of vestibular nystagmus, a poor optokinetic response, and saccadic pursuit with dysmetria despite normal saccade velocity. DNA testing to determine if there is an expansion in the number of CAG repeats present in either allele of the *CACNA1A* gene is the definitive test for SCA6.

Management

Genetic counseling is an important consideration for all patients and their families, particularly since many patients will have children of reproductive age by the time of diagnosis. As this is a progressive illness, it is important for physicians to be cognizant of how their patients are coping with their disease and managing their daily living activities with as much independence and safety as is possible. Physical therapy, especially for gait, balance, and strengthening trunk muscles, can be useful for maintaining functionality. Occupational therapies can assist with the independent performance of activities of daily living and speech therapies can assist with problematic dysarthria and dysphagia. Social work and mental health services may also be appropriate for certain patients.

No effective medical treatment for preventing or arresting the course of disease has been established through clinical trials, and management is therefore exclusively symptomatic. While no pharmacologic agents have been reproducibly shown to benefit SCA6 patients with slowly progressive ataxia, those with transient recurrent vertigo and ataxia have shown a response to acetazolamide (see Further Reading).

Prognosis

Like all other SCA patients, individuals with SCA6 experience progressive decline in cerebellar function and may become wheelchair-dependent and have significant difficultly with typical activities of daily living. However, SCA6 patients tend to have a later onset, milder symptoms, and slower disease progression. As brainstem and autonomic functions remain intact, lifespan does not appear to be significantly altered by the course of this disease.

SCA7, Spinocerebellar Ataxia with Macular Dystrophy

G Stevanin, A Sittler, and A Brice, CR-ICM UMR_S975 Groupe Hospitalier Pitié-Salpêtrière, Paris, France

Glossary

ADCA – Autosomal dominant cerebellar ataxia is a heterogeneous group of inherited neurodegenerative diseases.
CAG – Cytosine–adenosine–guanosine trinucleotide encoding glutamine at the protein level.
Dyschromatopsia – Loss of ability to perceive colors.
SCA7 – Spinocerebellar ataxia 7 designates the locus on chromosome 3, the gene name and the disease associating cerebellar ataxia with macular degeneration.
STAGA – SPT3/TAF9/GCN5 acetyltransferase complex involved in transcription regulation.
TFTC – Tata binding protein-free TAF-containing complex involved in transcription regulation.

Definition and History

Spinocerebellar ataxia 7 (SCA7) is a rare autosomal dominant neurodegenerative disorder initially described by Professor Jules Froment (Hospices Civils de Lyon, France) in 1937, and later designated olivo-ponto-cerebellar-atrophy type III or autosomal dominant cerebellar ataxia (ADCA) type II. Patients present with cerebellar ataxia and visual impairment because of moderate to severe neuronal loss in the cerebellum and associated structures and degeneration of cone and rod photoreceptors. The responsible locus, SCA7, was mapped to chromosome 3p in the 1990s, and the causative gene was subsequently identified in 1997, thanks to the marked phenomenon of anticipation that oriented researchers toward a trinucleotide CAG repeat expansion as the mutation. SCA7 is indeed caused by an unstable CAG repeat expansion (36–460 units) in the *SCA7* gene, leading to an elongation of a polyglutamine tract in the ataxin-7 protein – a mechanism involved in other disorders also known as polyglutamine diseases.

Pathogenesis

Molecular Bases

The *SCA7* CAG repeat is polymorphic, with sizes ranging from 4 to 35 units in controls, and from 36 to 460 in SCA7 and at-risk carrier chromosomes. Incomplete penetrance is suspected in patients with 36 repeats. Expansions are unstable, particularly during paternal transmissions. The size of the largest expansion and the degree of gonadal instability in SCA7 are greater than those observed in any of other known polyglutamine diseases, and the genomic context has been suspected to play a role in this phenomenon.

Normal Function of Ataxin-7

Ataxin-7 is a ubiquitously expressed protein of 892 amino acids and contains an N-terminal polyglutamine tract, several protein interaction domains, nuclear localization and export signals, and two caspase 7 cleavage sites. It is found in the cytoplasm of all the populations of neurons analyzed in control brains, but a nuclear labeling is observed in some neurons with a frequency and intensity weakly correlated with the topography of lesions in patients. Ataxin-7 is a component of the Tata binding protein (TBP)-free TAF-containing complex (TFTC) and the SPT3/TAF9/GCN5 acetyltransferase complex (STAGA), which is implicated in several steps of transcriptional regulation such as histone acetylation/deubiquitinylation and recruitment of the pre-initiation complex to promoters.

Pathophysiology

As in other polyglutamine diseases, the expansion is expected to confer toxic properties to the mutant protein, which also accumulates aberrantly in neurons in patients and cellular/animal models, leading to the formation of insoluble nuclear inclusions. The relationship between toxicity and aggregation is still a matter of debate. In SCA7, these inclusions were shown to contain cell stress markers in cell cultures and mouse models, but they are not restricted to the affected brain regions, suggesting that their presence is not sufficient to initiate the degenerative process. The inclusions may therefore be simply a pathological hallmark of the diseases and/or a cellular defense mechanism. If they are not responsible for the initiation of the disease, they may be implicated in disease progression and severity. Interestingly, withdrawal of the expression of pathological ataxin-7 in an inducible SCA7 model in Drosophila improved locomotion and longevity as well as disaggregation of inclusions, suggesting that a therapeutic intervention aimed at preventing the nuclear accumulation or increasing the clearance of the mutant proteins might be protective against polyglutamine toxicity. Clearance of the pathological protein was also obtained by increasing the expression of promyelocytic leukaemia protein (PML) that

often colocalizes with inclusions in the brains of SCA7 patient or other polyglutamine disorders, suggesting that PML nuclear bodies play a role in the pathogenesis of SCA7 and might be effective therapeutic targets.

On the other hand, the polyglutamine expansion in ataxin-7 might also impair the activity of TFTC/STAGA complexes independently of aggregate formation; this probably accounts for chromatin remodeling and transcription defects observed in SCA7 models.

Epidemiology/Risk Factors

Although rare, SCA7 is detected in patients of various ethnic and geographical origins. Its relative frequency among ADCA patients (prevalence of 1–5 out of 100 000 people) varies as a result of independent regional founders in each population, but the mean frequencies in many countries are between 2% and 5%.

De novo SCA7 expansions can occur during paternal transmission from intermediate size alleles with 28–35 repeats, which can be considered as at-risk alleles in the healthy population. This observation is important in clinical practice since 'apparently' sporadic patients can then carry pathological mutations in the *SCA7* gene.

Clinical Features and Differential Diagnosis

Symptoms

Clinical manifestations typically begin in the third or fourth decade, with ages of onset ranging from 3 months or less to over 70 years. Analysis of parent–child couples has revealed striking anticipation, greater in paternal than in maternal transmissions.

The SCA7 mutation is almost exclusively associated with the ADCA type II phenotype, which is distinguished by the presence of a retinopathy in most patients, although retinopathy is also sometimes found in other ADCA forms. Cerebellar ataxia is usually the presenting symptom, particularly in adults with onset over thirty, whereas in patients with earlier onset, decreased visual acuity alone or associated with cerebellar ataxia is the initial symptom. Some infantile cases may, however, result in early death without detectable retinal alteration. In some patients with late onset, visual acuity may never decrease.

Cerebellar ataxia is always associated with dysarthria, but patients present variably with a pyramidal syndrome, decreased vibration sense, dysphagia, sphincter disturbances as well as oculomotor abnormalities (supranuclear ophthalmoplegia and/or viscosity of eye movements). Extrapyramidal features (dystonia), myokymia, and mental impairment are rare.

Visual failure is progressive, bilateral and symmetrical, leading to progressive blindness that first affects the central vision, while night vision is not impaired. Interestingly, dyschromatopsia in the blue–yellow axis is found years before visual failure becomes symptomatic. In contrast, fundoscopic abnormalities consisting of a loss of the foveal reflex and progressive mottling of pigment at the macula are often delayed (**Figure 1**). Secondary optic atrophy can often be detected in later stages. Electroretinograms show abnormal scotopic responses, but photopic responses are preserved late.

Neuropathology and Brain Imaging

Brain imaging (**Figure 2**) and neuropathological studies show marked atrophy in the cerebellum, particularly in the superior part of the vermis where Purkinje cells and, to a lesser extent, granule cells degenerate. Extensive neuronal loss is observed in the inferior olive, with marked astrocytic gliosis. Mild cell loss also occurs in the dentate nucleus and in the brainstem, which may be associated with moderate atrophy of the cerebral cortex. Mild cell loss is also observed in the substantia nigra and the basis pontis, whereas the thalamus and the striatum are spared. Ponto-cerebellar pathways are spared, while spinocerebellar, olivocerebellar, and efferent cerebellar tracts are severely affected.

The distinctive neuropathological features of ADCA II are degeneration of the optic pathways and the retina. The pregeniculate visual pathways and the optic nerves are affected, probably as a consequence of retinal degeneration. In juvenile cases presenting with blindness, those systems may not be altered, probably because of the rapid course of the disease. Pathological examination of the retina shows early degeneration of photoreceptors and of bipolar and

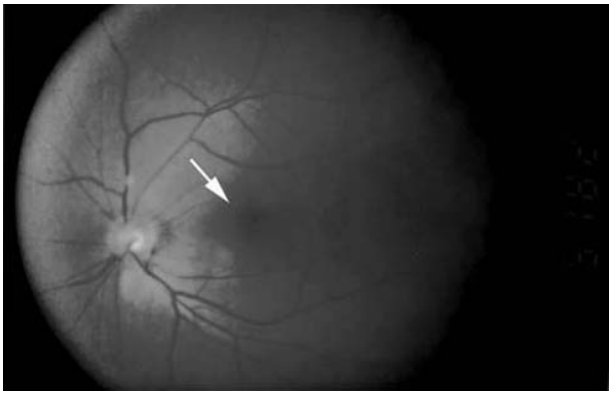

Figure 1 Fundus color picture/fluorescein angiography of the right eye of a SCA7 patient presenting with bilaterally reduced visual acuity (1/10). granular cells, particularly in the foveal and parafoveal regions. Later, patchy loss of epithelial pigment cells and their ectopic migration into the retinal layers are observed.

Phenotype–Genotype Correlations

There is a strong negative correlation between the size of the CAG expansion and age of onset, but other genetic and/or environmental factors likely play a minor role in determining the disease onset. This correlation, together with the increase in expansion size in successive generations, is consistent with the marked anticipation observed in patients. Disease duration until death is also negatively correlated with the number of CAG repeats on the expanded allele and is limited to a few months or years in early onset patients. Anticipation is also associated with increasing severity of symptoms in successive generations. The frequency of decreased visual acuity, ophthalmoplegia, scoliosis, and extensor plantar reflexes significantly increases with the size of the expansion. In some infantile cases with very large repeat expansions, progression is extremely rapid and cardiac involvement may occur.

Management

Confirmatory diagnostic testing and presymptomatic/ prenatal diagnoses are possible with a detection rate close to 100%. In patients with young onset, the largest allele rarely escapes detection; however, additional techniques (southern, long range PCR, etc.) should be used in very early onset patients with homozygous normal alleles.

There is no specific drug therapy for this neurodegenerative disorder. Therapy remains purely symptomatic (physiotherapy for gait and balance disturbances). Appropriate measures during careful neurological follow-up can reduce diplopia, swallowing, or sphincter disturbances. Dementia may be present and needs specific care.

SCA8

M D Koob, University of Minnesota, Minneapolis, MN, USA

Glossary

Antisense RNA – Single stranded RNA that is complementary to a messenger RNA strand.
Ataxia – Literally (Greek) absence of order. Clinically referred to as a specific motor syndrome with difficulty to stabilize the trunk against gravity, difficulty to stabilize gaze, difficulty in goal-directed limb movements and dysarthria.
CTG repeat disorder – A trinucleotide expansion of a CTG repeat tract found in SCA8 and myotonic dystrophy, different from the polyglutamine repeat disorders with CAG expansions (e.g., SCA 1, 2, 3, HD, among others).

Definition and History

SCA8, or spinocerebellar ataxia type 8, is a dominantly inherited 'pure cerebellar' (ADCA III) ataxia caused by a trinucleotide expansion of a CTG repeat tract. This pathogenic CTG expansion was identified in and isolated from the genomic DNA of an individual with a previously unknown familial form of SCA, which was in turn used to identify a large family in which ataxia was genetically linked to the *SCA8* locus on chromosome 13. SCA8 patients typically have a slowly progressive, predominantly cerebellar disease involving dysarthria, limb and gait ataxia, and impaired smooth pursuit and nystagmus. A broad range of other clinical symptoms has also been reported, including tremor, spasticity, and various kinds of cognitive impairment. Although this clinical picture is not clearly distinguishable from that of other forms of inherited ataxia, the underlying molecular cause of SCA8 appears to be unique among this family of diseases.

Pathogenesis/Pathophysiology

The SCA8 CTG repeat tract is part of the natural antisense RNA of the Kelch-like 1 (*KLHL1*) gene. *KLHL1* antisense transcripts (*KLHL1AS*) are transcribed from a promoter in the first intron of *KLHL1* across the splice donor site, the translation and the transcription start site of *KLHL1*, and are alternatively spliced and polyadenylated. We currently presume that the primary function of this antisense transcript, which is evolutionarily conserved, is to regulate the expression of the *KLHL1* gene. The KLHL1 protein encoded by the sense RNA is located exclusively in the cell bodies and dendrites of Purkinje cells and other neurons. Loss of expression from even a single allele in an SCA8 mouse model causes abnormal gait, progressive loss of motor coordination, and Purkinje cell dendritic deficits. Mice with *Klhl1* specifically deleted in only Purkinje cells have the same phenotype, indicating that Klhl1 is essential for normal motor coordination and for maintaining normal Purkinje cell functions. We hypothesize that pathogenic SCA8 CTG expansions cause ataxia in humans through a

mechanism involving the loss of KLHL1 activity in Purkinje cells and that loss of proper expression from even a single *KLHL1* allele would be sufficient to cause disease.

Ataxia patients analyzed with either magnetic resonance imaging or computed tomography typically have marked atrophy of the cerebellar vermis and hemispheres and relative preservation of the brainstem and other parts of the brain. The MRI findings from SCA8 patients were compared with those from SCA6 patients, who are also considered to have a pure cerebellar ataxia, and no statistically significant differences were found between these two patient groups on MRI. The slowly progressive nature of SCA8 was documented by MRI analysis in one study. MRI scans of an SCA8 patient taken 9 and 18 years after the disease onset were compared and showed little, if any, progression of the prominent cerebellar atrophy during those years. Published reports also indicate that atrophy found in MRI scans can be present during the preclinical stage of the disease and even in asymptomatic SCA8 carriers. A neuroradiological finding of cerebellar atrophy may therefore be the first or only sign of SCA8 neuropathology in some patients.

Clinical Features

A consistent clinical picture of SCA8 has emerged as researchers in various parts of the world have identified ataxia families with SCA8 expansions and published their findings The clinical features of SCA8 are similar to those of the other SCAs and include limb and truncal ataxia, ataxic dysarthria, and horizontal nystagmus, either gait ataxia or dysarthria being the initial clinical symptom. Many patients also had increased deep tendon reflexes, limb spasticity, and reduced vibratory sense. The most distinguishing clinical feature of SCA8 is that the disease progression is typically very slow.

Cognitive impairments have been observed in many of the reported SCA8 patients, and this may represent a significant but variable clinical feature of this disease. In the original SCA8 family, three of the 13 affected family members and two of the 22 carriers of SCA8 expansion without ataxia had been treated for depression and one affected family member was being treated for a psychotic disorder. Other published reports describe SCA8 patients with similar cognitive impairments. A recent case report indicates that these additional impairments may be associated with white matter hyperintense lesions on cranial MRI.

Diagnostic Test

Unlike many of the other spinocerebellar ataxias, there is little direct relationship between expansion size and disease severity, and some individuals with large SCA8 CTG alleles never develop ataxia. For these reasons, it is not currently possible to predict either the onset or the severity of the disease.

The size of the *SCA8* CTG tracts in a patient's genomic DNA can be determined by generating and electrophoretically sizing PCR products from both of the patient's *SCA8* alleles, using an oligonucleotide primer pair that flanks this repeat tract. The number of trinucleotide repeats present at this locus is extremely heterogeneous in the general population, and as a result, the genomic DNA from the vast majority of individuals will generate PCR products with two distinct sizes. In those instances where only a single size is detected, Southern analysis of the genomic DNA sample should be performed to differentiate between individuals with two SCA8 alleles of the same size and those who have one expanded allele that is too large to amplify by PCR (typically $\geq \sim 200$ CTG repeats).

Interpretation of the SCA8 CTG DNA test is not straight forward. Individuals who do not have CTG expansions at the SCA8 locus do not have and will not develop this form of ataxia, and this test is useful for providing this information. On the other hand, detection of a large SCA8 CTG repeat and determination of its size cannot be used to directly predict either the severity or the onset of ataxia. We feel that the underlying problem with using the size of the SCA8 CTG repeat in a predictive manner is that the CTG expansion in the genomic DNA that is analyzed in a DNA test is not in itself the direct molecular cause of the SCA8 neuropathology. Rather, we currently believe that the cerebellar neurotoxicity of this expansion mutation is mediated through the transcription of this repeat into RNA. Since direct analysis of patient cerebellar RNA is not a practical option, definitive predictive testing for SCA8 will probably not be possible until the precise molecular mechanism that leads to the neuropathology and the modifiers of this pathology are more fully understood.

Prognosis

Since SCA8 is predominantly a cerebellar disease, SCA8 patients can be expected to lose cerebellar function gradually over a number of decades while largely avoiding the brain stem involvement found in many other types of SCA. There is currently no known method for effectively treating SCA8 patients.

SCA10

A Rasmussen and S I Bidichandani, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA

Glossary

Anticipation – The tendency for the severity of a condition to increase in successive generations.
Autosomal – Any trait determined by a gene localized in chromosomes other than the sex-chromosomes, X and Y, and therefore, transmitted with equal probability through the mother or father.
Dominant – In human genetics, any trait that is expressed in a heterozygote.
Dynamic mutation – An unstable expanded repeat that changes size between parent and child.
Founder effect – Refers to the presence in a population of many individuals all with the same chromosome or chromosomal region derived from a single ancestor.
G-protein signaling – A widespread intracellular signaling system. G proteins are guanine nucleotide-binding proteins residing in the plasma membrane. They form inert trimeric complexes when bound by GDP. When GDP is replaced by GTP, the trimeric molecule is broken-down into subunits, one of which then activates or represses a target protein.
Microsatellite – Small stretch of usually less than 0.1 kb of tandem repeats of a very simple DNA sequence, usually 1–6 bp in length. They are often polymorphic.
Microsatellite repeat instability – A phenomenon where during DNA replication the repeat copy number of microsatellites is subject to changes. It is the underlying cause of more than 20 hereditary diseases, and often seen in cancerous cells.
Toxic gain-of-function – Protein expressed by the mutated gene has, in addition to all its normal cellular functions, some additional function that makes it toxic to the cell.

Definition and History

Spinocerebellar ataxia type 10 (SCA10; MIM 603516) is an autosomal dominant disorder characterized by progressive cerebellar dysfunction often associated with seizures.

The disease was initially described in two families of Mexican origin, and genome-wide linkage analysis localized it to a region on chromosome 22q13. In 2000, Matsuura et al. identified an expanded pentanucleotide ATTCT repeat in intron 9 of the *E46L* gene (later renamed *ATXN10*) that cosegregated with the disease in all affected members of five Mexican families. The ATTCT

repeat is polymorphic, ranging from 10 to 29 repeats in normal individuals and from 800 to 4500 repeats in patients. Anecdotal reports suggest that alleles with 280–800 repeats have reduced penetrance, although further evidence is needed to clarify this issue.

Pathogenesis

The *ATXN10* gene consists of 12 exons spanning 173 kb of genomic DNA, with an open reading frame of 1428 bp encoding a 475 amino acid protein. The polymorphic ATTCT pentanucleotide repeat is located in intron 9, ranging in normal individuals from 10 to 29 repeats. Eighty percent of normal individuals are compound heterozygotes for alleles in this range and 20% are homozygous. The normal repeat tract is usually a pure ATTCT stretch in small normal alleles (11–16 repeats), but more than half of normal alleles with $\geq$17 repeats have ATTGT–TTTCT or TTTCT interruptions confined to the penultimate repeating unit.

Only three affected SCA10 families have been analyzed for the purity of the repeat. In one of them, the mutant tract was apparently uninterrupted while the other two had interruptions. These families show differences in disease penetrance, severity and repeat instability, which may be influenced by the differences in their sequence configuration.

The causal role of the expanded *ATXN10* alleles in SCA10 is supported by the fact that these alleles cosegregate with the SCA10 phenotype in all affected families and were absent in more than 1000 normal chromosomes analyzed as controls. *ATXN10* is highly expressed in the cerebellum, which is the tissue primarily involved in disease pathology.

ATXN10 is an evolutionarily conserved cytoplasmic protein of unknown function; however, the discovery of some potential interacting proteins suggests that ATXN10 may promote G-protein signaling and increased neurite formation. A decrease in ATXN10 transcript in cultured neurons induced apoptosis, with cerebellar neurons being significantly more sensitive than cortical neurons. The significance of this finding in the context of SCA10 is unclear since it has been shown that the expanded ATTCT repeat does not interfere with either transcription or posttranscriptional processing of mutant *ATXN10*, and that the level of processed mRNA is unaltered in SCA10. More recent data point toward a toxic RNA gain-of-function by the expanded ATXN10 transcript.

Epidemiology

SCA10 has so far only been described in Latin-American populations, mainly in Mexican and Brazilian families, where it represents a common cause of autosomal dominant ataxia, second only to SCA2 in Mexico, and SCA3/MJD in Brazil. One family from Argentina has also been identified. Haplotype analyses flanking the *ATXN10* gene support the notion of a common ancestor.

Clinical Features

The common phenotype of SCA10 is that of a progressive pure cerebellar ataxia (ADCA type III) of adult onset. The initial manifestation is most commonly unstable gait and stance with limb ataxia, which is later followed by dysarthria. Neurological exam shows wide-based ataxic gait, difficulty in tandem-walking, dysmetria, dysdiadokinesia, intention tremor, and ocular dyskinesia. More variable findings are pyramidal signs and mild lower limb sensory loss. Age of onset ranges from 12 to 48 years.

As more families with SCA10 have been identified, it is possible to subdivide them into three subphenotypes: (1) pure cerebellar ataxia of slow progression, often accompanied by mild cognitive deficit; (2) cerebellar ataxia plus seizures; and rarely (3) cerebellar ataxia plus nonneurological symptoms.

The initial clinical description of SCA10 was that of cerebellar ataxia with epilepsy, with 25–80% of the Mexican patients experiencing seizures. Interestingly, only one patient of Brazilian origin has had seizures, and therefore, the epilepsy phenotype may be considered a 'Mexican' variant of SCA10.

Patients affected with epilepsy present with generalized motor seizures and/or complex partial seizures which may precede or follow the onset of overt ataxia, and can be severe enough to cause status epilepticus.

Genotype–Phenotype Correlation

A weak inverse correlation between repeat size and age of onset has been noted in SCA10 patients, with a correlation coefficient (r^2) of 0.34, which means that only about one-third of the variation in the age of onset is determined by the size of the repeat.

Anticipation has been described in SCA10, mainly via paternal transmission, and is associated with increased repeat instability in the male germline. In contrast, instability of expanded alleles is not seen during maternal transmission. Paradoxically, in some cases, clinical anticipation has also been seen despite a decrease in the size of the repeat. Whereas, the phenotypic significance of the repeat length per se needs further clarification; it has recently been suggested that the presence of non-ATTCT sequence interruptions may also act as modifiers of disease severity.

Diagnosis

The diagnosis of SCA10 should be considered in Mexican or Brazilian patients presenting with adult onset autosomal dominant cerebellar ataxia of slow progression, with or without seizures.

The brain imaging shows progressive pan-cerebellar atrophy with relative preservation of cerebrum and brain stem. They may have electroencephalographic evidence of diffuse cortical dysfunction, with or without cortical irritability or slow activity, and electrophysiologic abnormalities compatible with peripheral neuropathy.

The diagnosis is confirmed by molecular genetic testing to identify abnormally expanded ATTCT repeats in the *ATXN10* gene. Affected individuals have alleles that range from 800 to 4500 repeats. Reduced penetrance alleles may exist, as suggested by one asymptomatic woman carrying the same 280 ATTCT-repeat allele as her clinically affected daughter, and two alleles of 360 and 370 repeats reported in two asymptomatic Brazilian individuals.

Management

The main objective of treatment in SCA10 is the appropriate control of epilepsy, which if left untreated can lead to life-threatening status epilepticus. Otherwise, treatment is focused on symptomatic support and physical therapy. Appropriate genetic counseling should be provided to SCA10 families. SCA10 is transmitted as an autosomal dominant trait, therefore, offspring of an affected individual has a 50% chance of inheriting the mutation. Once the diagnosis is confirmed by molecular testing in the proband, prenatal diagnosis may be offered for future offspring, and predictive testing is also an option for at-risk family members.

SCA11

T Klockgether, University Hospital Bonn, Bonn, Germany

Glossary

Ataxia – Impaired coordination leading to problems of balance, finger and hand movements, and speech.
Cerebellum – Part of the brain that receives afferent fibres from the cortex, brainstem and spinal cord and sends efferent fibres via the cerebellar deep nuclei towards the thalamus and cortex. The cerebellum has an essential role in coordinating movements.
Linkage analysis – Genetic method that allows to map disease causing gene mutations on chromosomes.
Tau tubulin kinase-2 (*TTBK2*) – TTBK2 is a member of the casein kinase group of protein kinases. TTBK2 has the ability to phosphorylate tau and tubulin.

Spinocerebellar ataxia type 11 (SCA11) was first identified by Worth et al. in a large British family with ataxia ascertained in seven generations. Disease onset was 25 ± 8 years with no evidence of anticipation. Life expectancy was almost normal with mean age at death of 71 ± 14 years. All affected family members had gait ataxia, impaired smooth pursuit eye movements, gaze-evoked nystagmus, ataxic speech, and hyperreflexia. Most affected patients had also limb ataxia, while vertical nystagmus and diplopia were less frequent. Ataxia was mild; after a disease duration of 24 ± 13 years, no affected subject was wheelchair-bound.

Apart from a mild reduction of sensory nerve action potentials in one subject, nerve conduction studies were normal. MRI scans revealed isolated cerebellar atrophy. A neuropathological examination of one affected brain showed almost complete loss of cerebellar Purkinje cells and marked loss of cerebellar granule cells. Neurofibrillary tangles were found in several areas of the brainstem, midbrain, basal ganglia, and neocortex.

A genome-wide linkage study mapped the disease to a 7.6-cM region on the proximal long arm of chromosome 15 (15q14–21.3). Sequencing of the gene encoding tau tubulin kinase-2 (*TTBK2*), one of more than 50 candidate genes in the critical region, led to the identification of a one-base insertion in exon 13 at nucleotide 1329 that created a premature stop and truncated the normal protein of 1244 to 450 amino acids. In a second family of Pakistani origin, a frameshift deletion of two bases in exon 13, also leading to a premature stop, was found. Both mutations segregated with the disease and were not found in normal chromosomes. Semiquantitative polymerized chain reaction (PCR) of lymphoblast RNA from both families showed an ~50% reduction of *TTBK2* mRNA. *TTBK2* is expressed in all brain regions with a particularly high expression in the cerebellar cortex, hippocampus, midbrain, and substantia nigra. Whether the neurofibrillary tangles observed in one SCA11 brain are a consequence of the *TTBK2* mutation or rather an expression of normal ageing remains to be clarified.

SCA12

D A Hall, University of Colorado, Denver, CO, USA
E O'Hearn, Johns Hopkins University, Baltimore, MD, USA

Glossary

Endogamy – The practice of marrying within a social group.
Haplotype – The determination of markers close to and on the same chromosome as the mutation of interest.
Heterozygosity – Describes the condition where different alleles occupy the gene's position in each of the homologous chromosomes. In other words, it describes an individual who has two different alleles for a trait.
Penetrance – An index of the proportion of individuals with an allele who have manifestations of it.
Transmission – The transfer of genetic information from genes to another generation, or from one location in a cell to another. For example, maternal transmission is inheritance from the mother.

Definition and History

Spinocerebellar ataxia type 12 is an autosomal dominant ataxia caused by a CAG expansion that results in kinetic tremor, ataxia, hyperreflexia, and subtle parkinsonism. The first description of SCA12 came from the Holmes, O'Hearn group, and Margolis in 1999, in a large American family of German descent. A second family, of Indian descent, was discovered by Fujigasaki in 2000. Nineteen other families have now been reported in the Indian population, due to a founder effect. Subsequently, several groups have conducted screening studies for SCA12 repeat expansions and determined that the SCA12 mutation is a rare cause of ataxia in most populations.

Pathogenesis/Pathophysiology

SCA12 is caused by a CAG repeat expansion at 5q31–33 in the 5′ untranslated region of *PPP2R2B* gene. The repeat expansion is 133 nucleotides upstream from the transcription site of the gene, which codes for a brain-specific regulatory subunit of serine/threonine protein phosphatase PP2A. Normal CAG repeats at this locus are 7–32, most members of the general population having 10 repeats. Heterozygosity at the locus is 61–71%. Pathological repeats at this locus range from 55 to 78 CAG repeats; however, the exact cutoff is still uncertain. Ataxic individuals with 40–49 repeats have been reported, in addition to normal individuals in the same range. Evidence of polyglutamine expansions has not been seen with Western blots of protein in the one SCA12 brain examined, which is consistent with the location of this expansion in a nontranscribed region of the gene. There is a mild instability of the repeat size on transmission (±1–4 CAG) from parent to offspring, usually with paternal transmission. It is uncertain whether the penetrance is incomplete or age-dependent as some asymptomatic individuals with repeat expansions have been reported but may be too young to manifest symptoms. There is no correlation between the repeat size and the age of onset. Protein phosphatase (PP2A) is a highly conserved protein that is involved in the regulation of cellular processes, including tau regulation. It is widely expressed in the Purkinje cells of the cerebellum. The Bβ subunit (PPP2R2B), or regulatory unit, is the portion that is affected by the CAG repeat expansion. Preliminary evidence suggests that the SCA12 repeat expansion may alter the level of expression of the protein. The most likley mechanisms of pathogenesis include: toxicity at the level of the BB protein or its RNA (similar to the fragile X-associated tremor ataxia syndrome or myotonic dystrophy); alteration of splicing patterns; or direct inhibition of transcription with a secondary effect on associated proteins. Pathological findings in SCA12 show diffuse atrophy, most marked in the cerebral and cerebellar cortex, with loss of cerebellar Purkinje cells.

Epidemiology/Risk Factors

Multiple screening studies have been conducted to determine the prevalence and distribution of the SCA12 repeat expansion in various populations (**Table 1**). With the exception of the original American family of German descent, most families with the disorder have been Indian. Single patients from Singapore and China with SCA12 have been reported. The high prevalence of the disorder in India is due to a common founder. Ninety percent of the Indian SCA12 pedigrees (20 individuals in total) share a single haplotype associated with the majority of expanded chromosomes, as against the 4% of ethnically matched unrelated normal individuals. These Indian SCA12 families belong to the state of Haryana, which has a strictly

endogamous population. The SCA12 family of German descent does not share this haplotype, suggesting that that the Indian mutation arose from a different founder. Other studies in the Indian population show that there is a statistically significant difference in the number of normal controls with CAG repeat sizes over 12 in the Indian compared with the French controls.

Clinical Features and Diagnostic Criteria

The age of onset of disease is 8–55 years, with a mean age of onset of 34 years. The duration of disease in patients examined has varied from 3 to 13 years. In many of the patients, tremor is the first neurological sign, with many patients diagnosed initially with essential tremor. The tremor is kinetic or postural, intention tremor being frequent. A tremor frequency of 3 Hz was described in one patient. The tremor is usually in the upper extremities, but can also be seen in the mandible, voice, or with tongue protrusion. Head tremor, which is of large amplitude and low frequency, is also a feature. Cerebellar features tend to be milder than other forms of ataxia and include gait ataxia, limb dysmetria, dysdiadochokinesia, and dysarthia. Abnormal eye movements can be seen, with nystagmus on lateral gaze, slowed saccades, and broken pursuit – all reported. Parkinsonism is common in the American SCA12 kindred, with bradykinesia and rigidity most frequently seen, but has not been reported in Indian SCA12 patients. Focal dystonia, anteroflexion, and retropulsion have been reported. Hyperreflexia with extensor plantar responses is present in the majority of cases and a subclinical peripheral neuropathy was discovered on NCV in the majority of the affected Indian individuals in the Fujigasaki study. A subclinical peripheral neuropathy has also been observed in some members of the American SCA12 kindred. Facial myokymia, axial dystonia, laterocollis, and cognitive abnormalities are present in some patients, with cognitive decline seen most commonly in the older patients. Anxiety and depression are seen in a proportion of affected individuals.

Differential Diagnosis

Kinetic tremor may also be seen in SCA 2, 3, 6, and dentatorubropallidal luysian atrophy (DRPLA) and these disorders should be considered in the differential. Ethnicity of the patient and associated features may better refine testing. The fragile X-associated tremor/ataxia syndrome (FXTAS) should also be considered. This disorder is caused by a CGG repeat expansion in an untranslated portion of the *fragile X mental retardation 1* gene on the X chromosome. FXTAS manifests itself in kinetic tremor and gait ataxia, with varying degrees of parkinsonism, peripheral neuropathy, and executive dysfunction. However, individuals with FXTAS tend to be males over the age of 60 and will have an X-linked transmission pattern on family history, rather than an autosomal dominant pattern. Parkinsonism is also seen in SCA 2, 3, 6, and DRPLA. Hyperreflexia and extensor plantar responses can be seen in SCA 1–8, making this sign less helpful in diagnosis.

Diagnostic Work-up/Tests

Subclinical peripheral neuropathy may be seen on nerve conduction studies. Nerve conductions have shown sensory neuropathy and axonal sensorimotor neuropathy. Magnetic

resonance imaging and computed tomography show cortical and cerebellar atrophy in most individuals. SCA12 genetic screening may be considered in those individuals who have neurological signs in addition to cerebellar features, especially kinetic tremor. Ethnicity may be helpful, individuals of Indian descent being potentially more likely to have the mutation and an appropriate family history. Polymerase chain reaction testing using primers flanking the CAG repeat expansion in the *PPP2R2B* gene is diagnostic and can be ordered at several laboratories.

Management

Kinetic tremor in SCA12 has been reported to respond to primidone or beta-blockers in some patients. Alcohol was reported to help in one patient as well. This suggests that affected individuals with kinetic tremor should have trials of medications typically prescribed for essential tremor. Symptomatic treatment for gait ataxia may include medications that modify monoamine transmission, such as amantadine and buspirone, or physical therapy for gait training. Recently, case reports in three patients with ataxia show that varenicline, a partial agonist selective for $\alpha 4\beta 2$-nicotinic acetylcholine receptors and prescribed for tobacco cessation, may be helpful for gait ataxia. However, this medication may exacerbate tremor, and therefore, patients should be monitored closely. Dopaminergic therapy for parkinsonism and therapy for anxiety of depression should be considered, if appropriate.

Prognosis

Although disease progression is reported to be slow, there have not been studies reporting the prognosis or life expectancy of patients with SCA12.

Glossary

Deletion – A part of a gene or chromosome is missing.
Gene mutation – Change in a gene that leads to an altered or abnormal gene product.
Haploinsufficiency – The presence of a dominant mutation on one allele leads to only a single functional copy of the gene on the other allele, which is insufficient to maintain a normal function of the gene product.
Linkage study – The search for the chromosomal location of a disease gene, by identifying a specific set of selected genetic markers that are inherited jointly and segregate with disease transmission.
Missense mutation – Type of point mutation where a single nucleotide is changed, resulting in a different amino acid.
Myokymia – Spontaneous, small contractions of muscle fascicles.
Penetrance – The rate at which the presence of a genetic mutation actually leads to the development of the corresponding disease.
Purkinje cell – Large neurons in the cerebellar cortex with an extensive dendritic arbor.

Spinocerebellar Ataxia 13

Clinical Features

The phenotype of the original French SCA13 family consisted of a slowly progressive spinocerebellar ataxia with early childhood onset. Delayed motor milestones and mild mental retardation were observed in most affected family members. Occasional features included seizures, short stature, facial dysmorphia, and cervical dystonia. A second family, of Filipino descent, manifested a more isolated cerebellar syndrome with onset ages ranging from 22 to 48 years. No extracerebellar features were reported, except for brisk tendon reflexes.

Genetics and Pathophysiology

The SCA13 locus on chromosome 19q13.3–13.4 was found in 2000, and refined in 2005. The combined effort of the two research groups that were involved in the linkage studies led to the identification of two different missense mutations in exon 2 of the *KCNC3* gene in 2006. *KCNC3* encodes Kv3.3, a voltage-gated potassium channel that is expressed in the various cerebellar neuronal populations. Functional studies have indicated that both the Filipino R420H mutation and the French F448L mutation alter channel function, which presumably changes the activity of fast-spiking cerebellar neurons.

Epidemiology and Relevance

So far, only two SCA13 families have been published. However, as the gene identification was quite recent, large-scale screening for *KCNC3* mutations in ataxia cohorts are necessary to establish its actual relevance.

Spinocerebellar Ataxia Type 14

Clinical Features

To date, numerous SCA14 families have been reported. There is a markedly variable age of onset, ranging from early childhood to 60 years. Clinically, SCA14 patients mostly display a very slowly progressive, isolated cerebellar or spinocerebellar ataxia. However, some relevant noncerebellar features have been documented, of which extrapyramidal signs are the most important. In some early-onset cases, axial myoclonus and focal hand dystonia were the presenting features. Action myoclonus can be a predominant feature, leading to a Ramsay–Hunt phenotype, and extrapyramidal rigidity and chorea have occasionally been observed. In addition, some SCA14 patients manifested facial myokymia, depression, cognitive impairment, vertical gaze palsy, and rippling muscles. Incomplete penetrance has been suggested in some papers, but this has not been confirmed by others. Neuroimaging mostly reveals cerebellar atrophy.

Genetics and Pathophysiology

Linkage to the SCA14 locus on chromosome 19q13.4-qter was first described in a Japanese family in 2000, with a second American family of English–Dutch ethnicity showing linkage to an overlapping region 2 years later. The causative gene was identified in 2003 by Chen et al., who discovered exon 4 missense mutation in the *PRKCG* (protein kinase C, gamma) gene. Many mutations, mostly missense mutations, but also small deletions and possibly splice site mutations have been described. Mutations are

located in exons 1, 2, 3, 4, 5, 10, and 18, but exon 4 harbors most of the mutations reported so far, and thus, appears to be a mutational hotspot. *PRKCG* codes for the gamma isoform of protein kinase C (PKCγ), which belongs to the serine/threonine kinase family and is involved in second messenger signaling systems, and has been shown to play an important role in Purkinje cell morphology and function. The exact disease mechanism is yet unknown, but available studies suggest that most PKCγ mutations lead to an increased kinase activity and an increased redistribution of the protein to the plasma membrane accompanied by a reduced ability to phosphorylate target substrates. One consequence of this might be an increased cellular influx of calcium, which subsequently disturbs Purkinje cell signaling. However, further work is needed.

Epidemiology and Relevance

Some studies have assessed the relative contribution of *PRKCG* mutations in dominant ataxia cohorts of various ethnic origins. In the Netherlands, SCA14 represents ~4% of the total SCA population. In France, this percentage is 1.5. Contrary to this, SCA14 is quite rare in Japan, as only two mutation carriers were identified among 882 ataxia patients – although the authors only screened exon 4. In the United States, 2.6% of SCA patients who tested negative for the more common subtypes (SCA1, 2, 3, 6, and 7) were found to carry *PRKCG* mutations.

Spinocerebellar Ataxia 15

Clinical Features

The first SCA15 family, Australian but of Anglo-Celtic origin, was characterized by a slowly progressive, relatively pure cerebellar ataxia with a mean age of onset being 26 years (range 10–50). Hyperreflexia was noted in some. Subsequently, two Japanese SCA15 families were reported; the clinical picture was that of a progressive cerebellar ataxia, starting between 12 and 47 years, but with postural and action tremor of hands and trunk, pyramidal signs, and peripheral neuropathy.

Genetics and Pathophysiology

The SCA15 locus on chromosome 3p24.2–3pter was reported in 2003. The two Japanese families showed linkage to 3p26.1–25.3, thus partly overlapping the SCA15 locus. Missense mutations in an obvious candidate gene, *ITPR1* (inositol 1,4,5-triphosphate receptor type 1), were initially excluded as being causative. Later, deletions of a large part of *ITPR1*, as well as a part of the neighboring *SUMF1* (sulfatase-modifying factor 1) gene, were identified in the Australian SCA15 family, a finding that was reproduced in two British families (the clinical details of which have not been published in detail, but appeared to be an uncomplicated cerebellar ataxia). Findings were corroborated in the two Japanese SCA15 families, but the results in one of the two Japanese families, carrying a p.P1059L missense mutation in *ITPR1* rather than an *ITPR1–SUMF1* deletion, strongly suggest that *ITPR1* is indeed the culprit. *ITPR1* is predominantly expressed in Purkinje cells, and involved in an intracellular second messenger pathway. The exact pathophysiology is currently unknown, but probably involves haploinsufficiency resulting in disturbed intracellular calcium homeostasis.

Epidemiology and Relevance

It recently became evident that SCA16 is also due to partial deletions of the *ITPR1* gene (see below). Therefore, at present, six families with *ITPR1* mutations have been reported. Hara et al. did not observe mutations of this gene in 54 unrelated Japanese dominant ataxia families with unknown genotypes. Further screening efforts are awaited to assess the relative frequency of *ITPR1* mutations in dominant spinocerebellar ataxias.

Spinocerebellar Ataxia Type 16 (now also referred to as Type 15)

Clinical Features

In the single Japanese SCA16 family, onset of disease ranged from 20 to 66 years. In addition to the slowly progressive cerebellar features, mild cognitive impairment and a head tremor were noted in some affected members.

Genetics and Pathophysiology

Initially, SCA16 was mapped to chromosome 8q22.1–24.1, but was later reassigned to 3p26.2-pter, partly overlapping the SCA15 locus. A 'point mutation' (4.256C→T) in the 3′-UTR of the *CNTN4* gene, coding for contactin-4, was found to cosegregate with disease. After the finding of *ITPR1* mutations in SCA15, Iwaki et al. also tested for this gene given the overlap between the SCA16 and SCA15 loci. They identified a deletion of exons 1–48 of the *ITPR1* gene. The previously observed *CNTN4* variant is probably a rare polymorphism in linkage disequilibrium with the *ITPR1* mutation.

Epidemiology and Relevance

The single SCA16 family turned out to have an *ITPR1*/SCA15 mutation, and one could thus argue that the designation SCA16 is now invalid or perhaps vacant.

SCA17

S Tsuji, University of Tokyo Graduate School of Medicine, Japan

Definition

Spinocerebellar ataxia type 17 (SCA17) is an autosomal dominant neurodegenerative disorder caused by expansion of a CAG/CAA repeat coding for a polyglutamine stretch of the TATA-binding protein (TBP) gene. Expansions of polyglutamine stretches have been identified in at least nine hereditary neurodegenerative diseases including spinal and bulbar muscular atrophy (SBMA), Huntington's disease (HD), SCA1, 2, 6, 7, and 17, Machado–Joseph disease (also called SCA3), and dentatorubral-pallidoluysian atrophy (DRPLA). SCA17 is the latest member among these polyglutamine diseases.

Clinical Features and Diagnostic Criteria

The clinical features of SCA17 are characterized by ataxia, psychiatric symptoms including personality changes, cognitive impairment, and extrapyramidal symptoms including chorea, dystonia, and parkinsonism. The mean age of onset is about 30 years ranging from 3 to 55 years. The initial symptoms at onset are ataxic gait in many cases, but other symptoms including psychiatric symptoms, cognitive impairment, and extrapyramidal symptoms may appear first. Furthermore, it should be noted that the clinical presentations of SCA17 are highly heterogeneous and that some patients exhibit clinical presentations indistinguishable from those of HD, emphasizing the broad spectrum of the clinical presentations of SCA17.

Normal alleles range from 25 to 42 repeat units. Although affected individuals carry expanded alleles ranging from 43 to 63, alleles of 43–48 are not fully penetrant. The configuration of the expanded alleles is heterogeneous with interrupting CAA elements. As observed in other polyglutamine diseases, there is an inverse correlation between the size of expanded CAG repeats and the age of onset. Patients carrying expansions of CAG/CAA repeats in both alleles tend to exhibit earlier ages of onset, severer clinical presentations, and a more rapid disease progression compared with those carrying a single allele of expanded allele.

Expansion of the CAG repeat of TBP gene was first described by Koide et al. in a 14-year-old Japanese patient with a de novo partial duplication of the CAG/CAA repeat in the TBP gene. The patient had an expanded CAG/CAA repeat gene coding for 63 glutamines. The initial symptoms at the age of 6 years were ataxic gait and intellectual deterioration. The patient showed a severely impaired intellectual performance, cerebellar ataxia of the limbs and the trunk, dysarthria, dysphagia, and hyperreflexia with extensor plantar responses.

Subsequently, familial cases with expansion of the CAG repeats of the TBP gene have been reported. Nakamura et al. identified four Japanese pedigrees. The CAG/CAA repeats of the TBP gene were expanded to 47–55 repeat units. The mode of inheritance was an

autosomal dominant one with incomplete penetrance. The age of onset ranged from 19 to 48 years with the mean age of onset of 33.2 years. Including the case with de novo expansion of the CAG/CAA repeat, a strong inverse correlation between the age of onset and the size of expanded CAG/CAA repeats was observed. The clinical presentations included gait ataxia, dementia, hyerreflexia, and parkinsonism. Dystonia, chorea, and epilepsy were present in some patients. Stevanin et al. screened a group of patients with Huntingon's disease-like phenotype and identified two patients with expansions of CAG repeats (44 and 46 repeat units) in the TBP gene. The patient with 46 repeat units showed behavioral changes, chorea, ataxic gait, dysarthria, increased tendon reflexes, and parkinsonism. The other patient had gait instability, behavioral abnormality, dementia, and increased tendon reflexes with extensor plantar responses. Oda et al. conducted a large scale screening for CAG/CAA repeat expansions of the TBP gene. By screening 734 patients with SCA, 216 with Parkinson disease and 195 with Alzheimer disease, they identified eight SCA patients with alleles exceeding 43 CAG/CAA repeat units. Alleles with 43–45 repeats were seen in three of the normal subjects and in two patients with Parkinson disease. They further identified a 34-year-old patient carrying 47 and 44 repeats, who had developed progressive cerebellar ataxia and myoclonus at the age of 25 and exhibited dementia and pyramidal signs, while his father and mother were asymptomatic but carried 44 and 47 repeats, respectively, as a heterozygous state, strongly supporting a gene dosage effect of expanded alleles.

Differential Diagnosis

Given the highly heterogeneous heterogeneities of the clinical presentations, the possibility of SCA17 should be considered for patients with the family history compatible with autosomal dominant inheritance and with clinical presentations including ataxia, cognitive impairment, and psychiatric symptoms such as personality changes, chorea, dystonia, or parkinsonism. Differential diagnosis should include various forms of autosomal dominant SCAs, HD, and HD-like phenotypes and neuroferritinopathy. It should be noted that there are reports of sporadic cases of SCA17. The diagnosis is confirmed by molecular testing of the CAG/CAA repeats of TBP gene. There are no specific treatments for SCA17 available, and the treatment largely remains to be symptomatic treatment.

Pathogenesis/Pathophysiology

Among the nine polyglutamine diseases, the physiological functions of the gene products have been known only for SCA6, SBMA, and SCA17. Thus, SCA17 is a good target for investigating the pathophysiologic mechanisms of neurodegeneration. TBP is an important general transcription initiation factor and is the DNA-binding subunit of RNA polymerase II transcription factor D (TFIID), the multisubunit complex crucial for the expression of most genes. Intranuclear accumulation of mutant proteins carrying expanded polyglutamine stretches and subsequent nuclear dysfunction through association of mutant proteins with various transcriptional factors have been considered to play essential roles in the pathogenesis of polyglutamine diseases. Intranuclear inclusions identified in autopsied brains of SCA17 cases support this hypothesis. In contrast to the 'gain-of-toxic function' hypothesis, interference with the physiological functions of TBP may also be involved in the pathophysiologic mechanisms.

Recent studies have demonstrated that expansion of polyglutamine stretches causes abnormal interaction of TBP with the general TFIIB and induces neurodegeneration in transgenic SCA17 mice. Furthermore, it has been shown that mutant TBP with expanded polyglutamine stretches with a deletion spanning part of the DNA-binding domain does not bind DNA in vitro but forms nuclear aggregates and inhibits TATA-dependent transcription activity in cultured cells. These findings suggest that the polyglutamine stretches affect the binding of TBP to promoter DNA and that mutant TBP with expanded polyglutamine stretches can induce neuronal toxicity independently of its interaction with DNA.

SCA27

M Mario and M Daniele, Laboratoire de Neurologie Expérimentale, Bruxelles, Belgium

Glossary

Anticipation – When symptoms of a genetic disorder become apparent at an earlier age from one generation to the next.
Ataxia – A lack of coordination of movement.
Dyskinesias – Repetitive involuntary movements, similar to a tic or chorea. Can occur at any part of the body.
Dystonia – Sustained muscle contractions cause twisting and repetitive movements, or abnormal posture of a body segment.
Growth factor – Refers to a naturally occurring substance capable of stimulating cellular growth, proliferation, and differentiation.
Homeostatic factors – Factors regulating the internal environment to maintain a system stable.
Nav channel – Voltage-gated sodium channel.
Orthologous – Refers to any similarity between characteristics that is due to their shared ancestry.
Penetrance – A term used in genetics to describe the proportion of individuals carrying a particular variation of a gene (an allele or genotype) and expressing an associated trait (the phenotype).
Promoter – A region of DNA facilitating the transcription of a particular gene.
Proteoglycans – Glycoproteins heavily glycosylated.
Splice variants – Is the RNA splicing variation mechanism in which the exons of the primary gene transcript, the pre-mRNA, are separated and reconnected to produce alternative ribonucleotide arrangements.
Tremor – Rhythmic movement involving to-and-fro movements (oscillations) of one or several body parts.
Tyrosine kinase receptors – Are high-affinity cell surface receptors for many polypeptide growth factors, cytokines, and hormones.
Voltage-gated sodium channels – Membrane proteins forming ion channels, conducting sodium ions (Na^+) through the plasma membrane. They are activated at depolarized membrane potentials.

Definition and History

For autosomal dominantly inherited cerebellar ataxias (ADCA), about 25 genetic loci have been identified by linkage analysis, and mutations in $\geq$12 of the corresponding genes have been reported. Molecular analysis of these genes reveals expansions of tri- or penta-nucleotide repeat causing 10 spinocerebellar ataxias (SCAs). Trinucleotide repeats occurr in SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA12, SCA17, and DRPLA, while the pentanucleotide repeat expansion is found in SCA10.

Recently, a missense point mutation in the gene encoding for the fibroblast growth factor 14 (FGF14) on chromosome 13q34, FGF14*phe145ser* ($FGF14^{F145S}$), was identified in a Dutch family presenting with multiple neurological deficits including impaired cognitive abilities and spinocerebellar ataxia. The disorder is now classified as spinocerebellar ataxia 27 [OMIM (Online Mendelian Inheritance in Man) number 609307, SCA27].

SCA27 is characterized by the absence of anticipation and a complete penetrance.

The Family of Fibroblast Growth Factors (FGFs)

Fibroblast growth factors (FGFs) make up a large family of polypeptide growth factors found in organisms ranging from nematodes to humans. In vertebrates, the 22 members of the FGF family range in molecular mass from 17 to 34 kDa and share 13–71% amino-acid identity. Between vertebrate species, FGFs are highly conserved in both gene structure and amino-acid sequence. FGFs have a high affinity for heparan sulfate proteoglycans. They require heparan sulfate to activate one of four cell surface FGF receptors. During embryonic development, FGFs have diverse roles in regulating cell proliferation, migration, and differentiation. In the adult organism, FGFs are homeostatic factors and participate in tissue repair and response to injury. When inappropriately expressed, some FGFs can contribute to the pathogenesis of cancer. A subset of the FGF family, expressed in adult tissues, is important for neuronal signal transduction in the central and peripheral nervous systems.

Genetics of FGFs

The FGF gene expression has been hypothesized to be coincident with a phase of global gene duplications taking place during the period leading to the emergence of vertebrates (Coulier et al., 2000).

Most FGFs are found scattered throughout the genome. In mice, there are at least 22 FGF genes (Gene bank; Mouse Genome Informatics), and the locations of 16 of them have been identified. In humans, 22 FGF genes have been identified and the chromosomal locations (except for FGF16) are known (GenBank; HUGO Gene Nomenclature Database).

The prototypical FGF genes contain three exons. Exon 1 contains the initiation methionine, but several FGF genes (for instance FGF2 and FGF3) have additional 5′ transcribed sequence initiating from upstream CUG codons. The size of the coding portion of FGF genes ranges from under 5 kb (in FGF3 and FGF4) to over 100 kb (in FGF12). Some subfamilies of FGFs (such as FGF11–14) have alternative amino termini, due to the use of alternative 5′ exons. It is still unknown whether a common 5′ untranslated exon splices to these exons or whether an alternative promoter and regulatory sequences are used.

Across species, most orthologous FGF proteins are highly conserved and share more than 90% amino-acid sequence identity. To date, FGF 2, 4, 8, 12, 14, 18, and 19 have been identified in chicken (Gene Bank), whereas others have been identified in zebrafish and *Xenopus*. Most FGF share an internal core region of similarity, with 28 highly conserved and six identical amino-acid residues. Ten of these highly conserved interact with the FGF receptor (FGFR). FGF 11–14 lack signal sequences and are thought to remain intracellular.

The 22 members of the mammalian FGF family are differentially expressed in many tissues, but the patterns and timing of expression vary. Each FGF appears to have unique sites of expression. Some FGFs are expressed exclusively during embryonic development (FGF3, 4, 8, 15, 17, 19), whereas others are expressed in embryonic and adult tissue (FGF1, 2, 5–7, 9–14, 16, 18, and 20–23). The expression pattern of FGFs suggests that they play important roles in development. FGFs often signal directionally and reciprocally across epithelial–mesenchymal boundaries. The integrity of these signaling pathways requires an extremely tight regulation of FGF activity and receptor specificity.

Fibroblast Growth Factor 14 (FGF14)

The fibroblast growth factor 14 (FGF14) gene is located at chromosome 14q34 (**Table 1**). FGF14 belongs to the intracellular FGF homologous factor family (iFGFs), a set of neuronally expressed FGFs (iFGF11–14) that are not secreted and do not activate tyrosine kinase receptors.

Human FGF 14 (FHF 4) is a 245 amino-acid polypeptide containing no signal sequence and possessing a bipartite NLS with a secondary signal motif. The gene is composed of five exons. There are three splice variants: a 245 amino-acid (FGF 14A), a 252 amino-acid (FGF 14B), and a 163 amino-acid (mouse only, FGF 14C) isoform. Splice forms A and B are N-terminal extensions of the common to all 163 amino-acids of the C-terminal sequence of FGF 14.

FGF14 is highly expressed in the brain, in particular, in the cerebellum (the highest levels are in granule cells), the hippocampus, and the nondopaminergic cells in the striatum. The neurological phenotype developed by SCA27 individuals suggests that FGF14 is important for the normal function of several areas of the central and peripheral nervous system.

Protein structure studies suggest that substitution of the *phenylalanine* with a *serine* in position 145 strongly reduces the stability of FGF14, resulting in a loss of function of the protein (**Figure 1**).

The iFGFs interact directly with the pore forming (alpha) subunits of neuronal and cardiac voltage-gated Nav channels. Heterologous coexpression of FGF12, FGF13, or FGF14 with Nav α subunits affects Nav current densities and the voltage dependences of Nav channel activation and inactivation. $FGF14^{F145S}$ expression directly disrupts neuronal excitability by interfering with the functioning of Nav channels. Indeed, expression

of $FGF14^{F145S}$ attenuates peak Nav current densities in hippocampal neurons. More specifically, $FGF14^{F145S}$ disrupts the interaction between FGF14 and Nav1.2. Alterations in Nav channel expression or function modify neuronal membrane excitability and impair information processing in neuronal networks. As a general rule, mutations in genes encoding Nav channel subunits or alterations in the expression of proteins necessary for the localization of Nav channels affect the output properties of central neurons. These abnormalities could contribute to the deficits observed in FGF14.

Genetic ablation of FGF14 in mice ($FGF14^{-/-}$) causes ataxia, paroxysmal dystonia, and cognitive deficits. In fact, the similarities with the human symptoms led to the discovery of the mutation. The autosomal dominant nature of the $FGF14^{F145S}$ mutation and the analogy between the phenotypes of SCA27 patients and $FGF14^{-/-}$ mice further suggests that the $FGF14^{F145S}$ mutation induces a loss of FGF14 function, by blocking the interactions between wild-type FGF14 and Nav α subunits. In the hippocampus, FGF14 is expressed in pyramidal neurons and in the dentate gyrus, and loss of FGF14 in $FGF14^{-/-}$ mice results in an impaired long-term potentiation (LTP) at Schaffer collaterals–CA1 synapses and acquisition deficits in the Morris water maze. Globally, these transgenic mice exhibit altered presynaptic vesicle trafficking, docking, and synaptic protein expression.

Clinical Description

A large four-generation white family of Dutch descent with autosomal dominant ataxia was reported by van Swieten et al. Patients exhibit a high-frequency small-amplitude postural tremor of the hands starting in childhood, progressive ataxia involving the oculomotor system (dysmetric saccades, saccadic pursuit, gaze-evoked nystagmus), speech, limbs, posture and gait, as well as psychiatric manifestations or behavioral deficits (aggressive outbursts, depression), and facial- or orofacial-dyskinesias. Brisk knee jerks and diminished vibration sense at the ankles were noted for several patients.

Epidemiology

SCA-27 is a rare disorder. The precise incidence and prevalence of SCA-27 are unknown. Alterations of the FGF14 gene are not a major cause of SCA in Caucasians.

Ancillary Investigations

Brain MRI shows moderate cerebellar atrophy in some patients, but may also yield normal results. Reduced dopamine D2-receptor binding of the striatum may be

Table 2 Differential diagnosis of SCA27

demonstrated by brain SPECT. Neuropsychological testing shows deficits in memory and executive functioning. Low IQ scores are found in about 20% of cases. Nerve conduction studies disclose a mild axonal neuropathy.

Differential Diagnosis

The main differential diagnoses of SCA-27 are summarized in **Table 2**.

Prognosis and Management

The ataxia of SCA-27 is slowly progressive over decades. Life expectancy is normal. Therapy is based upon rehabilitation. Symptomatic therapy of dyskinesias provides some relief. We are lacking in an effective therapy for ataxic symptoms. Several studies are currently performed in animal models of SCAs, especially in mice, with the aim of either preventing or reducing neurodegeneration.

Scale for the Assessment and Rating of Ataxia (SARA)

T Schmitz-Hübsch, Unversitätsklinikum Bonn, Bonn, Germany

Glossary

Ataxia – Literally (Greek) absence of order. Clinically referred to as a specific motor syndrome, with difficulty to stabilize the trunk against gravity, difficulty to stabilize gaze, difficulty in goal-directed limb movements, and dysarthria.
Cerebellar sign – Neurological sign attributed to lesions of the cerebellum.
Clinical rating scale – Assessment tool used to document and compare disease status, for example, in clinical trials, that is based on a standardized clinical examination of selected disease features. Standardization refers to instructions of test performance and rating.
Outcome parameter – Type of assessment that is chosen to document and compare the effects of an intervention in clinical trials. This can be a clinical scale or any instrumental or laboratory test known to change with disease severity.
Reliability – Accuracy of an assessment tool, that is, how consistent or repeatable are the measurements. For clinical rating scales, reliability is usually documented by good internal consistency and minimal variance between different raters (interrater) or between test and retest.
Validity – Appropriateness of content of an assessment tool, that is, does it measure what it is intended to measure. It is usually documented by good correlations with other assessments of the same construct: for example a clinical scale supposed to measure disease severity could be compared to other measures known to change with disease severity.
Sensitivity – Ability of an assessment tool to pick up differences between different disease states. Sufficient sensitivity (or responsiveness) to change over time is a prerequisite for use of a clinical rating scale as an outcome parameter in clinical trials.

Definition and History

The conduct of multicenter therapeutic trials requires reliable and sensitive assessment tools. For this purpose, clinical rating scales have been established for different diseases and for the testing of potential therapeutic agents. Spinocerebellar ataxias (SCAs) are a clinically and genetically heterogeneous group of autosomal-dominantly inherited progressive ataxia disorders. In the most common genotypes, the disease is caused by translated CAG repeat expansion mutations in different genes. The size of this repeat influences the age at onset, phenotype and disease progression in some genotypes.

The Scale for the Assessment and Rating of Ataxia (SARA) was first published in 2006 as a short and reliable clinical rating scale validated in a two large SCA cohorts (**Figure 1**). However, later studies have recommended its use also for other ataxia disorders including Friedreich ataxia (FRDA).

Development

The clinical group of the European integrated project on spinocerebellar ataxias (EUROSCA) developed and validated a clinical rating scale for ataxia, in preparation of a large multicenter study on the natural history of spinocerebellar ataxias. The authors argued that although the previously published International Cooperative Ataxia Rating Scale (ICARS) was developed by an international consortium for use in ataxia, it was not sufficiently validated at that time and was perceived to have shortcomings in practicality, rating instructions, and scale structure. The authors acknowledged that follow-up in the rare and slowly progressive SCAs would require most reliable and sensitive outcome parameter. Their new clinical scale should be easy to use by being short and close to a standard neurological exam, without instrumental testing. Items were selected by expert agreement for their specificity for cerebellar ataxia and their assumed sensitivity to change. For example, gaze-evoked

Rater: _____date: _____patient:_____

Scale for the assessment and rating of ataxia (SARA)

1) Gait	**2) Stance**
Proband is asked (1) to walk at a safe distance parallel to a wall including a half-turn (turn around to face the opposite direction of gait) and (2) to walk in tandem (heels to toes) without support. **0 Normal, no difficulties in walking, turning and walking tandem (up to one misstep allowed)** **1 Slight difficulties, only visible when walking 10 consecutive steps in tandem** **2 Clearly abnormal, tandem walking > 10 steps not possible** **3 Considerable staggering, difficulties in half-turn, but without support** **4 Marked staggering, intermittent support of the wall required** **5 Severe staggering, permanent support of one stick or light support by one arm required** **6 Walking > 10 m only with strong support (two special sticks or stroller or accompanying person)** **7 Walking < 10 m only with strong support (two special sticks or stroller or accompanying person)** **8 Unable to walk, even supported**	Proband is asked to stand (1) in natural position, (2) with feet together in parallel (big toes touching each other) and (3) in tandem (both feet on one line, no space between heel and toe). Proband does not wear shoes, eyes are open. For each condition, three trials are allowed. Best trial is rated. **0 Normal, able to stand in tandem for > 10 s** **1 Able to stand with feet together without sway, but not in tandem for > 10 s** **2 Able to stand with feet together for > 10s, but only with sway** **3 Able to stand for > 10 s without support in natural position, but not with feet together** **4 Able to stand for > 10 s in natural position only with intermittent support** **5 Able to stand > 10 s in natural position only with constant support of one arm** **6 Unable to stand for > 10 s even with constant support of one arm**
Score	**Score**
3) Sitting	**4) Speech disturbance**
Proband is asked to sit on an examination bed without support of feet, eyes open and arms outstretched to the front. **0 Normal, no difficulties sitting >10 sec** **1 Slight difficulties, intermittent sway** **2 Constant sway, but able to sit > 10 s without support** **3 Able to sit for > 10 s only with intermittent support** **4 Unable to sit for >10 s without continuous support**	Speech is assessed during normal conversation. **0 Normal** **1 Suggestion of speech disturbance** **2 Impaired speech, but easy to understand** **3 Occasional words difficult to understand** **4 Many words difficult to understand** **5 Only single words understandable** **6 Speech unintelligible / anarthria**
Score	**Score**

Figure 1 (Continued)

Rater: _____date: _____patient:_____

5) Finger chase

Rated separately for each side
Proband sits comfortably. If necessary, support offeet and trunk is allowed. Examiner sits in front of proband and performs 5 consecutive sudden and fast pointing movements in unpredictable directions in a frontal plane, at about 50 % of proband´s reach. Movements have an amplitude of 30 cm and a frequency of 1 movement every 2 s. Proband is asked to follow the movements with his index finger, as fast and precisely as possible. Average performance of last 3 movements is rated.

0 No dysmetria
1 Dysmetria, under/ overshooting target < 5 cm
2 Dysmetria, under/ overshooting target < 15 cm
3 Dysmetria, under/ overshooting target > 15 cm
4 Unable to perform 5 pointing movements

Score	**R**ight	**L**eft
Mean of both sides (R+L)/2		

6) Nose-finger test

Rated separately for each side
Proband sits comfortably. If necessary, support of feet and trunk is allowed. Proband is asked to point repeatedly with his index finger from his nose to examiner's finger which is in front of the proband at about 90 % of proband's reach. Movements are performed at moderate speed. Average performance of movements is rated according to the amplitude of the kinetic tremor.

0 No tremor
1 Tremor with an amplitude < 2 cm
2 Tremor with an amplitude < 5 cm
3 Tremor with an amplitude > 5 cm
4 Unable to perform 5 pointing movements

Score	**R**ight	**L**eft
Mean of both sides (R+L)/2		

7) Fast alternating hand movements

Rated separately for each side
Proband sits comfortably. If necessary, support of feet and trunk is allowed. Proband is asked to perform 10 cycles of repetitive alternation of pro- and supinations of possible. Movement is demonstrated by examiner at a speed of approx. 10 cycles within 7 s. Exact times for movement execution have to be taken.

0 Normal, no irregularities (performs <10 s)
1 Slightly irregular (performs <10 s)
2 Clearly irregular, single movements difficult to distinguish or relevant interruptions, but performs < 10 s
3 Very irregular, single movements difficult to distinguish or relevant interruptions, performs > 10 s
4 Unable to complete 10 cycles

Score	**R**ight	**L**eft
Mean of both sides (R+L)/2		

8) Heel-shin slide

Rated separately for each side
Proband lies on examination bed, without sight of his legs. Proband is asked to lift one leg, point with the heel to the opposite knee, slide down along the shin to ankle, and lay the leg back on the examination bed. The task is performed 3 times. Slide-down movements should be performed within 1 s. If proband slides down without contact to shin in all three trials, rate 4.

0 Normal
1 Slightly abnormal, contact to shin maintained
2 Clearly abnormal, goes off shin up to 3 times during 3 cycles
3 Severely abnormal, goes off shin 4 or more times during 3 cycles
4 Unable to perform the task

Score	**R**ight	**L**eft
Mean of both sides (R+L)/2		

Figure 1 Illustration of full SARA text. Sum score is formed by addition of cells highlighted in grey.

nystagmus, although specific for cerebellar dysfunction, was not included in the scale, as it can disappear in later disease stages with the progression of (noncerebellar) ophthalmoparesis. Further, nonataxia signs and symptoms frequently occur in ataxia disorders and may contribute to disease severity. In contrast to the previously published Friedreich Ataxia Rating Scale (FARS), which includes rating of some noncerebellar symptoms, SARA claims to measure ataxia only, irrespective of additional symptoms. However, the authors proposed a complementary 30-item Inventory of Non-Ataxia Symptoms (INAS) to account for such extracerebellar involvement in spinocerebellar ataxias.

Scale Structure

The scale consists of eight items that reflect neurological manifestations of cerebellar ataxia: gait, stance, sitting, speech, finger-chase, nose-finger-test, fast alternating hand movements, and heel-shin-slide. The ratings in each item range from 0 (= normal, absence of sign) to a maximum of 8 (gait), 6 (stance and speech) and 4 (for the remaining items). The items of limb coordination are performed and rated separately for right and left sides. The average of both sides is included in the SARA total score, a simple sum score of all eight items that ranges from 0 (= no ataxia) to 40 (= maximal ataxia or unable to perform).

Metric Properties and Validation Studies

The scale was originally published with data from two large validation trials performed in 167 and 119 SCA patients and 110 controls. The patient group covered a wide range of disease severity with SARA ratings of 15.9±8.5 (range 1.5–40) while controls had ratings of 0.4±1.1 (range 0–7.5). Thus, at the lower end of the scale, some overlap between mild cerebellar syndrome and no affection was seen with this scale. Practicality was good with time to administer reported as 14 min. Factorial analysis determined one factor that explained 80% of SARA variance after exclusion of one oculomotor item contained in an earlier version of the scale. This supports the concept of SARA as a one- dimensional scale that measures one single construct, ataxia. Internal consistency of the scale was high (Cronbach's alpha 0.94). In a subgroup of 95 patients, interrater reliability was excellent (ICC 0.98) for the sum score and most items (less for finger–nose test and heel–shin slide on the left side). The results of factorial analysis, high internal consistency and high interrater reliability (less for upper limb kinetic items) have later been replicated in a smaller validation trial in 64 moderately affected patients with different ataxia disorders (mainly sporadic adult-onset ataxia) and, recently, in a cohort of 96 FRDA patients. The test-retest reliability of SARA in a subset of 15 assessments of the original cohort with 1–34 days intervals was also high (ICC 0.9). The linearity of the scale has been evaluated by regression of SARA ratings versus global assessments of ataxia severity from 11 video cases. Results supported a linear model (r^2 0.98). The relation of SARA ratings with global ratings of mobility or with different measures of functional independence in the original SCA cohorts, but also in the sample of 64 cases with other ataxia disorders and in another study of 96 FRDA patients support validity of the scale and clinical relevance of score differences in different ataxia disorders. Further, in FRDA patients, SARA was highly correlated with ICARS and FARS (part III) sum scores. A correlation of SARA with disease duration reported for SCA as well as FRDA patients, suggests sensitivity to change in disease status over time.

Clinical Trials

SARA is currently used in a large European multicenter trial to evaluate the natural history of SCAs. Data from the baseline assessment have been published: SARA total was independently predicted by disease duration, age of onset and length of the expanded repeat in multivariate models that explained 60% (SCA1), 45% (SCA2), and 47% (SCA3) of the variance. In SCA6, SARA total was only determined by disease duration and age of onset. The 30-item Inventory of Non-Ataxia Symptoms (INAS) as a measure of noncerebellar affection was related to SARA in some genotypes. In addition, SARA was related to measures of subjective health status (EQ-5D) in the same study. The EUROSCA clinical group also devised the Spinocerebellar Ataxia Functional Index (SCAFI) as a composite of three timed performance measures −8 m walk, 9-hole peg test and PATA rate – that was highly correlated with SARA ratings in SCA patients over the whole range of disease severity. Likewise, another study in 141 autosomal-dominant ataxia patients reported a high correlation of SARA with (dominant-hand) performance in two measures of hand dexterity. To date, three interventional pilot studies used SARA to evaluate the effect of pregabalin, aminopyridine, or recombinant erythropoietin on ataxia severity in different disorders. SARA is also included as a secondary outcome measure in an ongoing pilot study of Lithium in SCA1.

Criticism

Estimates of progression rates, which are required for sample size calculations in clinical trials, have only been reported from regression with disease duration for SARA and the proposed complementary functional measure SCAFI. The ongoing EUROSCA natural history study will yield such estimates prospectively for the most common SCA genotypes: SCA1, SCA2, SCA3, and SCA6. Whether timed performance measures will be more favorable than SARA in terms of objectivity and sensitivity in therapeutic trials remains to be shown. Of note, separate evaluations of progression rates in other ataxia disorders than SCA will be needed for the planning of interventional trials in other target groups. As SARA did not differentiate well between mild ataxia and the performance of healthy controls, some limitation in specificity has to be considered when used in mildly affected patient groups.

Conclusion

SARA is an 8-item short and simple clinical rating scale for use in ataxia disorders. Oculomotor dysfunction was excluded from the scale during the validation process to improve its metric properties that are otherwise favorable

for use in clinical trials. Practicality was reported as superior to the ICARS, and the high reliability allows the use of SARA for interindividual and intraindividual comparisons. Further, linearity of the scale was reported in the original publication. Validation data are currently most abundant for spinocerebellar ataxia, including the ongoing evaluation of progression rates. However, favourable metric properties for SARA have also been confirmed in other ataxia disorders including FRDA.

Schwab and England Activities of Daily Living Scale

A Siderowf, Parkinson's Disease and Movement Disorders Center, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Glossary

Convergent validity – The ability of a measurement scale to correlate with other measures of the same variable.

Inter-rater reliability – The degree of agreement among raters using the scale.

Definition and History

The Schwab and England (S & E) Activities of Daily Living (ADL) Scale was originally used to evaluate response to basal ganglia surgery (see **Figure 1**). The intent was to describe the functional capacity of Parkinson's disease (PD) patients as a proportion of full, normal function. The scale was also meant to have 'interval properties' such that a change of 10% at the bottom of the scale is equivalent to a change of 10% at the higher end of the scale.

The S & E Scale may be administered in a variety of ways. Although the scale contains 100 possible points, most raters use either 11 steps (with 10 points between each step) or 21 steps (with 5 points between each step). Common variants are to use the scale to rate function in the medication 'on' or 'off' state for fluctuating patients, or to use either physician and/or patient input to generate a score. At the time of the scale's original publication, specific instructions were not included so that there was no official method of administration or application. In practice and research, the choices of administration depend on the purpose of the individual clinical evaluation or research study.

Although the S & E Scale is widely used in research and clinical practice, there is little information regarding its metric properties. However, the available data suggest

100%-Completely independent. Able to do all chores w/o slowness, difficulty, or impairment.
90%-Completely independent. Able to do all chores with some slowness, difficulty, or impairment. May take twice as long.
80%-Independent in most chores. Takes twice as long. Conscious of difficulty and slowing
70%-Not completely independent. More difficulty with chores. 3 to 4X along on chores for some. May take large part of day for chores.
60%-Some dependency. Can do most chores, but very slowly and with much effort. Errors, some impossible
50%-More dependant. Help with 1/2 of chores. Difficulty with everything
40%-Very dependant. Can assist with all chores but few alone
30%-With effort, now and then does a few chores alone of begins alone. Much help needed
20%-Nothing alone. Can do some slight help with some chores. Severe invalid
10%-Totally dependant, helpless
0%-Vegetative functions such as swallowing, bladder and bowel function are not functioning. Bedridden.

Figure 1 Schwab and England ADL Scale.

that it has high inter-rater reliability, convergent validity with other PD rating scales, and responsiveness to change over time. It has also shown significant changes in a variety of therapeutic settings.

Summary

The S & E Scale is a well-established and recognized outcome in clinical trials of PD. Its mode of application varies according to different uses, but it provides a clinically pertinent measure of the daily function for PD.

Senataxin

M Anheim, Pitié Salpêtrière Hospital, Paris, France

Glossary

Aprataxin – Protein, encoded by the APTX gene, defective in ataxia with oculomotor apraxia type 1.
α-Fetoprotein serum level – Blood dosage of a tumor-associated fetal glycoprotein of 70 kD synthesized in the fetal yolk sac, liver, and intestines. α-Fetoprotein is the major protein of fetal serum, replaced by albumin after birth, and has a half-life of 5–7 days. α-Fetoprotein may bind and transport fatty acids, steroids, heavy metal ions, and drugs and plays a role as a growth regulator.
Oculomotor apraxia – Inability to generate volitional horizontal saccades with a characteristic compensatory headthrusting and synkinetic blinking. It is not a true apraxia, but rather an intermittent saccade failure responsible for dissociation between eyes and head movements during the rotation of the head, which reaches the target before the eyes.
Senataxin – Protein, encoded by the SETX gene, defective in ataxia with oculomotor apraxia type 2.

Clinical Features

Ataxia with oculomotor apraxia type 2 (AOA2) belongs to the autosomal recessive cerebellar ataxias (ARCA), which are rare and early disabling neurodegenerative diseases dominated by Friedreich ataxia. The onset of the disease

usually occurs between 12 and 20 years of age, and the patients become wheelchair bound near 30 years of age. The clinical phenotype, which is homogeneous, is characterized by cerebellar ataxia, which is the initial sign in more than 80% of cases and progressively worsens, axonal sensorimotor peripheral neuropathy (95%), oculomotor apraxia (OMA) characterized by hypometric horizontal saccades and normal or increased latencies (30–50%), strabismus (10–30%), chorea and/or dystonia (20–40%), and pyramidal signs (10–15%). Laboratory examination in AOA2 reveals prominently elevated α-fetoprotein (AFP) serum levels in 99% of patients and less frequently elevated creatine kinase (CK) serum levels. Slightly elevated AFP levels in healthy subjects with SETX heterozygous mutation have been reported. Brain magnetic resonance imaging (MRI) shows diffuse cerebellar atrophy with relative sparing of the brainstem (**Figure 1**) and electroneuromyography confirms the peripheral neuropathy. A postmortem study revealed a marked loss of cerebellar Purkinje cells as well as mild fibrous gliosis that was more severe in the vermis than in the hemispheres.

Figure 1 Sagittal T1-weighted brain magnetic resonance imaging of AOA2 patient: marked cerebellar atrophy.

Pathophysiology

The gene defective in AOA2 was localized to chromosome 9q34. AOA2 is caused by mutations in the SETX gene, which encodes a protein named senataxin due to its homology with the yeast protein SEN1p. SETX comprises 24 exons, and senataxin is 2677 amino acids long (with a large and poorly conserved domain encoded by the 4.2 kb-long exon 8) and contains at its C terminus a classical seven-motif domain found in the superfamily 1 of helicases. Senataxin is the ortholog of the yeast Sen1p, which is a helicase involved in tRNA, snRNA, and rRNA splicing and maturation. Senataxin is suspected to be a DNA/RNA helicase and is considered to be involved in the defense against DNA damage, in DNA double-strand breaks repair, and in the processing of noncoding RNAs. Senataxin belongs to a subfamily of helicases that comprises RENT1 involved in nonsense-mediated RNA decay and IGHMP2, which is mutated in spinal muscular dystrophy with respiratory distress. It has been demonstrated that senataxin is exclusively located in the nucleus but its nucleolus localization remains controversial. The conserved N-terminus of senataxin could be involved in protein–protein interaction and in subcellular localization. SETX missense mutations are mostly located either to the N-terminal domain or to the C-terminal helicase domain, supporting the fact they are both key functional domains.

Differential Diagnosis

AOA2 belongs to the group of ARCA with OMA, which are related to defect in DNA breaks repair and which also include ataxia-telangiectasia (AT) due to mutations in the ataxia telangiectasia mutated (ATM) gene with the first symptoms of the disease occurring mostly before 3 years of age, ataxia with oculomotor apraxia type 1 (AOA1) related to mutations in the aprataxin (APTX) gene with initial signs usually occurring early (between 2 and 5 years of age), and ataxia-telangiectasia-like disorder (ATLD), which is exquisitely rare and related to mutations in the MRE11 gene. AOA2 and AT patients also share elevated AFP levels but in contrast to AT, there is no increased sensitivity to ionizing radiation and no susceptibility to cancer in AOA2.

Mutations in SETX have also been reported to cause dominantly inherited juvenile amyotrophic lateral sclerosis (ALS4) and dominant tremor-ataxia. ALS4 occurs before 25 years of age and is defined by limb weakness, severe muscle wasting, pyramidal signs, normal sensation, the lack of bulbar and cerebellar signs, and a slow disease progression.

Diagnostic Work-up/Tests

Given the hurdles to sequence the large SETX gene, the strategy for AOA2 diagnosis in ataxic patients should be based on AFP serum level. In cases of ataxia with normal AFP levels ($< 7\ \mu g\ l^{-1}$) in the early stage of the disease, the diagnosis of AOA2 is unlikely, but a second assessment of AFP level, one year later for instance, is highly recommended. The AFP value of $7\ \mu g\ l^{-1}$ appears to be a good cutoff for selecting which patient should undergo sequencing of SETX.

Prognosis

Patients become wheelchair bound at a median age of 30 years (after a median disease duration of 15 years). No genotype-to-phenotype correlation or prognostic factors have been reported yet in AOA2, but the age of onset of the disease is negatively correlated to the severity of the disease (personal data). Strabismus is correlated to the severity, whereas OMA is negatively correlated to the severity of the disease. Missense mutations into the helicase domain, missense mutations outside the helicase domain, and deletion, truncating mutations were compared. There was a significant difference between the three groups considering the severity of the disease, the disease being more severe in the case of missense mutations out of the helicase domain than in the helicase domain. However, no difference was found for the severity between missense mutations out of the helicase domain and deletions or truncating mutations (personal data). Pyramidal signs and dystonia were more common and the disease was less severe with missense mutations in the helicase domain of *SETX* than with missense mutations out of the helicase domain and deletion and nonsense mutations.

Senile Chorea

F Cardoso, Internal Medicine Department, The Federal University of Minas Gerais, Belo Horizonte, MG, Brazil

Glossary

Chorea – Abnormal involuntary movements that are brief, random, usually distal, and without purpose.

Huntington's disease – Autosomal dominant illness characterized by chorea and other movement disorders, behavioral disturbances and cognitive decline.

Sydenham's chorea – Chorea resulting from autoimmune process triggered by β-hemolytic Streptococcus.

Definition and History

'Chorea' (derived from the Latin choreus meaning 'dance') refers to abnormal involuntary movements that are brief, random, usually distal, and without purpose. Senile chorea (SeC) is the expression used to designate chorea with late onset, generalized distribution, lack of family history, and no dementia. This is an ill-defined concept, and the term is not frequently used in the current medical literature. It is now clear that SeC is a descriptor that applies to many patients with chorea, some with a diagnosed explanation and others with movements of unknown etiology in elderly patients. Most of reports of this subject are from the age before the availability of genetic testing for Huntington's disease (HD).

Etiology and Pathogenesis

At least half of the patients who meet the diagnostic criteria of SeC are diagnosed with HD. Other conditions, however, have been identified as responsible for some of these cases: HD-like disease, neuroacanthocytosis, late-onset Hallervorden–Spatz disease, Sydenham's chorea (SC), systemic lupus erythematosus, vascular disease (usually in association with diabetes mellitus), exposure to drugs (dopamine-receptor blockers, amphetamine, cocaine), hyperthyroidism, and infections (AIDS, syphilis, and viral encephalitis).

Because of the casual heterogeneity, there is no well-established underlying mechanism of pathogenesis responsible for SeC, aside the hypoactivity of the subthalamic nucleus, common to all forms of chorea. Of note, SC can occur as a result of exposure to hormone-replacement therapy in patients with a past history of rheumatic fever (not necessarily with presence of chorea). In the few patients with the diagnosis of SeC of uncertain cause who have come to autopsy, the results have been quite heterogeneous: no specific anatomic abnormality, spheroids in the striatum, findings typical of Hallervorden–Spatz disease, and striatal degeneration of nonvascular origin.

Epidemiology

There are no formal epidemiologic investigations of SeC performed either in the community or even in tertiary centers. In a study involving a few academic units in Spain during three years, the authors found six patients who met the diagnostic criteria of SeC. In half of them, however, genetic testing showed that the diagnosis was in fact HD. Taking into account this study, the scarcity of reports of SeC in the literature and the clinical experience of the author, it can be stated that it is a very rare condition.

Clinical Features and Diagnostic Criteria

The typical features of SeC are generalized chorea with onset in the elderly without family history or dementia. The chorea is usually mild but in a few patients it can be severe enough to be labeled as ballism. As to cognitive changes, although lack of dementia is mandatory criterion for the diagnosis of SeC, all patients who underwent formal neuropsychological evaluation have been found to display abnormalities in some domains.

Currently, there are no validated diagnostic criteria of SeC. Most authors, however, make the diagnosis when the onset of chorea is (1) in the elderly age, (2) the patient does not present with dementia and family history of a similar condition, suggesting Huntington's disease, and (3) investigation fails to identify a clear cause. There are to date unsolved problems in this set of criteria: the age limit has not been defined (my personal recommendation is 65 years) and the extent of the investigation that needs to be done to rule out an underlying recognizable cause. A minimal medical diagnostic evaluation is suggested below (see section Diagnostic Work-up).

Differential Diagnosis

The conditions which can mimic SeC are HD, HD-like disease, neuroacanthocytosis, late-onset Hallervorden–Spatz disease, SC, systemic lupus erythematosus, vascular disease (usually in association with diabetes mellitus), exposure to drugs (dopamine-receptor blockers, amphetamine, cocaine), hyperthyroidism, paraneoplastic chorea associated with colon or lung cancers, and infections (AIDS, syphilis and viral encephalitis).

Diagnostic Work-Up

Elderly patients with de novo chorea should undergo a complete neurologic history with attention to drug exposure, specifically antipsychotics or other dopamine-blocking agents (tardive dyskinesia. They should have a neurological examination to define if chorea is an isolated finding or whether other neurological signs, and especially dementia (Huntington's disease) are present. Diagnostic testing will help to investigate the myriad causes of this hyperkinesia: genetic testing for HD; genetic testing for

HD-like disease; genetic testing for Hallervorden–Spatz disease; search of acanthocytes on fresh blood smear, CPK levels and electromyography; tests of acute phase reactants such as erythrocyte sedimentation rate, C-reactive protein, leukocytosis, rheumatoid factor, mucoproteins, protein electrophoresis, supporting evidence of preceding streptococcal infection (increased antistreptolysin-O, antiDNAse-B, or other antistreptococcal antibodies; positive throat culture for group A *Streptococcus*; recent scarlet fever), Doppler echocardiogram; serologic studies for systemic lupus erythematosus and primary antiphospholipid antibody syndrome must be ordered to rule out these conditions; search for antibodies associated with paraneoplastic syndromes; and neuroimaging helps to define the vascular nature of chorea and identify findings suggestive of HD (atrophy of head of the caudate), Hallervorden–Spatz disease (the eye of the tiger sign) or neuroacanthocytosis (which can present with atrophy of head of the caudate or the eye of the tiger sign).

Management

If a cause is found, the underlying disease should be treated. In the absence of an identified cause, dopamine receptor blockers are the mainstay of the pharmacological management of SeC. Despite the lack of controlled studies, there is consensus among experts that the most effective agents are neuroleptics with significant D2 receptor blocker activity. The personal choice of the author is risperidone. Use of these agents, however, is warranted solely when chorea is associated with meaningful disability since even these new agents may be associated with side-effects, particularly in the elderly. Among the latter, the most important ones are drowsiness, parkinsonism, and tardive dyskinesia. There is one report describing the effectiveness and safety of deep brain stimulation of the pallidum and thalamus in one patient with SeC.

Prognosis

Little is known about the long-term prognosis of patients with SeC. Clinical experience suggests that there is little, if any, progression of chorea and cognitive decline in the majority of patients.

Serotonin and Tryptophan

S Athar, Medical University of South Carolina, Charleston, SC, USA

Glossary

Extrapyramidal symptoms – Extrapyramidal symptoms (EPS) are a variety of movement disorders such as tardive dyskinesia, akathisia, or bradykinesia, suffered as a result of taking dopamine antagonists, usually antipsychotic (neuroleptic) drugs, which are often used to control psychosis, especially schizophrenia. Other antidopaminergic drugs like the antiemetic metoclopramide or the tricyclic antidepressant amoxapine can also cause extrapyramidal side effects.

Myoclonus – Myoclonus is a movement disorder, characterized by brief, involuntary twitching of a muscle or a group of muscles.
Serotonin – Serotonin (5-hydroxytryptamine, or 5-HT) is a monoamine neurotransmitter synthesized in serotonergic neurons in the central nervous system (CNS) and enterochromaffin cells in the gastrointestinal tract.
Tryptophan – Tryptophan is one of the 20 standard amino acids, as well as an essential amino acid for humans.

Definition and History

The chemical name for serotonin is 5-hydoxytryptamine (5-HT) which is often abbreviated as 5-HT. In the late 1940s, the laboratory of Dr. Irving Page at the Cleveland Clinic isolated a vasoconstricting substance in serum and named it serotonin. The exact structure of serotonin was reported in 1949. In 1952, Dr. Betty Twarog joined the Page Laboratory, and her research resulted in the identification of serotonin in the brain.

Neurochemistry and Neuroanatomy

The neurochemical anatomy of brain serotonin neurons was first studied by fluorescence histochemical detection. Serotonin producing cell bodies are present largely within the brainstem raphe nuclei and particular regions of the reticular formation. Raphe clusters of 5-HT neurons are found rostrally from the level of the interpeduncular nucleus in the midbrain to the level of the pyramidal decussation in the medulla. 5-HT is synthesized from L-tryptophan, an essential amino acid. Hydroxylation in 5-hydroxytryptophan is catalyzed by tryptophan hydroxylase, which is the rate limiting enzyme of the synthesis. This enzyme requires for its activity the presence of tetrahydrobiopterine, oxygen, NADPH2, and a metal, iron or copper. Subsequently, L-aromatic amino acid decarboxylase with pyridoxal-phosphate as coenzyme catalyzes the decarboxylation of 5-hydroxytryptophan into 5-HT.

Central Serotonergic Systems and Serotonin Stores Outside the Central Nervous System

In the brain, serotonin biosynthesis depends on the quantity of tryptophan which crosses the blood–brain barrier (whereas 5-HT does not). Only free plasma tryptophan, that is, unbound to albumin, enters the brain, and decrease of its free ratio reduces its penetration. Moreover, other amino acids compete with free tryptophan and limit its entry in the brain. Plasma cortisol, increased in depressed patients, decreases free L-tyrosine and free L-tryptophan concentrations in plasma, resulting in alterations in tryptophan delivery to the brain. Insulin decreases the transfer of many amino acids centrally, but tryptophan transport is not affected. Serotonin is found in many tissues outside the brain, especially the digestive tract. The average adult human possesses only 5–10 mg of serotonin, and over 90% is in the intestine. The remaining is located in blood platelets and the brain. In the gastrointestinal tract, serotonin is also localized in enterochromaffin cells. In the central nervous system (CNS), higher concentrations are found in brainstem than in cortex. Serotonin, released by presynaptic serotonergic neurons into synaptic clefts, activates specific receptors and is removed from the synapse primarily by reuptake into presynaptic neurons. Platelets do not synthesize serotonin but absorbed serotonin release into the plasma from enterochromaffin cells. Serotonin released from platelets in plasma has a relatively localized effect on blood vessels where it is released, during migraine. While the half-life of serotonin is long in platelets and intestine (days), it is very short in the brain (a few minutes), Once 5-HT is actively transported into cells, it is inactivated by biotransformations, including oxydative deamination of the lateral amino chain by monoamine oxidase (MAO), both within and outside the cell. MAO-A plays a more prominent role in this process than MAO-B. The metabolism of serotonin leads to 5-hydroxy-indol-acetaldehyde which is then oxidized into 5-hydroxy-indol-acetic acid (5-HIAA). This metabolite can be found in urine in quantities normally lower than 10 mg per 24 h and is the usual measurement tool to reflect serotonergic metabolism. Inactivation also involves conjugation by glucuronic acid or sulfate of the hydroxyl group OH in 5-position.

Serotonergic Receptors

Serotonin receptors are classified into seven types, 5-HT1 through 5-HT7. Each type can have subtypes (A, B, etc.). These receptors are localized in the brain and in peripheral organs but their distribution is not homogeneous. The majority of 5-HT receptors are postsynaptic, with some exceptions, most notably 5-HT1A and 5-HT1B that are mainly presynaptic and modulate serotonin release. The signaling pathways to which these receptors are coupled are known, but it is has not been possible to link direct clinical effects systematically to their stimulation. Serotonin receptors are coupled to G proteins except 5-HT3 receptors which are receptor-channels, also called

ionotropic receptors, which, in the activated state, are open and permeable to sodium and potassium cations.

Clinical Disorders and Serotonin

Effects of serotonin on the CNS are numerous and complex and of considerable importance from a pharmacological point of view because many drugs act by its intermediary. Serotonin is a neurotransmitter involved in many pathways and plays a role in various different states, psychiatric, medical, and neurological. These conditions include aggression, pain, sleep, appetite (suppressant effect), depression (antidepressant action), migraine, anxiety, temperature regulation and emesis is involved in the regulation of sleep, learning and memory, mood (antidepressant action), temperature, and appetite (appetite suppressant effect). Overstimulation of 5-HT2 receptors can induce productive and negative symptoms of psychotic disorders. LSD (Lysergic acid diethylamide, a semisynthetic psychedelic drug of the ergoline family) or lysergide a potent agonist of 5-HT2 receptors with additional effects on D1 and D2 dopaminergic receptors, has hallucinogenic properties.

Drugs Affecting Serotonergic Pharmacology Used in Clinical Medicine

Serotonin, through its various types of presynaptic and postsynaptic receptors, modulates the activity of other transmitters. It plays a determining part in adaptation. L-Tryptophan and L-5-hydroxytryptophan, precursors of serotonin, are used as regulators of sleep and antidepressants, L-5-hydroxytryptophan, called oxitriptan, has been proposed for the treatment of certain types of postanoxic myoclonus.

The compounds which specifically inhibit serotonin reuptake by neurons are named SSRIs, selective serotonin reuptake inhibitors. The SSRIs have antidepressant properties in patients, but their mechanism of action is not completely elucidated, as their antidepressant effect appears only in 2 or 3 weeks, whereas their inhibiting effect on the reuptake is immediate. This delay in onset of antidepressant effect suggests the intervention of complex mechanisms. Some of SSRIs have also appetite suppressant properties. When serotonin reuptake is inhibited, its concentration in the synaptic cleft increases. This increase induces postsynaptic and presynaptic effects, in particular a stimulation of 5-HT1A receptors, which reduces 5-HT release and, thus offsets the inhibition of its reuptake. The combination SSRI and an antagonist of 5-HT1A presynaptic receptors increase the serotonin release. Pindolol, a drug with β-adrenergic blocking effects and nonspecific antagonism of 5-HT1A receptors, accelerates and improves the effect of SSRIs. The main SSRIs are fluoxetine, fluvoxamine, paroxetine, citalopram, escitalopram, and sertraline. They do not have atropinic (antimuscarinic) effects. In addition to their use in the treatment of depressive disorders in which their efficacy is equal or higher than that of other antidepressants, SSRIs are used in the treatment of compulsive obsessive disorders, of panic attacks and social phobia.

Movement Disorders and Serotonergic Agents

SSRIs are the most commonly prescribed antidepressants. Movement disorders induced by antidepressants are much less common than those induced by antipsychotic medications. Often, movement disorders following the use of antidepressants are the result of drug–drug interactions or tend to occur in patients who have a history of previously using neuroleptic medications. Patients with depression may have altered neurotransmitter function, which may make them prone to the development of certain movement disorders. Generally speaking, in contrast to antipsychotic medications, antidepressants do not commonly induce permanent movement disorders. The incidence of movement disorders caused by antidepressants is largely unknown, since there have been no systematic studies and most data are derived from case reports. Tricyclic and tetracyclic antidepressants act by blocking the reuptake of norepinephrine (NE) and serotonin (5-HT) and also block muscarinic acetylcholine (Ach) and histamine receptors (H1 and H2) in varying degrees. SSRIs block the reuptake of 5-HT more effectively than NE and lack significant effect on muscarinic cholinergic, and histaminergic receptors.

Myoclonus

Serotonergic pharmacology has been linked to the movement disorder of myoclonus. In most reported cases, the movement disorder develops shortly after the SSRI was started. The predominant receptors involved in mediating serotonin toxicity in humans appear to be 5-HT2 receptors, whereas 5-HT1 receptors are responsible for the therapeutic effects of SSRIs. Excessive levels of serotonin have been implicated in the development of myoclonus. 5-hydroxytryptophan (5-HTP) can induce a syndrome characterized by altered muscle activity with myoclonus. Similarly, myoclonus may be induced by L-tryptophan and coadministration of a monoamine oxidase inhibitor (MAO-I) or by serotonin receptor agonists. The 5-HTP-induced syndrome has been shown to be antagonized by a central decarboxylase inhibitor and by 5-HT receptor blockers such as methysergide and cyproheptadine.

Serotonin Syndrome

The serotonin syndrome is a medical emergency that is characterized by high fever, rigidity, and altered mental status. It may be confused with the neuroleptic malignant syndrome (NMS). The latter is typically associated with treatment with a neuroleptic medication or sudden withdrawal of a dopaminergic drug, such as levodopa (L-dopa). The NMS shares some clinical features with the serotonin syndrome, including mental status changes, fever, rigidity, and autonomic dysfunction. Tremor, dystonia, dyskinesias, and chorea may also be seen. The presence of myoclonus, however is particularly characteristic of the serotonin syndrome, although all cases of serotonin syndrome do not demonstrate myoclonus. Proposed diagnostic criteria for the serotonin syndrome are: Coincident with the new administration or increase of an existing SSRI, there is presence of at least three of the following clinical signs: mental status changes, agitation, myoclonus, hyperreflexia, rigidity, diaphoresis, shivering, tremor, diarrhea, incoordination, fever. Other etiologies, such as infectious, metabolic, drug withdrawal, or substance abuse, must be excluded. When a neuroleptic medication has been started or increased within a recent time period before symptom onset and an SSRI has likewise been added or increased, the two syndromes cannot be distinguished. Symptoms of Serotonergic excess can be caused by serotonin overdose, drug interaction or as a complication of therapy. More likely than pure SSRI overdose, the combination of an SSRI and a MAO inhibitor or a reversible MAO-A inhibitor may result in significant serotonin toxicity (16% vs. 55%). To avoid the serotonin syndrome, SSRIs should not be administered along with MAO-A inhibitors or with mixed MAO-A/MAO-B inhibitors. Although the metabolism of serotonin primarily involves MAO-A, when physicians treat patients on MAO-B inhibitors with SSRIs they usually introduce the antidepressant with caution and monitor for possible serotonin syndrome symptoms and signs carefully.

Serotonergic pathways in the CNS are intimately involved in the modulation of motor behavior, and in the pathophysiology of human involuntary movement disorders. These observations are supported by recent reports demonstrating large serotonergic innervation of the striatum and substantia nigra, and a close interaction between the activity of serotonergic neurons with the dopamine system in the striatum and nigra. There are several reports in the literature of other movement disorders, such as dystonia or chorea, associated with the use of SSRIs. Some of these may represent less severe cases of the serotonin syndrome. The serotonin syndrome may be encountered in Parkinson's disease. It is often precipitated by concomitant use of selegiline and other medications, including meperidine (mostly used in postoperative pain control), and antidepressants.

Other Movement Disorders

A study published in 1998 summarized 127 published reports of SSRI-induced movement disorders. The reports included akathisia ($n = 30$), dystonia ($n = 19$), dyskinesia ($n = 12$), tardive dyskinesia ($n = 6$), parkinsonism ($n = 25$), and 15 cases of mixed disorders. Ten isolated cases of bruxism were identified. Ten additional reports could not be classified. Treatment strategies included discontinuation of the SSRI; dosage reduction; or the addition of a benzodiazepine, β-blocker, or anticholinergic agent. An earlier report stated that among patients with Parkinson's disease treated with SSRIs, there were 16 cases of worsening parkinsonism. Patients who developed dystonia, parkinsonism, or tardive dyskinesia were older on average than patients with akathisia; 67.6% of affected patients were females. Fluoxetine, the most commonly prescribed SSRI to date, was implicated in 74.6% of cases of SSRI-induced EPS (extrapyramidal symptoms).

SSRI-induced EPS or movement disorders are probably related to agonism of serotonergic input to dopaminergic pathways within the CNS. Several patient-dependent and pharmacokinetic variables may determine the likelihood that EPS will emerge. Although these side effects are infrequent, clinicians should be alert to the possibility of their occurrence. SSRI use appears to be associated with the development of movement disorders, either as a direct result of the drug or exacerbation of an underlying condition. Predisposing factors may include the use of neuroleptics, existing neurological diagnoses, or preexisting movement disorders. Clinicians should be aware of the potential for these reactions, as prompt recognition and management is essential in preventing potentially significant patient morbidity.

Serotonin Syndrome

J-P Ternaux, CNRS and Université de la Méditerranée, Campus de Luminy, Marseille, France

Glossary

Enterochromaffine cells – These cells are present all along the digestive tract in the musoca. They represent about 5 % of the total number of the enterocytes. They are called paraneurons according to their biochemical properties: they are able to synthesize 5-HT from L-tryptophan, an active release process and reuptake of 5-HT were also demonstrated in this type of cell.
Fluoxetine – Commercial name Prozac®, is a specific inhibitor of 5-HT reuptake in serotonergic neurons. The use of fluoxetine leads to an increase of 5-HT concentration in the brain.
Inhibitors of monoamine oxidases (IMAO) – These drugs specifically block the enzymatic conversion of 5-HT into 5-hydroxyindol acetic acid (5-HIAA). Such a blockade results in a specific increase of 5-HT content in brain.
Raphe nuclei – Cells bodies of serotonergic neurons are located in the raphe nuclei. According to the classification of Falck and Hillarp they are located in the sagital plane of the brainstem, in nine nuclei named B1–B9 from the posterior to the anterior part of the brainstem. B1–B3 (obscurus, pallidus and magnus nuclei) give axons towards the spinal cord, whereas B7 and B8 (dorsalis and centralis superior nuclei) innervate, through the medial forebrain bundle, all cortical areas as well as sub-cortical structures such as: thalamus, hypothalamus, limbic system, striatum, and hippocampus.
Serotonergic neurons – Different histological methods have been used to identify serotonergic neurons in the central nervous system. Fluorescence, immunohistochemistry, as well as autoradiography, have revealed the presence of these neurons in the brainstem of various species. If their cell bodies are all located in specific neurons along the midline of the brainstem (the raphe nuclei) their axon terminals are present in all the regions of the brain, including spinal cord and forebrain.
Serotonine – Serotonin or 5-hydroxytryptamine (5-HT) was first identified in 1947 as a vasoconstrictor factor released by blood platelets. Its name was chosen because of its presence in blood serum and specific vasoconstrictor properties. In 1952, a similar compound was also detected in the gut and named 'enteramine.' That substance was shown to be present in the enterochromaffine cells and responsible for smooth muscle contraction all along the digestive tract. The presence of 5-HT in the brains of rat and rabbit was demonstrated by Twarog and Page, in 1953. This discovery started a long period of investigations related to serotonin as a neurotransmitter in the central nervous system.
Serotonin degradation – In parallel to 5-HT reuptake, serotonin homeostasis at the synaptic level is dependent on the action of monoamine oxidases. Degradation of 5-HT into 5-hydroxyindol acetic acid (5-HIAA) occurs both in nerve terminals and glial cells. 5-HIAA is then transported by blood flow and excreted through the urinary tract.
Serotonin receptors – Seven classes of 5-HT receptors (from 5-HT_1 to 5-HT_7) can be distinguished. Their existences was formally established by cloning of corresponding genes. Except for 5-HT_3, they all belong to the family of

seven transmembrane domain receptors coupled with G proteins. They modulate either an enzymatic membrane activity (adenylate cyclase, phospholipase C, or phospholipase A2) or an ion channel. In the 5-HT_1 family, the subtypes 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F} are characterized by a high affinity (Kd of nanomolar scale) whereas the 5-HT_2 receptors will bind 5-HT with a lower affinity. Serotonergic neurons bear 5-HT autoreceptors, the stimulation of which triggers an inhibition of their electrical activity or an inhibition of 5-HT release from nerve terminals. Distribution of 5-HT_3 seems to be exclusively neuronal, in contrast with the other types which can be detected both in the peripheral and central nervous systems on the neuronal and glial cell membranes.

Serotonin release – When the action potential is generated in the axon of a serotonergic neuron, induces calcium entry in the presynaptic terminal. Under these conditions vesicles move to the presynaptic membrane and release their content into the synaptic cleft through exocytosis. Released 5-HT can be bound to specific 5-HT receptors which are present on the postsynaptic membrane. Fixation of 5-HT to the receptor triggers the opening of ion channels with ionic exchanges between internal and external compartments. Such changes in the ionic permeability will give rise to a new potential which will be propagated all along the target neuron. As now has been clearly demonstrated newly synthesized 5-HT is preferentially released.

Serotonin reuptake – Inactivation of serotonin present in the synaptic cleft is partly accomplished by reuptake of the neurotransmitter in the presynaptic serotonergic terminal. Such a mechanism can be blocked by drugs such as fluoxetine or tricyclic antidepressants, leading to a substantial increase of 5-HT concentration in the synaptic cleft.

Serotonin synthesis – 5-HT is synthesized from the free fraction of L-tryptophan. The first reaction of 5-HT biosynthesis which concerns the transformation of tryptophan into 5-hydroxytryptophan (5-HTP) by tryptophan hydroxylase is the limiting step of 5-HT biosynthesis. Then 5-HTP is transformed into 5-HT by means of a non-specific decarboxylase. 5-HT is stored into synaptic vesicles where it is protected from monoamine oxidase (MAO) degradation. Synthesis of serotonin mainly occurs at the level of the terminal.

Tryptophan – Tryptophan is an essential amino acid derived from food. L-tryptophan is the amino acid precursor of 5-HT. Tryptophan is present in circulating blood where it is bound at 90 % to serum albumin. The free fraction of circulating L-tryptophan can be taken up via glial cells by serotonergic neurons, using a specific transporter system. Transformation of tryptophan into 5-hydroxytrypothan (5-HTP) by means of tryptophan hydroxylase, the specific enzyme of 5-HT synthesis, exclusively located in serotonergic neurons, is the limiting step of 5-HT synthesis.

Serotonin Neurons and Biochemical Mechanisms

Serotonin (5-hydroxytryptamine, 5-HT) is a neurotransmitter that is synthesized in specific neurons, located in the raphe nuclei, in the medial part of the brainstem. These neurons play a major role in sleep–wakefulness cycles, mood, emotion, food behaviors, and thermoregulation. Dysfunction of serotonin neurones is generally observed in depression. Following 5-HT release in the synaptic cleft, the neurotransmitter can be bound to various post- and presynaptic 5-HT receptors. Inactivation of 5-HT at the synaptic level is the result of reuptake in the presynaptic element and catabolism by monoamine oxidase (MAO) in both neurones and glial cells. Increased doses of L-trytophan, the amino acid precursor of 5-HT, will proportionally increase 5-HT formation. Amphetamines and related drugs increase the release of 5-HT stored in presynaptic vesicles. Inhibition of MAO activity will increase presynaptic 5-HT concentration, and impairment of 5-HT transport by uptake blockers increases synaptic 5-HT content. Serotonin agonists can directly stimulate postsynaptic receptors, and lithium is also known to increase postsynaptic receptor responses (**Figure 1**).

Serotonin syndrome is the result of an overstimulation of 5-HT_{1A} receptors which are present in the central grey nuclei and in the medulla. Such an excess of stimulation can be associated with the use of selective reuptake inhibitors, tricyclic antidepressants, MAO inhibitors, or other serotonin agents that act directly on 5-HT receptors. Overstimulation of 5-HT_2 receptors has also been demonstrated. A competitive inhibitor of 5-HT_2 receptors such as promethazine was shown to cause hyperactivation of 5-HT_{1A} receptors in the presence of selective inhibitors of 5-HT reuptake. In summary, excess of 5-HT precursors or 5-HT agonists, increased release, decreased reuptake and reduced metabolic of 5-HT can all be causative factors in the serotonin syndrome.

In parallel with the changes observed in serotonin metabolism, noradrenergic neuronal activity is enhanced,

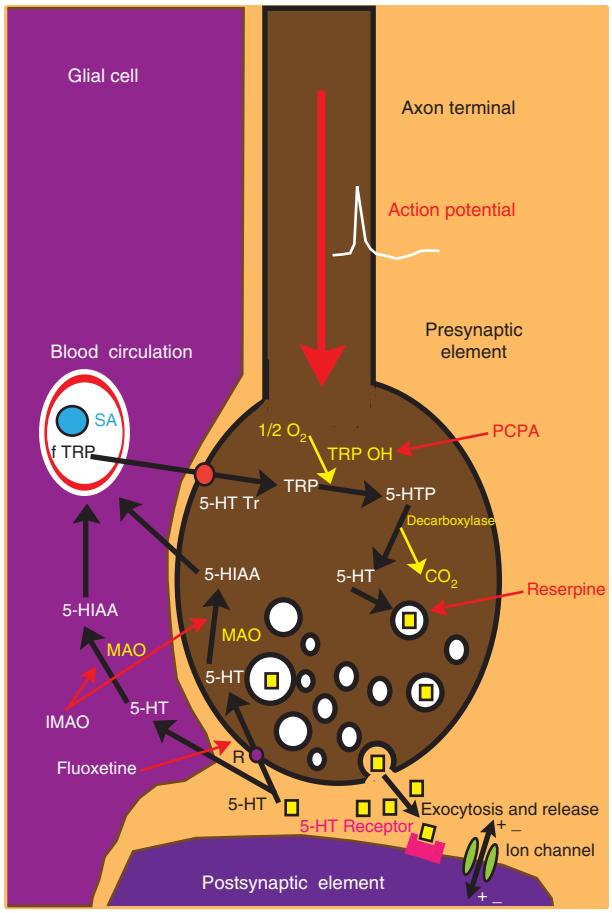

Figure 1 Schematic drawing of serotonin metabolism in serotonergic neurons. Serotonin (5-HT) is synthesized from L-Tryptophan (TRP). TRP is present in blood flow in two forms: 90 % of TRP is bound to serum albumin (SA) and the free fraction (f TRP) can be used for 5-HT synthesis in serotonergic terminals. Tryptophan is specifically transported in serotonergic neurons by mean of a 5-HT transporter (T) through the glial compartment. Tryptophan hydroxylase (TRP OH), in the presence of oxygen, catalyses the transformation of L-TRP into 5-hydroxytryptophan (5-HT). This biochemical reaction is the limiting step of 5-HT biosynthesis. 5-HTP is transformed in serotonin (5-HT) using decarboxylase. 5-HT is stored in vesicles. When the neuron is active, the action potential triggers the release of 5-HT in the synaptic cleft by an exocytosis mechanism. 5-HT which is released in the synapse can be bound to specific receptors. Inactivation of 5-HT can be the result of a 5-HT reuptake in the presynaptic terminal (R) or of an enzymatic degradation by monoamine oxidases (MAO) into 5-hydroxy indol acetic acid (5-HIAA). Such an enzymatic degradation occurs both in serotonin terminals and glial cells. 5-HIAA is transported through the blood flow and excreted in urine. Fluoxetine which blocks 5-HT reuptake, and inhibitors of MAO (IMAO) which reduce 5-HIAA formation, both enhance 5-HT concentration in the brain. Such drugs are suspected to be involved in the expression of serotonin syndrome.

and levels of norepinephrine in the brain appear to be correlated with clinical outcome. GABA and NMDA antagonists are also suspected to affect the development of serotonin syndrome, but their role is less clear.

Drugs Involved in Serotonin Syndrome Expression

A large number of pharmacological agents, used alone or in combination, have been reported to produce serotonin syndrome. These agents include antidepressant drugs such as: MAO inhibitors, selective serotonin transport inhibitors, tricyclic antidepressants (bupropion, nefazodone, tradozone), opioids (tramadol, pethidine, fentanyl, pentazocine, buprenorphine, oxycodone, hydrocodone), amphetamines and related molecules, and psychedelics (LSD, NMDA, MDA). LSD is an agonist of 5-HT_{2A} receptors, and the empathogen MDMA (ecstasy) releases 5-HT from synaptic vesicles of neurons and rather specifically targets the 5-HT_{1A} receptor. MDA (3,4 methylenedioxyamphetamine) also named 'psychedelic amphetamine' enters 5-HT neurons via the reuptake pump and affects 5-HT_2 receptor sites. Herbs (St John's Wort, Syrian rue, Panax ginseng, Nutmeg), and other molecules such as tryptophan, L-dopa, valproate, buspirone, lithium, 5-hydroxytryptophan, ritonavir, etc. were shown to produce large elevations in central serotonin levels. The combination of monoamine oxidase inhibitors with other serotonin agonists or precursors gives a high risk of causing serotonin syndrome.

Signs and Symptoms

Symptom onset is usually rapid, occurring within minutes of the administration of an overdose of serotonin pharmacological agents. Clinical manifestations of serotonin syndrome can range from mild to severe and even lethal symptoms. Serotonin syndrome is characterized by a triad of mental, autonomic and neurological disorders. While it can be fatal, in most cases there is a good prognosis when medication is immediately discontinued.

Mild symptoms generally include an increased heart rate, shivering, severe perspiration, and dilated pupils. Myoclonus and enhanced reflexes may also be present and lead, in some cases to impaired motor coordination. Hyperactive reflexes may be greater in the lower than the upper limbs. In moderate cases, additional features may include: hyperactive bowel sounds, diarrhea, high-blood pressure, and hyperthermia, which can reach 40 °C with moderate intoxication. Changes in mental status can also be noticed, including hypervigilance and agitation. In severe cases the increased heart rate and blood pressure may lead to shock. Agitated delirium, associated with rigidity and high muscular tension, has also been described. In such cases, the body temperature can reach 41.1 °C. Metabolic acidosis, rhabdomyolisis, seizures, renal failure, and disseminated intravascular coagulation have also been reported. These last symptoms, arising with hyperthermia, can be linked to metabolic 5-HT

peripheral changes occurring in both blood platelets and gut enterochromaffin cell compartments.

Diagnosis and Treatment

Serotonin syndrome has been reported in patients of all ages, including infants due to in utero exposure. The diagnosis of serotonin syndrome is guided by the criteria defined in 1991 by Harvey Sternbach, Professor of Psychiatry at UCLA. More recently, Australian researchers have developed the 'Hunter Serotonin Toxicity Criteria,' which have better sensitivity. There is no laboratory test for serotonin syndrome even if an elevation of the total creatine kinase and leukocyte count, elevated transaminase levels, or lower bicarbonate blood levels have been reported.

The most important clinical symptoms to be considered in serotonin syndrome are tremor, akathisia, or myoclonus. The physical examination of the patient should include assessment of deep tendon reflexes and muscle rigidity, the dryness of oral mucosa, the size and reactivity of the pupils, the intensity of bowel sounds, the skin color, and the quality of sweating. The physical examination must be complemented by a detailed history of any prescribed or illicit drug use. Serotonin toxicity usually gives a specific clinical picture, but at times may be mistaken for viral illness, an anxiety attack, neurological disorders, anticholinergic poisoning, sympathomimetic toxicity, or neuroleptic malignant syndrome (NMS). Serotonin syndrome and NMS can be distinguished by the fact that 5-HT toxicity has a rapid onset and responds to pharmacological blockade with drugs such as chlorpromazine and cyproheptadine. Dopamine blockade in NMS has a slow onset following the administration of a neuroleptic drug and responds to dopamine agonists such as bromocryptine.

The management of serotonin syndrome involves the removal of serotonergic agents. Supporting care includes the administration of intravenous electrolyte solution in order to maintain a physiological diuresis. Benzodiazepines may be used to control agitation and reduce anxiety. Upon initiation of therapy and discontinuation of serotonergic drugs, most cases of serotonin syndrome resolve within 24 hours. In some cases, muscle pain and weakness can persist for several months. Nevertheless, an appropriate medical management of serotonin syndrome is generally associated with a favorable prognosis.

Shy–Drager Syndrome

C Colosimo, Sapienza University of Rome, Rome, Italy
D Tiple, Sapienza University of Rome, Rome, Italy

Glossary

Multiple system atrophy (MSA) – A term coined to describe the clinical and pathological overlap among three major neurodegenerative diseases which were previously described separately: (1) Shy–Drager syndrome, (2) striatonigral degeneration, and (3) sporadic olivopontocerebellar atrophy.

Olivopontocerebellar atrophy – Indicates primarily cerebellar defects due to degeneration of neurons in specific areas of the brainstem (pons and inferior olives) and the cerebellum, with minor degrees of parkinsonism. It may be sporadic or genetically determined.

Orthostatic hypotension – Sudden fall in blood pressure that occurs when a person assumes a

standing position manifested by dizziness, lightheadedness, blurred vision, and syncope.
Shy–Drager syndrome – Neurological syndrome characterized by severe autonomic failure (orthostatic hypotension, urinary retention or incontinence, and male erectile failure) combined with parkinsonism, cerebellar and pyramidal signs.
Striatonigral degeneration – A disease caused by the degeneration of the striatum and substantia nigra, clinically presenting as parkinsonism with or without some degree of autonomic and cerebellar dysfunction.

Definition and History

In May 1960, Milton Shy from the National Institutes of Health and Glenn Drager from Baylor College of Medicine described a neurological syndrome associated with orthostatic hypotension, termed later as the Shy–Drager syndrome (**Figure 1**). In their original article, they described the clinical features of two male patients who developed autonomic failure followed by other neurological symptoms. Their description of the new syndrome comprised of a complex series of symptoms and signs, including autonomic failure (orthostatic hypotension, urinary and rectal incontinence, impotence, loss of sweating, and iris atrophy), parkinsonism (rigidity, tremor, loss of associated movements), involvement of the anterior horn cells (fasciculations, wasting of distal muscles, evidence of a neuropathic lesions in the electromyogram, and in the muscle biopsy), and external ocular palsy. They were also able to carefully study the neuropathologic changes in one of these patients, in whom neuronal degeneration at many sites was found, including the intermediolateral columns of the spinal cord.

Numerous clinical details were cited in the text, though other parts of the article were discordant (description of the rectal incontinence and ocular muscle paresis in both patients, presence of fasciculations in patient 2 instead of patient 1, and presence of distal wasting in patient 2, whereas the text stated there was none). Although meticulously delineated in the article text, the 'full syndrome' description also failed to mention cerebellar and pyramidal signs. Shy and Drager recognized that there was a link between low blood pressure during erect posture (orthostatic hypotension) and disturbance in the central autonomic nervous system. Since their seminal report, growing interest in autonomic disorders has spawned studies outlining the clinical and neuropathologic findings in such patients.

Figure 1 (a) Milton Shy (b) Glenn Drager.

The eponym Shy–Drager syndrome became popular, but then it has been progressively replaced by the use of a new term, multiple system atrophy (MSA). This was first coined in 1969 by two British authors, Graham and Oppenheimer. The term MSA recognized the significant clinical and pathological overlap among three major neurodegenerative diseases which were previously described separately: (1) Shy–Drager syndrome, (2) striatonigral degeneration, and (3) sporadic olivopontocerebellar atrophy.

Clinical Features and Diagnostic Criteria

For various reasons, some uncertainty in the terminology generated over the following years. For instance, Wenning et al. described a series of 100 patients with clinically probable MSA (15 of them pathologically confirmed); in none of them, the 'full Shy–Drager syndrome' was found. These authors described fecal incontinence in only two patients, but neither of them had suffered painful muscle cramps or iris atrophy, and only one had fasciculations, weakness, and focal muscle atrophy. Although they admitted that rectal incontinence, iris atrophy, external ocular palsies, and signs suggestive of anterior horn cell involvement can occur occasionally in MSA, these features should not be considered typical of the disease. In addition, they suggested that the term Shy–Drager should be restricted to the situation in which severe autonomic failure (male erectile failure, orthostatic hypotension, urinary retention, or incontinence) is combined with parkinsonism, cerebellar and pyramidal signs. Respiratory stridor (high-pitched breathing sounds due to airway obstruction) and stimulus-sensitive finger myoclonus, developing each in one-third of cases, were included as optional diagnostic criteria. Unlike the original description (which antedated the introduction of levodopa), information on the response to levodopa treatment (which is often poor or absent in MSA, except for 20–30% of the cases in whom it may be transiently good) was also included.

In a subsequent commentary, Quinn et al. substantiated that the Shy–Drager syndrome signifies autonomic failure plus central nervous system dysfunction attributable to MSA, and that it is inappropriate to use the term simply as a shorthand for parkinsonism with autonomic failure.

However, it later became clear that the new complex classification was not well served by the term 'Shy–Drager syndrome.' Thus, a new terminology was needed. The American Autonomic Society and the American Academy of Neurology eventually disapproved the Shy–Drager syndrome as a disease entity in 1996, and existing cases were redefined as MSA with autonomic involvement.

However, the term 'Shy–Drager syndrome' is still used occasionally for MSA when the primary symptom is autonomic failure. At the very least, this nomenclature implies that several areas in the central nervous system are involved in the neurodegenerative process.

MSA is defined as a sporadic, progressive, adult-onset disorder characterized by autonomic dysfunction, parkinsonism, and ataxia in any combination. Onset usually takes place in the sixth or seventh decade, and most patients are severely disabled within 5–7 years. More males are affected than females, and prevalence is less than one in 10 000 persons. The etiology is unknown. Depending upon which part of the central nervous system is affected first, MSA may present in different ways. According to the current diagnostic criteria, MSA is divided into two main clinical categories: (1) MSA–parkinsonism type (MSA–P), which implies parkinsonism with or without some degree of cerebellar dysfunction (striatonigral degeneration), and (2) MSA–cerebellar type (MSA–C), which indicates primarily cerebellar defects with minor degrees of parkinsonism (olivopontocerebellar atrophy). In both conditions, autonomic failure could be a predominant or an associated manifestation of the clinical spectrum of the disease.

The most prominent symptom of autonomic failure in MSA is what is known as 'postural hypotension.' In cases of severe autonomic insufficiency, wide swings in blood pressure without modification in pulse rate are observed. Upon standing or sitting, patient's blood pressure drops to such a low level that they get dizzy, lightheaded, or momentarily blackout.

Urinary and erectile (in males) dysfunction symptoms are also prominent early features in MSA patients. Urogenital symptoms in MSA are usually due to a complex mixture of central and peripheral nervous abnormalities, sometimes superimposed on previous local pathological conditions such as benign prostatic hyperplasia and perineal laxity.

Unfortunately, although orthostatic hypotension and bladder disorders can be managed successfully, no effective treatment is available for the other manifestations of autonomic dysfunction or for the cerebellar and pyramidal symptoms. MSA usually concludes by the patient's death within 7–10 years after diagnosis. Breathing problems such as aspiration, stridor, or cardiopulmonary arrest are common causes of death.

Sialidosis

S Igdoura, Departments of Biology and Pathology & Molecular Medicine, McMaster University, Hamilton, Ontario, Canada

Clinical Presentation

An inherited, primary deficiency of lysosomal sialidase was first demonstrated in the severe form of Sialidosis (type II). Shortly thereafter, several investigators described a similar deficiency in a clinically milder disorder, 'cherry-red spot-myoclonus syndrome,' now classified as Sialidosis type I, which becomes apparent during the second decade of life. Associated symptoms include cherry-red spots within the middle layers of the eyes; loss of visual clarity; and sudden, involuntary, 'shock-like' contractions (myoclonus) of muscles of the arms and legs. The myoclonus is progressive in nature and may be triggered by voluntary movements (action myoclonus) or certain external stimuli such as sound (reflex myoclonus).

Pathogenesis/Pathophysiology

In type I patients, increased excitability and reduced inhibition were found in some cortical motor pathways, but no abnormalities were found in the brain stem and spinal motor pathways tested. These findings suggest that the electrophysiological abnormalities are restricted to a level above the brainstem. While pathological features of lysosomal storage are apparent in the brainstem and spinal cord, circuits within the brainstem or spinal cord do not appear affected. Biochemically, this may be explained by the more profound role for Sialidase on the plasma membrane in the brain cerebellar cortex and the cerebellum.

Sialidase deficiency leads to defective lysosomal catabolism of sialoglycoconjugates with their subsequent accumulations in tissues and excessive excretion in the urine. The concentration of urinary oligosaccharides is reported to be correlated with the clinical severity of the affected patients, that is, over 3 times more in the infantile-type II Sialidosis patients than in the late-type I patients. Sialidosis patients will excrete high sialic acid conjugated molecules in the urine. Sialidosis has traditionally been diagnosed using enzyme assays that measure sialidase activity in blood leukocytes. Enzyme diagnostic tests for Sialidosis use a variety of both natural (sialyllactose, sialylhexasaccharides, and fetuin) and synthetic (3-methoxyphenyl-*N*-acetylneuraminic acid and 4-methylumbelliferyl-α-D-*N*-acetyl-neuraminic acid, muNANA) substrates. Only in recent times has it become possible to probe the disease at the level of the DNA lesion.

Human lysosomal sialidase (44 kDa) exists in a multienzyme complex consisting of β-galactosidase, cathepsin A, and sialidase (GCS complex). Cathepsin A is required to promote the formation of the enzyme complex. Mechanistically, the sialidase associates with cathepsin A in the endoplasmic reticulum and is then transported to the lysosomes. In fact, transport impaired cathepsin A prevents sialidase from reaching the lysosomes. The sialidase complex is also present on the cell membrane where it is involved in cellular signaling, particularly, in T-lymphocytes, where it activates the macrophage activating factor. Genetically, Sialidosis is inherited as an autosomal recessive trait. The human sialidase gene was mapped to chromosome 6p2l within the human major histocompatibility complex (MHC). The human and mouse sialidase genes are structurally similar (both about 4.5 kb). The two genes contain five introns which range in size from 96 bp to 1.2 kb. The levels of sialidase expression in different mouse tissues, evaluated by Northern blot analysis, were found to be high in kidney, epididymis, brain and spinal cord, and moderate to low in adrenal, liver, lung, spleen, and heart.

The isolation and cloning of the human lysosomal sialidase gene has allowed for the characterization of many disease-causing mutations. Thus far, more than

45 mutations have been identified. Previously, we have identified a frame shift mutation and two missense mutations (Phe260Tyr, Leu363Pro) in type II Sialidosis patients. Bonten et al. identified a point mutation that introduced a premature stop codon and the C-terminal truncation of 38 amino acids in two siblings with type I Sialidosis. The biochemical consequences of some of the identified missense mutations (such as Phe260Tyr) are difficult to explain, since they do not affect the putative active site residues of the enzyme and are not expected to introduce significant change in the conformation of the enzyme. Recently, Lukong et al. screened the genomic DNA of nine patients of diverse ethnic origin affected by type I and type II forms of Sialidosis for mutations in the sialidase gene. One patient had a frame shift mutation (G623delG deletion), which introduced a stop codon, truncating 113 amino acids. All others had missense mutations (Gly227Arg, Ala298Val, Gly68Val, Serl82GIy, Leu270Phe, and Gly328Ser). Two unrelated Japanese type I Sialidosis patients were found to have two missense mutations (Val217Met and Gly243Arg). Recently, we have identified five novel disease-causing mutations (Arg225-Pro, Ala298Val, Met1?, Arg341Gly, and Trp23Stop) and used diagnostic genetic technique to provide prenatal screening.

Treatment

While no effective therapy is available for lysosomal diseases so far, many innovative approaches have been used to slow down the disease or reduce its symptoms. Such approaches include enzyme replacement therapy, which provides functional enzyme through endocytosis. In addition, the use of chemical chaperones has shown to be effective in stabilizing misfolded enzymes and therefore increasing its transportation efficacy to the lysosome. The use of bone marrow transplantation is probably the most promising approach especially if used at the early stages of the disease. Finally, gene therapy utilizing adenoviruses or adeno-associated viruses is still in its infancy but holds much promise. However, progressive degeneration of multiple systems and somatic tissues, in clinical Sialidosis, including bone deformation, CNS, neuronal, sensory, skeletal muscle, and immunodeficiency, requires that potential therapies will need to correct a variety of cell and tissue types. This is not an easy task by any means.

Single Pulse TMS

K Udupa and R Chen, University of Toronto, Toronto, ON, Canada; Toronto Western Research Institute, Toronto, ON, Canada

Glossary

CMCT – Central motor conduction time; conduction time of corticospinal fibers from the motor cortex to motor neurons in the spinal cord or brainstem.
iSP – Ipsilateral silent period; reduction or pause in ongoing voluntary EMG activity produced by transcranial magnetic stimulation of the ipsilateral motor cortex.
MT – Motor threshold; the lowest stimulus intensity capable of eliciting small motor evoked potentials.
SP – Silent period; reduction or pause in ongoing voluntary EMG activity produced by transcranial magnetic stimulation of the contralateral motor cortex.

Definition and History

Transcranial magnetic stimulation (TMS) is a noninvasive method of brain stimulation through magnetic pulses generated by a coil placed on the scalp. It was first described in 1985 by Barker and colleagues who demonstrated that TMS of the motor cortex produced contralateral limb movements.

Physics and Physiology of TMS

TMS has been used to study the complex circuitries and mechanisms in the brain, and as a possible treatment in a variety of neurological and psychiatric disorders. TMS works by passing a large, brief current through a wire coil placed on the scalp. The transient current produces a large and changing magnetic field with lines of flux passing perpendicularly to the plane of the coil. Thus, TMS is based on the principle that a changing electric current in a wire coil induces a changing magnetic field (Ampere's law) perpendicular to the current flow in the coil. This changing magnetic field passes unimpeded through the scalp and skull, and induces an electric current in the brain that flows in the opposite direction to the current in the coil (Faraday's law). The TMS apparatus mainly consists of boosters, control panel connected to a computer, and a stimulating coil. Boosters are made up of a capacitor discharge system which works with voltages of 500–4000 V and stores energy in the range of 400–2000 J. Stimulating coil is made up of wire loops encased in insulated plastic and connected through a cable to one or more capacitors. Electrical current passes through the coil for brief periods of 100–200 ms. When the current flows through the coil, magnetic field in the range of 1.5–2 Tesla is generated.

The strength of the induced current is a function of rate of change of the magnetic field, which in turn depends on the rate of change of current in the coil. Magnetic field penetrates the scalp and skull much more easily than electrical energy. The induced electrical current depolarizes axons, most likely at the sites of bending. The effects of TMS depend on the intensity of the induced magnetic fields, the shape and orientation of the induced current. Some coils such as a circular coil, stimulate a large brain area. Other coil designs such as a figure-of-eight coil, produce more focal stimulation with the maximum stimulation at the junction of the two loops. Different current directions activate different groups of cortical neurons.

Effects of Focal TMS

The effects of focal TMS depend on the function of the underlying brain region. While TMS over motor cortex results in generation of the motor evoked potential (MEP) in the target muscle, TMS of occipital cortex can produce phosphenes and transient scotomas. Several studies showed that TMS can transiently block the function of the stimulated region. For example, TMS of V5 area of the visual cortex can selectively interfere with motion perception, suggesting that this region is required for motion perception. Similarly, TMS over left dorsolateral prefrontal cortex (DLPFC) impaired working memory as detected by the three-back working memory task. Thus, these 'virtual lesions' experiments can be used to map the functioning of the brain. TMS can also be used to identify the functional connections. For example, connection between premotor and motor cortex can be studied by TMS to these areas at different interstimulus intervals and coil orientations.

Measures Derived from Single Pulse TMS

The following parameters can be used in diagnosis and research in neurological disorders.

Motor Threshold (MT)

MT refers to the lowest TMS intensity capable of eliciting small MEPs, and is usually defined as more than 50 μV in amplitude in the muscles at rest or 200 μV in active muscles in at least five out of 10 trials. MT likely reflects the excitability of neuronal membrane as it is increased by drugs that block voltage-gated sodium channels. MT reflects both cortical and spinal excitability, and can be used to assess corticospinal excitability in disorders such as amyotrophic lateral sclerosis, stroke, and Parkinson plus syndromes.

Central Motor Conduction Time

Central motor conduction time (CMCT) is the conduction time of corticospinal fibers from the motor cortex to motor neurons in the spinal cord or brainstem. It is calculated by subtracting the peripheral conduction time from the latency of the MEP elicited by motor cortical TMS. Upon stimulating a motor nerve, the M wave is the direct muscle response, and the F wave is the muscle response produced by the activation of the alpha motoneuron by the antidromic volley. Thus, peripheral conduction time may be calculated using the formula (F wave latency + M wave latency − 1)/2. Other methods of obtaining the peripheral conduction time include electrical or magnetic stimulation over the spine. CMCT may be useful in the diagnosis of multiple sclerosis, stroke, amyotrophic lateral sclerosis, and compressive myelopathies. Prolonged CMCT is also found in patients with parkinsonian syndrome secondary to the multiple system atrophy or progressive supranuclear palsy.

Silent Period

Silent period (SP) is a pause in the ongoing voluntary EMG activity produced by TMS. It is elicited by single pulse TMS delivered during voluntary muscle contraction. While the first part of the SP is due in part to decreased spinal cord excitability, the latter part is almost exclusively due to cortical inhibition. Prolonged SP suggests hyperactivity, whereas shortened SP suggests hypoactivity of inhibitory circuits in the motor cortex. This type of inhibition is likely mediated by $GABA_B$ receptors.

Ipsilateral Silent Period

Ipsilateral silent period (iSP) is generated through transcallosal inhibition and has been proposed as the diagnostic tool for callosal functions.

Recruitment Curve

This parameter also known as the input–output or stimulus-response curve refers to the increase in MEP amplitude with increasing TMS intensity. Compared to MT, this measure assesses neurons that are intrinsically less excitable or spatially further from the center of activation by TMS. Recruitment curves are likely related to the strength of corticospinal projections, and are generally steeper in muscles with low MT such as intrinsic hand muscles.

Mapping of Muscle Representation

Mapping is performed by stimulation at a number of different scalp positions with a focal figure-of-eight coil. The number of excitable scalp positions, location of the optimal position for stimulation, and the center of gravity (an amplitude-weighted representative position on the motor map) can be determined. Motor maps are affected by both the location and excitability of the motor representation.

TMS and Movement Disorders

TMS can provide useful information of patients with movement disorders. Studies have shown that MT

Table 1 Single pulse TMS measures in movement disorders

Disorder	*Motor threshold (MT)*	*Central motor conduction time (CMCT)*	*Silent period (SP)*	*Motor evoked potential (MEP) amplitude*	*Recruitment curve*	*Mapping of muscle representation*
Parkinson's disease	↓/↔	↔	↓	↓	↓	Anterior displacement of hand muscle area
Dystonia	↔	↔	↓	↓	–	Distorted hand muscle in FHD
Huntington's disease	↔	↔	C	↔	–	–
Wilson's disease	↑	↓	↓	↓	–	–
Friedreich's ataxia	↓	–	–	↓	–	–

↔, normal; ↓, decreased; ↑, increased; C, controversial/not established; –, not been studied; FHD, focal hand dystonia. These findings represent results from multiple studies. If studies showed conflicting results, the findings of the majority of studies are shown here.

measurements, input–output curves, SP, and CMCT frequently disclose abnormal findings, but are not specific for any disease (**Table 1**). TMS has a role in demonstrating CMCT abnormalities in patients with secondary forms of movement disorders in whom pyramidal signs may be clinically equivocal. TMS proved to be a very useful research tool to investigate the pathophysiology of movement disorders.

Future Directions

TMS has helped to advance the understanding of the complex circuitry of human brain. This noninvasive investigative tool coupled with advanced imaging techniques would throw more light into the neurophysiological mechanisms of neurological disorders.

Sleep Attacks

M Park, Rush University Medical Center, Chicago, IL, USA

Glossary

Cataplexy – Sudden loss of voluntary muscle control triggered by an emotional stimulus such as laughter, surprise, or anger. Almost exclusively associated with narcolepsy.

Excessive daytime sleepiness (EDS) – Characterized by persistent sleepiness and general lack of energy compelling people to nap during the day.

Hypocretin – A neuropeptide hormone secreted by the lateral hypothalamus involved in wake promotion, also known as orexin. Often associated with narcolepsy.

Multiple sleep latency test (MSLT) – A series of 4–5 naps taken at 2 h intervals throughout the day after an overnight sleep study is performed in order to evaluate the extent of sleepiness in individuals.

Maintenance of wakefulness test (MWT) – A series of 20- or 40-min trials taken at 2 h intervals throughout the day after an overnight sleep study, during which the patient attempts to stay awake.

Polysomnography (PSG) – An overnight sleep study that typically includes electroencephalogram (EEG) to measure brain waves, electrooculogram (EOG) to measure eye movements, electromyogram (EMG) to measure muscle tone, electrocardiogram (EKG) to measure heart rate, limb electrodes to assess for leg movements, respiratory channels to assess for apnea, pulse oximetry to assess oxyhemoglobin saturation, and audiovisual recording.

Pathological hypersomnolence (PH) – Excessive sleepiness despite adequate amounts of nocturnal sleep. Includes narcolepsy, idiopathic hypersomnia, and Klein–Levin syndrome. Measured by MSLT.

Definition/History

'Sleep attacks' (SAs) are events of irresistible and overwhelming sleepiness. Any prodrome or warning of the attack

is typically absent so that preventative measures are useless in overpowering the urge to sleep. After much debate, SAs are no longer considered an exaggerated form of excessive daytime somnolence (EDS) but rather a severe form of pathological hypersomnolence (PH) similar to narcolepsy.

In the 1960s, SAs were described in narcolepsy and became pathognomonic for this disorder. The concept of SAs was specifically reintroduced in 1999 during investigations of Parkinson's disease (PD)-related motor vehicle accidents. SAs are now most commonly associated with dopaminergic agents (DAs), although they are also commonly reported with untreated obstructive sleep apnea (OSA) and restless legs syndrome (RLS). Assessment of PH is now considered crucial due to safety issues, particularly with regards to the medicolegal and psychosocial ramifications associated with SAs.

Pathogenesis/Pathophysiology

To discuss SA pathophysiology, it is essential to understand the basics of sleep and wake mechanisms. Although extensively interrelated, the drive for sleep and the processes for wake maintenance are essentially independent systems. Wake states are maintained by several neurotransmitters, including norepinephrine, dopamine, acetylcholine, and serotonin. Because these neurotransmitters also influence sleep, organization and communication among the nuclei that secrete these substances is critical. Orexin, a hypothalamic neuropeptide, helps coordinate and regulate these nuclei to allow for wake maintenance and to prevent sleep intrusion into wake periods. During sleep deprivation (SD), the drive for sleep increases but can be overcome by wake systems driven by certain motivational situations (e.g., interest, fear), as well as by substances (e.g., caffeine). For sleep onset to occur, the hypothalamic ventrolateral preoptic nucleus (VLPO) allows for coordinated dampening of wake systems, enabling coordination of various sleep systems to take over.

Narcolepsy research implicates loss of hypocretin neurons in as a cause of wake maintenance instability. Although SAs in PD are usually attributed to DAs, EDS can precede PD motor manifestations and drug treatment, leading to speculations that PH is inherent to PD pathophysiology. Pathological studies report early loss of hypocretin function in PD, which may be responsible for the early appearance of 'narcolepsy-like' symptoms, but hypocretin levels in the cerebrospinal fluid in PD are variably altered. As such, EDS in PD may not be solely due to hypocretin abnormalities, as the alerting properties of dopamine, norepinephrine, and serotonin are also affected.

Several studies correlate SAs in PD to disease severity, sleep fragmentation, and medication effect. One study evaluated sleep fragmentation by overnight polysomnograms (PSG), the drive to sleep by multiple sleep latency test (MSLT), and the drive for wake maintenance measured by the maintenance of wakefulness test (MWT). In PD, EDS correlated with overnight sleep fragmentation, but the degree of sleep fragmentation was independent of disease severity. PD patients compensated for EDS when asked to do so unless treated with high doses of DAs, which compromised their ability to stay awake. This suggests that PD-pathophysiology causes sleep fragmentation, thereby increasing sleep drive, but use of DA in combination with sleep fragmentation also alter wake mechanisms, causing PH. Although this theory may apply to PD, it does not explain DA-induced SAs in other cases, such as RLS. Further investigations should assess whether DA-sensitivity confers susceptibility to SAs and whether this carries implications for neurodegeneration.

Epidemiology/Risk Factors

Community-based studies report EDS in over 15% of PD patients. However, SAs are seldom differentiated from EDS, prompting one study to classify EDS into the following: sudden irresistible SA, definite SA, probable SA, possible SA, sleep episode, and sleep event not otherwise specified. In this article, DAs were implicated in SAs in 30% of PD patients. Despite admitted overestimation, this study highlights the need for evaluation of SAs apart from EDS.

Aside from DA, little is known about risk factors. Dysautonomia likely confers a higher risk, but age, disease severity, and sedatives are not considered specific risk factors in PD-related SAs. Sensitivity of subjective screening tools is low in evaluating EDS in PD.

Clinical Features and Diagnostic Criteria

In contrast to prodromal symptoms of sleepiness in traditional EDS, SAs are described as irresistible and sudden attacks with little, if any, warning. One description likened SAs to a 'short circuit' rather than 'falling asleep,' consistent with absence of EEG slowing preceding the SAs. Recovery from SAs is refreshing, which is not always reported with EDS-induced naps.

Diagnosis should begin with clinical interview, evaluating medical history, sleep habits, nocturnal sleep time, potential causes of sleep fragmentation, and daytime function. Overnight PSG is recommended to identify SD secondary to nocturnal sleep disorders such as OSA. Quantification of EDS is recommended with a next-day MSLT.

Differential Diagnosis

SAs are considered to be a disorder of PH, which includes narcolepsy and idiopathic hypersomnia. Before assigning a diagnosis of PH, assessment and resolution of SD is

recommended. SD can be due to several causes, including, but not limited to, primary sleep disorders, chronic insufficient sleep, and substances that influence sleep or promote wakefulness, such as alcohol or caffeine. Clinical interview and work-up should also include neurological history for seizures.

Diagnostic Work-up/Tests

Prior to PSG, clinical history should evaluate nocturnal sleep habits, substances and medications, and daytime habits. SD should be corrected with a regular sleep–wake schedule, allowing for 7–8 h of sleep per night. If a nocturnal sleep disorder is present, appropriate treatment should be instituted. After the above is complete, a PSG with a next-day MSLT is recommended to quantify the extent of PH. A urine drug screen should accompany the MSLT. MWT can also be clinically useful to assess the ability to maintain the wake and alert state despite situations, such as medication effect.

For those with clinical history suspicious for narcolepsy, MSLT is considered diagnostically definitive. Hypocretin levels and HLA genotype are generally reserved for atypical and research cases.

Management

Switching DAs, reducing DA dose, or adjusting DA intake may help reduce SA severity. Additional pharmacological management consists of wake-promoting medications such as modafinil and stimulants. Modafinil has an unclear mechanism of action, although norepinephrine and dopamine systems are likely involved. Dose typically starts at 100–200 mg each morning, with upward titration according to clinical symptoms. The most common side effect of modafinil is headache, exacerbated if dose titration occurs too quickly. Most patients take modafinil upon awakening, although a second dose is occasionally taken to sustain the wake-promoting effect into the late afternoon. Modafinil is FDA-approved for doses up to 400 mg for certain sleep disorders such as narcolepsy, shift-work sleep disorder, and OSA. If modafinil is ineffective, stimulants such as methylphenidate may be prescribed, but side effect profiles often limit their use. Despite reported effectiveness in narcolepsy, modafinil seems less effective in preventing SAs in PD. Few studies have evaluated stimulant effectiveness in controlling SAs in PD to warrant comment.

Nonpharmacological management must be emphasized. Patients should institute proper sleep hygiene, avoid SD, and avoid substances interfering with sleep. Sedating medications should be avoided, including limiting or lowering use of DAs. Safety habits should be routinely discussed, particularly driving. Scheduled naps may be helpful.

Prognosis

Although systematic reviews of SAs are limited, patients can respond to intervention. Follow-up studies are needed to determine whether SAs can be eliminated on a long-term basis with these techniques.

Somatoform Disorders

D T Williams and K J Harding, Columbia University Medical Center, New York, NY, USA

Glossary

Body dysmorphic disorder – Involves the preoccupation with a perceived defect in appearance that causes clinical distress and impairment in social and occupational functioning. Even If a slight physical anomaly is apparent, the individual's concern is markedly exaggerated and not better accounted for by anther psychiatric disorder.
Conversion disorder – Describes patients who present with symptoms affecting voluntary motor or sensory function that inappropriately suggest a neurological or other general medical condition. It inherently has all the features of somatoform disorders, including primary psychogenic etiology of an unconsciously based nature, being unexplainable on a physiological basis and not being due to the direct effects of a substance or a culturally sanctioned experience. Furthermore, the clinically impairing symptoms are not limited to pain or sexual dysfunction; are not part of a somatization disorder; and are not better accounted for by another mental disorder.
Hypochondriasis – Describes individuals who are debilitated by fear that they have a serious disease despite appropriate medical reassurance to the contrary. The fear is often based on catastrophizing normal bodily signs or symptoms as indication of serious illness. While beliefs cause clinical distress or functional impairment, they are not of delusional intensity: patients can often acknowledge that their concerns may be excessive, yet feel unable to stop worrying and seeking reassurance. To meet criteria for diagnosis of hypochondriasis, the preoccupation, and fear must persist for at least 6 months and not be better accounted for by another psychiatric disorder.
Somatoform disorder – A psychiatric disorder describing patients who experience distressing physical symptoms suggestive of a medical condition, yet without objective findings or adequate explanation by an existing general medical condition. Despite this, the symptoms lead to impairment in social, occupational, or other areas of functioning. Furthermore, the symptoms are not intentionally produced by the patient (i.e., are not under conscious, voluntary control).
Somatization disorder – Connotes a chronic history, lasting several years, of many physical complaints, beginning before age 30, that result in active treatment or significant impairment of social, occupational, or other important areas of functioning. As with all somatoform disorders, patients with somatization disorder have symptoms with primary psychogenic etiology of an unconsciously based nature, being unexplainable on a physiological basis and not being due to the direct effects of a substance or a culturally sanctioned experience. In addition, criteria for somatization disorder require the presence of at least four pain symptoms, two gastrointestinal symptoms, one sexual symptom, and one pseudo-neurological symptom.

Definition and History

Patients with somatoform disorders experience distressing physical symptoms suggestive of a medical condition, yet without objective findings or adequate explanation by an existing general medical condition. Despite this, the symptoms lead to impairment in social, occupational, or other areas of functioning. Furthermore, the symptoms are not intentionally produced by the patient (i.e., are not under conscious, voluntary control), distinguishing them from *factitious disorders* and *malingering* (see cross references) (**Table 1**).

The most important initial and continuing task in the evaluation of this group of disorders is the clarification of whether an underlying, initially undiagnosed physical condition exists that may be overlooked and that may coexist with a superimposed somatoform disorder. A second vital task is that of maintaining a therapeutic rapport with patients whose initial inclination is often to doubt or dismiss the possibility that psychological factors may underlie some or all of their presenting physical symptoms. A combination of tact on the part of the primary medical physician and continuing collaboration with the consulting and cotreating mental health professional is crucial to allow for a thorough and open-minded diagnostic process as a prelude to effective treatment. Maintaining a 'neuropsychiatric perspective' that emphasizes the universal impact of stress on physical processes is a helpful way of avoiding the defensive turnoff that leads some patients to flee precipitously if they feel that they are being viewed as either 'crazy' or malingering when the possibility of psychogenic contributions to their symptoms is raised.

Historically, somatoform disorders were a particular interest of both Charcot and Freud, with Freud having

Table 1 The somatizing disorders: defining characteristics

	Conscious intentionality	*Motivational factors*	*Coexisting psychopathology*	*Prognosis*
Somatoform disorders	Absent	1. Repress unacceptable wishes, feelings or conflicts 2. Any pragmatic benefits, if present, are secondary	Highly variable: may include affective, anxiety, dissociative, psychotic, developmental or personality disorders	Highly variable: depending on chronicity, coexisting psychopathology, patient resilience, support network, and treatment
Factitious disorders	Present	1. Assume the sick role 2. Any pragmatic benefits, if present, are secondary	Often includes dependent, histrionic, borderline or antisocial personality features	Often poor, especially if chronic
Malingering	Present	Pragmatic benefits: financial, legal, drugs; Circumvent authority	Often includes antisocial personality disorder	Symptoms are relinquished only when the goal is either obtained or seen as clearly unobtainable
Psychological factors affecting a medical condition	Variable	None. Any pragmatic benefits, if present, are secondary	Highly variable	Highly variable, depending on the medical condition, chronicity, patient resilience, support network, and treatment
Undiagnosed Medical Condition	Absent	None. Any pragmatic benefits, if present, are secondary	Highly variable	Depends on the medical condition and the stage at which diagnosed and treated

Reproduced from Williams DT, Harding KJ, Fallon BA (In press) Somatoform Disorders. In: Rowland LP, Pedley TA, (eds.) *Merritt's Neurology*, 12th edn. Philadelphia: Lippincott Williams and Wilkins, with permission from Lippincott Williams and Wilkins.

contributed substantially to our understanding of the unconsciously based dynamics involved and the possibilities of alleviation of disabling symptoms through supportive, insight-oriented psychotherapeutic intervention. More recent psychotherapeutic and pharmacological interventions have enhanced therapeutic leverage in treating coexisting and contributory anxiety, depression, and other psychopathology. Contemporary functional MRI studies have documented the presence of unconscious processes whereby emotional stressors can distort cognitive perceptions in ways clearly relevant to our better understanding the pathogenesis of these disorders.

Clinical Features and Diagnostic Criteria

The term 'somatoform disorders' is a grouping of related disorders involving medically unexplained symptoms.

Conversion disorder describes patients who present with symptoms affecting voluntary motor or sensory function that inappropriately suggest a neurological or other general medical condition. It inherently has all the features of somatoform disorders as outlined earlier, including primary psychogenic etiology of an unconsciously based nature, being unexplainable on a physiological basis and not being due to the direct effects of a substance or a culturally sanctioned experience. Furthermore, the clinically impairing symptoms are not limited to pain or sexual dysfunction, are not part of a somatization disorder (see next subsection), and are not better accounted for by another mental disorder. Commonly encountered conversion symptoms presenting to neurologists as 'movement disorders' include tremor, gait abnormality, dystonia, paroxysmal dyskinesias, and myoclonus, among others. Prospective studies of children and adolescents with untreated or unresolved mono-symptomatic conversion disorder disclose a pattern of symptom proliferation over time, suggesting that this is a developmental path leading to somatization disorder and its chronic variant, undifferentiated somatoform disorder.

Somatization disorder connotes a chronic history, lasting several years, of many physical complaints, beginning before age 30, that result in significant impairment of social, occupational or other important areas of functioning. As with all somatoform disorders, patients with somatization disorder have symptoms with primary psychogenic etiology of an unconsciously based nature, being unexplainable on a physiological basis and not being due to the direct effects of a substance or a culturally sanctioned experience. In addition, criteria for somatization disorder require the presence

of at least four pain symptoms, two gastrointestinal symptoms, one sexual symptom, and one pseudo-neurological symptom.

Undifferentiated somatoform disorder connotes the presence of one or more physical complaints of at least 6 months duration that manifest primary psychogenic etiology of an unconsciously based nature, being unexplainable on a physiological basis and not being due to the direct effects of a substance or a culturally sanctioned experience. This will include patients who are similar to, but do not meet all the criteria of, patients with somatization disorder.

Pain disorder involves pain where psychological factors play a major role in the onset, severity, or maintenance of the pain and requires clinical attention. The pain causes significant functional impairment and is not intentionally produced nor better explained by another psychiatric disorder. There are two subtypes of pain disorder: (1) *Pain disorder associated with psychological factors*, where psychological factors have a predominant role in the onset, severity, or maintenance of the pain and general medical conditions play either no role or a minimal one and (2) *Pain disorder associated with both psychological factors and a general medical condition*, where both psychological factors and a general medical condition have important roles in the clinical course.

Hypochondriasis describes individuals who are debilitated by fear that they have a serious disease despite appropriate medical reassurance to the contrary. The fear is often based on catastrophizing normal bodily signs or symptoms as indication of serious illness. While beliefs cause clinical distress or functional impairment, they are not of delusional intensity: patients can often acknowledge that their concerns may be excessive yet feel unable to stop worrying and seeking reassurance. To meet criteria for diagnosis of hypochondriasis the preoccupation and fear must persist for at least 6 months and not be better accounted for by another psychiatric disorder.

Body dysmorphic disorder (BDD) involves the preoccupation with a perceived defect in appearance that causes clinical distress and impairment in social and occupational functioning. Even If a slight physical anomaly is apparent, the individual's concern is markedly exaggerated and not better accounted for by anther psychiatric disorder.

Pathogenesis/Pathophysiology

Conceptualizations regarding pathogenesis of somatoform disorders have addressed considerations of predisposition, precipitating influences, and perpetuating influences.

Predisposition includes biological factors (e.g., genetics and emerging data on immunological factors influencing amplification of symptom sensitivity), past experiences (e.g., trauma, abuse, or exposure to disabling physical illness in oneself or others), and personality factors (e.g., internalizing, as opposed to externalizing style). A variety of family studies show higher rates of somatoform and related disorders (i.e., depression and obsessive compulsive disorder) in first-degree relatives. For instance, genetic factors are suggested by pedigree studies finding a higher incidence of somatization disorder in female first-degree relatives of index cases, whereas male first-degree relatives have a higher incidence of alcoholism and antisocial (externalizing) personality features. Additionally, recent advances in understanding of psychoneuroimmune pathophysiology, including the role of cytokines in illness behavior, suggest that some individuals are more vulnerable to experiencing amplified somatic symptoms and pain sensitivity. Past experiences such as trauma or illness may underlie chronic activation of the immune system. Comorbid psychiatric or neurological disorders may also be contributory. Biologic factors can be compounded by limitations of communicative ability due to intellectual, emotional, or social constraints predisposing some to a 'body language expression of distress.'

Precipitating stressors may involve proximate activation of psychological conflicts, such as those regarding sexual, aggressive, or dependency issues. Traumatic events, such as those threatening one's physical integrity or self-esteem, are commonly cited precipitants.

Perpetuating factors include 'primary gain' or the ways in which the symptom may resolve or diminish the psychological conflict that generated the symptom, as well as 'secondary gain' or the pragmatic benefits of the symptom.

Somatoform disorders embody dissociative features, since they involve development of somatic symptoms or preoccupations based on psychological mechanisms outside the individual's conscious awareness. One may conceptualize such an individual as overwhelmed with stress beyond the capacity for effective, conscious processing of the related affect, leading to communication of distress via 'somatic metaphor' or symptom production.

Epidemiology

Psychogenic neurological symptoms have been estimated to account for between 1% and 9% of all neurological diagnoses. In psychiatric epidemiologic studies, children have an equal incidence of conversion disorders in boys and girls, which shifts in the direction of female preponderance as age progresses. Somatization disorder appears more commonly among women (lifetime prevalence 0.2–2%, vs. 0.2% in men). When the number of symptoms required for a somatoform diagnosis is reduced, however, (e.g., in undifferentiated somatoform disorder) an

increased prevalence is encountered: in primary care patients, this is estimated at ~16.6%. Pain disorder is relatively common (estimated 12 month prevalence of 8%) and is also noted to be more common in females (11%) than males (4%). Hypochondriasis is seen in ~4–6% of patients in general medical practice. It presents typically in adulthood and is found equally commonly in men and women. Body dysmorphic disorder has a prevalence estimated ~1–2%; however, prevalence may be significantly higher in some dermatologic and plastic surgical populations. It occurs equally commonly in males and females and typically presents in adolescence or early adulthood.

Differential Diagnosis

Undiagnosed medical illness is the most crucial category of differential diagnosis for the somatoform disorders, presenting substantial hazards for patients as well as clinicians. While it is beyond the scope of this article to address the complex issue of what constitutes an adequately thorough medical workup for movement disorders with initially uncertain etiology, it is clear that this is a crucial foundation for the diagnosis of any somatoform disorder and for the effectiveness of any therapeutic intervention. Certainly, the presence of nonphysiologic features on physical examination does not rule out the possibility of an underlying undiagnosed physical illness coexisting with a superimposed somatoform disorder. Furthermore, the patient's need for reassurance that all plausible organic causes of the presenting symptoms have been considered and evaluated is a prerequisite to seriously considering a judiciously introduced discussion of possible psychogenic contributants.

Factitious disorders involve the *intentional, or conscious,* production of physical or psychological symptoms with the primary purpose of *being cared for medically.* Patients with factitious disorders may seek numerous medical evaluations and treatments, including hospitalizations, invasive procedures, and surgery. Factitious disorders differ from malingering in that pragmatic incentives for this behavior, such as economic gain or evasion of responsibility, are absent or subsidiary. A more chronic and intractable pattern of factitious disorder is known as 'Munchausen's Syndrome.' These patients may migrate to different treatment sites to avoid detection that would be more likely in a single follow-up site. Duplicity in assuming the patient role is often associated with severe dependent, histrionic, borderline, and antisocial personality characteristics. Prognosis is generally less favorable than in cases of somatoform disorder.

Malingering involves purposeful production of physical or psychological symptoms in pursuit of a pragmatic goal, which may include financial gain, avoidance of school or military duty, evasion of prosecution, or obtaining controlled substances. Associated features include poor cooperation during diagnostic evaluation and treatment, pending litigation, and antisocial personality disorder. Although there may be underlying psychopathology, malingering is not considered as a mental disorder.

Psychological factors affecting a medical condition is a diagnosis that requires documentation of a general medical condition. Psychological factors can impact a general medical condition in two main ways: (1) the psychological factors influence the development of the medical condition, as reflected by a close temporal proximity between the psychological factors and the evolution of the medical condition; or (2) stress-related physiological responses exacerbate the medical condition. A neurologically relevant example is the exacerbation of a parkinsonian or essential tremor by anxiety.

Coexisting psychiatric conditions, such as affective disorders, anxiety disorders, dissociative disorders, psychotic disorders, developmental disorders and personality disorders, may mimic, contribute to, or exacerbate somatoform disorders. Examples include cardiovascular symptoms seen in panic disorder, vegetative symptoms of depression suggesting a neurodegenerative, endocrine or metabolic disorder, or somatic delusions seen in schizophrenia. In addition to inquiring about contemporary psychosocial stressors and psychiatric symptoms, clinicians should ask about histories of physical, sexual, or emotional abuse or neglect, which may predispose to somatization.

Diagnostic Workup

It is inevitable that medical illness will sometimes be missed on initial assessment by the primary medical clinician who suspects a possible somatoform disorder. This fact may lead some clinicians to an overly aggressive medical diagnostic workup and an untoward delay in seeking psychiatric consultation. This, in turn, may lead the patient to the presumption that there must be some esoteric medical cause for the unexplained symptoms that has simply not yet been found at the conclusion of the workup, prompting migration to a new medical specialist. On the other hand, premature presentation of a firm diagnosis of psychogenic etiology before adequate medical workup has been completed can lead to an alienation of the patient and an embarrassment for clinicians who have prematurely grasped a misdiagnosis, undermining the patient's confidence in the treatment team. A more judicious path, requiring seasoned judgment of the primary medical physician, is to introduce the recommendation of a psychiatric consultation when a somatoform disorder is strongly suspected, with the psychiatrist presented as another specialty consultant seeking elucidation of symptoms that may have multifactorial causation, including the possible role of 'stress.'

Management

Conversion Disorder

Physical therapy can be a valuable face-saving intervention in cases of fixed postures, weakness, or gait abnormalities. This physically based format of recovery may be particularly helpful for patients who have difficulty in assimilating psychodynamic interpretations. The physical therapist provides hands-on encouragement and reassurance. Physical therapy is also crucial in treating disuse atrophy or contractures that complicate persistent somatoform motor symptoms.

Psychotherapy allows patients to manage conflicts that led to symptom formation through a process of emotional and cognitive 'restructuring.' Such treatment ideally addresses as many relevant etiological variables as possible, with a strategy that strengthens the patient's capacity to impact relevant psychological, biological, and social variables to generate a healthier mode of adaptation. Patients may be receptive to 'stress management techniques,' which utilize cognitive behavioral strategies, as a contemporary adaptation of the traditional psychodynamic treatment of these disorders.

Hypnosis is a psychotherapeutic technique that provides patients with a benign desensitizing experience of dissociation under the protective supervision of the therapist along with suggestions for symptomatic improvement. Initial assessment of hypnotizability provides a 'mind-body' dissociative experience that conveys a model for understanding and experiencing the dissociation central to conversion symptoms. Self-hypnosis techniques provide a confidence-building strategy of enhanced self-control and healing.

Behavior modification strategies address the contingencies of reinforcement that contribute to symptom formation and perpetuation. Insight-oriented psychotherapy and positive suggestion have more motivational traction when combined with the alteration of environmental forces that generated primary and secondary gain benefits that precipitated the symptoms. Behavior modification often requires collaboration of motivated family members, who are often inadvertent 'contributants' to the symptomatic pattern, either by aversive influence or by 'enabling' of the sick role. This route of therapeutic influence via family intervention is often easier with child and adolescent patients, by working with parents. However, it should not be overlooked with adults, where spouses or significant others can often wield a crucial influence.

Pharmacotherapy is often indicated for coexisting psychiatric conditions, such as depression, anxiety, or psychosis. These *neuropsychiatric* medications can reasonably be presented as an aid to attenuate abnormalities of neurotransmitter balance that appear to play a central role in many *neuropsychiatric conditions,* including somatoform disorders.

Other treatment interventions include family therapy, which addresses conflicts, dependency, abuse, or enabling issues; intravenous infusions, such as amobarbital or loazepam, to evaluate for possible contractures in fixed, dystonic posturing; electroconvulsive therapy for treatment-resistant depression or mania; or speech therapy when indicated.

Somatization and Pain Disorders

Practical outpatient strategies for patients with chronic medically unexplained symptoms include centering the treatment with the primary care physician, who maintains a dual role of monitoring the patient's physical status, while supportively encouraging that exploratory attention be paid to those psychosocial stress factors that inevitably impact on this chronic condition. Helpful adjunctive techniques include scheduling patients in a time-contingent rather than symptom-contingent manner and avoiding unnecessary treatment and repetition of tests. While approaching patients with somatization and pain disorders with empathy and an appreciation for their genuine suffering, one does not want to be overly reassuring. It is helpful to reframe treatment expectations from symptom 'cure,' if that is unattainable, to improved accommodation.

Psychosocial treatments: Cognitive behavioral therapy (CBT) is a moderately effective treatment for somatization disorder. The CBT model of somatization stresses the interplay of sensory physiology, cognition, emotion, behavior and environment. CBT aims at facilitating patients' identification of their incorrect beliefs about their symptoms and bodily functioning as well as identification of related dysfunctional, avoidable behaviors. One then moves to challenge these beliefs and behaviors, eventually replacing them with more realistic and adaptive ones. The efficacy of treatment for somatoform disorders was recently addressed in a review by Kroenke et al. of 34 randomized controlled trials involving 3922 patients. Two thirds of the studies involved somatization disorder and its variants. Cognitive behavior therapy was effective in most studies (11 of 13), as were antidepressants in a small number (4 of 5).

Pharmacotherapy: Since there is frequent comorbidity with somatization and chronic pain disorders involving anxiety, depression, and personality disorders, the use of antidepressant medication may be helpful in treating these comorbid conditions, as well as in having some impact on the associated somatoform disorder. Some added, independent benefit from antidepressant medication regarding unexplained pain disorder may also ensue. There may be advantage in this regard for medications that enhance both serotonin and norepinephrine reuptake inhibition, such as duloxetine and venlafaxine.

Other potential treatment interventions, including physical therapy, hypnosis, and family therapy, as discussed earlier regarding conversion disorders, may similarly be helpful.

A well-formulated treatment strategy involves drawing upon all relevant interventions that may constructively impact on these chronic syndromes with multifactorial determinants. These combined initiatives, reflecting concerted efforts by the collaborating clinicians, can foster a therapeutic alliance that engenders hope for gradual improvement, based on systematic efforts, further extended by the patient, to attenuate chronic distress and disability. A calm and reassuring therapeutic optimism, supported by regular monitoring and reinforcement of the patient's progress, can be helpful.

Hospitalization: An outpatient setting for the evaluation and treatment of somatoform disorders is favored by the current 'managed care model' that seeks to minimize the time in hospital. In clinical experience, however, the diagnosis of a somatoform disorder may be first entertained when the patient has been admitted to a medical service for the evaluation and treatment of undiagnosed, disabling symptoms. Precipitous discharge without adequate diagnostic clarification to the patient and family, and without establishment of an acceptable, coordinated treatment plan, can be quite counterproductive, generating patient resentment, resistance to appropriate treatment, and prolongation of the course of illness.

Alternatively, a consulting physician may conclude at initial office visit, based on the patient's response to the physician broaching this subject, that while a somatoform disorder is indeed the most likely diagnosis, the patient is resistant to accepting this diagnosis and the associated recommended treatment without a more intensive, integrated evaluation, which can more effectively be done on an inpatient setting. Although there have not been any controlled clinical trials done to systematically evaluate this, it has been the impression of our movement disorder group that such an admission has enabled us to afford a transformative therapeutic opportunity to some patients, who by reasons of geography or other limitations of access to integrated diagnosis and treatment, would not otherwise have achieved symptomatic remission. Under the rubric of a 'multidisciplinary inpatient diagnostic and treatment approach,' such patients have been seen intensively by the admitting neurologist, the consulting psychiatrist, and a physical therapist. This hospitalization removes the patient from those environmental influences that contributed to the symptom formation and perpetuation, while it also allows us to evaluate the patient more thoroughly in a controlled environment. Further, the introduction of the psychiatrist as a routine member of the evaluation and treatment team makes it more difficult for the patient to reject this intervention and allows for the development of a therapeutic alliance while multiple diagnostic and treatment strategies are ongoing simultaneously, assuring the patient that no organic contributions to symptoms are being overlooked.

Within a few days of admission, with our initial diagnostic impressions usually further clarified, we arrange for a conjoint debriefing session with both the neurologist and psychiatrist present, to supportively present to the patient our diagnostic impressions and treatment recommendations. If neurological workup was negative or disclosed a substantial somatoform component, this is supportively reviewed, together with the more favorable prognosis for recovery than would be the case with a degenerative neurological disorder. We observe further that stress of various types can contribute to physiological aberrations that generate clear physical symptoms despite the absence of structural lesions on the various diagnostic tests performed. Commonly encountered clinical examples of how stress can activate the symptoms of hypertension, peptic ulcer disease, and asthma, among others, facilitates patient recognition of the plausibility and relevance of this conceptual model. A treatment plan is then outlined, tailored to the needs of the individual patient. Elements of this treatment plan, generally including psychotherapy, pharmacotherapy, and physical therapy, are started in the hospital in an effort to achieve as much symptomatic improvement as possible, to be continued on an outpatient basis as individually needed. A follow-up appointment is recommended with both the neurologist and the psychiatrist, to assure the patient and family that both spheres are being appropriately monitored in an effort to achieve full symptom resolution.

While there are substantial expenditure and associated insurance hurdles inherent in this intervention, it can be argued from a public health perspective that for some patients who are not otherwise effectively engaged in treatment, the cost of chronic care for years of unremitting somatization disorder far outweigh the cost of a 1–2 week admission, which in our experience, is sometimes dramatically transformative in generating a 'sprint into health.'

Hypochondriasis and Body Dysmorphic Disorder

Cognitive-behavioral therapy and serotonin reuptake inhibitors (SRIs) have the most empirical support for both the treatment of hypochondriasis and Body Dysmorphic Disorder. Both can also be helpful for reducing comorbid symptoms of anxiety and depression.

Psychotherapies: CBT improves patient functioning by modifying dysfunctional thoughts and behaviors in response to symptoms. Therapy may focus on areas such as learning to tolerate and attenuate symptoms without necessarily chasing an unobtainable 'cure.'

Pharmacotherapy. There is increasing evidence that SRIs, such as fluoxetine, fluvoxamine, and paroxetine, help to attenuate both hypochondriasis and BDD. Much like the treatment of obsessive–compulsive disorder,

symptoms of hypochondriasis and BDD may be most responsive to higher does of these medications (e.g., fluoxetine 60 mg day^{-1}).

Prognosis

The prognosis for patients with a somatoform disorder is determined by many factors: Contributants include the nature, chronicity, and severity of the comorbid psychopathology; the nature, chronicity, and severity of life environmental stressors; the intrinsic resilience of the patient; the strength of the available support system; and the effectiveness of treatment.

Follow-up studies of patients with impairing, undiagnosed illness presenting as 'neurological disorders,' the majority of which are apparently somatoform, report a low rate of spontaneous remission and a high rate of long-term impairment in patients not receiving active psychiatric treatment. It therefore behooves the physician who has a clinical suspicion regarding the possible existence of a somatoform illness to document this diagnostic impression clearly to the referring clinician, to communicate it tactfully and empathically to the patient, as well as to make sustained efforts to implement psychiatric referral for further evaluation and treatment. Neurological follow-up is advisable to avoid the patient's feeling abandoned and to reassure all concerned that relevant neurological illness has not been missed.

Spasm

S Horn, University of Pennsylvania, Philadelphia, PA, USA

Glossary

Amyotrophic lateral sclerosis (ALS) – A group of adult onset degenerative conditions resulting in both upper and lower motor neuron findings. ALS causes degeneration of the anterior horn cells with secondary degeneration of the pyramidal tracts.

Dystonia – A condition caused by abnormalities in the basal ganglia. This condition results in involuntary contraction of muscles. The muscular contractions may occur at rest, but are

often worsened after activation of the affected muscles.

Spasticity – Increased tone in muscles due to disruption of descending motor pathways resulting in increased extensor tone in the lower extremities and increased flexor tone in the upper extremities.

Overview

Muscle spasms are defined as involuntary contractions of a muscle group. These spasms can often be forceful and painful. The etiology of muscle spasms may range from benign conditions such as electrolyte disorders that alter muscle physiology to more severe neurological and degenerative conditions such as motor neuron disease and stroke where muscles spasms occur because of abnormalities in the pathways that normally activate muscles. **Table 1** contains a list of conditions that may result in muscular spasms and presents these conditions from the perspective of the primary anatomical site of involvement.

The evaluation of muscular spasms should begin with a history of the distribution, onset, severity, occurrence, and frequency of cramps. A thorough review of systems should be completed for underlying neurological or medical illness and a complete list of medications and supplements. Physical examination can help to elucidate benign from more severe conditions, and the examination must pay close attention to tone, reflexes, bulk of muscles, and sensory changes. In patients with abnormalities on examination, further evaluation is warranted with neuroimaging, laboratory testing, electromyography, and possibly, muscle biopsy. Treatment of muscular spasms is usually directed at the underlying cause, although some treatments may be beneficial regardless of etiology.

Nocturnal leg cramps
Exercise induced cramps

Primary Muscle Impairments

Contraction of muscles at the cellular level is a complex process through electrical potentials at the cell membrane and release of calcium with subsequent contractile protein interaction and fiber shortening. This process may be disrupted by electrolyte abnormalities and muscle disorders. Electrolyte disorders and medical illnesses are often acute and short lived. Even in normal people without neurological disease, overuse of muscles from intense exercise can generate mild degrees of lactic acidosis and cause muscle spasms. Single episodes of spasms do not require neurological evaluation in most cases. Recurrent or chronic spasms are best assessed with laboratory studies of muscle enzyme levels and electrolytes, especially immediately during an episode of cramping. In more prolonged medical conditions such as thyroid disease, electromyography may be helpful.

Primary muscular diseases may cause longer term spasms often with accompanying symptoms such as weakness or muscular tenderness. These disorders tend to be progressive over months to years. Muscle diseases can be assessed with electromyography and possibly muscle biopsy.

Peripheral Nerve Impairments

Neurogenic causes are likely the most common type of spasm. This condition results from denervation of the

motor unit with resultant hyperactivity of uninhibited muscle fibers. Neurogenic cramps are seen in a number of peripheral nervous system disorders, including radiculopathy, neuropathy, plexopathy, and anterior horn cell disorders such as amyotrophic lateral sclerosis and spinal muscular atrophy. These conditions can be diagnosed on clinical examination with confirmation by electromyogram.

Hemifacial spasm is a particular form of spasm involving one side of the face and can be associated with a prior history of facial nerve (cranial nerve VII) palsy. In some cases, hemifacial spasm is due to compression of the facial nerve by aneurysm or an ectatic basilar artery. This can be assessed with an MRI and MRA of the brain. Hemifacial spasm may be treated with anticonvulsants, but the most effective therapy remains botulinum toxin injections into the affected facial musculature.

Central Causes of Muscular Spasms

Spasticity is an increase in muscle tone due to lesions of the descending motor pathways at any level from the cerebral hemispheres to the spinal cord. Spasticity is the result of a number of disorders, including, but not limited to cerebral palsy, multiple sclerosis, stroke, and trauma. It is most often associated with other upper motor neuron signs such as increased reflexes, paresis, Babinski signs, and clonus. Spasticity results in increased extensor tone in the lower extremity and increased flexor tone in the upper extremity. The exact pathophysiology of spasticity is not understood, but may be due to the loss of inhibition in descending pathways from the brainstem. Treatments of spasticity and resultant spasms are aimed at reduction of the hypertonicity to facilitate activities of daily living and improve quality of life. Treatment of spasticity includes physical therapy and medical therapy. Medications, including baclofen, tizanidine, benzodiazepines, gabapentin, dantrolene, and botulinum toxin, have been used to decrease tone and spasms.

Dystonia is a movement disorder seen as a primary or secondary disorder due to abnormalities in the basal ganglia. Dystonia is discussed in further detail in its own entry, but its symptoms are primarily those of muscle spasm and deviation of postures, often with pain.

Summary

Spasms that are recurrent require laboratory evaluations to assess electrolytes, acid–base balance, and muscle enzyme levels. If weakness accompanies spasms, electromyography is needed to assess the possibility of myopathy, plexopathy, or neuropathy. If the neurological examination shows increased or decreased reflexes, alterations in ambient tone, or other neurological findings, further evaluations of the spinal cord, brain stem, and brain are needed.

Spasmodic Dysphonia: Focal Laryngeal Dystonia

A Blitzer, NY Center for Voice and Swallowing Disorders, New York, NY 10019, USA

Glossary

Abductor laryngeal dystonia – Focal dystonia of the laryngeal muscles causing a 'whispering' dysphonia or speech with breathy breaks.
Adductor laryngeal dystonia – Focal dystonia of the laryngeal muscles causing a 'strain-strangled' voice.
Adductor breathing dystonia – Focal dystonia of the laryngeal muscles causing paradoxical motion with adduction on inspiration.
Botulinum toxin – A neurotoxin produced by the bacterium *Clostridia botulinum* which blocks the release of acetyl choline into the neuromuscular junction.
Electromyography – Measurement and recording of mini end plate potentials from muscle.

Definition and History

Spasmodic dysphonia (SD) is an action-induced, laryngeal motion disorder producing interference with a fluent speech pattern. Most cases represent manifestations of primary dystonia, but many are secondary to other neurologic entities. In 1871, Traube coined the term 'spastic dysphonia' when describing a patient with nervous hoarseness. Schnitzler, in 1895, used the terms 'spastic aphonia' and 'phonic laryngeal spasm' to describe such patients. Fraenkel, in 1887, used the phrase 'Mogiphonia' for a slowly developing disorder of the voice characterized by increasing vocal fatigue, spasmodic constriction of the throat muscles, and pain around the larynx. In 1899, Gowers described functional laryngeal spasm whereby the cords were brought together too forcibly while speaking (adductor type) and contrasted this to phonic paralysis whereby the vocal cords could not be brought together while speaking (abductor type). Critchley, in 1939, described the voice pattern as a condition in which the patient sounds as though he were 'trying to talk whilst being choked.' Jacome, in 1980, associated SD with Meige disease, and this association with dystonia was confirmed by Blitzer, Marsden, and others in the 1980s.

Epidemiology

SD is a rare disorder (1 per 100 000). It typically begins in the mid to late 1930s and is more common in women (63%). Almost 12% of the patients have a positive family history for dystonia. More than 80% of these patients remain focal, but almost 15% will develop other cranial involvement (usually blepharospasm), and less than 5% will progress to an extracranial site.

Clinical Features

Two main types of SD have been identified. The adductor type produces an irregular hyperadduction of the vocal folds during speaking, producing a 'strain-strangled' voice with harshness and voice breaks. There is also a less common abductor type in which there are irregular and inappropriate abductor spasms during speaking, producing breathy breaks, or whispering. There are also cases of compensatory or pseudoabductor patients who whisper as a compensatory strategy for the tight adductor spasms they experience. Therefore, these patients may need to be seen several times and put through various challenging vocal tasks to make the correct diagnosis. Cannito et al. believe that all of the patients are a mixed adductor/abductor with a predominance of one form. We have seen several patients who are truly mixed and have both adductor and abductor spasms. We also have seen several patients in whom their primary form changed with time (e.g., adductor to abductor). Many other laryngeal functions, including breathing, laughing, swallowing, and, at times, singing and humming, are usually unaffected.

In addition, we have identified a 'Singer's laryngeal dystonia' in which the vocal abnormalities occur during singing. There is also a rare form of laryngeal dystonia in which there are adductor spasms during respiration. The paradoxical motion during breathing produces stridulous noises during inspiration, but usually does not produce hypoxia. Other laryngeal activities in these patients are normal.

Dystonic movements can be rapid and repetitive, and tremor may be seen in dystonia affecting any segment of the body. The tremors are typically irregular and have a directional preponderance, and thought to be produced by simultaneous agonist/antagonist actions. Many patients with SD have an irregular vocal tremor that is both audible and can be recorded on EMG. This tremor is to be differentiated from the regular tremor that is commonly seen in benign essential voice tremor that often occurs with tremor in other body parts.

Sensory tricks, often, can ameliorate dystonic movements and postures. A sensory trick is also known as

'geste antagonistique' or 'gegendruckphaenomen.' Many laryngeal patients speak better after a yawn or sneeze, or when they sing or yell.

Differential Diagnosis

The differential diagnosis is important because there are no quantitative tests to secure the diagnosis, unless the condition is the result of a secondary dystonia (e.g., head trauma, stroke, Wilson's disease, and tardive dystonias). Patients with a strain-strangled voice or whispering dysphonia include tremor disorders, including essential tremor, cerebellar disorders, muscle tension dysphonia, Parkinson's disease, laryngeal myoclonus, and psychogenic voice disorders.

Diagnostic Evaluation

Diagnostic evaluation should include speech analysis and a fiberoptic endoscopy. The endoscopy will reveal an irregular tremor in some patients and hyperadduction at the glottal level, the false cord level, and/or at supraglottic closure. In the abductor group, there will be abductor spasms producing aphonic breaks in connected speech. In the adductor respiratory laryngeal dystonia, there will be paradoxical adductor closure with inspiration. Brain scans and blood analysis are not very valuable in the diagnosis.

Management

Specific pharmacotherapy to treat underlying identified etiology is available only for a limited number of symptomatic dystonias (secondary dystonias) such as Wilson's disease. For the other patients, the current treatment strategy is aimed at the management of symptom complexes.

Management of focal dystonias has been attempted through a variety of local surgical procedures. Dedo theorized that if sustained contractions of the vocal cords prevented normal phonatory activity, impairing one of the cords would allow for more normal speech. He also found that injection of one recurrent laryngeal nerve (RLN) with lidocaine that cause a paresis could provide temporary speech improvement. Dedo then performed and advocated RLN section as a permanent therapy. Although initial reports of the RLN section technique were promising, many surgeons found late-onset failures. Aronson and DeSanto's review of the Mayo Clinic series found that, by 3 years, only 36% of the patients continued to have some improvement and only one patient maintained a normal voice. Others have suggested a role for laser myectomy, implantable nerve stimulators, and selective dennervation–reinnervation procedures with limited data available.

Botulinum toxin was first given by Blitzer et al., in 1984, for the management of SD. Although not curative, botulinum toxin may significantly ameliorate the muscle spasms and restore a patient's function and quality of life. Some patients require a combination of an oral agent and botulinum toxin. The botulinum toxin is administered through the anterior neck, using a 27 gauge hollow bore, Teflon-coated EMG needle. The active part of the muscles is identified by the interference pattern heard and visualized on the EMG machine while the patient is phonating. The adductor SD patients receive injections into the thyroarytenoid muscle, and some in the lateral cricoarytenoid or interarytenoid muscles. For the abductor SD patients, injections are given into the posterior cricoarytenoid muscles.

Botulinum toxin injections have several advantages over surgical therapy. The patient remains awake and avoids the risks associated with general anesthesia. Graded degrees of weakening can be achieved by varying the dose injected. Dosing begins with small amounts and can be increased until good voice is achieved without prolonged weak voice after the injection. Some patients may have transient dysphagia to liquids. Most adverse effects are transient and are due to diffusion of the toxin. If there is too much weakening produced, the patient will recover with varying amounts of time. If a new and better treatment emerges, the toxin may be stopped and the patient would return to full function. The disadvantage is that the results are not permanent. The adductor SD patients achieve, on average, better than 90% of normal function for a period of 3–4 months. The abductor patients achieve about 70% of normal function. This is because of the limit to how much weakness can be achieved in the posterior cricoarytenoid (PCA) muscle before they begin to have stridor and dyspnea.

Prognosis

SD is a chronic neurologic disorder for which there is presently no cure. There is a very small number of patients who have spontaneous remissions. All of the other patients require management of their symptoms to allow them continued function.

L Samaranch, Center for Applied Medical Research, Pamplona, Spain
P Pastor, Center for Applied Medical Research, Pamplona, Spain; University of Navarra School of Medicine, Pamplona, Spain

Glossary

Ataxia – Lack of coordination in movements due to cerebellar disorders or loss of proprioception.
Leukodystrophy – Progressive degeneration of brain's white matter due to defective development of the myelin sheath that surrounds neural axons.
Nystagmus – Eye movements characterized by alternating slow movements in one direction and fast (saccade-like) phases in the opposite direction.
Spastic paraparesis – A condition by which continuous muscle activity causes stiffness in lower limbs and gait impairment.
Spasticity – A state of continuous muscle activity of agonistic and antagonistic muscular groups that causes stiffness, and interferes in the normal movement.

Definition and History

Spastic paraparesis results from restless muscle activity of lower limbs that hinders leg movements, causing impaired gait. In this article, we will mainly focus on the hereditary spastic paraplegia (HSP).

HSP, also called as familial Strümpell–Lorrain syndrome, was described by Ernest A. Strümpell and Maurice Lorrain in the late nineteenth century. It comprises a heterogeneous group of inherited neurodegenerative pyramidal tract dysfunctions causing progressive spasticity and weakness of the lower limbs.

HSP can be classified according to the clinical presentation or the mode of inheritance. Clinically, HSP is classified as either pure (uncomplicated) or complex (complicated). HSP most often presents with an autosomal dominant inheritance (ADHSP), but can also be inherited by autosomal recessive (ARHSP) or X-linked transmission. In the last 10 years, identification of the causative genes linked to HSP has provided an essential aid in classifying HSP, despite the fact that the frequent phenotypical variability of mutations located in the same gene, as seen in *PLP1*, *paraplegin*, or *spastin* mutations, can give rise to either pure or complex HSP. Fifteen different genes and 22 different loci with unknown gene have been associated with HSP to date (**Tables 1** and **2**). Some genes cause a specific phenotype such as *atlastin*, associated with pure ADHSP starting in childhood, or *spatacsin*, which causes mental retardation, thin corpus callosum, and polyneuropathy.

Pathogenesis and Pathophysiology

HSP is characterized by corticospinal tract degeneration caused by the derangement of microtubule dynamics and organelle transport. Neuronal degeneration starts distally in the axons of pyramidal neurons that have synapses with spinal interneurons. These neurons activate the second motor neurons, which are located at the ventral horn of the spinal cord, whose axons run through the peripheral nerves and end in the neuromuscular junctions. Functional loss or gain of mutated proteins impairs mitochondrial metabolism, axonal transport, and cytoskeletal organization.

Table 1 Hereditary spastic paraplegias caused by mutations of known genes

Locus	*Chromosome region*	*Type of inheritance*	*Gene*	*Function*	*Pathway*	*Pure/ complex*	*Age at onset*	*Clinical features*
SPG3A	14q12–q21	AD	SPG3A/ *Atlastin*	Transmembrane GTPase, Golgi apparatus	Trafficking	Pure	Predominantly early onset	Common cause of dominant hereditary spastic paraplegia
SPG4	2p22–p21	AD	*Spastin*	Microtubule severing protein	Trafficking	Pure and complex	Variable from second to seventh decade	Most common form of autosomal dominant hereditary spastic paraplegia. Some cases with cognitive impairment. Lower motor neuron dysfunction may be found. Occasional bulbar dysfunction and respiratory insufficiency. Mild cerebellar signs may occur
SPG6	15q11.2–q12	AD	*NIPA1*	Transmembrane protein	Unknown	Pure	Predominantly adult onset, as early as second decade	
SPG8	8q24	AD	*KIAA0196*			Pure	Predominantly adult onset	
SPG10	12q13	AD	*KIF5A*	Molecular motor	Trafficking	Pure	Predominantly adult onset

SPG31	2p12	AD	*REEP1* (receptor expression enhancing protein 1)	Transmembrane protein	Mitochondria	Pure	Variable from second to fifth decade	
SPG5A	8q21.3	AR	*CYP7B1*			Pure	From childhood to adulthood	
SPG7	16q	AR	*Paraplegin*	Mitochondrial metalloproteinase	Mitochondria	Pure and complex	From childhood to adulthood	Cerebellar signs, polyneuropathy, pes cavus, optic atrophy
SPG11 (autosomal recessive hereditary spastic paraplegia with thin corpus callosum)	15q21.1	AR	*Spatacsin*			Pure and complex	First and second decades	Mental retardation or cognitive impairment, polyneuropathy, thin corpus callosum

Continued

Table 1 Continued

Locus	*Chromosome region*	*Type of inheritance*	*Gene*	*Function*	*Pathway*	*Pure/ complex*	*Age at onset*	*Clinical features*
SPG15 (Kjellin syndrome)	14q24.1	AR	ZFYVE26/ *Spastizin*			Complex	Childhood to adulthood	Pigmented maculopathy, distal amyotrophy, pes cavus, dysarthria, cerebellar signs, mental retardation, dementia, saccadic pursuit, thin corpus callosum, axonal peripheral neuropathy, extrapyramidal signs, white matter abnormalities
SPG20 (Troyer syndrome)	13q12.3	AR	*Spartin*	Microtubule and mitochondria associated	Trafficking	Complex	Early childhood	Distal muscle wasting, dysarthria, mental retardation, cerebellar signs, developmental delay and short stature
SPG21 (Mast syndrome)	15q22.31	AR	ACP33/ *Maspardin*	Vesicular transport, Golgi apparatus	Trafficking	Complex	Childhood-early adulthood	Premature aging, developmental delay, dementia, dysarthria, pseudobulbar, cerebellar, and extrapyramidal syndrome, thin corpus callosum, periventricular white matter hyperintensities, cataract, dystonia, polyneuropathy, chorea, distal wasting
ARSACS (autosomal recessive spastic ataxia of Charlevoix Saguenay)	13q11	AR	*Sacsin*	Chaperone-mediated protein folding		Complex	Early childhood	Pyramidal and cerebellar progressive symptoms, distal muscle wasting, peripheral neuropathy, dysarthria, nystagmus, retinal striation
SPG1 (MASA syndrome, CRASH syndrome or L1 syndrome)	Xq28	X-linked	*L1CAM* (L1 cell adhesion molecule)	Neurite outgrowth, myelination	Signaling	Complex	Infancy	Mental retardation, aphasia, shuffling gait, absence of extensor pollicis longus muscle, microcephaly, or macrocephaly with hydrocephaly, exaggerated lumbar lordosis
SPG2	Xq22	X-linked	*PLP1* (myelin proteolipid protein)	Myelination	Myelination	Pure and complex	First and second decades	Mental retardation, optic atrophy, nystagmus, diplopia, dysarthria, hypoestesia, cerebellar signs

AD, autosomal dominant; AR, autosomal recessive; SPG, spastic paraplegia.

Table 2 Hereditary spastic paraplegia caused by unknown genes to date

Locus	*Chromosome region*	*Type of inheritance*	*Pure/ complex*	*Age at onset*	*Clinical features*
SPG9	10q23.3–q24.2	AD	Complex	Infancy to adulthood	Cataract, motor neuropathy, short stature, skeletal abnormalities, gastroesophageal reflux
SPG12	19q13	AD	Pure	Predominantly adult onset	Trend to earlier age of onset in subsequent generations
SPG19	9q33–q34	AD	Pure	Predominantly adult onset	Slow and relatively benign progression, polyneuropathy
SPG29	1p31–p21	AD	Complex	Second decade	Sensorineural hearing impairment, pes cavus, urinary urgency due to detrusor muscle hyperactivity, neonatal hyperbilirubinemia without kernicterus, hiatal hernia. Hyperreflexia may also affect upper limbs
SPG37	8p21.1–q13.3	AD	Pure	Variable, from childhood to seventh decade	Affects both lower and upper limbs, slowly progressive, incomplete penetrance
SPG38	4p16–p15	AD	Complex	Second decade	Pes cavus, amyotrophy of small hand muscles, polyneuropathy
SPG14	3q27–28	AR	Complex	Adult	Distal motor neuropathy, mental retardation, pes cavus, visual agnosia
SPG23 (Lison syndrome)	1q24–32	AR	Complex	Early childhood	Skin and hair pigmentary abnormalities, facial and skeletal dysmorphia, postural tremor, cognitive impairment, premature aging, cerebellar signs, perypheral neuropathy
SPG24	13q.14	AR	Pure	Early childhood	
SPG25	6q23.3–24.1	AR	Complex	Adult	Prolapsed intervertebral disks, multiple disc herniation, bilateral cataract, congenital glaucoma
SPG26	12p11.1–q14	AR	Complex	Adult	Intellectual impairment, distal muscle wasting, dysarthria, polyneuropathy, pes cavus, wasting of small muscles
SPG27	10q22.1–q24.1	AR	Pure and complex	Adult	Polyneuropathy, dysarthria, abnormal somatosensory-evoked potentials
SPG28	14q21.2–22.3	AR	Pure	First and second decades	
SPG30	2q37.3	AR	Complex	Second and third decade	Slow progression, cerebellar signs and atrophy, saccadic eye movements, distal sensory loss
SPG32	14q12–q21	AR	Complex	Childhood	Pontine dysraphia, mental retardation, thin corpus callosum, cortical and cerebellar atrophy
SPG35	16q21–q23.1	AR	Complex	Childhood	Dysarthria, epilepsy, cognitive decline
Thin corpus callosum and epilepsy	8q	AR	Complex	Childhood	Thin corpus callosum, mental impairment, epilepsy
SPOAN (spastic paraplegia, optic atrophy, and neuropathy)	11q13	AR	Complex	Infancy	Optic atrophy, polineuropathy, dysarthria, distal amyotrophy, exacerbated startle response, scoliosis
ARSAL (autosomal recessive spastic ataxia with frequent leucoencephalopathy)	2q33–34	AR	Complex	Variable	Highly variable severity. Ataxia from onset, spasticity, leucodystrophy, scoliosis, dystonia, cognitive impairment, urinary urgency, dysathria, horizontal nystagmus, optic atrophy, cataract, mild hearing impairment
SAX2 (spastic ataxia 2)	17p13	AR	Complex	Variable	Dysarthria at onset, ataxia, spasticity in all limbs, muscle fasciculations, horizontal nystagmus
SPG16	Xq11.2	X-linked	Pure and complex	Infancy	Mental retardation, visual impairment, motor aphasia, nystagmus
SPG34	Xq25	X-linked	Pure	Second and third decade	Slow progression, sensory polyneuropathy late in evolution.

AD, autosomal dominant; AR, autosomal recessive; SPG, spastic paraplegia.

The ongoing identification of several genes responsible for HSP is providing a better understanding of the pathological mechanisms involved, and opens the way to discovery of future therapies targeted at the specific causes of HSP.

Proteins such as atlastin (SPG3A), spastin (SPG4), NIPA1 (SPG6), KIAA0197 (SPG8), KIF5A (SPG10), BSCL2 (SPG18), spartin (SPG20), and ACP33 (SPG21) are involved in neuronal trafficking. Mutated spastin protein leads to microtubule disassembly and accumulation of organelles and cytoskeletal components, producing axonal swelling and cell death.

Paraplegin (SPG7), HSP60 (SPG13), spartin (SPG20), and REEP1 (SPG31) mutated proteins impair the mitochondrial metabolism. Paraplegin protein is a metalloprotease localized in the inner mitochondrial membrane, which acts as a molecular chaperone. Mutated paraplegin protein increases the sensitivity to oxidative stress by decreasing complex I activity in the mitochondria. HSP60 is another mitochondrial chaperone that prevents protein misfolding, especially in an oxidative environment. REEP1 is a mitochondrial transmembrane protein involved in protein folding. Spartin protein may be involved in endocytosis, vesicle trafficking, mitogenic activity, and protein binding. Loss-of-function *spastin* mutations cause mitochondrial dysfunction.

One similarity is shared by some HSP clinical forms linked to different genes. *KIF5A*, *spastin*, *spartin*, and *atlastin* all impair the intracellular membrane trafficking.

The function of spatacsin protein remains unknown, but its highly conserved leucine-zipper motif and Myb domain suggest it may have a role in regulating the DNA replication and transcription.

Epidemiology and Risk Factors

Studies on prevalence have yielded different figures, depending on the clinical criteria used to distinguish between pure and complex forms.

The prevalence of HSP varies across the world (0.004–0.01%). When clinical criteria are followed, the prevalence of HSP is 2–10 out of 100 000. Even when similar patient selection methods are used, there is variability among different populations: figures such as 18.4 in Guam, 2.0 in Zealand (Denmark), 2.1 in Benhazi (Libya), 9.6 in Cantabria (Spain), 2.7 in Molise (Italy), 4.3 in Valle d'Aosta (Italy), 2.0 in Viano do Castelano (Portugal), or 1.27 in Ireland have been described. These differences are probably due to the geographical origin of the HSP related genes.

HSP clinical subtypes have a different prevalence according to geographical distribution and depending on the model of inheritance considered. There are 10 000 cases of HSP in the United States and 10% of them are complex forms. The most common genetic form of HSP among the Europeans is the autosomal dominant form. The frequency of HSP in Europe is estimated at 1–9 out of 100 000. Pure ADHSP is the most frequent form in Europe, and complex ARHSP is more prevalent in Southern Europe that in Northern Europe.

Autosomal Dominant Forms

About 70% of HSP cases have an autosomal dominant inheritance. *Spastin* gene mutations (SPG4) are the most frequent cause of ADHSP accounting for 50% of HSP. More than 130 *spastin* gene mutations have been described. Nonsense, splicing, or frameshift mutations truncate spastin protein. Missense mutations are less common (29%). *Atlastin* gene is the second most frequent cause of ADHSP, explaining ~10% of pure HSP. *Atlastin* testing should precede *spastin* analysis in HSP when ADHSP starts before the age of 10 (**Table 1**).

Several other genes have been found to be involved in ADHSP such as *NIPA1* (SPG6), *KIAA0196* (SPG8), *KIF5A* (SPG10), *HSP60* (SPG13), *seipin* (SPH17), and *REEP1* (SPG31) (**Table 1**). Several other chromosomal loci (SPG9, SPG12, SPG19, SPG29, SPG37, and SPG38) have been identified, although the genes responsible still remain unknown (**Table 2**).

Autosomal Recessive Forms

About 30% of HSP show an autosomal recessive inheritance. Some cases may have an apparently sporadic presentation of disease and consanguinity is often associated with ARHSP. In a Portuguese and Algerian family study, 53% of the families had pure ARHSP, whereas 47% had complex ARHSP. The most frequent gene was *spatacsin* gene (SPG11), in which homozygous or compound nonsense, frameshift, and heterozygous exonic rearrangements can cause a loss of spatacsin function. SPG11 produces a rapidly progressive HSP with onset in the first or second decades. SPG21 and SPG32 are also associated with thin corpus callosum and mental retardation.

Homozygous mutations of *CYP7B1* (SPG5A), *paraplegin* (SPG7), *ZFTVE26* (SPG15), and *spartin* (SPG20) genes have been associated with ARHSP (**Table 1**). Other loci, such as SPG14, SPG23, SPG24, SPG25, SPG26, SPG27, SPG28, SPG30, SPG32, and SPG35 have been linked to ARHSP, but the gene responsible has not yet been found (**Table 2**).

X-linked Forms

The X-linked inherited HSP forms are rare. Mutations in *L1CAM* gene (SPG1) and *PLP1* (SPG2) are involved in HSP disorders. The SPG16 and SPG34 loci have both been associated with a few isolated families, but the gene is still unknown (**Table 2**).

In SPG1, the spastic paraplegia is always complicated by other features (**Table 1**). About 200 mutations in the *L1CAM* gene that causes L1 syndrome have been described. These mutations change the L1 protein structure which plays an important role in the nervous system development such as neuronal migration, differentiation, and formation of myelin and synapses.

More than ten mutations in the *PLP1* gene have been identified. The deletion of the entire *PLP1* gene causes a more severe clinical phenotype. SPG16 can also be associated with complex and pure HSP forms. SPG34 has been associated with pure spastic paraplegia affecting only the lower limbs in a large Brazilian family spanning five generations.

Clinical Features and Diagnostic Criteria

HSP is characterized by clinical manifestations derived from the degeneration of corticospinal axons. Corticospinal track degeneration starts distally and advances in retrograde direction, so that fibers of the lower limbs are most severely affected. Muscle weakness is most noticeable at the iliopsoas and tibialis anterioris muscles. Hip weakness causes the pelvis to tilt down on the contralateral leg during the stance phase of gait (Trendelenburg sign). Weakness and spasticity hamper foot dorsiflexion and hip flexion, frequently causing lumbar hyperlordosis while walking. There may be stumbling, tripping, and gait circumduction. Progressive weakness and spasticity are predominantly found in the lower limbs wherein brisk tendon reflexes and extensor plantar responses are found. Pes cavus is often present. Muscle contractures may develop over time.

Sensory manifestations, such as paresthesias and decreased perception in the lower limbs, are often present, and urinary sphincter disturbances may occur in pure HSP. Individuals sometimes complain of fluctuating stiffness and temperature in the lower limbs. As in other spinal diseases, stress or tiredness may exacerbate the symptoms. HSP is clinically divided into pure and complex forms.

Pure HSP

Pure HSP forms only have motor symptoms arising from corticospinal track dysfunction. The age of onset varies from infancy to old age, though most patients start in second through fourth decades of life. Diagnostic criteria for the pure type and a clinical severity scale have been suggested (**Tables 3** and **4**).

Complex HSP

Complex HSP forms have additional neurological and extraneurological findings. Corticospinal symptoms are combined with different signs, such as mental retardation, cognitive decline, deafness, amyotrophy, cerebellar ataxia, epilepsy, dysarthria, ichthyosis, optic atrophy, peripheral neuropathy, pigmentary retinal degeneration, and cataracts.

Table 3 Diagnostic criteria of hereditary spastic paraplegia

A subject is definitely affected if all of the following occurs:
1. Alternative disorders have been excluded
2. Family history supports inheritance of an X-linked, autosomal recessive, or autosomal dominant disorder
3. Patient reports progressive gait disturbance
4. Neurologic examination shows frank corticospinal tract deficits in the lower limbs, including grade 4 hyperreflexia and extensor plantar responses
A subject is probably affected if all of the following occurs:
1. The subject is asymptomatic
2. There is lower-extremity hyperreflexia associated with extensor plantar responses
3. It is not possible to know whether these findings have been present from birth (raising the suspicion of an alternative diagnosis, such as spastic cerebral palsy)
A subject is possibly affected if:
1. The subject is asymptomatic
2. The subject belongs to a HSP kindred
3. Neurologic examination is questionably abnormal, showing possible corticospinal tract deficits (mildly hyperactive deep tendon reflexes and 3–4 beats of ankle clonus), but plantar responses are flexor

HSP, Hereditary Spastic Paraplegia. See Fink et al. (1996) *Neurology* 46:1507–1514.

Table 4 Classification of severity of hereditary spastic paraplegia

Grade 1	Spastic gait without functional limitation
Grade 2	Abnormal gait with functional limitations but not requiring consistent use of an assisting device
Grade 3	Gait abnormality requiring a consistent use of a cane, crutches, or a walker, or occasional use of a wheelchair only for long distances (up to 10% of the time) but still with an ability to walk short distances using assistive devices
Grade 4	Gait abnormality requiring frequent use of a wheelchair (up to 50% of the time) but still with an ability to walk short distances using assistive devices
Grade 5	Marked functional impairment with an inability to walk with crutches, requiring a wheelchair more than 50% of the time

See Hedera et al. 1999 *Neurology* 53:44–50.

Differential Diagnosis

Diagnosis of HSP is clear when there is family history of progressive spastic paraparesis, though sometimes differential diagnosis with other hereditary neurological diseases can prove difficult.

However, spastic paraparesis can also be caused by noninherited neurological conditions. Incomplete penetrance, de novo mutations, autosomal recessive, or X-linked inheritance can cause the disease in the absence of a family history of HSP.

Magnetic resonance imaging (MRI) of the brain and spinal cord, serum vitamin levels, and viral antibody levels are recommended before establishing a diagnosis in cases where the diagnosis of HSP is very unlikely or screening of appropriate genes is negative. Neurophysiologic studies can be helpful in distinguishing pure and complex HSP forms.

Familial Disorders with Spasticity other than HSP

Other neurological entities can be confused with HSP. Spinocerebellar ataxias can show spasticity, as is the case with Machado–Joseph's disease, but in this case ataxia is pronounced. Adrenoleukodystrophy and adrenomyeloneuropathy show white matter abnormalities in brain MRI and high plasma long-chain fatty acid levels. Krabbe's disease is an autosomal recessive condition due to galactocerebrosidase deficiency; it can also be diagnosed by MRI, slow nerve conduction velocities, and delay in visual and auditory evoked potentials.

Hereditary progressive dystonia with diurnal variation, also known as dopamine-responsive dystonia (Segawa's disease), is caused by mutations either in the *GTP cyclohydrolase I* or *tyrosine hydroxylase* genes. Segawa's dystonia improves with L-dopa treatment. Therefore, a trial of low dose L-dopa is advised in children with progressive gait disturbance.

Sporadic Spastic Paraparesis

Multiple sclerosis (MS) can mimic spastic paraplegia. MS individuals show demyelinating white matter lesions in brain MRI, oligoclonal bands in the cerebrospinal fluid (CSF), and impairment of evoked potentials. Amyotrophic lateral sclerosis (ALS) predominantly impairs the motor function of the upper limbs and bulbar muscles, and shows fasciculations, amyotrophy, and muscle denervation. Interestingly, *spastin* mutations have been reported to cause a clinical picture resembling juvenile-onset ALS. Spastic diplegic cerebral palsy secondary to complicated birth delivery can be confused with HSP.

Structural spinal cord or brain abnormalities, such as Arnold-Chiari or other cervical spinal cord conditions, can be diagnosed by cranial or spine MRI.

Subacute combined degeneration, due to vitamin B12 deficiency, causes peripheral neuropathy and dorsal column involvement. Vitamin E deficiency can cause distal muscle weakness and sensory deficits, visual-field constriction, nystagmus, ophtalmoplegia, arrhythmia, and dementia.

Differential diagnosis with infectious diseases, such as tertiary syphilis, tropical spastic paraparesis, and HIV myelopathy, can be performed by serologic tests.

Diagnostic Work-up and Tests

In patients with spastic paraparesis, cerebral and spinal MRI are useful to differentiate HSP from other diseases.

The diagnostic work-up in HSP includes neuroimaging, blood and electrophysiological tests, including reflex studies to detect abnormal responses of the lower limbs, electrophysiological studies such as electromyography, nerve conduction tests, or electroencephalography. CSF analysis could be performed in some cases. A genetic evaluation is recommended when family history of a similar condition is present.

Spinal MRI can show atrophy of the spinal cord, and in some complex HSP cases such as SPG11, SPG21, and SPG32 and autosomal recessive spastic ataxia with leukoencephalopathy (ARSAL) syndrome, brain MRI can show cortex atrophy and a thin corpus callosum.

SPG11 is characterized by mild frontal and temporal cortical atrophy, mild ventricular dilatation, widening in the frontal fissure, thin corpus callosum, decreased number of methylation fibers, axonal degeneration, abnormal Schwann cell inclusions, thalamic and cortical glucose hypometabolism on positron PET scan, and supratentorial symmetric white matter lesions.

Some forms of spastic paraparesis have abnormal nerve conduction as in autosomal recessive spastic ataxia of Charlevoix Saguenay (ARSACS), which shows reduced motor conduction velocities, a decrease in amplitude of sensory potentials, and vermian cerebellar atrophy. Spastic paraplegia, optic atrophy and neuropathy (SPOAN) syndrome is associated with axonal neuropathy.

ARSAL syndrome has abnormal brain MRI findings, such as cerebellar atrophy and sometimes brain atrophy, corpus callosum atrophy, and leukodystrophy.

Neurophysiological studies of HSP are consistent with the degeneration of long motor pathways.

Transcranial magnetic stimulation (TMS) responses are abnormal in HSP. TMS responses can vary from decrease or delay of potentials to their complete absence in the lower limbs. Less often, TMS responses are impaired in the upper limbs. TMS also can show a shorter cortical silent period. Similarly, somatosensory evoked potentials are frequently abnormal in the lower limbs.

Management

Unfortunately, there is no treatment that can modify the natural course of HSP. Symptomatic and supportive medical treatment should be offered. Muscle relaxants such as

the γ-aminobutyric acid receptor agonist Baclofen and Dantrolene, available in some countries, could lessen spasticity. Baclofen can be administered orally and intrathecally. Benzodiazepines and Tizanidine, a centrally acting α-2 adrenergic agonist, can be used to treat muscle spasms. Programmed bladder evacuation can help in urinary symptoms. Intramuscular botulinum toxin can alleviate spasticity. Orthopedic surgery to lengthen ankle plantar flexors and hip adductors may help some patients. Physical activity should be encouraged, including aerobic and strengthening-stretching exercises to reduce atrophy and maintain muscle strength as well as a range of joint motion. As the disease progresses, assistive devices such as canes, crutches, or walkers may be necessary.

Prognosis

Prognosis of HSP is highly variable. In pure HSP forms, age of onset is not a good predictor of disability and the rate of progression varies depending on the gene involved.

Life expectancy can be normal in some pure HSP, though there is an increased morbidity due to an increased risk of falls and urinary infections.

Though adult onset is most common, SPG4 HSP can have a wide range of ages of onset (2–70 years) suggesting incomplete penetrance. Some SPG4 mutation carriers are asymptomatic, whereas others are severely disabled. SPG4 produces moderate disability proportional to time since onset, but some cases of SPG4 develop bulbar weakness and respiratory insufficiency.

SPG3A HSP usually has an onset in early childhood, although some cases begin in adult life. These patients may very early become clinically stable. Though this type has almost full penetrance, intrafamilial variability of the severity of HSP associated with the same mutation is frequent.

Some of the complex HSP forms such as SPG1, SPG2, SPG11, SPG21, SPG23, SPG26, and SPG32 have a more disabling disease course due to the presence of cognitive impairment.

SPECT Imaging in Movement Disorders

A Antonini, Parkinson Institute, Milan, Italy

Glossary

Brain perfusion – Perfusion is defined as the passage of fluid through the lymphatic system or blood vessels to an organ or a tissue. Perfusion scanning is the process by which this perfusion can be observed, recorded, and quantified. The term perfusion scanning encompasses a wide range of medical perfusion modalities. In the case of brain perfusion, cerebral blood flow is coupled to local brain metabolism and energy use. The tracers ECD (99mTc-ethylcysteinate dimer and HMPAO (99mTc-hexamethyl propyleneamine oxime) are commonly used to assess brain metabolism regionally.

Dopamine Transporter (DAT) – A membrane protein that binds dopamine. DAT provides the primary mechanism through which dopamine is cleared from synapses, transporting dopamine from the synapse into the dopamine nerve terminal. DAT is present in the peri-synaptic area of dopaminergic neurons in areas of the brain where dopamine signaling is common. Because DAT terminates the dopamine signal, it is implicated in a number of dopamine-related disorders, in addition to Parkinson's disease including attention deficit hyperactivity disorder or bipolar disorder. The gene that encodes the DAT protein is located on human chromosome 5.

SPECT – Single photon emission computed tomography is a nuclear medicine tomographic imaging technique using γ-rays. It is similar to the conventional nuclear medicine planar imaging using a gamma camera. However, it is able to provide 3D information. This information is typically presented as cross-sectional slices through the patient but can be freely reformatted or reconstructed as required.

Its application to the study of movement disorders regards the investigation of the dopamine system as well as brain perfusion.

FP-CIT or (^{123}I)-Ioflupane ([I-123] *N*-ω-fluoropropyl-2β-carbomethoxy-3β-(4-iodophenyl) nortropane).

A cocaine derivate used as neuroimaging radiopharmaceutical for the differentiation of Parkinson's disease from essential tremor. It is injected into a patient and viewed with a SPECT gamma camera. It binds to dopamine nerve terminals in the striatum. Ioflupane is distributed under the tradename DaTSCAN and is manufactured by GE Healthcare. It is not marketed outside of Europe.

SPECT Utilization for Movement Disorder Diagnosis

Diagnosis of Parkinson Disease: Motor Symptoms

The clinical diagnosis of Parkinson's disease (PD) is based on the presence of characteristic motor symptoms: bradykinesia, rigidity, postural instability, and resting tremor but neuropathology is still considered the gold standard for definite diagnosis. Differentiating PD from other movement disorders (e.g., essential tremor and atypical parkinsonism) can be challenging throughout the disease course, because signs and symptoms often overlap. Indeed, neuropathology studies reveal that clinical diagnosis of PD can be confirmed with an accuracy of about 75%. Good response to levodopa is often used to support the diagnosis of PD. However, cases of pathologically proven PD with poor response to levodopa have also been reported.

Misdiagnosis of PD can occur for several reasons. In a community-based study of patients taking antiparkinsonian medication, the most common misdiagnosis were essential tremor, Alzheimer's disease, and vascular parkinsonism. In addition, many of the prominent features of PD (e.g., rigidity, gait disturbance, bradykinesia) may also occur as a result of normal aging or from comorbid and multifactorial medical conditions (e.g., diabetes, cancer).

Diagnosis of Parkinson Disease: Premotor Stage

A number of nonmotor symptoms, not explained by dopamine deficiency alone, can precede the classical features of PD. Premotor symptoms in PD include constipation, loss of smell, sleep disturbances such as REM sleep behavior disorder, and mood disturbances such as depression. Many of these symptoms find a possible explanation in the theory introduced by Braak and colleagues, suggesting a caudal–rostral progression of Lewy body pathology in PD, from brainstem to the cortex. According to this theory, at least two stages precede the onset of motor signs and involve the serotonin and norepineprhine systems. Briefly, at stage 1, there is a degeneration of the olfactory bulb and

nucleus, which can clinically manifest as olfactory dysfunction. Stage 2 shows a progression to the lower brainstem with lesions in the lower raphe nuclei, magnocellular portions of the reticular formation, and locus coeruleus, areas that could mediate symptoms such as olfaction, sleep homoeostasis, and other autonomic symptoms. The pedunculopontine tegmental nucleus and dopaminergic neurons of the substantia nigra (relay centers of the visceromotor system and nuclei of the somatomotor system) are damaged at stage 3. In stage 4, the disease extends to anterior and posterior thalamic intralaminar nuclei that project to the striatum and cerebral cortex and in stages 5–6 neocortical association areas and the premotor areas are damaged.

SPECT Imaging as a Biomarker for Early Parkinson's Disease

A biomarker (biological marker) is an indicator of normal biological processes, pathogenetic processes, or pharmacological responses to a therapeutic intervention. In the past decade, the search for treatments of PD that protect against disease progression (neuroprotectors) has intensified, raising the issue of the need for biomarkers of both disease and severity of disease in PD.

Single photon emission tomography (SPECT) with radioligands binding selectively to striatal dopamine nerve terminals provides an objective and reproducible measurement of the nigrostriatal dopaminergic system in early PD patients with additional high sensitivity to disease progression. Uncertainty about an interaction between therapeutical drugs and tracer binding, however, has raised debate on whether imaging is a valid biomarker for progression of nigrostriatal pathology in PD. These unresolved issues are the focus of current research efforts.

SPECT with Receptor-Binding Tracers

Dopaminergic System: Presynaptic Issues

Target and tracers

Available presynaptic ligands for SPECT bind selectively the dopamine transporter (DAT). The DAT is a 620-amino acid protein with 12 α-helical hydrophobic transmembrane domains, two to four extracellular glycosylation sites, and up to five intracellular phosporylation sites. Ex vivo studies have shown the expression of DAT in the dopaminergic neurons of the substantia nigra and in the ventral tegemental dopaminergic neurons. DAT controls dopaminergic neurotransmission by spatial and temporal buffering, making the molecule an imaging target for diseases affecting the dopaminergic nigrostriatal pathway. DAT levels correlate with striatal dopamine concentration.

Introduction of radioactive iodine (^{123}I) into the tracer molecules provides a suitable method for DAT-SPECT imaging. A large number of ^{123}I-labeled compounds have been prepared, and DAT receptor-specific imaging agents are routinely used for SPECT imaging studies. All of the successful agents for imaging DAT belong to a group of tropane derivatives that share a similar backbone structure of cocaine. The first successful DAT imaging agent for SPECT, [^{123}I]β-CIT, was reported in the early 1990s, and studies suggested a strong correlation between the decrease in localization in the putamen area and PD symptoms. Currently, [^{123}I]β-CIT, [^{123}I]FP-CIT, [^{123}I]IPT, and [^{123}I] altropane are being developed for this purpose.

The two most widely used ligands to study PD patients are [^{123}I]β-CIT and [^{123}I]FP-CIT. A direct comparison of the two compounds has been attempted in only a few studies; briefly: (1) the nonspecific uptake of [^{123}I]FP-CIT is greater than [^{123}I]β-CIT, causing [^{123}I]β-CIT to have a lower ratio of specific to non-displaceable striatal uptake (V''_3); (2) [^{123}I]β-CIT shows a lower selectivity for DAT, having an equivalent affinity for the serotonin transporter (SERT), which results in a higher thalamic/midbrain [^{123}I]β-CIT uptake; (3) washout period of [^{123}I]β-CIT is about 1% per hour and of [^{123}I]FP-CIT is 5–8% per hour, making striatal V''_3 values of [^{123}I]FP-CIT stable as early as 3–6 h, whereas [^{123}I]β-CIT stabilizes only after 18–27 h. In Europe [^{123}I]FP-CIT (DatScan, Amersham PLC, Buckinghampshire, UK) is commercially available for routine clinical use.

One of the major drawbacks of using ^{123}I-labeled compounds for routine imaging is the availability of the isotope. Produced by cyclotrons or by accelerators, it is not readily available in standard nuclear medicine clinics and requires overnight shipment from production sites. As a consequence, it is relatively expensive and inaccessible. As an alternative, ^{99m}Tc-labeled tropane derivatives have been investigated. Only [^{99m}Tc] TRODAT-1 has been tested successfully in normal subjects and parkinsonian patients. This compound has some logistical advantages over the most commonly used SPECT ^{123}I-ligands, including absence of thyroid uptake, ready availability, ease of use, and lower cost.

Clinical application

Diagnosis of PD

The effectiveness to demonstrate changes in presynaptic DAT sites in vivo in PD patients has been demonstrated by using [^{123}I]β-CIT, [^{123}I]FP-CIT, [^{123}I]IPT, [^{123}I]altropane, and [^{99m}Tc]TRODAT-1.

At the point when cardinal motor signs required for a clinical diagnosis of PD appear, as many as 58–64% of dopaminergic neurons in the substantia nigra (SN) have been lost, and striatal dopamine content has been reduced by 60–80%. Imaging studies of the dopaminergic system and postmortem cell counts of pigmented neurons in the SN suggest that the onset of dopaminergic neuronal loss

precedes the clinical diagnosis of PD by approximately 4–6 years. Abnormalities have been shown in individuals at risk for the disease years before disease onset.

In some large clinical drug trials of PD where patients were enrolled based on their clinical diagnosis of early 'untreated' PD, a significant proportion of patients has normal scans. These individuals have been defined 'subjects with scans without evidence of dopaminergic deficit' (SWEDD) and represented from 5.7% to 14.7% of cases clinically diagnosed as early PD. Uptake values measured by fluorodopa PET (REAL-PET study) and by [^{123}I]β-CIT (ELLEDOPA study) remained normal after 2- and 4-year follow up respectively, thus questioning the diagnosis of a progressive and neurodegenerative disorder as PD in these subjects. Alternative explanations on false-negative PD at DAT SPECT are the theoretical possibility of scans in the normal range at a very early stages of the disease and greater specificity of quantitative versus qualitative analysis of the SPECT scans.

Differential diagnosis

Essential tremor

Although distribution, frequency, severity, age of onset, and evolution of symptoms should ensure a correct separation of PD from essential tremor (ET) overlapping features may make differential diagnosis a challenge. Both [^{123}I]β-CIT and [^{123}I]FP-CIT showed no evidence of PD-like dopaminergic disruption in ET, and [^{123}I]FP-CIT/SPECT proved a specificity of 95% and sensitivity of 80% in discriminating ET from PD patients (**Figure 1**). Comparable results have been recently shown with SPECT and [^{99m}Tc]TRODAT-1. Recent evidence suggests that DAT imaging is cost effective for separating PD and ET.

Atypical parkinsonism

Presynaptic tracers have low accuracy in differentiating PD from atypical neurodegenerative parkinsonism (APS) (e.g., multiple system atrophy (MSA) and progressive supranuclear palsy (PSP)). However, marked asymmetry in reductions of putaminal DAT finding is more typical for PD when compared to APS. A recent study found reduced midbrain [^{123}I]β-CIT uptake in patients with the Parkinson variant of multiple system atrophy (MSA-P), and the authors were able to correctly classify 95% of MSA-P and PD patients.

Vascular parkinsonism

Presynaptic dopaminergic circuitry is generally preserved in vascular parkinsonism (VP) although a slight reduction in lateral substantia nigra may occur probably due to transneuronal degeneration. Because VP is a somewhat controversial clinical concept and there are no clear cutoff values to separate VP from PD according to striatal DAT availability, conventional techniques such as CT and MRI are still considered necessary diagnostic tools.

Drug-induced parkinsonism

Drug-induced parkinsonism (DIP) is a frequent cause of secondary parkinsonism, developing in patients during treatment with antipysychotic or dopamine receptor blocking agents. The same syndrome can develop after treatment with agents that deplete dopamine. About 60–70% of patients recover after medication withdrawal in 2 months. In the remaining cases, motor symptoms persist or sometimes worsen in the following months suggesting that DIP unmasked an already low dopaminergic state that was preclinical before drug exposure and that the patients had very early PD. DIP is clinically not easily distinguishable from PD because similar clinical signs may occur in both diseases

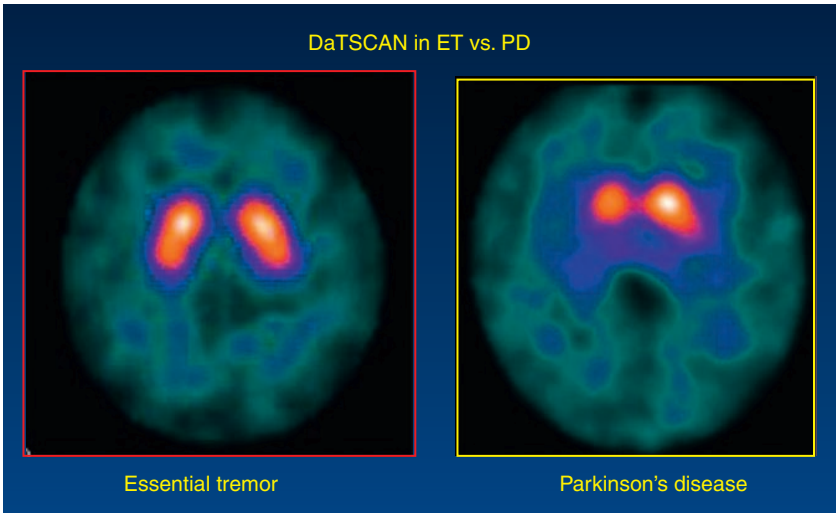

Figure 1 DAT binding in patients with essential tremor (left: normal tracer distribution in the head of the caudate nucleus and the putamen) and Parkinson's disease (right: reduced uptake mainly in the right putamen).

making the differential diagnosis a challenge Few SPECT studies are available on DIP and all with [^{123}I]FP-CIT/SPECT. Significant putaminal [^{123}I]FP-CIT/SPECT binding abnormalities may be found in some DIP patients, consistent with loss of dopamine nerve terminals.

Assessment of disease progression

Disease progression in PD was originally evaluated with [^{123}I]β-CIT/SPECT. The mean reduction of [^{123}I]β-CIT binding in PD patients versus healthy controls was reported of 5.8% for a period of 15 months and, when calculated for 1 year, 5.6%. Further studies with [^{123}I]β-CIT showed similar results with an annual rate of progression ranging between 5% and 8%, although one report documented a higher rate of 11.2% per year. One study with a 2 years follow up reported striatal [^{123}I]IPT binding decreases of 6.6% in the first year and 5.3% in the second year. Similarly, [^{123}I]FP-CIT/SPECT showed a mean annual decrease in striatal binding ratios of about 8% (of the baseline mean) (**Figure 2**).

Dopaminergic System: Postsynaptic Issues

Target and Tracers

Dopamine receptors (D_1–D_5) are a class of metabotropic G protein-coupled receptors. D_2 receptors are the major target for in vivo imaging studies. Among the radiotracers proposed for D_2 quantification, the benzamide derivative [^{123}I]IBZM gained wide acceptance for SPECT imaging. Although [^{123}I]IBZM has a high nonspecific brain uptake, it offers the advantage of a fast kinetic profile and a great susceptibility to synaptic dopamine release. It is also approved and commercially available for clinical use in some countries. The best analogue of [^{123}I]IBZM is [^{123}I]IBF. [^{123}I]IBF affinity for D_2 and basal ganghia-to-frontal cortex ratio are higher than [^{123}I]IBZM.

Clinical applications

There is little clinical value of postsynaptic studies with SPECT to confirm the clinical diagnosis of PD or to measure progression over time. The main (and only) clinical application for postsynaptic SPECT imaging is the differential diagnosis of PD from APS. At an early stage of PD, postsynaptic receptors are normal or upregulated in the putamen, but decreased in APS (**Figure 3**). At a later stage of PD, with increasing disease severity, binding values are in the range of control subjects or lower, possibly due to the decline in the presynaptic dopaminergic drive, [^{123}I]IBZM SPECT cannot discriminate among different APS. Similarly [^{123}I]IBF does not provide accurate discrimination between PD and APS.

Serotonergic System

Among the many premotor symptoms in PD patients, depression is the most common and disablin. It is generally accepted that alterations in serotonergic neuronal function occur in patients with major depression, and SPECT imaging of the serotonin transporter (SERT) may play an important role to study depression in PD patients at an early stage of the disease.

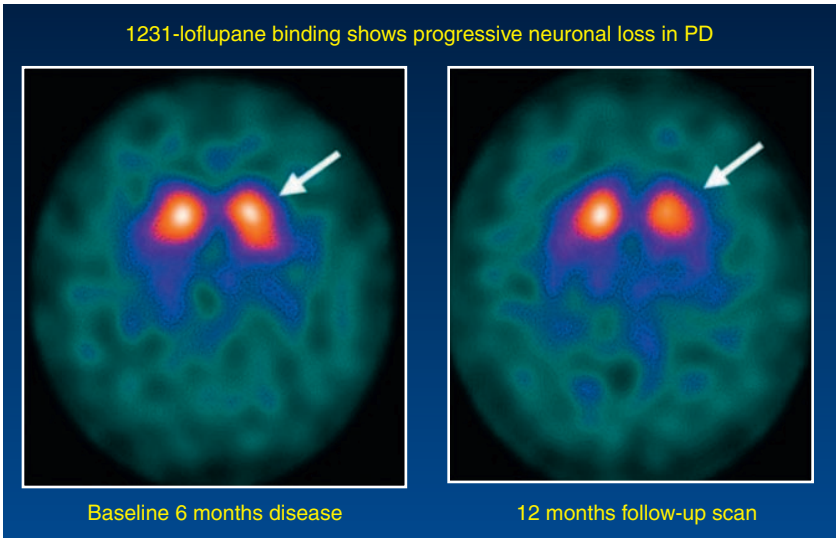

Figure 2 Progressive loss of dopamine nerve terminals in the putamen in a patient with Parkinson's disease. The loss (see arrow becomes evident at the 12-month follow-up scan in the left putamen).

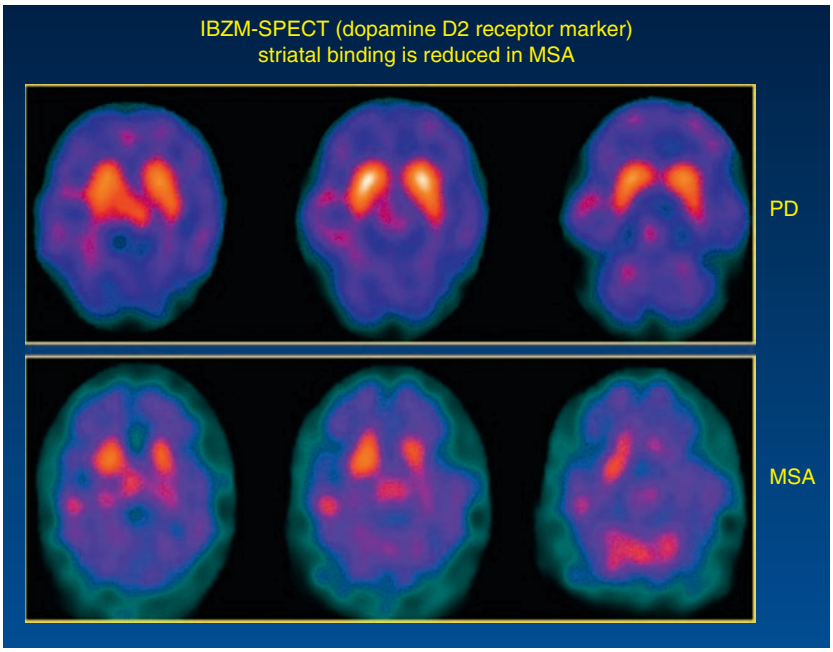

Figure 3 IBZM Binding to striatal dopamine D2 receptors is normal in Parkinson's disease (upper row) but reduced in multiple system atrophy (lower row).

The SERT is an integral membrane protein that transports the neurotransmitter serotonin (5-HT) from synaptic spaces into presynaptic neurons in a sodium-dependent manner. The first successful ligand to target the SERT was [^{11}C]R(+)McN5652 for PET imaging. It showed excellent inhibition of 5-HT reuptake, good correlation with known densities of SERT sites in the human brain and moderate selectivity toward other monoamine transporters (DAT and norepinephrine transporters, NET). The main disadvantage of this ligand is the presence of active metabolites, which appear to penetrate the brain, enhancing background activity and limiting quantitative measurement.

Several iodinated compounds have been evaluated in the search for a SPECT ligand for SERT. Previously, investigators suggested that [^{123}I]β-CIT binds to both DAT and SERT, thus allowing a tool to detect pathological changes in both dopaminergic and serotonergic systems. However, further studies documented overlapping uptake regions and differential kinetics of [^{123}I]β-CIT binding to DAT and SERT. Recently, [^{123}I]β-CIT/SPECT imaging showed a significant reduction (30%) of SERT binding in the midbrain area in depressed PD subjects compared with the controls. More selective compounds, such as nor-β-CIT (*N*-demethylated analog of β-CIT), improved SPECT imaging for SERT, but binding to both DAT and SERT still occurred with insufficient selectivity to distinguish between the two monoamine transporter sites in vivo.

Finally, investigators have been working with a series of derivatives based on the substituted phenylthiophenyl core structure. Among them [^{123}I]IDAM and [^{123}I]ADAM are the most promising candidates. Preliminary SPECT imaging with [^{123}I]IDAM demonstrated an excellent localization of regions in the midbrain area known to have a high concentration of SERT binding sites and excellent affinity to SERT sites over the norepinephrine transported (NET) and DAT. A small modification of the substitution group on the benzene rings of [^{123}I] IDAM produced significant improvements on the imaging properties, producing a new ligand, [^{123}I]ADAM. Currently, [^{123}I]ADAM has been tested only on healthy volunteers.

Noradrenergic System

Many nonmotor symptoms of early PD may be related to a dysfunction of the norepinephrine system, and the possibility of in vivo imaging the norepinephrine (NE) transporter (NET) would be of great value in the early diagnosis of PD. The NET is a protein with 12 transmembrane-spanning domains, located at the presynaptic terminal of noradrenergic neurons. The principal physiological function of NET is to remove NE from the synaptic cleft into the presynaptic neuron. There is no successful NET imaging agent for SPECT currently available for human study. The only tracer available for SPECT, [^{123}I]INER, has been tested in nonhuman primates. The in vivo specificity, selectivity, and kinetics of [^{123}I]INER make it a promising agent for imaging NET in vivo by SPECT imaging.

SPECT and Brain Perfusion

Presynaptic and postsynaptic imaging may not fully describe the complexities of neural systems involved in a neurodegenerative process and their modulation with treatment. On the contrary, cerebral blood flow (CBF) can be used to quantify the effect of nigrostriatal degeneration on brain regions functionally related to the dopaminergic system. Regional cerebral perfusion is determined by both the density of synapses in a certain brain area and the state of activity of these synapses. In general terms, decreases of CBF indicate reductions in neuronal activity because of local cell loss or deafferentation of these regions by lesions in remote brain areas.

Targets and Tracers

There are three compounds available to investigate CBF with SPECT: [^{99m}Tc]ECD, [^{123}I]IMP, and [^{99m}Tc]HMPAO. [^{99m}Tc]ECD has high initial cerebral extraction and very slow clearance from the brain. Brain uptake is rapid, and peak brain activity compares favorably with that of other brain perfusion agents, reaching 6% of the injected dose by 5 min after intravenous injection. Blood clearance is also rapid, resulting in high brain-to-soft-tissue activity ratios early after injection.

[^{123}I]IMP is highly lipophilic, and moves across the blood–brain barrier with almost complete extraction during a single passage through the cerebral circulation. It distributes proportionally to CBF under normal physiologic conditions and over a wide range of flow. Brain uptake of [^{123}I]IMP is rapid, reaching 6–9% of the injected dose by 30 min. The clearance of the tracer from the brain is relatively slow. Thus, brain activity remains constant from 20 min to at least 60 min after injection. Uptake of unbound ^{123}I by the thyroid gland should be blocked by Lugol's solution given orally before injection.

[^{99m}Tc]HMPAO is a lipid soluble macrocyclic amine. Brain uptake of the radiotracer is rapid and reaches its maximum within 10 min post-injection time. The distribution of the radiotracer remains constant for many hours post-injection. Once it crosses the blood–brain barrier it is converted into a hydrophilic compound in the presence of intracellular glutathione and is trapped, with slow blood clearance. Limitations of this compound are perfusion defects and chemical instability in vitro by 30 min after preparation.

Both [^{99m}Tc]HMPAO and [^{99m}Tc]ECD exhibit less brain extraction than [^{123}I]IMP, but its more favorable dosimetry permits a substantially higher dose (20–30 mCi) and a higher photon flux.

Clinical Application

[^{99m}Tc]ECD/SPECT can discriminate PD patients from healthy age-matched controls; it is also of great value in the diagnosis of MSA-P (MSA parkinsonian variant) where scans show a significant perfusion decrement in the striatum, mainly in the posterodorsal putamen. However, due to the high overlap between PD and MSA patterns, [^{99m}Tc]ECD/SPECT cannot be used without other tests, and additional morphologic information (e.g., 1.5 T MRI), are often needed to discriminate between PD and MSA (**Figure 4**). [^{99m}Tc]ECD/SPECT may have some

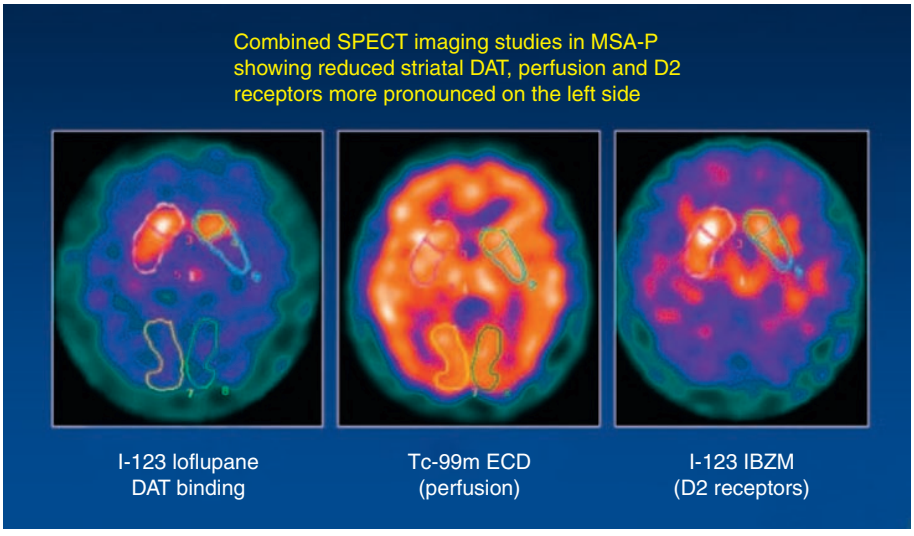

Figure 4 This figure shows loss of DAT (image on the left), reduced perfusion (middle image) and decreased striatal dopamine D2 receptors (image on the right) in the left putamen of a patient with multiple system atrophy.

clinical value in detecting patterns distinctive to early-stage dementia in PD patients, but this application is still a research tool.

Limited data are available on [^{123}I]IMP, and conflicting results preclude its clear clinical applications. Early-PD patients showed occipital hypoperfusion in comparison to healthy controls, but this result was not validated. Two studies reported parietal and occipital hypoperfusion and cerebellar hyperperfusion in PD, and frontal and cerebeller hypoperfusion in MSA-P. Recently, [^{123}I]IMP showed a significant CBF reductions in the left frontal association cortex in PD with dementia.

[^{99m}Tc]HMPAO/SPECT is not able to differentiate among parkinsonian syndromes, nor can it detect early PD. However, clear defects in energy metabolism can be seen in PD with a dementing process, and a correlation was suggested between region-specific CBF decreases and dementing conditions such as Alzheimer type, diffuse Lewy body dementia, frontotemporal dementia, and PSP (**Figure 5**).

Cardiac Perfusion SPECT

Targets and Tracers

Metaiodobenzylguanidine (MIBG) is an analog of noradrenaline without pharmacologic activity. MIBG can be labeled with ^{131}I ([^{123}I]MIBG) or ^{123}I ([^{123}I]MIBG). MIBG is actively taken up across the membrane of adrenergic cells by the sodium-dependent and energy-dependent human norepinephrine transporter. It is then actively taken up into intracellular storage vesicles by an ATPase-dependent proton pump via the vesicular monoamine transporter and is secreted after stimulation of the neurons with acetylcholine. Thus, [^{123}I]MIBG acts as a tracer not only for the localization but also for the functional integrity of the catecholaminergic structures.

Clinical Application

In PD, neuronal degeneration is not only restricted to the central nervous system, but also affects the peripheral autonomic nervous system. [^{123}I]MIBG scintigraphy is useful for the diagnosis of PD, being markedly reduced even in the early stages. It is less useful than DAT binding SPECT ligands for ranking disease severity. At present, it remains to be determined at which phase PD reductions in MIBG uptake occur, and particularly whether changes in [^{123}I]MIBG scintigraphy can be detected prior to the occurrence of motor signs in PD. Other than the heart, no organ, with sympathetic innervations, such as the lung, muscles, or glands, show [^{123}I]MIBG uptake reduction. The reason for the reduction in cardiac [^{123}I]MIBG tracer uptake is unclear. This finding does not likely reflect damage and degeneration of postganglionic sympathetic neurons, and more reasonable explanation is a change in monoaminergic metabolic pathways, as indicated by a higher wash-out rate in sympathetic neurons of PD patients. In addition to the early diagnosis of PD, quantification of cardiac [^{123}I]MIBG uptake appears to be a valuable tool to discriminate PD from other neurodegenerative disorders. Indeed, MSA, PSP, corticobasal degeneration and vascular parkinsonism show normal or only mild reduction of cardiac [^{123}I]MIBG uptake (**Figure 6**).

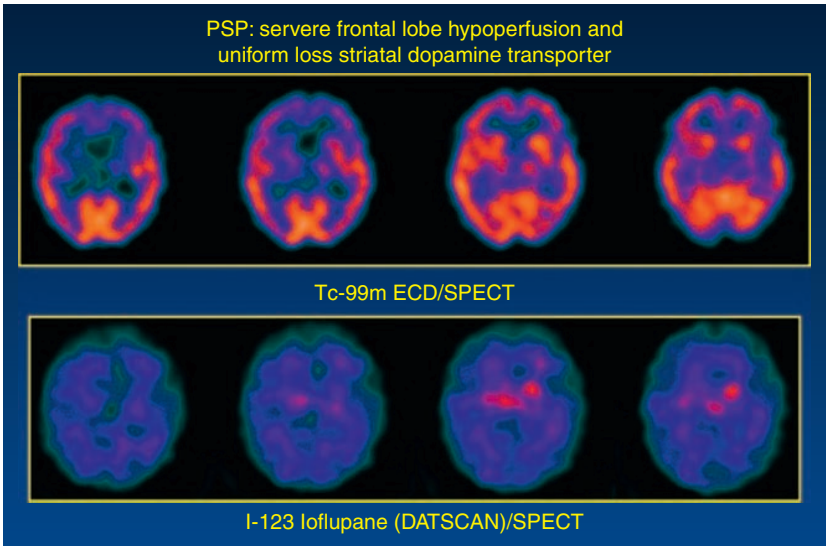

Figure 5 Reduced brain perfusion (upper row) primarily in the frontal lobe and the basal ganglia associated with severe DAT loss in the whole striatum of a patient with progressive supranuclear palsy.

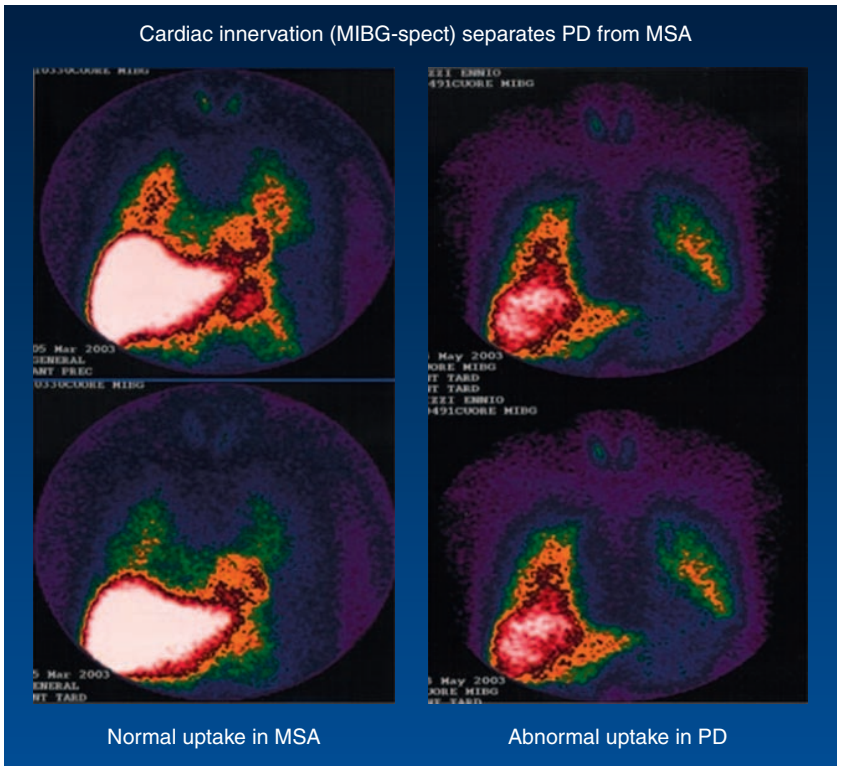

Figure 6 Reduced MIBG is observed in the heart of a patient with Parkinson's disease (right panel) vs. normal control subject (left panel).

The main drawback of [^{123}I]MIBG/SPECT is low specificity (37.4%) while the sensitivity of is relatively high (87.7%). One study directly comparing [^{123}I]MIBG and [^{123}I]FP-CIT in early-stage PD subjects showed higher sensitivity for [^{123}I]FP-CIT (83% vs. 72%).

Spinal Segmental Myoclonus

S Lo, Clinical Faculty at Georgetown University Hospital, Washington, DC, USA
E A Shamim, Clinical faculty at Georgetown University Hospital, Washington, DC, USA; National Institutes of Health, Bethesda, MD, USA

Glossary

Myoclonus – Lightning movements of muscles sufficient to move a body part.
Spinal myoclonus – Myoclonic activity originating within the spinal cord.
Segmental myoclonus – Myoclonic activity involving multiple contiguous muscle groups over several spinal segments.

Clinical Characteristics

Segmental myoclonus is characterized by myoclonic activity at a particular segment or at multiple contiguous muscle groups over several spinal segments. The generators are thought to be at a particular segment of the spinal cord and are therefore classically relatively unaffected by the state of consciousness, motor activity, or stimulus. These movements often occur spontaneously and rhythmically, but irregular jerks may also occur. Segmental myoclonus may occur bilaterally and if it does, it is usually synchronous in corresponding body parts on each side, but asynchronous bilateral myoclonus has also been described. Unilateral segmental myoclonus has been described as well in a case of right arm myoclonus involving the deltoid, biceps, supinator, and triceps muscles of a patient who had a cervical cord astrocytoma. The frequency of this type of jerk is usually in the range of 0.5–3 Hz. The myoclonic discharge ranges from 50 to 500 ms. Some consider the palatal tremor a type of segmental myoclonus.

Pathophysiology

Various structural and pathologic processes in the spinal cord are known to cause this phenomenon, including arteriovenous malformations, tumors and cysts, infections, multiple sclerosis plaques, spondylitic myelopathy, inflammatory processes, and trauma. The precise mechanisms for the spinal myoclonus are not fully understood, but in general, spinal interneuron dysfunction is thought to be a primary cause, via reduced inhibitory mechanisms. In some cases, dysfunction in motor neurons in the spinal cord has been suggested to be the cause of repetitive muscle jerks. In one case report, spinal myoclonus was associated with a systemic cancer not localized to the central or peripheral nervous system.

Treatment

Treatment of spinal myoclonus should first be directed towards treating the cause. Symptomatic treatments have included levetiracetam, clonazepam, valproic acid, tetrabenazine (recently approved in the United States), baclofen, carbidopa–levodopa, 5-HTP, carbamezapine, diazepam, propofol, and topiramate. Chemodenervation with botulinum toxin has shown to be of some benefit. Of these listed, clonazepam is often considered to be the drug of first choice.

Spinocerebellar Ataxia Type 19, 20, 21, 22, 23, 26

T Klockgether, University Hospital Bonn, Bonn, Germany

Glossary

Ataxia – Impaired coordination leading to problems of balance, finger and hand movements and speech.
Cerebellum – Part of the brain that receives afferent fibres from the cortex, brainstem and spinal cord and sends efferent fibres via the cerebellar deep nuclei towards the thalamus and cortex. The cerebellum has an essential role in coordinating movements.
Dysphonia – Hoarseness or other disorders of phonation.
Linkage analysis – Genetic method that allows to map disease causing gene mutations on chromosomes.
Lod score – Lod score stands for logarithm of the odds and describes the likelihood that a disease causing gene is in close vicinity to a chromosomal locus. A lod score larger than 3 is considered significant for linkage.
Myoclonus – Involuntary, short muscle contraction resembling the muscle twitch caused by electrical nerve stimulation.

SCA19

Schelhaas et al. identified a four-generation Dutch family with autosomal dominant inherited ataxia associated with cognitive impairment, postural tremor, and myoclonus. In all examined patients, cerebellar ataxia was relatively mild. Ataxic speech was an early feature, while limb ataxia occurred only in the later course of the disease. Two out of 10 patients had additional neurological features in the form of a slow irregular postural tremor (Holmes tremor) and myoclonus. All patients had mild cognitive impairment that did meet the criteria of dementia. Neuropsychological testing revealed impaired frontal executive function. Age of onset ranged from 20 to 45 years with a median of 31 years. Disease progression was estimated to be relatively slow. MRI showed marked cerebellar atrophy and in some patients mild cerebral atrophy. The brainstem was not affected. A genome-wide linkage analysis allowed assignment of the disease locus to a 35 cM region on the short arm of chromosome 1.

SCA20

Knight et al. described a four-generation Australian family of Anglo-Celtic origin with autosomal dominant inherited ataxia. The clinical syndrome was that of a largely pure cerebellar syndrome with ataxic speech, often occurring as the presenting symptom, ataxia of gait and stance, incoordination of limb movements and oculomotor disturbances including impaired smooth pursuit, hypermetric downward saccades, and impaired suppression of the vestibulo-ocular reflex. Five out of 14 examined family members who were affected had minor pyramidal signs consisting of exaggerated tendon reflexes in the lower extremities without extensor plantar responses or spasticity. Apart from that, most patients were presented with dysphonia reminiscent of adductor spasmodic dysphonia and a 2 Hz palatal tremor. Disease onset ranged from 19 to 64 years with a median of 46 years. Disease progression was slow: only one patient required a wheelchair 40 years after the onset of first symptoms. A highly characteristic imaging feature was pronounced dentate calcification on CT that was not regularly accompanied by calcifications in other brain regions. MRI showed diffuse cerebellar atrophy and increased signal in the region of the inferior olives as a correlate of palatal tremor.

A genome-wide linkage analysis revealed a chromosomal locus in the pericentromeric region of chromosome 11 with a maximal lod score of 4.47 at marker D11S4191. Although the critical region partially overlapped with the SCA5 region, the locus was provisionally assigned as SCA20 due to the distinct clinical phenotype. After identification of mutations in β-III spectrin gene (*SPTBN2*) causing SCA5, the exons, intron–exon boundaries, the 5′UTR and parts of the 3′UTR of the *SPTBN2* gene were sequenced in an affected family member. Sequencing did not yield causative mutations making it unlikely that SCA20 is allelic to SCA5.

A survey of Portuguese families suffering from dominant inherited ataxia revealed six families with cerebellar ataxia and spasmodic cough. One patient had dentate calcification on CT. Thus, these families share phenotypical features with SCA20. As linkage data for these families are not yet available, it remains a matter of speculation whether the Portuguese families correspond to SCA20.

SCA21

Devos et al. described a four-generation French family with autosomal dominantly inherited ataxia and mild cognitive impairment. The clinical syndrome consisted of gait and limb ataxia as well as ataxic speech. In some patients, ataxia was associated with akinesia, tremor, and rigidity. In almost all patients, a mild degree of cognitive impairment was evident. Disease onset ranged from 6 to 30 years with a median of 20 years. An analysis

of 10 parent–sib pairs revealed a median anticipation of 10 years between generations. Disease progression was slow. The index case was still able to walk unassisted after a 40 year disease history. MRI revealed an isolated cerebellar atrophy without brainstem involvement.

A genome-wide linkage analysis yielded a locus on the short arm of chromosome 7 flanked by markers D7S2464 and D7S516 named SCA21. Direct sequencing of a number of candidate genes in this region did not reveal causative mutations.

SCA22

Chung et al. described a four-generation Chinese Han family with autosomal dominantly inherited ataxia. The clinical syndrome was purely cerebellar in all examined patients. The age of onset ranged from 10 to 46 years. Disease progression was reported to be slow. Only one affected individual was unable to walk unassisted 20 years after onset of first symptoms. An MRI was available in one patient and showed an isolated cerebellar atrophy.

Genome-wide linkage analysis revealed linkage to a 43 cM region on the short arm of chromosome 1 with a maximal lod score of 3.78. Schelhaas et al. pointed out that this locus named SCA22 overlaps with the SCA19 locus to which a Dutch family with ataxia, cognitive impairment, postural tremor, and myoclonus had been previously mapped.

SCA23

Verbeek et al. reported a Dutch three-generation family with autosomal dominantly inherited ataxia. All examined patients had gait and limb ataxia. In addition, slowed saccades, impaired vibration and position sense, and extensor plantar responses were encountered in about half of the patients. Disease onset ranged from 43 to 56 years with a median of 51 years. One subject who had a disease duration of 23 years required a wheelchair. All other affected members with a disease duration ranging from 1 to 13 years still walked unassisted. MRI was available in one subject and showed isolated cerebellar atrophy and multiple small subcortical white matter lesions. Neuropathological examination of one brain showed neuronal loss in the Purkinje cell layer, dentate nuclei, and inferior olives. Posterior and lateral columns of the spinal cord were demyelinated.

A genome-wide linkage analysis showed linkage with a region on the short arm of chromosome 20 with a maximal lod score of 3.46.

SCA26

Yu et al. reported a six-generation family of Norwegian origin with autosomal dominantly inherited ataxia. All affected family members had a pure cerebellar syndrome including gait and limb ataxia, ataxic speech and impaired smooth pursuit. Disease onset ranged from 26 to 60 years with a median of 42 years. Disease progression was reported to be slow. Only 2 out of 15 examined patients were wheelchair-bound. MRI showed isolated cerebellar atrophy without brainstem involvement.

By genome-wide linkage analysis, the disease was assigned to a 15 cM region on the short arm of chromosome 19 flanked by the markers D19S886 and D19S894. Maximal lod score was greater than 15. Although the SCA26 locus maps close to SCA6, *CACNA1A*, the gene affected in SCA6, does not lie into the SCA26 region. In addition, the CAG repeat expansion mutation causing SCA6 was not found. Sequencing of the exonic regions of four candidate genes did not reveal any mutations.

Spinocerebellar Ataxias Genetics

T Klockgether, University Hospital Bonn, Bonn, Germany

Glossary

Gain and loss of function – Mechanism by which a genetic mutation exerts its pathogenic effect. Gain of function means that the disease is caused by a new deleterious function acquired by the mutated gene. In a loss of function mechanism, the pathogenesis is due to a loss of the physiological function of the mutated gene.

Ion channel – Pore forming membrane protein that allows and regulates the flow of ions across membranes of excitable cells.

Neuronal nuclear inclusions – Small, light microscopically visible accumulations of proteins present in the nuclei of neurons. Neuronal nuclear inclusions are the pathological hallmarks of polyglutamine disorders.

Polyglutamine disorders – Group of inherited neurodegenerative diseases that are caused by translated CAG repeat expansion mutations which lead to the formation of polyglutamine-containing disease proteins.

Repeat mutation – Disease causing gene mutation characterized by a pathological expansion of a repetitive gene sequence.

Translated and untranslated regions – Translated regions are the exonic parts of a gene that are transcribed and translated into a protein. The untranslated regions are the parts in the 3′ and 5′ region of a gene that are not translated into a protein. They have regulatory functions.

Ubiquitin protease – Enzyme that removes ubiquitin molecules from ubiquitinaned proteins.

Genetics

Of the mutations that have been identified, spinocerebellar ataxias, SCA1, 2, 3, 6, 7, 17 are translated CAG repeat expansions coding for an elongated polyglutamine tract within the respective proteins. These diseases belong to a larger group of polyglutamine disorders that also include Huntington's disease, dentatorubro-pallidoluyisian atrophy and spinobulbar muscular atrophy. Three SCAs, SCA8, 10, 12 are caused by untranslated repeat expansions in non-coding regions of the respective genes. In SCA5 (beta-III spectrin, SPTBN2), SCA11 (tau tubulin kinase-2, TTBK2), SCA13 (voltage-gated potassium channel, KCNC3), SCA14 (protein kinase Cγ, PKCγ), SCA15 (inositol 1,4,5-triphosphate receptor type 1, ITPR1), SCA27 (fibroblast growth factor 14, FGF14), and 16q22-linked autosomal dominant cerebellar ataxia (ADCA) (puratrophin), nonrepeat mutations have been found in the respective genes. In all other SCAs, the affected genes and mutations have not yet been identified.

The genetic heterogeneity of the SCAs implies an even greater heterogeneity of their molecular pathogenesis. Even the polyglutamine SCAs that were initially assumed to share a common mechanism of polyglutamine toxicity, have diverse pathogenic mechanisms that are related to the specific properties of the respective disease proteins. While there has been considerable progress in the understanding of the pathogenesis of the polyglutamine disorders, there is still very limited knowledge of the mechanisms that underlie the SCAs due to untranslated repeat expansions and to nonrepeat mutations.

Epidemiology

There are only few prevalence studies of SCAs. According to these studies, the prevalence ranges between 0.8 and 3.0: 100 000 inhabitants. Due to founder effects, the prevalence may be much higher in certain regions. For example, the prevalence of SCA2 is 43:100 000 in the Cuban province Holguin. The worldwide most frequent SCAs are the polyglutamine SCAs SCA1, 2, 3, and 6 which together account for more than half of all SCA families.

Polyglutamine SCAs

Genetics: The polyglutamine SCAs (SCA1, 2, 3, 6, 7, 17) are caused by CAG repeat expansions in the coding regions of the respective genes. The critical threshold above which the expansion causes the disease ranges from 20 in SCA6 to 51 in SCA3. In all polyglutamine SCAs except SCA3 and SCA7, the normal and pathological range border at each other, or may even have some overlap, as in SCA1. In contrast, the largest normal SCA3 alleles have a length of 40 CAG repeats, while the shortest pathological SCA3 allele observed so far has 51 repeats. There is an inverse correlation between CAG repeat length and age at disease onset. Statistical analyses of large cohorts of SCA patients showed that the repeat length explains 56% (SCA6) to 80% (SCA2) of the observed variability of the age at disease onset.

A quantitative assessment of disease severity in large cohorts of SCA1, SCA2, and SCA3 patients showed that larger expansions are associated with a more severe ataxia in these genotypes while disease severity in SCA6 was mainly determined by age. Clinical observations in SCA7 and SCA17 families suggest that that there is a similar relationship between repeat length and disease severity. There is indirect evidence that longer repeats are also associated with more rapid disease progression, but prospective studies are lacking. Further, the repeat length partly determines which nonataxia symptoms occur in a particular SCA disorder. Thus, longer repeats are associated with peripheral neuropathy, brainstem oculomotor signs, and dystonia in SCA2. In SCA3, larger repeats are associated with spasticity and hyperreflexia. SCA7 patients with large expansion have visual loss preceding ataxia, while those with shorter expansion may have isolated ataxia without major visual deterioration.

While normal alleles are stable, expanded alleles are unstable and often change their length during transmission to the next generation. Instability of expanded alleles is amplified by the loss of non-CAG interruptions in the expanded alleles. In general, there is a tendency that abnormal alleles further expand during transmission to the next generation which results in anticipation, that is, earlier age of onset in the next generation. This tendency is particular strong during paternal transmission in SCA2 and SCA7.

Non-CAG interruptions do not only influence allele stability, but may also determine the clinical phenotype. In SCA2, uninterrupted alleles are associated with cerebellar ataxia, while the less common alleles carrying CAA interruption are found in patients with a parkinsonian phenotype.

Pathogenesis: That expanded polyglutamine tracts themselves exert powerful neurotoxic actions has been convincingly shown in transgenic models in which overexpression of expanded polglutamines in arbitrary proteins in neurons caused neurodegeneration. Several observations suggest that cleavage of the disease proteins and formation of smaller polyglutamine-containing protein fragments is a prerequisite for polyglutamine-mediated neurodegeneration. However, the enzymes mediating protein cleavage have not yet been fully identified. In most polyglutamine diseases, a nuclear localization of the disease protein is required for its deleterious action.

Elongated polyglutamines have a strong tendency to misfold and aggregate. According to current view, oligomeric intermediates originating from the aggregation process are responsible for the pathogenesis, while the light microscopically visible neuronal inclusions found in neurons of SCA brains are thought to be inert or even protective. Oligomeric intermediates exert their deleterious action by abnormally interacting with other cellular proteins. Potential interaction partners are transcription factors which themselves contain polyglutamine tracts. As a result, a general suppression of gene transcription has been found in models of polyglutamine diseases. The important role of transcriptional dysregulation in the pathogenesis of polyglutamine disorders is underlined by the discovery that SCA17 is caused by a CAG repeat expansion in the gene of an essential transcription factor, TATA-binding protein (TBP).

With the exception of SCA6 (α_{1A} voltage-dependent calcium channel subunit, CACNA1A) and SCA17 (TBP), the function of disease proteins of all SCAs of the polyglutamine group was completely unknown when the respective gene mutations were discovered. The physiological roles of these proteins which have been named ataxins are currently under intense investigation.

In SCA1, the polyglutamine expansion stabilizes ataxin-1 and leads to its accumulation. Ataxin-1 interacts in a polyglutamine-independent way with the mammalian transcription factor senseless/Gfi-1 which is expressed in cerebellar Purkinje neurons. Loss of Gfi-1 leads to degeneration of cerebellar Purkinje neurons suggesting that ataxin-1/Gfi-1 interaction contributes to the neurodegeneration in SCA1. Apart from transient interaction with a number of proteins including senseless/Gfi-1, ataxin-1 forms stable protein complexes with RNA-binding motif protein 17 (RBM17), a protein involved in RNA metabolism, and capicua, a transcription factor. Polyglutamine expansion favours the formation of complexes with RBM17 which contribute to neurodegeneration due to a gain of function mechanism, while formation of complexes with capicua are attenuated resulting in a loss of function. The observations lead away from simple models of polyglutamine toxicity and suggest opposing effects of the polyglutamine expansion on cellular function resulting in both gain and loss of function.

Ataxin-3, the disease protein of SCA3, binds polyubiquitin chains and acts as an ubiquitin protease. In addition, ataxin-3 has been shown to bind to DNA and form a transcriptional repressor complex. The transcriptional repressor function is lost in expanded ataxin-3. Overexpression of normal ataxin-3 prevents polyglutamine-induced neurodegeneration raising the question whether a loss of the physiological function of ataxin-3 amplifies the polyglutamine-mediated toxicity in SCA3. Thus, SCA3 pathogenesis like SCA1 has aspects of both, gain and loss of function.

SCA6 is caused by a CAG expansion in the CACNA1A gene that encodes the α_{1A} transmembrane subunit of the P/Q type voltage-sensitive calcium channel that is strongly expressed in cerebellar Purkinje neurons. It is therefore conceivable that the polyglutamine expansion which is located in the C-terminal part of the channel protein impairs the physiological function of these channels and that this contributes to the neurodegeneration in. However, electrophysiological studies in cells overexpressing the mutant channel subunit failed to provide a

consistent picture. More recently, it was found that that the deleterious action of the polyglutamine expansion depends on the cleavage and nuclear localization of the C-terminal part of the protein. This finding suggests that the mutant protein has pathogenic effects which are independent of its channel function.

Neuropathology: Given the diverse pathogenesis of the polyglutamine SCAs it is not surprising that autopsy findings vary. Even within one genotype, neuropathology is not uniform. SCA1, 2, and 7 are prototypes of a degeneration pattern that was previously designated as olivopontocerebellar atrophy with degeneration of the cerebellar cortex, pontine nuclei, and inferior olives. In SCA2 brains, there is almost always additional severe loss of dopaminergic neurons of the substantia nigra. In SCA3, there is degeneration of the cerebellar nuclei, brainstem, basal ganglia, and spinal cord, while the cerebellar cortex is widely spared. In contrast, the degeneration in SCA6 is largely confined to cerebellar Purkinje neurons without major involvement of other parts of the brains or spinal cord. In some polyglutamine SCAs, in particular SCA2, SCA3, and SCA7, degeneration in the central nervous system is accompanied by a peripheral neuropathy of axonal type.

An almost common morphological feature of polyglutamine disorders are neuronal nuclear inclusions formed by the respective elongated disease proteins. Such inclusions are prominent in SCA1, 3, 7, and 17, while they are less common or absent in SCA2 and SCA6. As these inclusions contain additional proteins, such as chaperones, proteasomal subunits and transcription factors it has been hypothesized that the inclusions contribute to the disease pathogenesis by depleting the cell from essential proteins. However, this hypothesis has not been supported by experimental evidence. Instead, it has been shown that the neurodegeneration can be dissociated from the formation of nuclear inclusions.

SCAs Due to Untranslated Repeat Mutations

Three SCAs are caused by repeat expansion mutations in untranslated parts of the affected genes. SCA8 is associated with a CTG expansion in the 3′ untranslated region of the ATXN8 gene. In contrast to all other known SCAs, penetrance of the mutation is incomplete, and expansions have been found in healthy individuals and in individuals with brain diseases other than ataxia. The normal SCA8 alleles have a length ranging from 15 to 37 CTG repeats, while expanded alleles are longer than 100 repeats. It was initially hypothesized that the SCA8 mutation exerts its effects through an RNA gain of function mechanism in which the transcript, in a mechanism resembling that in myotonic dystrophy, has toxic effects by sequestering RNA-binding proteins, or in which the transcript functions as an antisense and disrupts the expression of neighboring genes. More recently, it has been suggested that the ATXN8 gene is transcribed in a bidirectional manner resulting not only in a potentially toxic CUG-containing RNA, but also in a second transcript that is translated into a pure polyglutamine stretch. The SCA8 pathogenesis might thus involve toxic gain of function mechanisms at both the protein and RNA levels.

SCA10 is due to large unstable intronic pentanucleotide (ATTCT) expansions which may have a length up to 4500 repeats. Normal repeat length shows a range from 10 to 22 repeats.

SCA12 is caused by a CAG repeat expansion in the 5′ untranslated region of the PPP2R2B gene that encodes a brain-specific regulatory subunit of the protein phosphatase PP2A. Normal repeat size ranges from 7 to 32, the expanded repeat size from 55 to 93.

SCAs Due to Nonrepeat Mutations

SCA5, 11, 13, 14, 15, 27, and 16q22-linked ADCA are due to nonrepeat mutations, mainly missense mutations and deletions. Although the genes affected in these disorders have very diverse functions, all SCAs due to nonrepeat mutations have a number of features in common that distinguish them from the polyglutamine SCAs. SCAs due to nonrepeat mutations often have an early disease onset, that is, in adolescence or early adulthood. In addition, progression is much slower than in the polyglutamine SCAs. Many patients suffering from one of these disorders are mentally retarded. These features have led to the suggestion that the SCAs due to nonrepeat mutations are rather developmental than true neurodegenerative disorders.

An overview of the affected genes and mutations is given in **Table 1**. Among this group of disorders, 16q22-linked ADCA deserves special consideration. 16q-linked ADCA is frequent in Japan. The chromosomal region to which this disorder is linked overlaps with the SCA4 region, thereby raising the question whether both disorders are allelic. A strong argument against this assumption is the different clinical phenotype. 16q-linked ADCA is clinically characterized by progressive cerebellar ataxia. Correspondingly, imaging and autopsy studies show cerebellar degeneration. In contrast, the two SCA4 families described so far – one in Utah/USA and other in Germany – suffer from sensory ataxia without cerebellar involvement. In addition, the mutations present in the Japanese families were not detected in the German SCA4 family.

It is thought that the pathogenesis of the SCAs caused by point mutations is more closely related to the physiological function of the affected proteins than that of the SCAs which are due to repeat mutations. An example of this assumption is SCA5. SCA5 is caused by mutations of the SPTBN2 gene which is highly

Table 1 Molecular genetics of the SCA

Disorder	*Mutation*	*Gene product*
SCA1, 2, 3, 7	Translated CAG repeat	Ataxin-1, 2, 3, 7
SCA6	Translated CAG repeat	Voltage-gated calcium channel subunit
SCA17	Translated CAG repeat	TATA box-binding protein
SCA8	Untranslated/ translated CTG repeat (3′)	Ataxin-8
SCA10	Untranslated AATCT repeat (intron)	Ataxin-10

expressed in cerebellar Purkinje neurons. SPTBN2 acts as a stabilizer of the glutamate transporter EAAT4. Mutations might thus result in abnormal glutamate signaling and excitotoxicity. On the other hand, point mutations of the PKCγ gene in SCA14 have been shown to lead to the formation of intracytoplasmic aggregates suggesting a disease mechanism resembling that in polyglutamine disorders. In general, the pathogenesis of the SCAs due to nonrepeat mutations is insufficiently studied so that statements about the mechanisms leading to these diseases at this point are speculative.

St. Vitus Dance

K M Shannon, Rush University Medical Center, Chicago, IL, USA

Glossary

Chorea – Brief, random involuntary movements that tend to flow from body part to body part.
Psychogenic illness – Constellation of signs or symptoms without an organic basis.

Definition and History

St. Vitus dance is now believed to result from mass psychogenic illness/mass hysteria. Mass hysteria is a social illness, defined as 'a constellation of symptoms suggestive of organic illness, but without an identified cause in a group of people with shared beliefs about the cause of the

symptoms.' Mass hysteria is sudden in onset, preceded by the illness of an index patient in whom there has been a prominent response. The illness is propagated by proximity and along sight lines. Symptoms spread rapidly but involve few hard physical signs.

During the time of St. Vitus dance, bizarre dancing behavior developed in a group of people who shared a belief system that spiritual forces could provoke severe physical manifestations. Similar bizarre behavior developed in groups of people in Italy who thought they had been bitten by tarantulas (tarantism), and mass hysteria was the origin of witchcraft panics in Europe and New England. Modern episodes of mass hysteria are more likely to occur in the context of environmental concerns or heightened sensitivity to possible terrorist episodes or other criminal behaviors.

Epidemiology/Risk Factors

St. Vitus dance first affected the poor, though it did spread to affect members of all classes. Those who led a sedentary life (shoemakers, tailors) were thought to be preferentially affected, but even robust farmers were stricken. Although little can be gleaned from the descriptions of St. Vitus dance, other episodes of mass hysteria have been more common in women than in men.

Clinical Features and Diagnostic Criteria

> The effects of the Black Death had not yet subsided, and the graves of millions of its victims were scarcely closed, when a strange delusion arose in Germany, which took possession of the minds of men, and, in spite of the divinity of our nature, hurried away body and soul into the magic circle of hellish superstition.
>
> Hecker, 1888

St. Vitus dance is more an historical than a clinical syndrome. It has been variably known as the dancing mania, St. John's dance, and St. Guy's dance. Once they began, episodes of dancing mania spread across Europe over a period lasting more than 300 years.

Hecker dates the first cases to 1374, at Aix-La-Chapelle. The region had been visited by serious flooding, and there was unrest and lawlessness. In this context, men and women began to exhibit a strange ritual. They joined hands and formed circles, dancing deliriously for hours until falling to the ground, exhausted. When dancing, they seemed insensitive to the environment, though influenced by visions. The dancing was often followed by 'tympany' and flatulence, which was treated by bystanders who thumped or stepped on the dancers, or bound them tightly around the waist. Dancers took over houses of worship and inspired processions, prayer, and exorcisms. Although the affliction was largely confined to the poor at first, it did spread to other more privileged community members.

The connection to St. John the Baptist is believed to be related to a manner of his worship that involved jumping through flames or smoke as a means of securing protection from fevers or other disease. The connection to St. Vitus occurred after the malady spread to Strasburg in the early fifteenth century. Eager to control the affliction, the town council appointed superintendents to protect them and the townspeople from harm. Afflicted persons were brought to the chapels of St. Vitus, where they were attended to by the priests. A procession to the altar of St. Vitus frequently cured the sufferers of their torment.

Over time, the attacks became temporally attached to their patron saints, occurring around the time of feast days. Episodes of the dancing mania continued for hundreds of years, and their treatment was entirely the purview of the church. In many cases, musicians were enlisted to speed the course of the illness, since exhaustion seemed the first step to cure.

In the early sixteenth century, they drew the attention of Paracelsus, who divided St. Vitus dance into three subcategories: chorea imaginativa, chorea lasciva, and chorea naturalis. Chorea imaginativa arises from the imagination (dancing mania), chorea lasciva arises from sensual desires, and chorea naturalis arises from corporeal causes.

Differential Diagnosis

Despite the derivation of the word chorea from the Greek word for dance, choreic movements do not suggest an organized motor activity that would resemble dancing or jumping. Rather, the movements are brief and random, and tend to flow from one body part to another.

St. Vitus dance is of historical interest, though it can best be considered a mass functional or psychogenic illness. In this sense, functional/psychogenic chorea must be differentiated from organic choreas, including immune-mediated chorea (Sydenham's chorea, lupus chorea, antiphospholipid antibody syndrome), hereditary chorea (benign hereditary chorea, Huntington's disease, and Huntington-like illnesses), metabolic and hormonal chorea (hyperthyroidism, chorea gravidarum), drug-induced chorea (neuroleptic, sympathomimetic agents, oral contraceptives/hormonal treatments), and others. Like other psychogenic/functional movement disorders, psychogenic/functional chorea is often sudden in onset, variable and distractible, and it may be associated with other psychogenic/functional signs.

Diagnostic Work-up/Tests

Psychogenic/functional movement disorders are diagnosed clinically by their characteristic tempo, appearance, and associated symptoms. Neuroimaging studies, immune and metabolic studies, and genetic testing may be useful to distinguish these from organic causes.

Management

Paracelcus recommended treatment for his three types of St. Vitus dance. For the first type, chorea imaginativa, the sufferer was to make a wax image of himself, and concentrate all his blasphemies and sins into it, then burn the image. For chorea lasciva, Paracelsus recommended strict fasting and isolation followed by gradual return to society. The third type was to be treated with a number of potions applied internally in water or wine, and externally, as an ointment, with particular attention paid to the ticklish areas.

For individual victims of psychogenic/functional movement disorders, the course of treatment is not yet clear. In the absence of controlled clinical trials, various strategies are employed. These include cognitive behavioral therapy, pharmacological intervention, and various psychotherapies.

The management of modern outbreaks of mass hysteria is difficult. There are no pathognomonic signs of mass psychogenic illness, and expensive and prolonged investigation is the rule. Even when all organic causes of the symptoms are ruled out, there may be persistent beliefs that such a cause exists and has escaped detection or been 'covered up.' A detailed follow-up of a mass psychogenic illness in Tennessee suggested that the episode, in which 186 persons who had symptoms related to an 'abnormal smell' in a school, resulted in loss of 18 000 person-days of school, 178 emergency room visits, $93 000 in medical expenses, 200 person-hours, $9000 for toxicological studies, and 3000 person-hours of additional labor costs involving 12 government agencies, eight laboratories, and seven private consulting groups.

Prognosis

Although in most cases, St. Vitus dance was 'cured' by devotions to the saint or other interventions, there are reports of its sufferers sustaining permanent injury, even death while in its throes. Moreover, annual episodes surrounded the feast days of the patron saint in question.

There are little long-term prospective data to guide prognosis in today's victims of psychogenic/functional illness, but a monophasic illness seems more common. In outbreaks of mass psychogenic illness, recovery is the rule, though some victims may complain of chronic dysfunction.

Staircase (Skilled Reaching) Test

S B Dunnett, Cardiff University, Cardiff, South Wales, UK

Glossary

6-Hydroxydopamine (6-OHDA) – A neurotoxin that induces selective degeneration of catecholamine neurons, frequently used following injection into the vicinity of midbrain dopamine neurons to induce an animal model of Parkinson's disease.

Brain-derived neurotrophic factor (BDNF) – A member of the neurotrophin family trophic factors, that enhances survival of dopamine neurons both in vitro and in vivo.

Glial cell line-derived neurotrophic factor (GDNF) – An endogenous trophic molecule that enhances survival and fibre outgrowth of dopamine neurons both in vitro and in vivo.

Introduction

The staircase test was introduced by Montoya in 1990 to provide an objective and flexible alternative to a range of other tests used to assess forelimb use and motor skills in rats.

Very many studies of motor function involve the manipulation of systems, such as basal ganglia or forebrain dopamine pathways, in which bilateral lesions can yield animals that are akinetic, unmotivated and extremely ill, rendering them effectively untestable. This can be resolved by studying motor asymmetries in unilateral lesioned animals, but to be effective any test must be able to evaluate unilateral deficits and performance independently on the two sides of the body.

Hitherto, many tests involved observing rats or mice reaching to pick up food pellets in trays, tubes, and troughs either by direct observation or by video recording of performance for subsequent analysis. Such tests had clear face validity but suffered from several disadvantages: (1) they were time consuming and labor intensive; (2) they were scored by observer rating with all the attendant problems of potential experimenter bias; (3) even if skilled reaching is affected, rats are efficient at scooping up pellets with the open hand or tongue; and (4) rats with unilateral lesions are adept at finding strategies to use their unaffected limb, making rating of the affected limb problematic without use of further restraints such as casts or forelimb injections of local anesthetic. The alternative strategy has been to use operant paradigms with force transducers attached to lever press or lever release operanda. Such tests can be automated for objectivity and efficiency, but the need to restrict use of the unaffected limb, as opposed to simply measuring changes in preference or bias, was again problematic.

The Staircase Test

The staircase test emerged out of a variety of attempts to reconfigure lateralized reaching wells and tubes in a restricted cage so that the rat could only use one or the other limb in a particular location. The solution that emerged was to develop a platform within a narrow corridor, along which a rat (or mouse) can crawl, and reach down either side to pick up food pellets (**Figure 1**). However, the corridor is too narrow to allow the rat to turn around so it can only reach pellets from the left side using the left forepaw and from the right side using the right forepaw. A double staircase with a series of steps with a shallow well in each step and two food pellets placed in each well, then provided a linear series of distances the rat must reach to retrieve pellets and a corresponding graded level of difficulty. On each test, the mildly food-deprived rat is placed in the staircase apparatus for 15 min, at the end of which the number of pellets retrieved can be counted.

Two measures are typically recorded: *pellets retrieved*, the total number of pellets removed, which provides an index of the distance over which the animal can reach and coordinate an effective grasp and retrieval under proprioceptive feedback; and *maximum reach*, the furthest step with one or less pellets remaining, which provides an index of the maximum distance over which the animal can make a reaching attempt. In practice, the two indices yield very similar experimental outcomes, and for most purposes, simply recording the pellets retrieved provides a reliable and efficient metric. Nikkhah and colleagues have undertaken more detailed analyzes using color coded pellets on each step to differentiate more clearly retrieved from displaced pellets, but again for most purposes, the additional information acquired may not offset the cost in efficiency. Similarly, Whishaw has provided detailed and elegant video analysis of the precise motor choreography of reaching movements by rats, but this level of analysis is not required for most experimental neurobiological purposes.

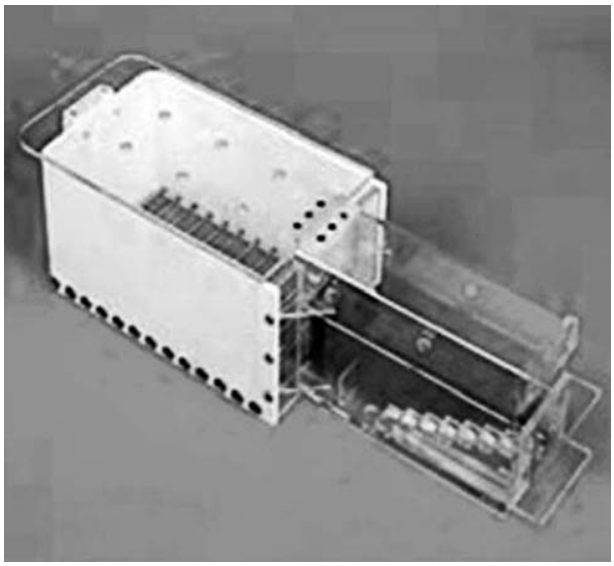

Figure 1 The staircase test apparatus.

Training is important to yield clear results. Early studies used only rather brief training preoperatively, whereas studies by Fricker–Gates have shown that more extensive training over 2–4 weeks to attain a stable baseline prior to experimental manipulation not only provides tighter variance and greater experimental power, but stabilizes ipsilateral performance and yields more selective impairments on the contralateral side. Conversely, studies that undertake task acquisition in animals that have already sustained unilateral lesions typically never acquire high levels of performance even with the supposedly intact ipsilateral limb.

Moreover, although most studies have been in the rat, the task can be readily adapted for other species, once allowance is made for species difference in patterns of behavior, and versions of the staircase test have been validated for the mouse and marmoset.

Key Results

The staircase was first validated with unilateral lesions of the motor cortex, but has been subsequently used most widely in experimental studies of basal ganglia function. Notably, both unilateral nigral and unilateral striatal lesions induce marked impairments of successful reaching with the contralateral paw in adult rats; however, profiles of recovery differ. When nigrostriatal lesions are made in neonatal rats they can develop normal reaching behavior. However, by the time the animals are weanlings, 3–4 weeks of age, even partial dopamine-depleting lesions produced sustained impairments in the staircase tests, while other tests such as stepping and cylinder can indicate partial recovery. Unilateral striatal lesions can be even more marked and long lasting. More recently, other experimental studies have adopted the staircase test to provide sensitive and efficient measurement of disturbed forelimb function relating to cortical damage, spinal trauma, and unilateral stroke, and the task has proved efficient for evaluation efficacy of symptomatic and neuroprotective drug treatments.

The staircase test has proved particularly informative in studies of cell transplantation. From the first studies, striatal grafts have been found to be effective in alleviating skilled reaching deficits in animals with excitotoxic lesions of the striatum, and indeed the staircase test has emerged as perhaps the most reliable and sensitive test of functional recovery in this lesion and graft model of Huntington's disease. Conversely, several authors have found that nigral grafts, which alleviate a range of simple motor asymmetries and akinetic deficits induced by nigrostriatal lesions, fail to yield recovery in the staircase test. Although, from the more diverse neuronal loss, the striatal lesion might be predicted to be the more difficult lesion to reconstruct, in this model the grafts are placed back into a homotopic site which allows for the extensive reformation of appropriate connections. By contrast, nigral grafts need to be placed ectopically in the striatum and although effective in replacing a dopaminergic striatal innervation do not restore nigrostriatal connectivity. Pharmaceutical studies provide compatible data, with beneficial effects in the staircase test of neuroprotective agents that reduce nigrostriatal degeneration (such as riluzole, melatonin, glial cell line-derived neurotrophic factor (GDNF), or brain-derived neurotrophic factor (BDNF)), but a failure of stimulant drugs (such as caffeine or apomorphine) to alter deficits in staircase performance, even when deficits in other simple motor tasks (such as rotation or reflexive stepping) are markedly reversed.

Such data suggest that the staircase apparatus provides an effective test of goal-directed skilled reaching, dependent upon the integrity of functional nigrostriatal and corticostriatal circuits, rather than on simple striatal activation per se.

Glossary

Huntington's disease – Huntington's disease is a neurodegenerative genetic disorder that results in abnormal movement.
Neural stem cells – Neural stem cells are self-renewing cells that generate the main cell types of the nervous system.
Parkinson's disease – Parkinson's disease is a chronic and progressive disease of the brain that impairs motor control, speech, and other functions.
Stem cells – Stem cells are cells that are characterized by the ability to renew themselves through cell division and have the ability to become specialized organ-cell types.

Introduction

The myriad of neurological pathologies that can affect the human brain from prenatal development and throughout lifespan along with the brain's limited self-repair capacity call for new therapeutic strategies. Our increasing knowledge about the fundamental biology and therapeutic potential of various stem cell types opened a new chapter in regenerative medicine. The initial work on rodent stem cells over the last two decades is now being successfully continued with stem cells of human origin and from different developmental stages. We have learned about key genes and cellular mechanisms that maintain the stem cell status or lead to differentiated progeny. We have also learned about the multiple roles of stem cells during development, disease, and aging. It is now well established that stem cells are not only a valuable tool for cell replacement but are equipped with important additional properties that may be harnessed for cell protection, detoxification, and gene therapy ('chaperone effects').

Stem cell biology is being recognized as a continuum of developmental processes that are tightly regulated, both temporally and spatially. Better understanding of these developmental events is considered to be a key strategy for the successful use of both endogenous and grafted stem cells for CNS repair and functional recovery. For instance, the generation of functional neurons and glial cells during brain development requires a concerted coordination of cell proliferation, migration, cell-type specification, and synaptic integration, all of which are also crucial for a successful stem cell therapy.

Stem Cell Prototypes

Stem cells give rise to organs and maintain tissue integrity and homeostasis in an adult organism. There are different types of stem cells, including embryonic and somatic (fetal or adult derived), from which new cells can be derived. To fulfill the criteria of a stem cell, as opposed to a 'progenitor' cell, a single clonal cell must have the following functional properties: (1) should be able to generate the cell types from the organ it was derived from and (2) should possess 'self-renewal,' that is, the ability to produce daughter cells with identical properties. The ability to populate a developing or injured region with appropriate cell types upon transplantation is another important stem cell feature that is well established with hematopoetic stem cells and awaits standardization in other organ systems, including the brain. In the following sections, we introduce two prototypical stem cells, the embryonic stem cells (ESCs) and neural stem cells (NSCs), and discuss their potential for neural repair.

Embryonic Stem Cells

ESCs are derived from the inner cell mass of blastocysts of different species, including human. They can be totipotent (be able to generate all cell types in an organism except the placenta), pluripotent (the ability to yield mature cell types from all different germ layers), or multipotent (be able to give rise to all cells within an organ). Work performed with mouse ESCs has provided proof-of-principle that pluripotent cell lines can be harnessed for developmental biological studies as well as for new therapeutics. Since significant species differences exist between

mouse and human ESCs (hESCs) regarding signaling pathways and molecular regulation of pluripotency, it is pivotal to fully characterize and define the molecular mechanisms in human ESCs. Currently, our understanding of human ESCs cells is increasing and knowledge is being accumulated on improved cell culture conditions, long-term propagation, controlled differentiation, and transplantation into animal models of human disease.

The list of various cell types differentiated from human ESCs (e.g., neurons, cardiomyocytes, hepatocytes) is continuously increasing. Pluripotent ESCs can be stepwise differentiated in the culture dish by recapitulating aspects of in vivo development and the use of relevant epigenetic factors. Importantly, the acquisition of a particular developmental stage of a cell is best characterized by considering morphological, immunophenotypic, and functional criteria. The unlimited access to specific functional human cells is expected to play an important role not only in therapeutic cell replacement but also for disease modeling and drug screening.

Neural Stem Cells

In contrast to pluripotent hESCs, somatic stem cells are believed to be multipotent, thereby capable of generating the major cell types limited to the tissue of origin. Typically, NSCs are capable of producing neurons, astrocytes, and oligodendrocytes. Somatic/tissue-specific stem cells are the building blocks of organs during development and survive in specialized microenvironments ('stem cell niche'), contributing to new cells throughout life. NSCs (1) are multipotent (the ability to yield mature cells in all three fundamental neural lineages throughout the nervous system: neurons; astrocytes; and oligodendrocytes), (2) have the ability to populate a developing region and/or repopulate an ablated or degenerated region of the CNS with appropriate cell types, and (3) undergo 'self-renewal,' that is, the ability to produce daughter cells with identical properties. NSCs are highly abundant during embryogenesis, with a sharp decline shortly after birth. In the adult nervous system, NSCs are confined to the subgranular zone (SGZ) in the dentate gyrus of the hippocampus and the subventricular zone (SVZ) lining the lateral ventricles. The newly born neurons in hippocampus have been suggested to improve memory and play a role in mood behavior such as stress and depression. Neuroblasts born in the SVZ migrate along the rostral migratory stream (RMS) to the olfactory bulbs, where they differentiate into periglomelular and granule neurons. Isolation of cells from brain regions such as amygdala, substantia nigra, and cortex has included cells with stem cell characteristics in vitro. Morphologically, NSCs share properties with both astrocytes and radial glia. The main characteristic is a long process that extends radially. Although no definitive marker has been suggested for neural stem cells, a substantial amount of work shows that they are positive for nestin, an intermediary filament protein, and glial fibrillary acidic protein (GFAP), used traditionally to identify astrocytes.

NSCs or progenitor cells with a more restricted developmental potential can be generated from hESCs or directly isolated from the developing CNS as well as from neurogenic regions of the adult brain. Historically, the first established NSCs lines exploited the knowledge accumulated on tumor viruses and immortalization. These cell lines have been invaluable in expanding our experience on basic stem cell biology and neural repair. Some of these multipotent cell lines, such as the C17.2 NSC line, are still widely used. However, NSCs that have not been genetically modified can also be propagated in vitro for extended periods of time, using high concentrations of mitogenic factors such as basis fibroblast growth factor (bFGF) and epidermal growth factor (EGF). Neural stem/progenitor cells have been cultured as monolayers on coated substrates or as free-floating spherical aggregated, termed neurospheres.

Stem Cell Repertoire

Chaperone Effects

Initially, stem cells were considered as exclusive tools for cell replacement. However, there are multiple evidence now for robust additional biological properties ('chaperone effects') of stem cells that may be exploited therapeutically. Chaperone effects of stem cells include the natural delivery of neurotrophic, cytoprotective, and antiinflammatory molecules (e.g., GDNF, BDNF, NT-3) in order to rescue dysfunctional cells. This concept of stem cell-based chaperone effects was first demonstrated in the brain of aged and parkinsonian mice and later confirmed and extended to other organ systems and various diseases (e.g., bone marrow-derived mesenchymal stem cells or embryonic stem cells for cardiac disease, umbilical cord cells in stroke).

Environmental Cues

Increasingly, the microenvironments within the CNS are providing insight into the molecular milieu regulating stem cell biology. A specialized microenvironment in the neurogenic regions is responsible for the continued self-renewal and differentiation of the stem cell pool. For example, these regions have a higher density of blood vessels releasing factors, such as vascular endothelial growth factor (VEGF) and brain-derived neurotrophic factor (BDNF), contributing to increased proliferation and neurogenesis. Different levels of growth factors can have fundamentally different effects on proliferation and differentiation. For example, low levels of insulin-like

growth factor-1 (IGF-1) promote neurogenesis, whereas higher levels increase proliferation and oligodendrogenesis. Established protocols for the isolation of neural stem cells include the growth factors epidermal growth factor (EGF) and bFGF that sustain self-renewal of NSCs. Injection of these factors intracranially into mice have shown to regulate both proliferation and differentiation in vivo. Neurotrophins such as BDNF in collaboration with retinoic acid and Wnt signaling regulate neurogenesis; with ciliary neurotrophic factor (CNTF)/leukaemia inhibitory factor (LIF) or bone morphogenic proteins (BMPs), induce gliogenesis. It is also know that the cellular milieu contributes to fate determination and cortical development, specifically through the effects of resident astrocytes in both the subventricular zone (SVZ) and hippocampus. Physical exercise and enriched environment have been shown to promote neurogenesis in the SGZ. The effects from physical activity are partly mediated by IGF-1, VEGF, BDNF, and endogenous opioids. The characterization of the stem cell microenvironment will provide the molecular and cellular scaffold upon which stem cell therapy, both endogenous and exogenous, can be built.

Stem Cells as Vectors for Gene Therapy

Brain lesions can be focal and restricted to a certain region or widely distributed in the parenchyma. Ideally, both lesion types would be targeted with a specific and efficient delivery of therapeutic molecules and drugs. In fact, efficient delivery is still a major hurdle in gene therapy. The finding that endogenous and grafted NSCs display an extensive migratory potential and tropism toward brain lesions founded the idea that these cells may be used as therapeutic vectors. Proof-of-principle experiments in animal models of lysosomal storage diseases (example for a widely distributed brain lesions) and brain tumors (example for a focal lesion) have shown that genetically modified NSCs are powerful therapeutics to cross-correct hereditary enzymatic deficiencies or to dramatically reduce a tumor mass. Thus, NSCs hold great promise for both cell and gene therapy.

Stem Cell-based CNS Repair

It is manifest that stem cells can be used to replace neuronal, astrocytic, and oligodendroglial cells lost because of various brain diseases. However, it is important to note that a successful use of stem cells is probably dependent on many factors, including the nature and degree of injury, disease history and age of the patient, primarily affected cell types, type of stem cell chosen for transplantation, and the site of grafting. A deeper insight into these parameters is important to tailor patient-specific treatment paradigms in a clinical context.

Stem cells have been explored in a number of rodent and primate models of human neurological diseases. These studies showed successful survival, differentiation, and synaptic integration of grafted stem cells which led to functional restoration and amelioration of symptoms. In the following, we highlight some examples of stem cell-based CNS repair and discuss the challenges that remain to be addressed prior to clinical application.

Parkinson's Disease

Parkinson's disease (PD) is characterized by a progressive deterioration and loss of nigrostriatal dopaminergic neurons in the substantia nigra. The consequence of this cell death in the ventral midbrain is a deficient dopamine neurotransmission in the target region, the striatum. Clinically, the PD presents with clinical symptoms such as tremor, rigidity, and bradykinesia. Patients transplanted with fetal mesencephalic grafts in the early 1990s have demonstrated that an ectopic transplantation of dopamine-producing cells into the striatum can restore motor function and ameliorate clinical symptoms. Because of the limited availability of fetal tissue, stem cells are expected to provide unlimited numbers of transplantable dopamine neurons.

Several studies using rodent and primate models of PD have demonstrated successful integration and functional improvement after the grafting of dopaminergic neurons derived from both ESCs and NSCs. In primate models, monkey embryonic stem cells have been transplanted and animals evaluated for behavioral improvements. As with the rodent models, functional improvements occur. Furthermore, these behavior assessments can be corroborated with functional neuroimaging (**Figure 1**).

The considerable progress in stem cell-based treatment of PD in animals still faces many challenges before clinical translation. Human ESCs differentiate to dopaminergic neurons under various protocols, yet the creation of a purified and homogenous population of dopaminergic neurons is challenging and needs improvement. Animal models for future investigation should increasingly include primates in order to refine the mechanics and logistics of transplantation. Patients in whom stem cell therapy will be the most effective with the least side effects should be defined. The effects of posttransplantation training and rehabilitation need to be better understood. It appears that these contribute to improved functional outcome in experimental animal models. The clinical experience with fetal grafts suggests that the patient's disease history is an important parameter and that cell therapy will fail to be the method of choice for every parkinsonian patient, and therefore, patient selection will be pivotal to clinical improvements after graft

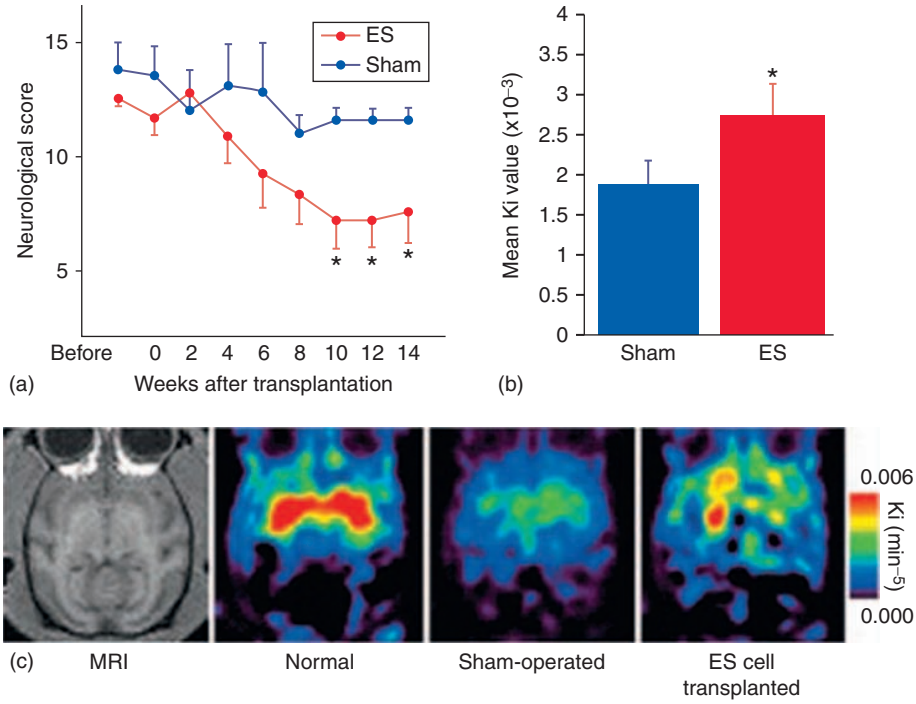

Figure 1 Function of ES cell-derived neurospheres in MPTP-treated monkeys. Behavioral scores (a) and PET study (b, c) of ES cell-transplanted ($n = 6$) and sham-operated animals ($n = 4$). (b) Mean K_i values from entire putamen. (c) Increased ^{19}F-fluorodopa uptake in the putamen of ES cell-transplanted animals. All values are mean ± SD. $P < 0.05$. (2005) Dopaminergic neurons generated from monkey embryonic stem cells function in a Parkinson primate model. *The Journal of Clinical Investigation* 115: 102–109.

placement. Finally, the adverse effects such as dyskinesias observed in some patients after transplantation of fetal grafts need careful consideration, and further, the safety of hESCs needs to be established prior to clinical transplantation.

Huntington's Disease

Huntington's disease (HD) is a progressive neurodegenerative disease resulting in cognitive and motor impairments and death. Neuronal dysfunction and degeneration contribute to progressive physiological, motor, cognitive, and emotional disturbances characteristic of HD. The mechanism of the disease is not fully understood, but a number of factors have been identified. A mutation in the Huntingtin gene causes the production of an abnormal form of the protein huntingtin, which in turn produces cellular and anatomical changes in the brain. There is no cure for HD, although there are treatments to relieve some of its symptoms. Research into the treatment of HD has centered on cell therapy strategies to protect vulnerable neuronal cell populations or to replace dysfunctional or dying cells that include therapy with the potential for self-repair through the manipulation of endogenous stem cells and/or neurogenesis, the use of stem cell transplantation as a cell replacement strategy, and the administration of neurotrophic factors to protect susceptible neuronal populations. These approaches have shown some promising results in animal models of HD.

Stem cell therapy in adult patients with HD has received an increasing attention for its potential to alleviate pathological neurodegeneration by replacing lost neuronal and/or glial populations, by triggering endogenous repair mechanisms, or by protecting existing cells primarily through trophic support. Stem cell transplantation is a promising field in cell therapy for HD, as stem cells are relatively easy to obtain compared with primary fetal tissue and have the potential to be manipulated to eliminate possible problems of host rejection. Transplanted ESCs have been shown to differentiate into neurons in the HD-affected striatum and appear to migrate to nearby cortical regions where they have been found to express markers of immature neurons.

Recent work in stem cell therapy has been conducted in animal models of HD. However, protocols and procedures developed from trials of hESCs transplantation in patients with HD will lay the groundwork to move stem cell therapy into the clinic. One of the first challenges to stem cell therapy in HD is to determine which source of stem cells is most efficacious, and many sources have been examined. In addition to hESCs, stem cells derived from mesenchymal cells in adults have been investigated

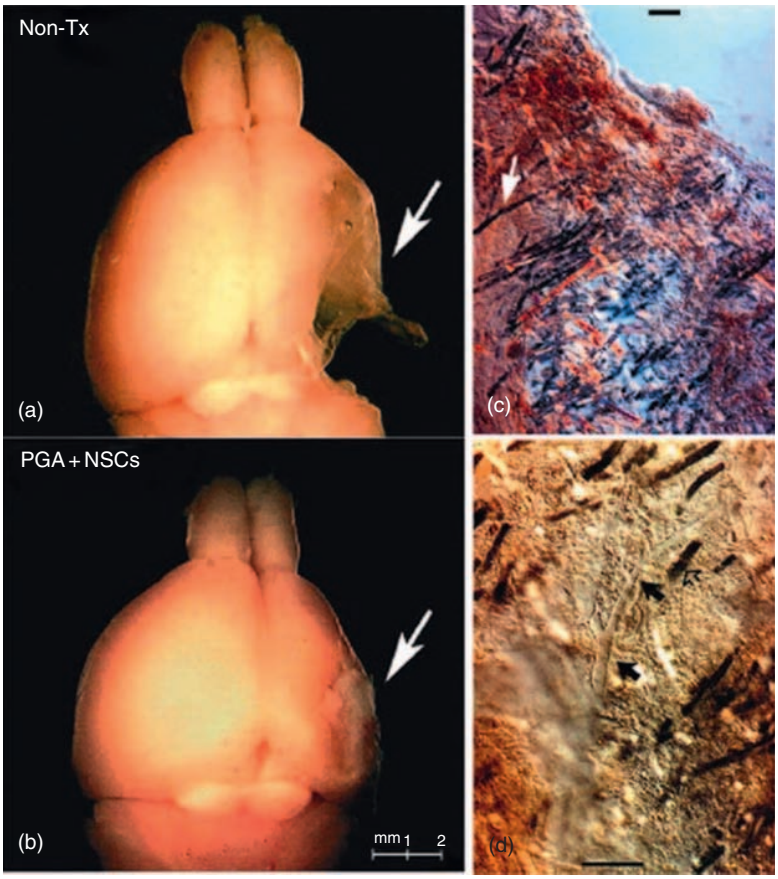

Figure 2 Implantation of NSC–PGA complexes into a region of cavity formation following extensive HI brain injury and necrosis. (a) Brain of an untransplanted (non-Tx) mouse subjected to right HI injury with extensive infarction and cavitation of the ipsilateral right cortex, striatum, thalamus, and hippocampus (arrow). (b) Contrasting with (a), the brain of a similarly injured mouse implanted with an NSC–PGA complex (PGA + NSCs), generated in vitro as described in (a), into the infarction cavity seven days after the induction of HI (arrow; $n = 60$). At maturity (age-matched to the animal pictured in (a)), the NSC–scaffold complex appears, in this whole mount, to have filled the cavity (arrow) and become incorporated into the infarcted cerebrum. (c, d) Higher magnification of representative coronal sections through that region, in which parenchyma appears to have filled in spaces between the dissolving black polymer fibers (white arrow in (c)) and even to support neovascularization by host tissues, as seen in (d). A blood vessel is indicated by the closed black arrow in (d); open arrow in (d) points to degrading black polymer fiber. The neural composition of that parenchyma is examined by immunocytochemistry in **Figures 4** and **5**; degrees of monocyte invasion and glial scarring are examined in Fig. 6. Scale bars: (c, d) 100 μm. Reproduced from Park KI, Teng YD, Snyder EY (2002) The injured brain interacts reciprocally with neural stem cells supported by scaffolds to reconstitute lost tissue. *Nature Biotechnology* 20: 1111–1117.

as a readily available source of stem cells in HD. Although few neurons have been formed from mesenchyme-derived stem cell grafts, transplantation of these grafts has elicited some behavioral recovery.

The differentiation of stem cells or treatment with growth factors in vitro prior to transplantation may facilitate fate determination while decreasing the risk of tumor formation posed by stem cells. One such protocol in which mouse embryonic cells directed toward a GABAergic fate retain their neuronal identity after transplantation into a rodent lesion model of HD has proved successful. Therefore, stem cell therapy for HD has the potential to alleviate cognitive and motor deficits in degenerative disease through the replacement of degenerating cells and the restoration or preservation of proper network function.

Endogenous Stem Cell Recruitment for CNS Repair

The alternative or compliment to stem cell transplantation would be the manipulation of endogenous stem cells for therapeutic purposes. The advantages would include using the patient's own cells, not needing an invasive procedure, and obviating the concern over the immunogenicity of transplanted cells. It appears that adult neurogenesis is restricted to the olfactory bulb and dentate gyrus of the hippocampus, yet it is possible that some NSCs exist along the entire adult neuraxis.

Exploiting endogenous NSCs would require successful coordination of cell proliferation, differentiation, migration, and integration, and it does appear that some

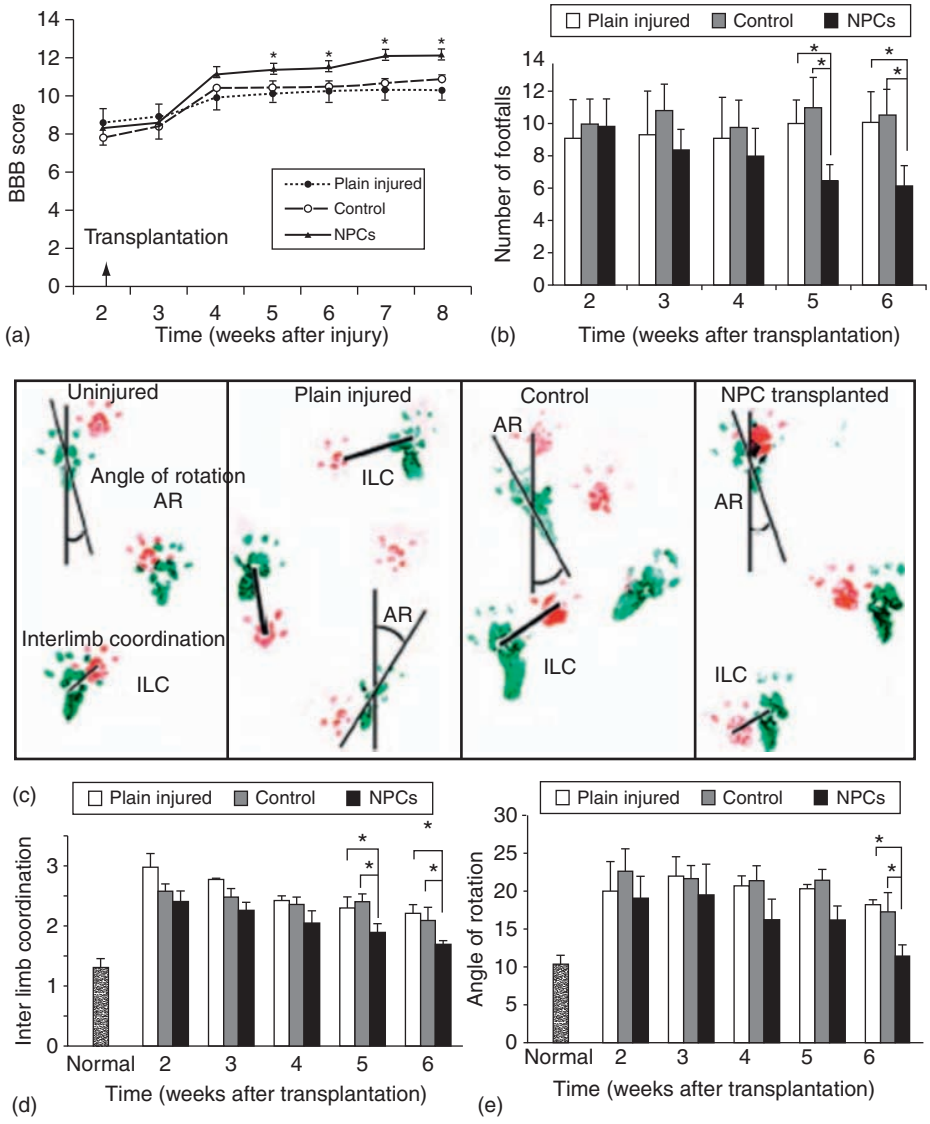

Figure 3 Subacute transplantation of YFP-NPCs resulted in a significant locomotor recovery compared with injured rats in the control group. (a) BBS rating scale showed a significant improvement in the locomotor BBS score in transplanted rats at 3 weeks after transplantation compared with the plain injured and control groups ($n = 5$ for plain injured group and $n = 8$ for other groups). (b) Using grid-walk analysis, transplanted rats also showed fewer errors in hindlimb placements at 5 and 6 weeks after transplantation compared with the plain injured and control groups ($n = 5$ for plain injured group and $n = 8$ for other groups). (c) Representative footprints of normal, plain injured, control, and grafted rats ($n = 5$ for plain injured group and $n = 8$ for other groups) shows improvement in interlimb coordination as well as angle of rotation in the transplanted group compared with the plain injured and control groups. (d, e) Footprint analysis revealed that transplantation with adult NPCs significantly improved interlimb coordination and reduced the hindlimb angle of rotation at 5 and 6 weeks after transplantation. The data show the mean ± SM. $^*p < 0.05$. Reproduced from Karimi-Abdolrezaee S, Eftekharpour E, Wang J, et al. (2006) Delayed transplantation of adult neural precursor cells promotes remyelination and functional neurological recovery after spinal cord injury. *Journal of Neuroscience* 26: 3377–3389.

instructive signals remain in the adult CNS. However, most CNS regions are not permissive for neurogenesis under normal in vivo conditions, yet some studies suggest that endogenous NSCs are primed to respond to environmental signals that exist primarily during pathological states. Accordingly, one approach to accentuate endogenous stem cell proliferation is with the administration of growth factors. Intraventricular infusion of transforming growth factor α (TGF-α) into rodents with lesions of the substantia nigra dopaminergic neurons has led to functional improvements, putatively through recruitment of endogenous stem cells. Other likely bioactive molecules with potential to evoke a proliferative response, in regions of the brain with multipotent cells, are neurotrophins. Physiologically, neurotrophins are involved in cell cycle regulation, cell survival, and differentiation and are

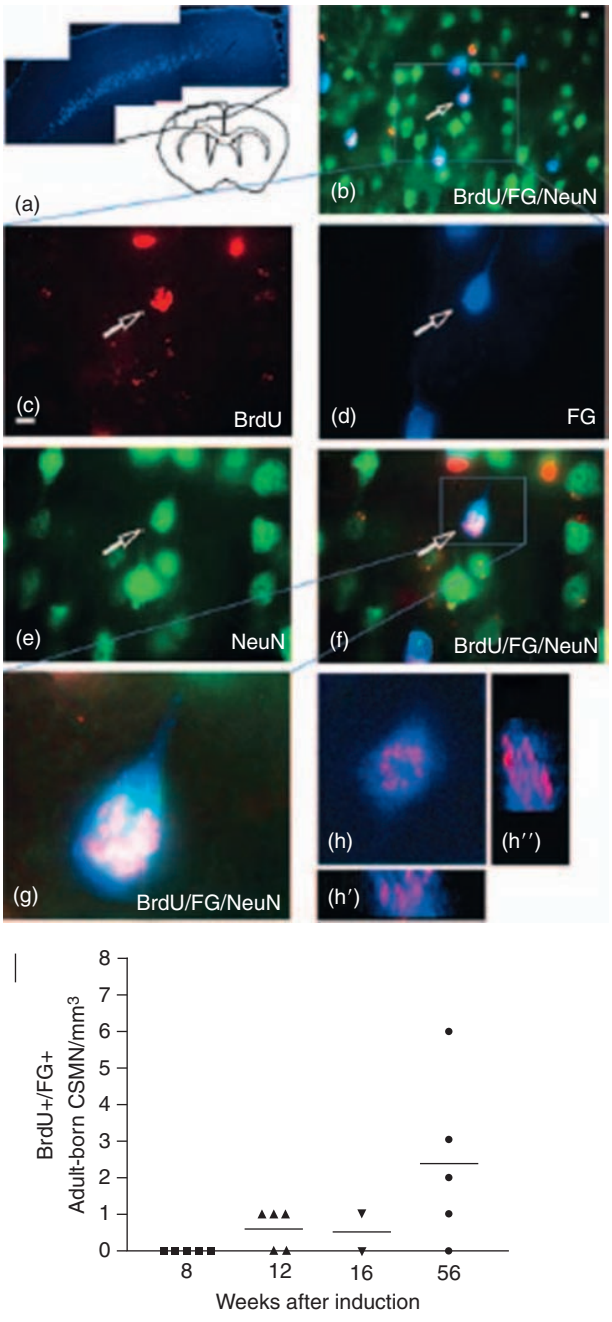

Figure 4 A subset of newborn layer V cortical neurons extends axons to the cervical spinal cord. (a) Both newborn and original layer V CSMN were retrogradely labeled by FG (blue). (b) Field expanded in C–F showing a BrdUrd+/NeuN+/FG+ triple-labeled adult-born neuron (arrow). (Bar, 10 μm.) (c–e) Individual images show that this BrdUrd+ nucleus (c, red) is located within this neuron, which is retrogradely labeled with FG from the cervical spinal cord (d, blue) and express NeuN (e, green). (Bar, 10 μm.) (f) Overlay showing BrdUrd+/FG_/NeuN+ neuron colocalization. (g) Higher-magnification overly of the same neuron from (c) to (f). (h) A separate example of an adult-born neuron with a projection to the spinal cord. Laser-scanning confocal images were combined to produce 3D reconstructions of newborn neurons. Viewing a BrdUrd+/FG+ newborn beuron along its *x*(*H*′), *y*(*H*′′), and *z* axes (*H*) unequivocally demonstrates the colocalization of BrdUrd and FG. (i) Quantification of BrdUrd+/FG+ adult-born CSMN extending spinal projections from 12 to 56 weeks after induction of original CSMN apotosis. Each point indicates the number of adult-bron BrdUrd+/FG+ neurons per mm^3 in an individual animal; each bar indicates the mean. Reproduced from Chen J, Magavi SS, Macklis JD, et al. (2004) Neurogenesis of corticospinal motor neurons extending spinal projection in adult mice. *PNAS* 46: 16357–16362.

critical during normal development. Growth factor infusion can also promote proliferation of SVZ-derived progenitor cells that gave rise to hippocampal CA1 pyramidal neurons in rodent stroke models, with improvements in spatial orientation. Whether the neurogenic response creates neurons with long-term viability remains to be shown. Another candidate with efficacy in stroke models is erythropoietin (EPO), which has been shown to induce neurogenesis and functional improvement in rats. Furthermore, endogenous neural precursors can differentiate into new neurons that extend long-distance projections to the spinal cord, in the adult rodent. Targeted apoptosis of corticospinal motor neurons was induced and it was demonstrated that adult-born corticospinal motor neurons were generated extending from the motor cortex to the spinal cord (**Figure 4**).

The horizon for neural repair includes continued investigation into whether the diseased CNS can be treated with growth and differentiation factors to induce neural repair. As more is learned about the molecular signals and environmental cues, endogenous stem cells may prove to be a compliment or even replacement to transplantation of exogenous stem cells.

Other Stem Cells

The use of embryonic or somatic stem cells for brain repair is currently in the focus of rigorous scientific investigation. Other stem cells have also been suggested as sources for cell therapy. For instance, some groups have found that mesenchymal stem cells (MSCs) can differentiate into astrocytes and neurons *in vitro* and *in vivo*, and may have the advantage over ESCs or NSCs of being a highly accessible source for the patient's own stem cells. However, there is ongoing controversy about the plasticity and developmental potential of MSCs. Some groups suggested that the findings made with MSCs may be cell culture artifacts rather than being true differentiation into unexpected cell types. Therefore, it is crucial to assay the differentiation of any stem cell into a particular cell type by combining morphological, immunophenotypic, and functional criteria. Currently, MSCs do not appear as a realistic alternative to the use of ESCs or NSCs for neural repair.

Conclusion

Stem cell biology represents a strong foundation for neural repair. So far, gained experimental evidence suggests that this technology may be applicable to treat patients in the future. Since hESCs can be multiplied indefinitely and have the potential to give rise to a variety of functional human cells, it is conceivable to believe that stem cells will play an important role in disease modeling and drug testing. Moreover, since stem cells mimic aspects of normal development, these cells may be used to study early steps of human development that would not be accessible to experimentation otherwise.

We have highlighted current problems in the rapidly progressing stem cell field which involve safety issues, standardization of the protocols used, development of rigorous assays for characterization, and accumulation of experimental data in primate models of human disease. Realistic candidate diseases and patients that may benefit from stem cell therapy need to be defined before any clinical application. Since clinicians and stem cell biologists share a strong common interest to understand and treat human disease, stem cells have the true potential to transform modern medicine.

Stepping (Forelimb Akinesia) Test

T Schallert, University of Texas at Austin, Austin, TX, USA

Glossary

Adjusting step – A catch-up step by the legs to maintain center of gravity and stable balance in response to being pushed over-ground. This movement is impaired in animal models of Parkinson's disease.

Akinesia – A loss or severe reduction in the ability to self-initiate walking movements.

Bracing – A leg-skid reaction to being pushed over-ground that reflects impaired capacity to make catch-up steps, but helps to maintain stable equilibrium and center of gravity when the legs cannot step adequately.
Catalepsy – Loss of spontaneous movement characterized by muscle tension in the flexor and extensor muscles without loss of the capacity to engage in bracing reactions or labyrinthine righting reactions to maintain static stable balance.
Catch-up step – A leg step to adjust to an imposed shift of weight. The step helps to maintain center of gravity and stable balance in response to being pushed over-ground. This motor response is impaired in animal models of Parkinson's disease.
Dopamine – A neurotransmitter that is progressively lost in the brains of patients with Parkinson's disease.
Parkinson's disease – A neurological disorder characterized by a progressive loss of dopamine cells in the substantia nigra of the midbrain, and by severe motor symptoms that include difficulty in initiating stepping and related movements for walking.

Introduction

Progressive degeneration of dopamine (DA) neurons in the substantia nigra, in Parkinson's disease, leads to impaired capacity to initiate movement (akinesia). Patients with this disorder often freeze when trying to walk. They also do not respond quickly enough and effectively when pushed off balance, and must be caught by the examiner to prevent falling. These parkinsonian symptoms also appear in patients with schizophrenia who have been treated with high doses of traditional antipsychotic agents that block the DA synaptic transmission. To explore brain events associated with akinesia and postural instability, and to develop new treatments, it is imperative to be able to model these motor symptoms in animal models. Parkinsonian signs can be observed and quantified in rats that have been given a neurotoxin that kills DA cells or DA antagonist drugs.

Rat Tests to Assess Stepping Deficits

The effects of severe bilateral loss of DA neurons or drugs that completely interfere with DA synaptic transmission in rats are marked. Spontaneous movement is lost. The animal cannot initiate stepping, and when pushed forward or sideways on a smooth surface, it will brace against the movement or will drag its limbs. If the rat's hindlegs are lifted off the ground, it is unable to initiate stepping with the forelegs. In contrast, normal rats can walk on their forelegs without any problem, and respond to being pushed in this wheelbarrow-like fashion with excellent reactive stepping, each step precisely adjusted in size to maintain center of gravity.

If the DA deficiency is limited to one hemisphere, stepping can be assessed in each foreleg independently by lifting not only the hindlegs but also each foreleg, one at a time. In this case, the animal can self-initiate walking when the weight is supported by the ipsilateral foreleg, but not when its weight is supported only by the foreleg contralateral to the DA deficiency. When pushed by the experimenter on a smooth surface, the contralateral foreleg may brace or drag instead of making adjusting (catch-up) steps to maintain center of gravity. The number of catch-up steps made over a set distance is reduced as a result.

This test may be comparable to the push–pull exam used to observe postural instability in Parkinson patients, who fail to step adequately or quickly enough to maintain center of gravity. In rats, if the surface is sticky (e.g., sandpaper), and the animal's center of gravity is slowly relocated by the experimenter, the contralateral limb does not drag or brace, but instead will lag behind substantially and make an adjusting step only when the extent of the imposed weight shift is abnormally large. That is, the distance (step size) covered by the contralateral foreleg during the weight shift will be longer than normal in this case. This effect may be analogous to the patient with Parkinson's disease who does not respond adequately to being pushed or pulled by force, and must be caught by the examiner to prevent falling.

The anti-Parkinson drug levodopa can partially reverse stepping deficits in rats if the DA depletion is not complete, but the occurrence of dyskinesia makes assessment difficult. However, if levodopa is combined with an anticholinergic drug, both self-initiated and experimenter-imposed stepping reactions are improved markedly.

Summary and Conclusion

Normal rats can walk on their forelegs when their hindlimbs are lifted off the ground. Rats with neurotoxin-induced bilateral DA deficiency cannot walk. When pushed forward or laterally they drag their forelegs. If the DA deficiency is unilateral, each foreleg can be evaluated independently by lifting both hindlegs plus one of the forelegs. When the contralateral (impaired) foreleg bears the weight, it cannot initiate stepping or react appropriately to an imposed shift of weight with a normal size catch-up step to maintain center of gravity. These unilateral deficits can be quantified easily in rats, and contribute to the reduced use of the impaired foreleg and increased use of the nonimpaired foreleg, during spontaneous vertical–lateral exploration of the walls of a cylindrical enclosure, proportional to the extent of DA cell loss.

Stereology

D A Peterson, Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA

Glossary

Density ratio – When the value obtained is related to the ROI, it is said to be a density ratio (number per unit area, etc.). By definition, this is a fraction and the result could be due to changes in either (or both) the numerator or denominator. Failure to recognize this can lead to the investigator falling into the ''Reference Trap'' where an erroneous conclusion is made about which parameter changed. This can be avoided by determining total values instead of relying on density ratios.

Probe – A probe is a sampling device (line, circle, box, etc.) that interacts with the tissue being examined to generate a numerical value. This is not the physical insertion of this device into the tissue but the projection of tissue being sampled upon the probe (accomplished by a computer overlay on the microscope image). For counting cells, the optical disector probe places a two-dimensional counting frame upon the microscopic image to sample cells as they are encountered while the probe moves through the tissue.

Region of interest – The a priori definition of what is to be sampled, also abbreviated ROI. When this is not readily defined by natural boundaries, it should be clearly defined by whatever reliable anatomical references exist to ensure reproducibility of the data.

Systematic random sampling – To be statistically valid, cells should be counted at random. However, to make random sampling more efficient, systematic random sampling (SRS) randomizes the initial start site, and then subsequently moves the sampling field at a systematic defined distance through the tissue. This type of sampling is most powerful when applied in a nested sampling scheme, also known as a fractionated sampling scheme, where all levels of specimen examination (sectioning, staining, placement under the microscope, and focus depth) are initially randomized.

Definition and History

Stereology is the process of sampling and counting material using specific protocols to obtain an estimate of a quantitative parameter, such as number, length, volume, etc. Obtaining accurate estimates is a critical component of producing a study outcome with statistical validity. By using appropriate sampling procedures and applying counting or measuring protocols (known as probes), stereology makes it possible to avoid potential artifacts and errors that could significantly skew results. When appropriately applied, stereology can allow for reliable detection of differences only slightly greater than interanimal variation, that is, on the order of 15–20% differences between mean values. As changes of physiologically relevant ranges within tissue are often far below a fold difference, stereology provides a powerful analytical tool for in vivo histological studies. Stereology can often be applied to in vitro studies to improve sampling validity for quantitative parameters. The concepts related to stereological sampling have their roots in the mathematics of geometric probability that extend back to the Golden Age of Greece. While it has been applied to physical sciences and geology since the nineteenth century, the use of stereology in the biological sciences only began in the last half of the twentieth century. A major advance came in the mid-1980s when a number of papers established that it was possible to design conceptual probes to independently sample tissue, rather than relying upon geometric models of tissue structures themselves. This new design-based stereology has almost completely replaced the use of the older geometric model-based stereology in most biological research applications.

For studies of movement disorders, stereology can readily be applied to document pathological changes or loss of cells or innervation in experimental injury models. Careful quantitative outcomes from these studies can provide far more information than qualitative or semi-quantitative descriptions alone. Furthermore, they can be used in conjunction with quantitative values obtained from protein, molecular, or behavioral studies to explore relationships and potential correlations. Stereology is especially important for intervention studies where it becomes necessary to evaluate if the experimental manipulation can produce improvement in cell survival or outgrowth beyond the extent of spontaneous recovery. The quantitative resolution that stereology provides may permit conclusions to be drawn from such studies. As a result of the required comprehensive sampling necessary for a stereological study, the outcome measures can be known to apply to the entire structure with assurance. For example, the traditional approach of examining only sections through the middle of the substantia nigra for comparison has, at its core basis, validity only for the middle of that nucleus. If there were organizational or parametric changes that displaced or altered nuclear arrangement, these may bias the assumption that the centers were equivalent samples. All of these considerations are avoided by stereological sampling where sections through the entire structure provide the basis for the quantitative estimate. For cases where only a subset of the structure is the focus of study, such as the dorsolateral quadrant of the striatum for example, the region of interest can be defined to include just that region, provided sufficient objective landmarks can be used to make such a definition.

Modern design-based stereology has as its foundation the principle that any object within the tissue should have an equal probability of being counted. This is in contrast to the traditional histological studies that simply counted cells observed in the microscope field without allowance for the spatial organization of these cells with respect to the histological section in which they were embedded. Cells and fibers in tissue are distributed in three-dimensional space and any given section through the tissue will capture only parts of the cell. This reality can produce a number of artifacts, for which it is difficult to calculate a correction. Rather than attempting to correct for these problems, design-based stereology uses a probe that is designed (hence the name) to approach the object so that it will be encountered for measuring with equal probability in three-dimensions. These probes are not physical items inserted into the tissue, but rather frames that are superimposed upon the histological image. With the use of computer imaging, these can be seamlessly blended with the microscopic image for counting. In the case of counting cells, the optical disector probe places a box of known size within the tissue and cells are counted according to how they interact with this box. The optical disector probe avoids the problem of sampling large cells with higher probability, as would be the case if cells are counted in a single focal plane. For measuring length, it is possible to generate a sphere of known size and count the intersections of fibers with the sphere, a probe commonly known as 'spaceballs.'

While the probes themselves are powerful tools for avoiding the artifacts created by generating a tissue section, the nested sampling design in which they are applied to the tissue prevents the investigator from being led astray by changes in tissue parameters. The classical approach to evaluating changes in, for example, cell number was to express the results as a number per field or area or section. Of course, all of these are density ratios, meaning that the comparison between conditions is valid only if the parameter to which the number is related (field, area, section, etc.) does not differ between groups. However, pathological or experimental changes can often produce overall changes in tissue volume and the use of density measurements can produce erroneous conclusions, a problem known as the reference trap. Thus, stereological probes must be applied to tissue with appropriate systematic random sampling so that the entire

structure being examined is thoroughly sampled with statistical validity. The most efficient sampling design is a nested one where the fraction of sampling density is used to calculate the estimate of the total parameter. Such designs are known as fractionated sampling (i.e., a known fraction, such as 1/50th, of the structure was sampled) and they are named together with the probes they use (i.e., optical fractionator). Fractionated sampling schemes are not sensitive to volume changes and are thus the approach of choice for generating accurate estimates.

The statistical validity of the study is dependent upon the robustness of the estimate for each individual in the study. To ensure that each estimate was produced with sufficient rigor, it is necessary to assess the variance due to sampling for each individual in the study. Simply stated, this is a question of how much does one need to count to get a good estimate. The measure of this is assessed by calculating the coefficient of error (CE). The sampling density should be sufficient to produce a low CE value, in general, below 15% (0.15). If the value is too high, then the sampling should be redone at a higher density (more sections and/or more sites per section). However, it must be kept in mind that the CE is also a reflection of the heterogeneity of cell distribution and clustering, and that, with some tissue, it may not be possible to obtain such a low value, no matter how dense the sampling is.

While stereology is a powerful tool, there are some common pitfalls that the user must consider and potential artifacts that must be recognized. The following points are recommended as best practices for using stereology:

1. The entire structure to be quantified must be included in the available sections. If only a portion of the structure is sampled, the estimate produced is only relevant to that portion and any assumption that the data can be extrapolated to the entire structure will require validation.
2. As any portion of the section must be available for sampling, the specimen preparation must be uniformly suitable. Too many sample sites that are unavailable for counting due to preparation artifacts will erode the robustness of the estimator.
3. Most probes in design-based stereology rely on three-dimensional sampling through the tissue. Therefore, tissue section thickness must be thick enough (typically $>20\ \mu m$) to be useful.
4. It is necessary to validate that staining extends throughout the depth of the tissue section. The presence of a region in the section center devoid of staining will lead to an underestimation of an unknown extent.
5. The structure to be sampled (the region of interest) must be objectively designated as much as possible. Some structures have clear boundaries (e.g., the edge of the corpus callosum), however, many internal CNS structures blend into adjacent structures at their margins. Establishing a clear definition of structure margins (likely based upon cytoarchitecture) will assure reproducibility between investigators. Fortunately, fractionated sampling, such as obtained by using the optical fractionator procedure, does not require a firm bounding edge for estimation (as no area–volume calculations are needed), so this sampling is ideal for structures such as the substantia nigra.
6. Once a sampling scheme is decided upon, evaluate the coefficient of error (CE) values for each individual in the study. If the tissue is homogeneous, it should be possible to reduce this below 15% (0.15). If too high, increase sampling density to produce a reliable estimate. Ideally, this should be worked out early in the study to determine the optimal sampling. Each group in the study (i.e., experimental group versus control group) can be independently adjusted for optimal sampling. However, all individuals within a group should be sampled with the same scheme.

Stiff Person Syndrome and Variants

M R Baker, University of Newcastle upon Tyne, Newcastle upon Tyne, UK

Glossary

Central motor conduction time (CMCT) – The CMCT is a measure of corticospinal tract function, normally assessed by stimulating the motor cortex transcranially using a magnetic stimulator, which produces a motor cortical evoked potential (MEP) in contralateral muscle. The CMCT is estimated by subtracting the peripheral motor conduction time from the MEP latency.

Continuous motor unit activity (CMUA) – Involuntary sustained EMG activity distinguishable from other forms of repetitive EMG discharge and diagnostic of SPS.

Glutamic acid decarboxylase (GAD) – Enzyme and rate-limiting step in the synthesis of GABA.

GAD65 – The synaptic vesicle associated 65 kDa isoform of GAD.

H-reflex (or Hoffmann reflex) – A muscle reflex generated by the electrical stimulation of muscle afferent nerves (Ia fibers) analogous to the mechanically induced spinal stretch reflex.

Intracortical facilitation (ICF) – Paired pulse paradigm using transcranial magnetic stimulation (TMS), with an interstimulus interval of 6–15 ms, to test motor cortical excitability.

Long interval intracortical inhibition (LICI) – Paired pulse paradigm using TMS, with an interstimulus interval of 50–200 ms, to test cortical excitability.

Progressive encephalopathy with rigidity and myoclonus (PERM) – Variant of stiff-person syndrome.

Short interval intracortical inhibition (SICI) – Paired pulse paradigm using TMS, with an interstimulus interval of 2–5 ms, to test motor cortical excitability.

Stiff-limb syndrome (SLS) – Variant of stiff-person syndrome.

Witebsky postulates – A series of criteria originally developed by the German–American immunologist Ernst Witebsky to determine whether a condition could be considered autoimmune. These postulates require that

1. an autoimmune reaction is identified either by the presence of auto-antibodies or a cell-mediated immune response (typically by transfer of pathogenic antibody or pathogenic T cells into experimental animals);
2. the corresponding auto-antigen is known; and that
3. an analogous response causes a similar disease in experimental animals.

There should also be circumstantial clinical evidence to support a diagnosis of autoimmune disease (e.g., response to immunotherapy).

Definition and History

Stiff-person syndrome (SPS) was first described in 1956 by Moersch and Woltman, who reported a series of 14 patients (10 male and 4 female) collected over 32 years with fluctuating rigidity, spasms, and gait disturbance, but without evidence of extrapyramidal or pyramidal disease. Their first case was a 49-year-old man who farmed in Iowa and first presented to the Mayo Clinic in 1924, and consequently, the original report described the condition as 'stiff-man syndrome.' With increasing recognition of the syndrome, it has become apparent that the sexes can be affected equally, and therefore, the condition is now generally referred to either as SPS or Moersch–Woltman syndrome.

SPS is a rare, insidiously progressive autoimmune disease of the central nervous system, characterized by axial and appendicular rigidity, with superimposed stimulus-sensitive spasms. Antiglutamic acid decarboxylase (anti-GAD) antibodies, and more particularly, antibodies to the GAD65 isoform are present in serum or cerebrospinal fluid (CSF) of 60–80% of patients with SPS. Paraneoplastic SPS accounts for about 5% of cases and can be associated with antiamphiphysin antibodies (thymoma, bronchogenic adenocarcinoma, and breast carcinoma), anti-Ri (ANNA-2) antibodies (bronchogenic adenocarcinoma), and antigephyrin antibodies (undifferentiated mediastinal carcinoma), in addition to anti-GAD antibodies (breast carcinoma, multiple myeloma, thymoma, and renal cell carcinoma). However, paraneoplastic antibodies are not always detected. Postinfectious SPS and drug-induced SPS have also been described. The latter has only been reported with oral retinoids (e.g., isoretinoin, etretinate) and resolves following treatment cessation.

Prototypic SPS is considered to be part of a spectrum of related disorders, including stiff-limb syndrome (SLS), Jerking SPS, and progressive encephalomyelitis with rigidity and myoclonus (PERM), that share clinical, laboratory, electrodiagnostic, and histopathological features.

Some patients can present initially with SLS and progress over a period of years to classical SPS and PERM.

The annual incidence of SPS and its variants is about one per million in the European population. There is no consensus in the literature as to the distribution of SPS between the sexes; in some series, it appears to affect males more than females (~2:1), whereas in other series the reverse is true (~1:3). Typically, the condition first presents in the fourth to sixth decade.

Clinical Features and Diagnostic Criteria

The core features of classical SPS are stiffness and rigidity, in axial and proximal limb muscles, with superimposed stimulus-sensitive axial and appendicular spasms, but without evidence of brainstem, pyramidal, extrapyramidal or lower motor neurone signs, sphincter disturbance, sensory disturbance, or cognitive impairment (for diagnostic criteria see **Box 1**). Spasms can be provoked by stimuli, including voluntary movement, emotional triggers, and unexpected somaesthetic or auditory stimuli; are associated with intense pain; and can sometimes persist for days (*status spasticus*). Spasms can affect facial muscles and larynx causing stridor, and occasionally can be so severe in the limbs that they cause fractures. Continuous muscle contractions can cause board-like rigidity in the abdominal muscles, and cocontraction of abdominal and paraspinal muscles results in an abnormal axial posture, typically lumbar hyperlordosis. The gait is usually deliberate and slow and examination often reveals an exaggerated startle and head retraction (or glabellar) reflex, which fails to habituate. Paroxysmal dysautonomia, in the form of hyperpyrexia, diaphoresis, tachypnoea, tachycardia, pupil abnormalities, and arterial hypertension, can also occur.

Ocular abnormalities, including autoimmune retinopathy and scleritis, have been described in SPS. Motility disorders, including horizontal diplopia and nystagmus, and vertical diplopia and downbeat nystagmus, have also been described, but only in ataxic SPS or coexistent myasthenia gravis.

SPS is often mistaken for a psychogenic disorder, and historically, before Moersch and Woltman original report, all cases were considered thus. However, it is also recognized that psychiatric disorders, including anxiety, depression, alcohol abuse, agoraphobia, paroxysmal fear, task-specific phobia (fear and avoidance of situations because of motor symptoms of SPS), and phobic anxiety without avoidance, are frequent amongst patients with SPS. The absence of premorbid or inherent psychiatric disease would suggest that such disorders develop in SPS either as a consequence of the condition (and delayed diagnosis or misdiagnosis) or as a manifestation of the condition.

Box 1 Diagnostic criteria

Core diagnostic criteria

A. Positives

Stiffness and rigidity in axial muscles
Abnormal axial posture (90% lumbar hyperlordosis)
Stimulus-sensitive spasms (stimuli include voluntary movement, emotional upset, unexpected somaesthetic or auditory stimuli, e.g., see **Figure 1**)
EMG evidence of CMUA in at least one axial muscle (see **Box 2** and **Figure 1**)

B. Negatives

Absent brainstem, pyramidal, extrapyramidal and lower motor neurone signs
No sphincter disturbance
No sensory disturbance
Absence of chronic pain syndrome
No cognitive impairment (except seizure-related)

Supplementary diagnostic criteria

Stiffness and rigidity in proximal limb muscles
Resolution of rigidity and stiffness with IV benzodiazepines
EMG evidence of abnormal exteroceptive reflexes (see **Box 3**)
Serum anti-GAD65 antibodies > 20 nmol l^{-1} (60-90% of classical SPS patients)
CSF protein >0.6 g l^{-1} and/or WBC>5 and/or OCBs (60% of classical SPS)
CSF anti-GAD antibodies
Non-habituating startle response
Non-habituating head retraction reflex (i.e., glabellar reflex)

Associated clinical features

Ocular signs (see text)
Paroxysmal dysautonomia (hyperpyrexia, diaphoresis, tachypnoea, tachycardia, pupillomotor, hypertension)
Paroxysmal fear

Box 2 Electrodiagnostic criteria

Diagnostic features	Notes
CMUA	In at least one axial muscle (see **Figure 1**)
Cutaneomuscular (exteroceptive) reflexes	Widespread, non-habituating, low threshold responses to stimulation of tibial nerve, with simultaneous co-contraction of antagonists
Additional features	
Nonhabituating acoustic startle reflex	EMG recorded from axial and leg muscles
Increased cortical excitability	Silent period reduced by 20% compared to controls, increased ICF, and reduced SICI and LICI
Spasmodic reflex (propriospinal) myoclonus	Sequence of 1–3 synchronous myoclonic EMG bursts in trunk muscles 60–70 ms after median nerve stimulation
Blink reflex	R2 EMG component of blink reflex does not suppress after conditioning stimulus, whereas in controls R2 component suppresses for up to 1 s
Head retraction reflex	Stimulation of trigeminal nerve produces 12.5–20 ms response and 44–70 ms response in trapezius, which does not habituate

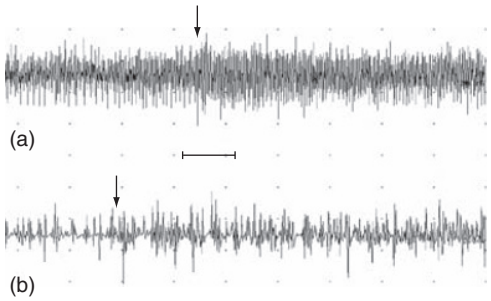

Figure 1 (a) Unrectified EMG recorded with a needle electrode from a lumbar paraspinal muscle in a patient with SPS showing continuous motor unit activity (CMUA) at rest. Recordings were made while the patient was lying prone and motionless on an examination couch. The arrow indicates the time at which an auditory stimulus was delivered. Note that the background firing frequency of the multiunit recording increases following the auditory stimulus and remains elevated (timebase is 20 s per division and amplitude is 2 mV per division). (b) The same recording as illustrated in (a) but displayed on an expanded timebase (10 s per division).

Pathophysiology

Impaired γ-amino butyric acid (GABA)ergic and glycinergic synaptic transmission is central to the pathophysiology of SPS. This functional impairment is thought be the result of reduced presynaptic transmitter synthesis, immunological destruction of inhibitory interneurones, or reduced postsynaptic receptor number. Both magnetic resonance spectroscopic studies and 11C-flumazenil positron emission tomography (PET) have shown either reduced GABA levels or reduced GABA binding (either representing receptor downregulation or neuronal attrition) in sensorimotor and limbic cortex of patients with SPS. Electrophysiological studies in SPS have shown that both GABAergic (vibration-induced inhibition of H-reflex) and glycinergic (early reciprocal inhibition and nonreciprocal (Ib) inhibition) inhibition is impaired within the spinal cord. However, in the same studies the GABAergic pathways mediating the presynaptic component of reciprocal inhibition, and recurrent (Renshaw) inhibition were normal, arguing against an indiscriminate autoimmune process involving only spinal inhibitory interneurones. One explanation for these findings is that stiffness and rigidity, much like spasticity, is determined by an imbalance in the strength of descending input, as a consequence of changes in the brainstem or intracortical inhibition.

Histological findings at postmortem have been variable. Initial reports failed to identify any abnormalities. However, more recent reports have described selective loss of GABAergic neurones within the cerebellum and the spinal cord, or a more aggressive inflammatory picture of perivascular lymphocytic infiltration and gliosis within spinal cord, brainstem, basal ganglia, and cerebral cortex. An autopsy in one patient, who presented initially with SPS but died several years later of PERM, showed both GABAergic neuronal attrition and evidence of perivascular lymphocytic infiltration and gliosis, suggesting perhaps that the spectrum of pathological findings is a reflection of the spectrum of disease severity and duration.

The evidence that SPS (and its variants) is an autoimmune disease, as defined by the Witebsky postulates, is manifold:

1. *Antibodies (including paraneoplastic antibodies) against a number of components of GABAergic and glycinergic synaptic function* (*see* **Figure 2**) *are found in the serum and CSF of 80–90% of patients with SPS.* Antibodies target the synthesis of GABA by anti-GAD65, trafficking of GABA receptors by GABARAP (GABA receptor associated protein), anchoring of GABA receptors by gephyrin and synaptic vesicle, and receptor recycling by amphiphysin.
2. *Only antibodies in CSF and serum from patients with SPS inhibit GABAergic function in vitro.* Electrophysiological studies have shown that CSF or serum anti-GAD65 antibodies from SPS (or ataxic) patients reversibly inhibit GABAergic transmission in rat cerebellar slices, whereas anti-GAD65 antibodies from patients with polyendocrine syndrome or type I diabetes mellitus do not.
3. *Serum antibodies from SPS patients can reproduce the clinical features of SPS in rats in vivo.* In rats, intraperitoneal injection of the purified IgG fraction of plasma from a patient with paraneoplastic SPS (breast carcinoma

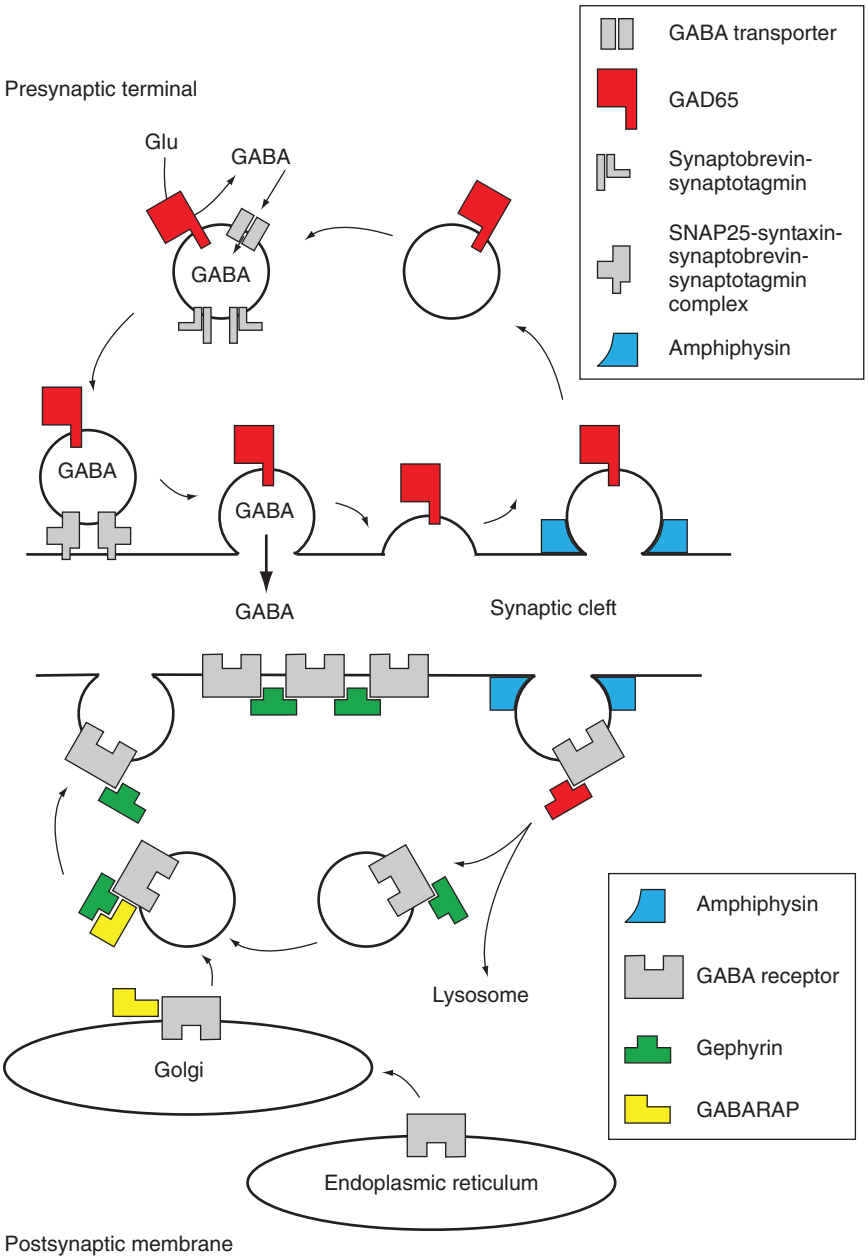

Figure 2 Auto-antibodies target cytosolic proteins in SPS. Most auto-antibodies in SPS target cytosolic proteins responsible for membrane trafficking at synapses and GABAergic synaptic function (except anti-Ri which targets an unidentified neuronal nuclear antigen). Protein targets are illustrated in colour in this simplified diagram of a GABAergic synapse, including presynaptic terminal, synaptic cleft, and postsynaptic membrane. GAD65 (glutamic acid decarboxylase) is the rate-limiting step in the synthesis of GABA from glutamate. Amphiphysin interacts with dynamin and cytoskeletal proteins during endocytosis to close-off the vesicle, and is therefore involved in synaptic vesicle formation and receptor recycling. Gephyrin anchors GABA (and glycine) receptors to the cytoskeleton, both for receptor trafficking and membrane stabilization. GABARAP (GABA receptor associated protein) binds to GABA receptors and is involved in receptor trafficking.

and antiamphiphysin antibodies) causes behavioral and electrophysiological changes consistent with SPS.

4. *Other antineuronal antibodies are found in SPS.* These include anti-ICA105 antibodies, anti-17β-hydroxysteroid dehydrogenase type 4 antibodies, and anti-Ri (ANNA2) antibodies in paraneoplastic SPS, which target a nuclear antigen within neurones.
5. *SPS is associated with other autoimmune diseases (and the presence of other tissue specific auto-antibodies).* For example, type I diabetes mellitus, Grave's disease, Hashimoto's thyroiditis, and pernicious anemia.
6. *SPS is associated with human lymphocyte antigen (HLA)-DQB1*0201 and HLA-DRB1*0301.*
7. *SPS responds to treatment with immuno-modulatory agents.*

The observation that GAD65 reactive CD4 positive T helper cells are present in SPS would also seem to support the hypothesis that SPS is a B-cell mediated disease. The molecular homology of peptide sequences from coxsackie virus, CMV, West Nile virus, and GAD65 might point to an environmental trigger for autoimmunity in SPS, and the description of postinfectious cases of SPS would appear to support this. However, disease severity in SPS is not correlated with anti-GAD titres, and although there is transmission of maternal anti-GAD antibodies to the fetus, unlike myasthenia gravis, neonates do not show evidence of SPS.

Whether anti-GAD65 antibodies (or any of the other SPS associated auto-antibodies described to date) directly cause SPS, are markers of autoimmunity, or are an epiphenomenon of neuro-degeneration, as seen in Batten disease (juvenile neuronal ceroid lipofuscinosis), is unclear. One well-rehearsed argument is that SPS autoantibodies must be an epiphenomenon, because they target intracellular proteins (see **Figure 2**), which are inaccessible to antibodies because of the barrier presented by the plasma membrane. GAD65, which is a synaptic vesicle associated protein, is a potential exception to this (see **Figure 3(a)**). However, only the membrane anchoring component is exposed during exocytosis, and not the enzymatic unit, which is largely cytosolic.

There is now increasing evidence that some antibodies can penetrate the cell membrane. Particularly polyreactive anti-DNA antibodies containing positively charged lysine and arginine-rich polypeptide sequences, as seen in systemic lupus erythematosus (SLE). These antibodies

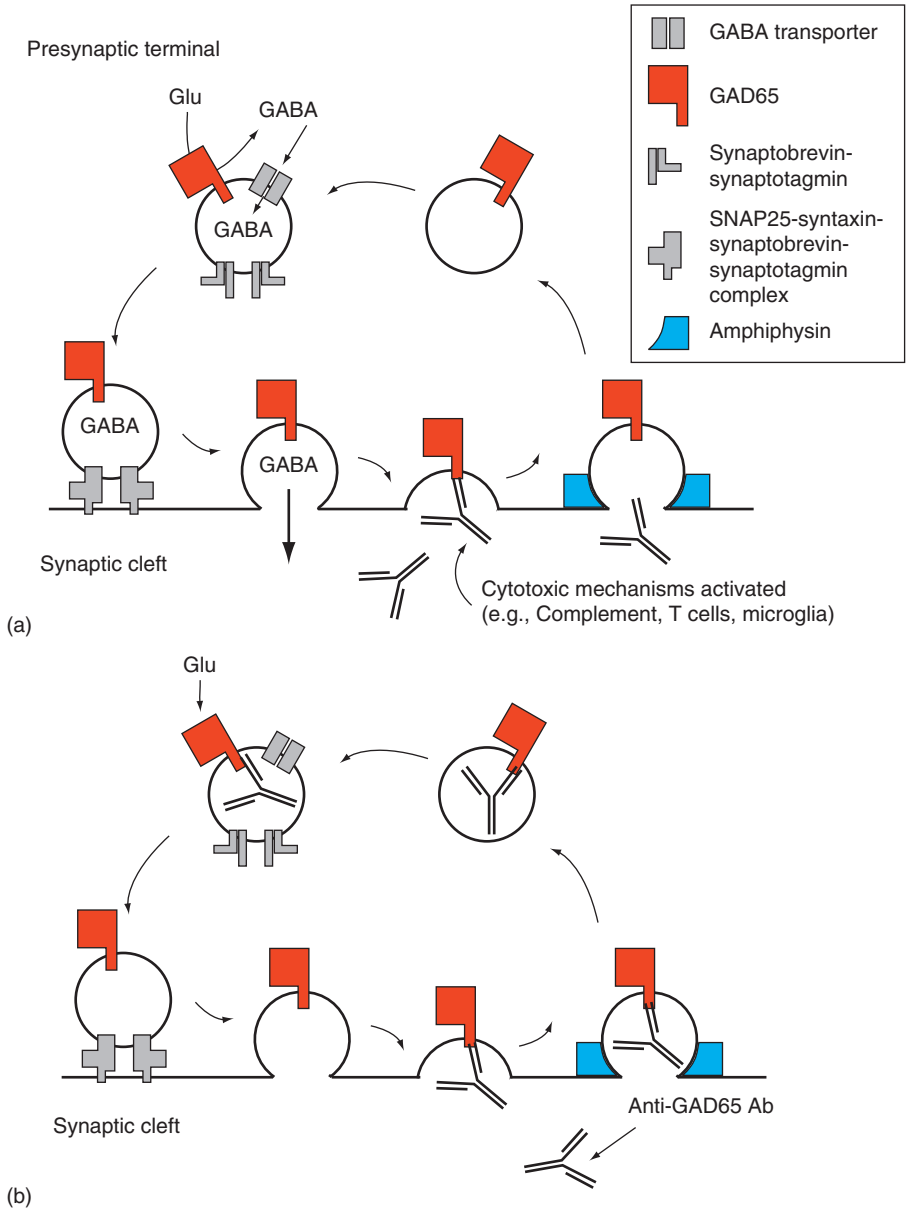

Figure 3 (Continued)

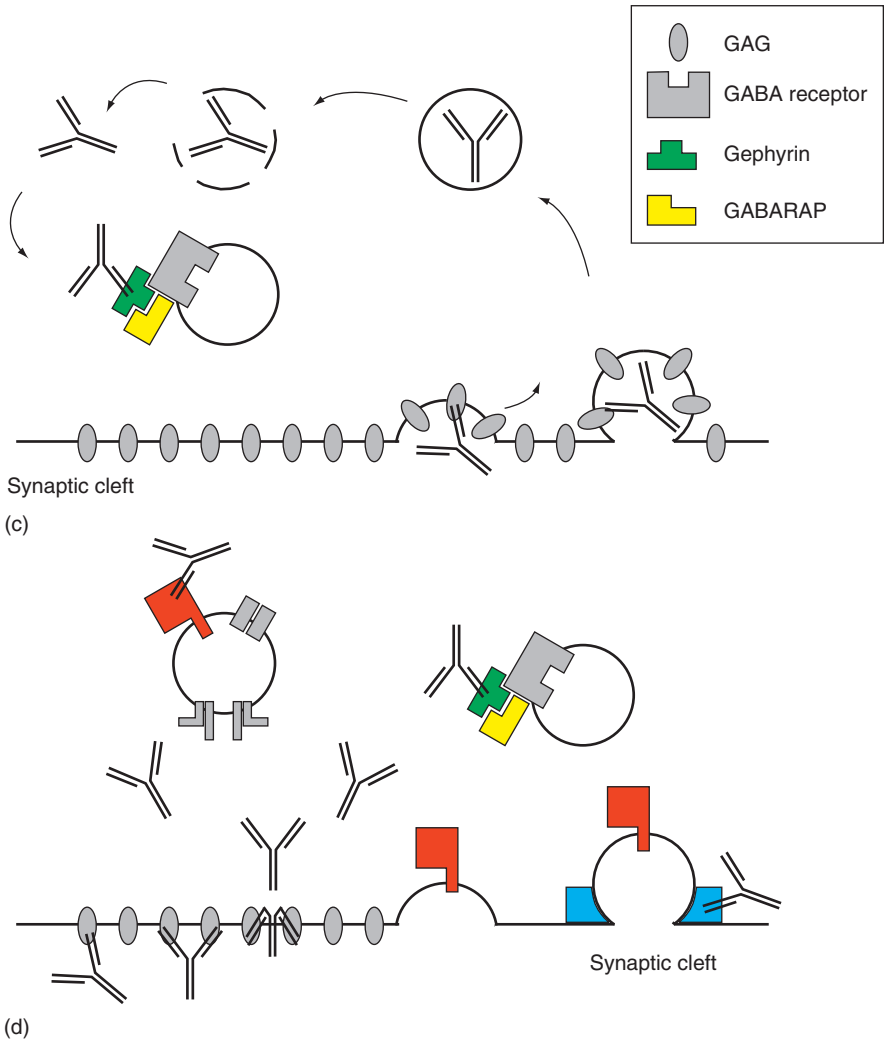

Figure 3 (a) Putative mechanisms by which auto-antibodies targeting cytosolic proteins inhibit GABAergic synaptic transmission in SPS. GAD65 is a vesicle associated protein. During exocytosis the membrane anchoring element is exposed to the extracellular milieu, presenting a potential target for antibody-mediated cytotoxic mechanisms. (b) Alternatively, antibody binds to GAD65 during exocytosis and is then incorporated into synaptic vesicles following endocytosis, where it inhibits GAD65 and prevents vesicle recycling. However, GAD65 antibodies bind to the enzymatic subunit, which is entirely cytosolic, and is not exposed during exocytosis. (c) SPS associated auto-antibodies bind to specific glycosaminoglycans (GAGs) and are endocytosed via energy-dependent mechanisms. The vesicle membrane is lysed by unknown mechanisms once the vesicle is intracellular (d). SPS associated auto-antibodies bind to specific glycosaminoglycans (GAGs), undergo conformational changes that result in amphiphatic alpha-helical structure that facilitates their insertion into the lipid bilayer and translocation into the cytosol.

bind strongly to specific glyosamino-glycans (GAGs) and enter the cell either by energy-dependent endocytotic mechanisms (**Figure 3(c)**), or by energy-independent conformational changes that result in amphiphatic alpha-helical structures that facilitate their insertion into the lipid bilayer (see **Figure 3(d)**).

Investigation

Box 3 contains a list of potential differential diagnoses of SPS and its variants, most of which can be excluded either by a thorough history and examination, or by routine laboratory or radiological investigations. If SPS is suspected, serum should be screened for anti-GAD antibodies (specifically anti-GAD65 antibodies), anti-GABARAP antibodies (if available), and paraneoplastic antibodies (anti-Ri, anti-amphiphysin, anti-gephyrin), and other tissue-specific auto-antibodies (e.g., antigastric parietal cell antibodies, antithyroid microsomal antibodies). Serum anti-GAD65 antibody titres are typically high (>20 nmol l^{-1}). Electromyography should demonstrate evidence of CMUA in at least one axial muscle (see **Figure 1**), with normal motor unit morphology (see **Figure 4**), which resolves with

Box 3 Differential diagnosis of axial and appendicular rigidity with continuous involuntary anterior horn cell activity and spasms

SPS (axial rigidity with CMUA ± spasms)
Trauma (Cervical spinal cord injury)
Cervical syringomyelia
Subacute necrotizing myelopathy
Inflammatory myelopathy (Atypical SPS)
Intrinsic spinal cord neoplasm (Cervical spinal cord astrocytoma)
Spinal cord infarction/ischaemia (Anterior spinal artery territory)
Acute/chronic/relapsing tetanus (Chronic toxin production in deep wounds)
Encephalomyelitis lethargica
Strychnine poisoning
Hyperekplexia (e.g., described in GLRA1 mutations)
Generalized dystonia (e.g., DYT1 causing stiff-child syndrome)

SLS/focal SPS (focal rigidity with CMUA ± spasms)
Neuroborreliosis
Acute poliomyelitis
Tetanus ascendans (See above)
Neuromyotonia/Isaac's syndrome (Easily differentiated on EMG)
Focal dystonia

Jerking SPS (rigidity + myoclonus)
MSAp
SCA-2

PERM (encephalopathy + rigidity + myoclonus)
Subacute sclerosing panencephalitis
Encephalitis lethargica
Drugs (e.g., neuroleptic malignant syndrome)
Serotonin syndrome
Opiate toxicity
Corticobasal degeneration
Creutzfeldt–Jakob disease
SCA3/Machado–Joseph disease (Single patient with 73 CAG repeats in the MJD gene)
Leigh syndrome

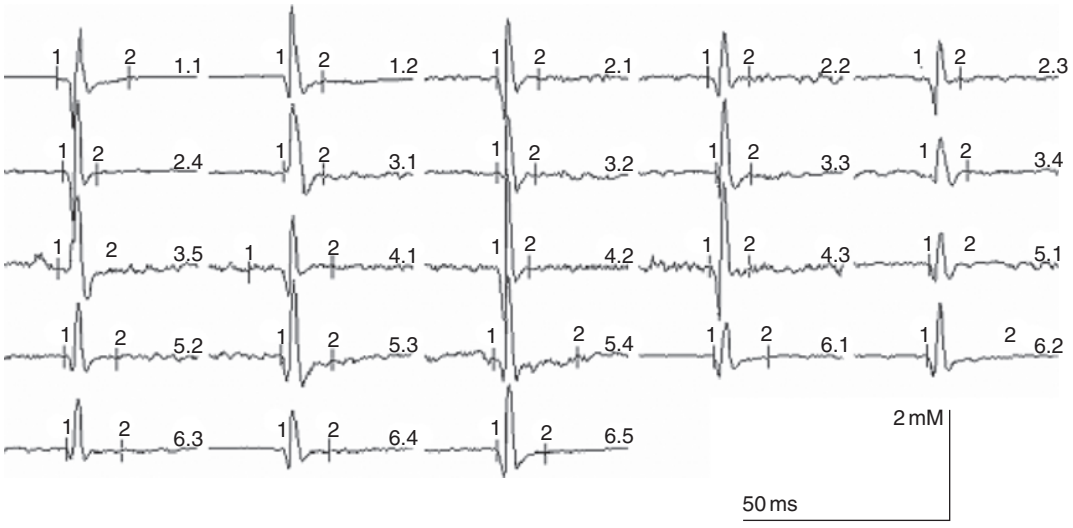

Figure 4 Averaged motor unit action potentials, generated using the Multimap™ program, from the recording illustrated in **Figure 1**. Note the normal duration, amplitude, and shape of the averaged motor unit potentials (Timebase 50 ms and amplitude 2 mV as indicated by horizontal and vertical bars).

intravenous benzodiazepines, and abnormal exteroceptive reflexes (see **Box 2**). CSF is abnormal in up to 60% of classical SPS (either protein $> 0.6\ g\ l^{-1}$ and/or WBC > 5 and/or oligoclonal bands (OCBs) and/or CSF anti-GAD antibodies). Magnetic resonance imaging of the neuraxis is normal in SPS.

If paraneoplastic antibodies or tumour markers are positive (or conversely if auto-antibodies, anti-GAD65 and paraneoplastic antibodies are all negative), further investigations should include CT chest, abdomen, and pelvis, mammography and PET, since treatment of an associated malignancy can either stabilize or reverse the features of SPS. In PERM, the risk of underlying malignancy is ~20%, and therefore, all patients should be screened, irrespective of the serology.

Management and Prognosis

Rigidity and spasms usually respond to GABA agonists such as benzodiazepines, baclofen, and tiagabine, and pain crises are usually managed with intravenous or subcutaneous opiates. Patients in whom rigidity and spasms are, or become, resistant to benzodiazepines can benefit from treatment with levetiracetam, intravenous propofol infusion, or intrathecal baclofen. Botox is a useful adjunct for treating severe rigidity as is muscle afferent block. Patients who continue to progress despite adequate symptomatic therapy, or who fail to respond symptomatically from the outset should be considered for disease-modifying therapy with immunomodulatory or immunosuppressive agents. Steroids, cyclophosphamide, and plasma exchange have all been used with varying success. However, the only disease-modifying therapy with prospective, randomized, controlled trial evidence is regular treatment with intravenous immunoglobulins. More recently, the specific B-cell depleting monoclonal antibody rituximab has been used successfully in a number of cases and is part of an ongoing trial in the USA.

Patients with prototypic SPS generally progress and then stabilize over a period of months to years. However, 10% will require prolonged admission to intensive care at some stage during the disease, and sudden death has been reported in as many as 10% of patients with prototypic SPS, typically because of unexplained metabolic acidosis or autonomic crises. The prognosis in SPS variants is more variable.

SPS Variants

Stiff-Leg (Limb) Syndrome (SLS) or Focal SPS

At least 30% of patients with SPS present initially with asymmetrical or unilateral rigidity and spasms in the arm or leg. However, there is a distinct entity first described as stiff-leg syndrome, but known either as SLS or focal SPS, in which stiffness and spasms are typically limited to the legs. Lumbar hyperlordosis is not a presenting feature, and progression to classical SPS is slow and only occurs in 75% of patients. Symptoms usually start in one leg before progressing to both legs after an interval of 6 months to 4 years, but in ~15% of cases SLS initially appears in the arm. Interestingly, unlike other variants of SPS, ~40% of patients have a preceding illness. Symptoms can resolve after 12 months, but typically persist for several years, and sometimes for as many as 20 years. In about 54% of patients with SLS, there is a relapsing-remitting course. Symptoms or signs of brainstem involvement, which are often transient, appear after 2 years in ~40% of patients. Sphincter involvement, including frequency, urgency, and urge incontinence, is present in 54% of patients after ~5 years. Unlike prototypic SPS with axial rigidity, the prognosis in terms of disability in SLS is poor, and about 50% of patients are wheelchair dependent after an average interval of 3.5 years.

SLS is twice as common in females and the age range at presentation is 18–71. Only three cases of paraneoplastic SLS has been described: in association with bronchogenic small cell carcinoma, breast carcinoma (and anti-GAD antibodies), and myeloma (and anti-GAD antibodies). Symptomatic therapy with diazepam and baclofen, while providing some relief from spasms, is ineffective at reducing stiffness and disability in ~75% of patients with SLS.

Alternative causes of focal stiffness and rigidity, with or without spasms (see **Box 3**), can easily be excluded by appropriate investigations. In SLS electrophysiological investigations are the most sensitive diagnostically and demonstrate core features of SPS (see **Box 2**). However, in 20% of patients, there is also evidence of denervation; in 75% there is an abnormal interference pattern on electromyogram (EMG) of the affected limb; and 13% have abnormal central motor conduction times (CMCTs). There is also asymptomatic evidence of CMUA in paraspinal and abdominal muscles in 30% of SLS patients. Of the 24 cases described in the literature, 11 (46%) had anti-GAD antibodies in CSF or serum, and 16 (70%) had auto-antibodies of some description. When the CSF is examined, in about 40% of SLS patients, there is a raised protein ($>0.6\ g\ l^{-1}$); in 10% there is pleocytosis (WBC $> 5\ \mu l^{-1}$); and in 20% there are unmatched oligoclonal bands. Histological examination of postmortem tissue from a single patient with paraneoplastic SLS was normal.

Jerking SPS

In the earliest descriptions of jerking SPS, patients had a protracted history of progressive appendicular and axial rigidity with spasms, identical to classical SPS,

before developing nocturnal myoclonus. The term 'jerking stiff-man syndrome' had not emerged until 1980, with the description by Leigh et al., and the condition is now generally referred to as jerking SPS. Patients initially present with the diagnostic features of SPS (see **Box 1**) and in the cases described there is progression over 2.5–14 years, with increasing appendicular and axial rigidity and spasms, before the onset of reflex reticular myoclonus. Although according to strict criteria there should only be clinical features of SPS and myoclonus, seizures, downbeat nystagmus, hyperreflexia, ankle clonus, and ataxia have been described in a minority of cases. Such features usually herald a more widespread encephalopathic process, involving cerebellum, brainstem, and cerebral cortex, akin to PERM.

In the patients from whom information is available, CSF parameters were normal (CSF was not tested for oligoclonal bands or anti-GAD antibodies), but postmortem histology confirmed clinical suspicions of a more widespread encephalopathic process. An autopsy in one patient, who died of chronic obstructive pulmonary disease, showed evidence of Purkinje cell loss within the cerebellum and neuronal loss within the lateral nuclei of the ventral horn of spinal cord, thalamus, and lateral *substantia nigra*. In a second patient, who died of central apnoea, there was widespread perivascular lymphocytic infiltration in the spinal cord, brainstem, thalamus, hippocampus, and amygdala, with a dense polyclonal mononuclear infiltrate within the ventral horm of the cervical and lumbar cord with preservation of axons and myelin.

Progressive Encephalomyelitis with Rigidity and Myoclonus (PERM)

PERM was first described by Campbell and Garland in 1956, as 'subacute myoclonic spinal neuronitis,' but the term progressive encephalomyelitis with rigidity was only introduced 20 years later with the description of two further patients, one of whom had myoclonus. PERM is typically a subacute or chronic polioencephalomyelitis predominantly involving spinal cord and brainstem, but occasionally including the limbic system and cerebral cortex. Patients display core features of SPS (see **Box 1**), but with brainstem myoclonus affecting all limbs. They also have evidence of more diffuse brainstem and cerebellar involvement (e.g., oculomotor abnormalities, nystagmus, vertigo, dysarthria, dysphagia, pathological startle response, ataxia, etc.), and in two-thirds of patients, there are upper motoneurone signs. Two-thirds of patients will also have evidence of autonomic disturbance, which is typically manifest during spasms as pyrexia and diaphoresis. In at least 10% of cases, there are clinical signs of a more diffuse cortical disturbance (e.g., cognitive impairment, seizures). As with SPS, psychological abnormalities are evident, including paroxysmal fear. Less commonly, there are signs of lower motoneurone disease and sphincter disturbance. Of the 49 cases reported in the literature to date, 60% were female, the age range at presentation was 13–81 years with a mean of 49 years, and the duration of disease ranged from 10 days to 8 years.

Serum anti-GAD antibodies are positive in 75% of patients with PERM and up to 90% of patients with PERM have CSF abnormalities (protein > 0.6 g dl^{-1}, pleocytosis, OCBs or CSF anti-GAD antibodies or CSF paraneoplastic antineuronal antibodies). Radiological investigations in PERM are usually normal. Electrophysiology shows the typical features of SPS (see **Box 2**). At autopsy there is histological evidence of widespread perivascular lymphocytic cuffing with neuronal loss and gliosis, particularly in the medial part of the ventral horn, Clarke's column, and brainstem, but also within areas of cerebral cortex and cerebellum.

The prognosis is generally poor with 25% of patients requiring prolonged intensive care treatment. PERM is the cause of death in as many as 40% of patients, and in 10% of patients with PERM, death is sudden, typically as a result of metabolic acidosis or dysautonomia. In 20% of patients with PERM, there is underlying malignancy and associated paraneoplastic antibodies (e.g., anti-Ri, antiamphiphysin, antigephyrin). Typically, paraneoplastic PERM has a poor response to treatment with both symptomatic and immunomodulatory agents, and there is gradual deterioration and death within 1–6 months. However, stabilization and recovery can occur if the underlying malignancy is identified and treated early. In a very small number of cases, PERM is preceded by a viral prodrome, and therefore presumably postinfectious. In such cases, there is spontaneous resolution of symptoms and signs within a month of initial presentation.

Ataxic SPS

Cerebellar ataxia is an almost universal feature of both jerking SPS and PERM, and has been reported in at least 11 patients with prototypic SPS. In ataxic SPS, signs of ataxia can precede, succeed, or present simultaneously with signs of SPS. The interval between ataxia and SPS can be months or years. When cerebellar ataxia associated with anti-GAD antibodies develops without features of SPS, it is known as cerebellar ataxia with polyendocrine autoimmunity (CAPA). Occasionally, ataxia can present with a 'stroke-like' onset.

Striatal Hand

R Katzenschlager, Department of Neurology, Donauspital/SMZ-Ost, Vienna, Austria

Glossary

Botulinum toxin – A biological toxin that is used therapeutically to decrease the release of acetylcholine from the neuromuscular junction. It can be useful in treating various forms of dystonia and is of particular use in treating striatal hand.
Parkinsonism – A descriptive term for neurological conditions characterized by different combinations of tremor, rigidity, bradykinesia (slowness), and gait/posture impairments. The prototype of parkinsonism is Parkinson's disease, but other conditions in this category include multiple system atrophy, corticobasal degeneration, and progressive supranuclear palsy.
Striatal hand – A specific postural and functional abnormality in the upper extremities of patients with basal ganglia disorders, in particular Parkinson's disease and neurodegenerative disorders predominated by parkinsonism or dystonia.

Definition and Clinical Features

The term striatal hand refers to specific postural and functional abnormalities in the upper extremities of patients with basal ganglia disorders, in particular Parkinson's disease (PD). Striatal hand also occurs in multiple system atrophy (MSA), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), neurodegeneration of the brain with iron accumulation, and dystonia-complex regional pain syndrome (D-CRPS). Striatal hand is usually characterized by a flexion of the metacarpophalangeal (MCP) joints, extension of the proximal interphalangeal joints, and often a milder degree of flexion at the distal interphalangeal joints. Wrist flexion and ulnar hand deviation are common. In many patients with PD, a typical posture with extension of the index finger, flexion of the third, fourth, and fifth MCP joints, and thumb adduction is observed and the term, "clenched fist" has been used to describe the more marked and fixed forms of this abnormality (**Figures 1** and **2**).

The side of striatal deformity is usually ipsilateral to the side of initial bradyinesia or rigidity but bilateral manifestation occurs in many patients. Striatal hand typically occurs as a late complication in PD, but in some patients, it may be seen at early stages. Similar to the abnormal postures that may occur in the feet, neck, and trunk in parkinsonian syndromes, abnormal hand postures are often wrongly attributed to causes such as rheumatoid arthritis or Dupuytren's contracture, particularly when they occur in the absence of marked parkinsonism. Patients often present to primary care physicians, rheumatologists, or orthopedic surgeons, thus delaying diagnosis and treatment.

Loss of function, pain, and disfigurement are the major associated problems. Pain may be intense and is often exacerbated by passive stretching. Difficulties with hand hygiene often occur, caused by the nails digging into the palm or by excessive flexion at the MCP joints and leading to skin maceration and palmar infections. The hand deformity often progresses rapidly over weeks to months, and once the "clenched fist" posture develops, it is usually irreversible due to contractures.

Pathophysiology

The underlying pathophysiology of these deformities is not well understood, but animal models demonstrate an involvement of the basal ganglia. It is believed that striatal dopamine deficiency is the primary chemical alternation leading to striatal hand deformities. In this way, the phenomenon is similar to the transient dystonias that develop in PD patients before treatment with dopaminergic drugs is begun or as a problem that occurs late in the disease when patients experience motor fluctuations in medication responses and develop painful dystonia when their dopaminergic medications are not working (OFF dystonia). However, no factors are currently known to predict which patients will develop fixed striatal postural abnormalities. A correlation with the degree of rigidity in the affected limb has been suggested. Reduced numbers of sarcomeres have been demonstrated in rigid limbs, which are believed to be precipitated by prolonged immobilization of the muscles with short lengths during sustained contraction and by secondary alterations in soft tissue plasticity and viscoelasticity, leading to atrophy and fibrosis. This process produces further reduction in muscle compliance and exacerbates muscle hypertonicity. Although it is not clear if these further changes are part of the primary postural abnormality or a secondary phenomenon, they may ultimately result in a combination of muscle contraction and contractures.

Patient 1 (moderate) Patient 3 (mild)

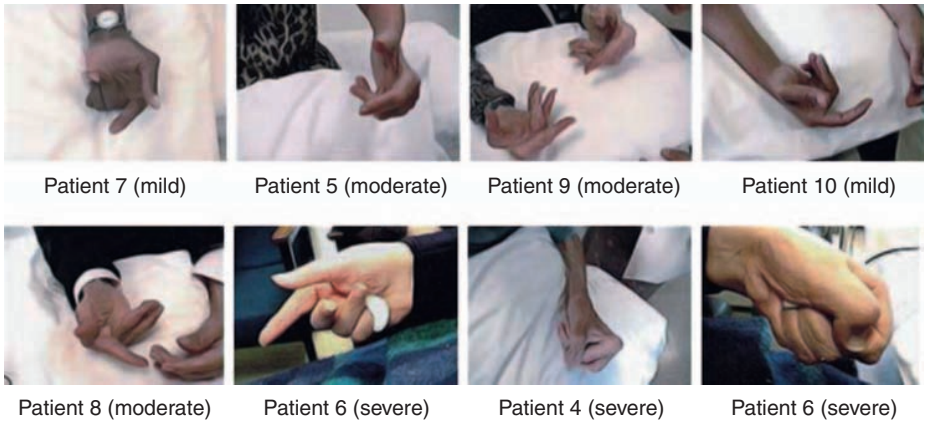
Epidemiology and Risk Factors

Hand deformities in PD patients were first described in the nineteenth century but no epidemiological studies have systematically investigated their prevalence in patients with parkinsonian disorders. A study from a tertiary referral center reported postural abnormalities of the hand in 8.4% of 202 consecutive patients with parkinsonian syndromes. Striatal limb (including foot) deformities were present in 12.8% of PD patients, 26.3% of MSA patients, and 5.3% of PSP patients. The study was retrospective and did not grade severity. In an earlier series of 86 patients with parkinsonism, some deformity of the hands was reported in 40% overall and in 24% of PD patients. Not all studies report high prevalences, and one study reported a low frequency in a PD clinic without giving details on the patient population. It is likely that the definition of the deformities and the search methods have a considerable impact on detection rates. Subtle postural changes may not be recognized, and prospective epidemiological studies are needed to determine the accurate prevalence and impact of striatal deformities in patients with parkinsonism.



Patient 7 (mild) Patient 5 (moderate) Patient 9 (moderate) Patient 10 (mild)

Patient 8 (moderate) Patient 6 (severe) Patient 4 (severe) Patient 6 (severe)

Figure 2 Hand deformity in seven patients with PD. Reproduced from Cordivari C, Misra VP, Catania S, and Lees AJ (2001) Treatment of dystonic clenched fist with botulinum toxin. *Movement Disorders* 16: 907–913, with permission from Wiley-Liss.

Most studies show that female PD patients are more commonly affected by striatal hand than male patients. In one study, the mean duration of PD before the development of clenched fist was 12 years (range 7–30). Patients with striatal deformity tend to be younger and to have an earlier age of onset of parkinsonism. The reasons for this occurrence are unknown, but it has been speculated that the higher rate of dystonia in young-onset PD, including those due to monogenic forms including *Parkin* mutations, may be related to the neuroplasticity of younger brains in response neurodegeneration and resultant abnormal neurophysiologic processing, expressed as dystonia.

Ergot-derived dopamine agonists have been implicated in the development of soft tissue changes, but in one study, no differences in agonist treatment were found between patients with and without striatal hand. Mean Unified Parkinson's Disease Rating Scale (UPDRS) scores, indicating more severe parkinsonism, were higher in patients with striatal limb deformities.

Management

Drug treatment for these deformities is usually unsatisfactory although in some cases response to dopaminergic drugs including L-dopa and anticholinergics has been observed. Improvement following subthalamic stimulation or thalamotoy has been reported in rare cases, and orthopedic procedures, including Z-lengthening and capsulotomy have been performed. Recent reports point towards botulinum toxin injections as the most promising treatment approach. Experience with this modality was reported in CBD and has more recently been reported in patients with PD and D-CRPS. Muscle relaxation, pain relief, and improved palmar hygiene are most commonly observed following botulinum injections, although the literature does not yet permit conclusions on percentages of responders or degrees of improvement. Functional improvement is more commonly observed in PD than in CBD, where additional underlying problems such as apraxia and cognitive dysfunction often preclude practical use of the affected hand. However, even in these patients, improved pain and palmar hygiene can have an impact on the quality of life. As with other indications for botulinum toxin, the duration of response is usually around 3–6 months, and repeated injections on a regular basis are therefore needed.

Because of the complexity of muscle involvement, botulinum toxin injections are best performed under EMG guidance, using the amount of EMG activity from affected muscles recorded at rest and in response to passive stretch, to guide the choice of muscles and the dose of botulinum toxin injected. EMG is presumed to allow a distinction between muscle contraction (increased EMG activity at rest and with passive stretch) and contractures (no or very little activity). The degree of improvement appears to be related to the severity of associated contractures, and the absence of EMG activity at rest has been found to be a negative prognostic factor and to correlate with poor response to botulinum toxin. The muscles for injection most commonly found to result in an improvement in typical striatal hand are the lumbricals, flexor digitorum superficialis, and the short adductors of the thumb. However, each case must be considered separately, and the muscles to be injected must be chosen clinically depending on the posture.

In PD, functional improvement is particularly observed when treatment is started soon after the appearance of the deformity. A study showed that in these patients, EMG showed prominent ongoing muscle activity, suggesting a significant element of abnormal muscle contraction rather than contractures. This observation suggests that early treatment with botulinum toxin may prevent contractures. Even when muscle contractures have developed, botulinum toxin may help maintain muscle length, reduce painful spasms, and possibly prevent progression to severe clenched fist.

Physiotherapy is recommended in clinical practice, although its role in this condition has not been investigated in studies. Further research is needed to define causes, treatments, and outcomes in striatal hand.

Striatonigral Degeneration

A Park and M Stacy, Duke University Medical Center, Durham, NC, USA

Glossary

α-Synuclein – One in a family of structurally related proteins that are prominently expressed in the central nervous system. Aggregated α-synuclein proteins form brain lesions that are hallmarks of some neurodegenerative diseases (synucleinopathies), such as PD, Lewy body dementia, and multiple system atrophy.
Anterocollis – Anterior flexion of the neck.
Dysarthria – Speech that is characteristically slurred, slow, and difficult to produce and to understand. There may be problems controlling the pitch, loudness, rhythm, and voice qualities of speech.
Dystonia – Involuntary movements and prolonged muscle contraction, resulting in twisting body motions, tremor, and abnormal posture.
Glial cytoplasmic inclusions – Intracytoplasmic predominantly oligodendroglial argyrophilic inclusions that exhibit modest tau and strong alpha-synuclein immunoreactivity.
Impotence – The consistent inability to sustain an erection sufficient for sexual intercourse or the inability to achieve ejaculation, or both.
Incontinence – The inability to keep urine in the bladder.
Orthostatic hypotension – Temporary lowering of blood pressure due usually to standing up suddenly (by 30 mmHg systolic or 15 mmHg diastolic).
Parkinsonism – A group of neurodegenerative disorders characterized by tremor, rigidity, akinesia or bradykinesia and postural instability.
Tau inclusion bodies – Protein involved in fibrillogenesis found in neurons and glia of various neurodegenerative disorders (tauopathies), such as FTD Complex, Pick's Disease, CBG and PSP.

Definition and History

The term striatonigral degeneration (SND) was first introduced in 1964 to characterize a new syndrome of parkinsonism associated with other signs of neurological dysfunction (e.g., cerebellar tremor, ataxia, chorea, pyramidal signs, syncope, and incontinence). The term, SND, was specifically chosen as it captured the concept of primary neuronal degeneration of small nerve cells in the anatomical areas that were thought to be involved (i.e., putamen, substantia nigra, globus pallidus, caudate and subthalamic nucleus). The term olivopontocerebellar atrophy (OPCA) was coined decades earlier in 1900 by Dejerine and Thomas to describe two sporadic cases of parkinsonism associated with progressive cerebellar degeneration. On pathology, they found loss of neurons in the pontine and inferior olivary nuclei and cerebellar cortex. In 1960, Shy and Drager published a clinicopathological study of patients presenting with idiopathic orthostatic hypotension, bladder dysfunction, and syncope, associated with neurodegeneration of the intermediolateral cell column of the spinal cord, medulla, pons, midbrain, cerebellum, and basal ganglia. In 1969, Grahm and Oppenheimer conceptually unified these three disorders, SND, OPCA, and Shy-Drager syndrome, stating, "...What we wish to avoid is the multiplication of names for 'disease entities,' which in fact are merely the expression of neuronal atrophy in a variety of overlapping combinations. We, therefore, propose to use the term multiple system atrophy (MSA) to cover the whole group." Thus, MSA represents a spectrum of related clinical syndromes characterized by varying degrees of parkinsonism, cerebellar dysfunction, and autonomic insufficiency. SND represents a form of MSA identified by predominant involvement of the extrapyramidal and pyramidal systems.

Pathogenesis/Pathophysiology

The pathogenesis of SND is unknown. In a neuropathological review of 33 patients with pure SND, macroscopic findings include severe atrophy and a brownish discoloration of the putamina from iron deposition. The substantia nigra was depigmented from loss of dopaminergic neurons. Microscopically, the putamina contain dark brown-pigmented granules mainly in the glial and neuronal cytoplasm. These glial cytoplasmic inclusions (GCIs or Papp-Lantos inclusions) have recently been recognized as a unique cellular pathological marker for MSA. They surround the nuclei of oligodendroglia with crescent or flame-shaped morphology. GCIs exhibit modest τ- and strong α-synuclein immunoreactivity. Since α-synuclein is such an important constituent of GCIs, MSA is now classified as α-synucleinopathy. There is selective degeneration of Met-enkephalin-containing neurons in the putamen and ventrolateral portion of the globus pallidus

externa, but preservation of these in the caudate nucleus. There are no consistently identified abnormalities of the remaining basal ganglia, cerebellum, pons, and medulla oblongata. Lewy bodies are rarely found, and this finding, in addition to the severe degeneration of the putamina, is a characteristic that differentiates SND from idiopathic Parkinson's disease (PD). In addition, some have found marked loss of tyrosine hydroxylase-immunoreactive neurons in the A1 and A2 regions of the medulla oblongata, suggesting that medullary involvement may play a role in the diminished vasomotor control characteristic of SND.

Epidemiology/Risk Factors

Given that the absolute diagnosis of SND requires neuropathological confirmation, there have been very few studies reporting the incidence or prevalence of SND. However, based on previous autopsy studies, it is estimated that 4–8% of patients with clinical parkinsonism have SND, with a mean duration of disease of 4.5 years. There are rare familial associations. MSA has a prevalence of about 4.4 per 100 000 in the United Kingdom, and is known to affect both sexes equally. In one meta-analysis of pathological proven cases of MSA, the mean age of onset was 54.2 years with a median survival of 6.2 years.

Clinical Features and Diagnostic Criteria

SND is clinically difficult to distinguish from PD, but the prototypical signs of SND are parkinsonism, severe neck flexion (anterocollis), and extrapyramidal features, such as spasticity brisk reflexes and Babinski sign. These two disease entities share many of the same features, and the diagnosis can be particularly challenging in the early stages of disease or when patients present with atypical PD. In fact, ~25% of patients initially diagnosed with PD are found to have parkinsonism as part of another disorder, and clinicopathological studies have shown significant inaccuracy in diagnosing these disorders in vivo. Patients with both SND and PD have parkinsonism, characterized by tremor, rigidity, akinesia or bradykinesia, and postural instability. Also, patients with both diseases typically develop at least some degree of autonomic failure, such as constipation, impotence, orthostatic hypotension, and urinary symptoms. Urinary symptoms may include urgency, frequency, nocturia, incomplete bladder emptying, and incontinence. However, in patients with SND, dysautonomia is a prominent feature, and symptomatic autonomic failure tends to present early in the disease course. One study showed that symptomatic orthostatic hypotension occurring within the first year of disease predicted MSA in 75% of pathologically confirmed cases. Another distinguishing feature is that patients with SND respond very little, if at all, to levodopa. Conversely, patients with idiopathic PD typically maintain this response throughout the disease course. Many patients with SND have no tremor, whereas the presence of an asymmetric resting tremor is quite specific for idiopathic PD. Patients with SND also seem to have more rigidity/hypokinesia as their initial symptom compared to patients with PD (84% versus 27%, respectively). Other suggestive symptoms and signs of SND include early slowness of gait with or without falls, severe dysarthria with marked hypophonia, dysphagia, respiratory stridor, dystonia, and myoclonus. Patients with SND also tend to have a more rapid progression of disease compared to PD, and may become wheelchair bound sooner.

Although these clinical findings can be helpful in identifying probable SND, there are no specific diagnostic criteria for SND. However, in 1998, a consensus committee developed diagnostic criteria for MSA based on four clinical domains: autonomic and urinary dysfunction, parkinsonism, cerebellar dysfunction, and corticospinal tract dysfunction (**Table 1**). Based on this, the recommended current nomenclature is MSA-P, where parkinsonism is prominent, and MSA-C where cerebellar dysfunction is prominent. Most cases of SND fall into the MSA-P category, and the added features of anterocollis and pyramidal tract abnormalities typify this subgroup within MSA-P. Using the four clinical domains as listed in **Table 1**, possible MSA is defined as one criterion plus two features from other separate domains. When the criterion is parkinsonism, a poor levodopa response counts as one feature (hence only one additional feature is required). For probably MSA, one needs to fulfill the criterion for autonomic failure/urinary dysfunction plus have poorly levodopa responsive parkinsonism or cerebellar dysfunction. A definite diagnosis of MSA requires neuropathological confirmation showing the characteristic distribution of GCIs and degenerative changes. The exclusion criteria include symptomatic onset under the age of 30, family history of a similar disorder, systemic diseases, laboratory evidence or other identifiable causes for the features listed in **Table 1**, and hallucinations unrelated to medication. The exclusion criteria based on physical examination include DSM criteria for dementia, prominent slowing of vertical saccades or vertical supranuclear gaze palsy and evidence of focal cortical dysfunction. While these guidelines have not yet been validated, these criteria provide an extremely useful tool for diagnostic consistency.

Differential Diagnosis

As with many neurodegenerative diseases, time is the most useful tool for the accurate diagnosis of SND.

Table 1 Consensus criteria for the diagnosis of MSA

Clinical domain	*Features*	*Criteria*
Autonomic and urinary dysfunction	Orthostatic hypotension (by 20 mmHg systolic or 10 mmHg diastolic); urinary incontinence of incomplete bladder emptying	Orthostatic fall in blood pressure (by 30 mmHg systolic or 15 mmHg diastolic) and/or urinary incontinence (persistent, involuntary partial or total bladder emptying, accompanied by erectile dysfunction in men)[a]
Parkinsonism	Bradykinesias, rigidity, postural instability and tremor	1 of 3 (rigidity, postural instability, and tremor) and bradykinesia
Cerebellar dysfunction	Gait ataxia; ataxic dysarthria; limb ataxia; sustained gaze-evoked nystagmus	Gait ataxia plus at least one other feature
Corticospinal tract dysfunction	Extensor plantar responses with hyperreflexia	No corticospinal tract features are used in defining the diagnosis of MSA[b]

[a]Note the different figures for orthostatic hypotension depending on whether it is used as a feature or a criterion.
[b]This criterion is ambiguously worded. One possible interpretation is that, while corticospinal tract dysfunction can be used as a *feature* (characteristic of the disease), it cannot be used as a *criterion* (defining feature or composite of features required for diagnosis) in defining the diagnosis of MSA. The other interpretation is that corticospinal tract dysfunction cannot be used at all in consensus diagnostic criteria, in which case there is no point mentioning it.

A patient's initial presentation merely represents one cross-section of time in a disease that is continually evolving and progressing. Therefore, it is important to bear in mind the broad differential diagnosis for SND when evaluating a patient, especially as many of these diseases have overlapping symptomatology.

SND is known to be difficult to clinically distinguish from PD. In one study, SND was misdiagnosed as idiopathic PD in 31% of cases. Some features that might help differentiate SND from PD include significant dysautonomia, minimal or lack of response to levodopa, presence of pyramidal or cerebellar signs, and no resting tremor. Patients with SND may also develop cranial or cervical dystonia, most frequently seen as or anterocollis. While early autonomic dysfunction is an important distinguishing feature of SND, these symptoms are also reported with diffuse Lewy body disease (DLB) and PD. SND can also easily be confused with PSP, especially early in the course of the disease. Early postural instability can be a feature of both diseases; however, recurrent falls within the first year have been shown to be a strong predictor of PSP (68% of pathologically confirmed cases). PSP is also more frequently characterized by prominent supranuclear vertical ophthalmoparesis. If postural instability is associated with urinary incontinence and dementia, normal pressure hydrocephalus should also be considered. Early postural instability can also be seen in PD, called 'postural instability gait disorder (PIGD),' and this tends to have a worse prognosis than tremor-predominant PD. Patients with SND may have a tremor with a jerky quality, indicating the coexistence of myoclonus, however this can also be seen in corticobasal degeneration (CBD). CBD is more frequently distinguished from SND by the presence of cortical dysfunction (i.e., apraxia and cortical sensory loss), and in time, the combination of apraxia, dystonia, rigidity, akinesia and myoclonus can make the affected limb/s functionally useless. Significant cognitive disability is rare in SND, and should lead one to consider CBD or PSP.

Diagnostic Work-up/Tests

The diagnosis of SND is a clinical one, but ancillary testing can prove useful in supporting a diagnosis, as well as excluding other conditions. In patients with SND, there have been some reported characteristic findings on brain MRI. These include putaminal atrophy and abnormal putaminal hypointensity on T_2-weighted imaging with hyperintensity on the lateral edge (which can also be seen on proton density images). These findings correlate with neuronal loss, iron deposition, microgliosis, and astrocytosis in the putamen. When present, these findings can be helpful; however, negative MRI results do not rule out the diagnosis of SND. PET scanning using 18F-fluorodeoxyglucose has been shown to reveal decreased glucose metabolism in the caudate and putamen in patients with SND. Using proton magnetic resonance spectroscopy (MRS), patients with SND have a significantly reduced *N*-acetylaspartate/creatine ratio and choline/creatine ratio in the putamen and globus pallidus, compared to the preserved ratios in patients with PD. Again, whether these findings can truly distinguish SND from other forms of parkinsonism is unknown.

Sphincter electromyographic (EMG) studies can reveal external anal sphincter denervation showing changes suggesting chronic reinnervation, with markedly

prolonged motor units. Tilt table testing can be used to evaluate postural hypotension. Other useful supportive studies include swallow studies for dysphagia, urodynamic studies for urinary problems, and sleep studies for respiratory stridor.

Management

There is no straightforward treatment for SND, and management will depend on each patient's constellation of symptoms. While many patients with SND may not respond to levodopa, there is a wide range of therapeutic effects and each individual response will vary. Therefore, it is reasonable to start with a trial of carbidopa/levodopa, knowing that patients with SND may require larger doses of this medication compared to patients with PD. Dopamine agonists are generally thought to be less effective than levodopa. While oral agents such as baclofen and benzodiazepines (e.g., valium, klonopin) can be used for spasticity and anterocollis, botulinum toxin injections may be the most beneficial. Autonomic dysfunction is difficult to treat. Symptomatic orthostatic hypotension can be managed with sodium and fluid replacement. Fludrocortisone, a mineralocorticoid, and midodrine, an α-adrenergic agonist, may be helpful. Urinary frequency can be treated with anticholinergics such as oxybutynin. Sildenafil citrate and similar medications have been used for the treatment of erectile dysfunction; however, this has been known to worsen orthostatic hypotension.

Prognosis

SND is a progressive, unrelenting neurodegenerative disease. One study examined the disease progression and survival of 230 patients with MSA, and found that the median time from initial symptom to combined motor and autonomic dysfunction was 2 years. Median intervals from onset to aid-required walking, confinement to a wheel chair, a bedridden state, and death were 3, 5, 8, and 9 years, respectively. Patients with MSA-P had a more rapid functional deterioration than MSA-C patients, but showed similar survival. There was no gender difference in survival.

Subacute Sclerosing Panencephalitis

J Gutierrez and C Singer, University of Miami, Miami, FL, USA

Definition and History

Subacute sclerosing panencephalitis (SSPE) is a persistent chronic measles virus (MV) encephalitis that causes widespread demyelination of the central nervous system (CNS). It was first clinically described in 1993 by J.R. Dawson as 'subacute inclusion encephalitis' since type A inclusion (suggesting viral etiology) were seen in the brain biopsies. Later, in the next decade, the Belgain neuropathologist van Bogaert described 'subacute sclerosing leukoencephalitis' in a case of deep lethargy.

Pathogenesis/Pathophysiology

There are several factors influencing the chronic infections of mutant MV in the brain. The earlier in life the host is exposed to the MV, the greater the possibility of developing SSPE due to the immaturity of the immune system.

There are genetic factors predisposing to MV chronic infection such as polymorphism of interleukin-2, interleukin-4, or interferon receptor factor-1 involving the cellular response. A weak or less robust cellular immunity may allow the MV to persist for years, while the humoral response is insufficient to clear the organism.

The virus itself is less pathogenic due to several mutations accumulated intracellularly; the protein M gene (matrix) of the wild-type MV that causes SSPE has been identified as the main hypermutated gene, while the hemagglutinin and nucleocapsid genes remain highly preserved. The mutated virus is rendered less cytophatic than its nonmutated progenitor, which leads to a level of tolerance to the infection and a more protracted course over the years. After primary entry through the CD46 neuronal receptor, the virus spreads trans-synaptically probably using Neurokinin-1 as its anchor.

Epidemiology/Risk Factors

The epidemiology of SSPE is inversely linked to the extent of measles vaccination coverage. In the developed world, the prevalence has declined steadily since the introduction of the MV vaccine in the 1960s. Prevalence figures in the United States in 1963 were 0.61 per million as against the current 4–5 cases per year. Twenty-one cases per million are still reported in India, 11 per million in Japan, and 0.06 per million in Canada. Overall, 4–11 cases of SSPE are expected for every 100 000 cases of clinically diagnosed measles. The incidence changes dramatically with age at the time of primary infection and vaccination status.

The prevalence is higher in males, while females have longer latency periods with a later age of onset of symptoms. There is a higher risk of SSPE in Hispanics and Asians and less prevalence in blacks. Other risk factors are rural dwelling, poverty, overcrowding, poor schooling of parents, older mothers, fewer cultural events, and higher order of birth. The MV vaccination has been largely ruled out as risk factor for SSPE and is considered to be the best currently available preventive measure against it.

Clinical Features and Diagnostic Criteria

The onset usually occurs 6 years after the primary infection; early onset is associated with a fulminant course and early death. The mean age at presentation is 8 years and is manifested as poor school performance, behavioral changes, and personality changes. Twenty percent of patients are diagnosed in this stage. Abnormal movements, usually myoclonus and seizures, occur followed by prominent pyramidal tract signs and dementia leading to a vegetative state and death.

Adult onset SSPE is initially manifested by ocular complaints that precede the behavioral changes and abnormal movement up to 2–5 years. The mean age of onset is 20.9 ± 4.9 years. Although it has a higher incidence of spontaneous remissions, survival is shorter.

The clinical stages that have been proposed under a wide consensus include

Stage I: Personality changes and behavioral disturbances
Stage II: Myoclonus, seizures, and severe intellectual deterioration
Stage III: Rigidity and progressive deterioration
Stage IV: Coma leading to death.

The disability can be graded by the Neurological Disability Index created specifically for this pathology. Diagnosis is primarily clinical and supported by the immunological evidence of intrathecal anti-MV response as well as ancillary findings such as EEG and MRI (see **Table 1**).

Differential Diagnosis

Generally, any patient with rapidly evolving dementia, myoclonus, and seizures should be considered for the

Table 1 Subacute sclerosing panencephalitis diagnostic criteria

Major	Elevated CSF measles antibody titers
	Typical or atypical clinical history:
	Typical: Acute (rapidly) progressive, subacute progressive, chronic progressive, chronic relapsing/remitting
	Atypical: Seizures, prolonged stage I, unusual age (infancy/adult)
Minor	Typical EEG (PC)
	CSF IgG increased
	Brain biopsy (See in text)
	Specials: Molecular diagnostic test to identify MV mutated genome

Usually two majors plus one minor required, the more atypical, the more criteria 5 and/or 6 are needed.

diagnosis of SSPE. Other conditions that may mimic SSPE include acute disseminated encephalomyelitis, tumors, multiple sclerosis, metabolic white matter disease, chronic Rasmussen's encephalitis, Unverricht–Lundborg disease, Lafora disease, juvenile ceroid lipofuscinosis, myoclonic epilepsy with ragged fibers, and neuraminidase deficiency.

Diagnostic Work-up/Tests

Serology

Increase IgG against MV is seen with a 1:40 to 1:1280 ratio in serum and 1:5 to 1:40 ratio in cerebrospinal fluid (CSF). The ELISA technique in CSF for MV IgG has a sensitivity of 100%, specificity 93.3% and positive predictive value of 100% in a patient with a clinical picture suggestive of SSPE.

EEG

Periodic complexes (PCs) are described as stereotyped, bilaterally synchronous, and symmetrical 100–1000 mV, 1–3 Hz waves, sometimes intermingled with spikes or sharp waves. Duration ranges from 1 to 3 s and the interval between complexes varies 2–20 s. These PCs may occur during sleep, and in early stages, can be elicited by external stimuli.

Magnetic Resonance Imaging (MRI)

Hyperintense lesions on T2 sequences are observed early in the disease, mostly in the cortex; they tend to have asymmetric distribution with posterior predilection. As the disease progresses, the lesions disappear and new lesions occur symmetrically in the periventricular white matter with mild cortical atrophy; latter involvement of deeper structures and brain stem marked with progressive atrophy is evidenced. These changes do not correlate to clinical stages.

Pathology

Major changes are observed in the cortex and the white matter with predominance of the posterior parts of the brain and medial thalamus with relative cerebellar sparing. Edema corresponds to early phases, followed by neuronal loss, demyelination, perivascular lymphocytic infiltration, spongiosis, and gliosis in addition to acidophilic hyaline nuclear and cytoplasmic inclusions suggestive of viral nucleocapsids.

Management

Certain trials have shown a benefit in 30–40% of the patients, depending on the study design. The benefit is determined by either slower progression or stabilization of the disease course or increased survival or – less commonly – clinical improvement. The benefit offered, although relatively modest, is significantly better than the 5% of spontaneous remission reported in the literature.

The most common therapy used is the combination of intrathecal interferon-α (INF-α) and oral inosiplex beneficial in around 35% of patients; no clear advantage of this treatment has been obtained in comparison with inosiplex monotherapy. Complications are mainly associated with the intrathecal reservoir used for the INF administration. High-dose ribavirin has shown some benefits with rare side effects. Amantadine and intravenous immunoglobulin have been used but lack sufficient evidence to recommend their use.

The patients who respond to treatment have later relapses that might warrant life-long treatment. Once a therapeutic option has failed, another one should be probably considered.

Prognosis

SSPE is relentlessly progressive with a fatal outcome in 95% of the patients. Spontaneous remissions occur in 5% of cases with higher remissions in the adult onset form. The median survival is 1.8 years with 5% dying in the first 3 months and only 20% alive after 4 years. The impact of treatment on prognosis is still uncertain due to poor follow-up after relapses.

Substantia Nigra

Y Smith and J G Masilamoni, Emory University, Atlanta, GA, USA

Glossary

Dopamine – Major neurotransmitter used by many neurons in the central nervous system. It mediates its effects through activation of two major families of receptors called D1 and D2 receptor families. It plays an important role in motor control, reward-related behavior, and cognition. Dopaminergic neurons in the substantia nigra pars compacta degenerate in Parkinson's disease.
Drug addiction – Pathological condition by which progressive drug use results in the development of drug-seeking behavior, constant cravings with obtaining the drug, experiencing tolerance to the substance of abuse, withdrawal symptoms and decreased motivation for normal life activities.
Nigrostriatal pathway – Major bundle of axons that originate from dopaminergic neurons in the substantia nigra and terminate in the striatum. This pathway degenerates in Parkinson's disease.
Parkinson's disease – Second most common neurodegenerative disease after Alzheimer's disease characterized by the severe loss of dopaminergic neurons in the substantia nigra. The main symptoms are slowness of movements, muscular rigidity, rest tremor, and postural instability. Some patients also suffer of nonmotor symptoms such as depression and cognitive deficits.
Reward – Incentive given for the accomplishment of a task. The rewards used in animals to perform tasks often include food or liquid.
Visual saccades – Fast, simultaneous movements of both eyes in the same direction. Used as a mechanism for fixation and rapid eye movement. The relationships between the substantia nigra pars reticulata and the superior colliculus play an important role in the regulation of saccadic eye movements.

Definition and History

The substantia nigra (SN) is a brain structure that was first recognized by Vicq d'Azir in 1786, as a large cell mass located dorsal to the cerebral peduncle at the basis of the mesencephalon. It is made up of two major neuronal populations that can be differentiated by their neurotransmitter content, connectivity, and function. The substantia nigra pars compacta (SNc) in a cell-rich zone that comprises densely aggregated pigmented neurons along the dorsal part of the structure, while neurons of the substantia nigra pars reticulata (SNr) are less abundant, more diffusely distributed along the ventral part of the structure and do not contain pigmentation (**Figure 1**).

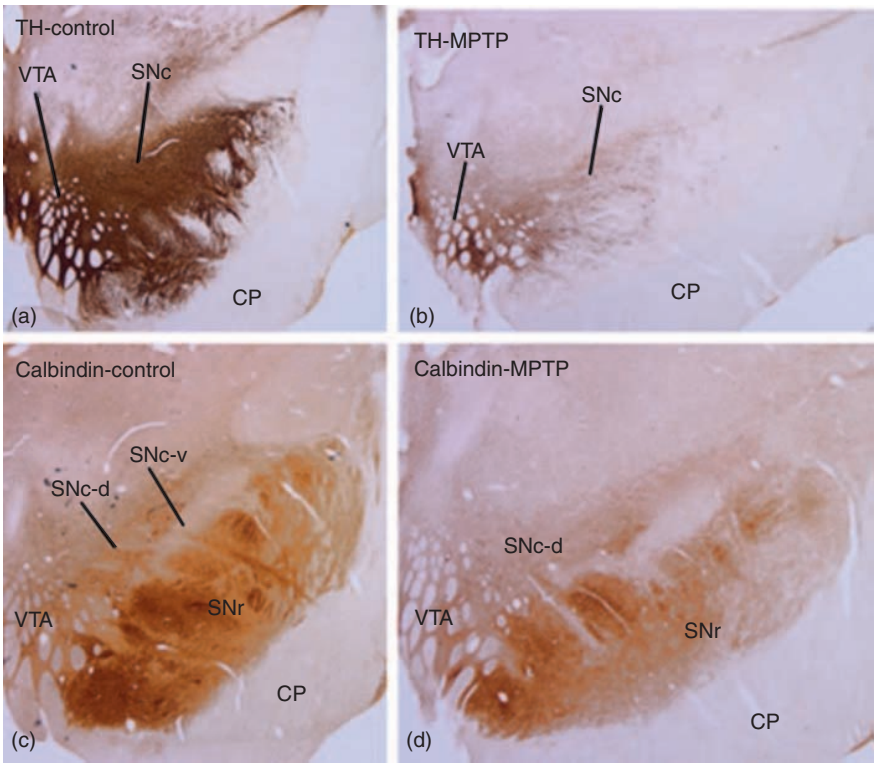

Figure 1 Transverse section of control (a and b) and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated (c and d) rhesus monkey brains immunostained for tyrosine hydroxylase (TH) or calbindin D28K showing the localization of the dorsal and ventral tiers of the SNc (SNc-d and SNc-v) and the VTA. The SNr is also labeled on these micrographs. CP, cerebral peduncle.

Together, these two neuronal groups are integrative components of the basal ganglia circuitry; the SNc being the main source of dopamine to the striatum (often referred to as the nigrostriatal pathway), while the SNr is one of the main output nuclei of the basal ganglia. In the following account, the functional and anatomical characteristics of each of these neuronal groups will be discussed in more detail and their respective role in the normal and pathological basal ganglia circuitry will be highlighted.

The SNc and Other Ventral Midbrain Dopaminergic Cell Groups

General Organization and Neurochemical Phenotypes

The SNc is a key component of the ventral midbrain dopaminergic cell groups originally recognized by Dahlstrom and Fuxe in 1964 using histofluorescence method to visualize catecholamines. Two other major components of this region include the medially located ventral tegmental area (VTA) and the more caudal retrorubral field (RRF). According to the nomenclature of catecholaminergic cell groups introduced in the mid-1960s, these structures correspond to the A8 (RRF), A9 (SNc), and A10 (VTA) regions.

The SNc is made up predominantly or large densely packed dopaminergic neurons that form a clearly distinguishable structure in humans because of their high content in neuromelanin, a byproduct of dopamine autooxidation. The content in neuromelanin in SNc neurons is much higher in humans than in any other primate species and is age-dependent, increasing significantly until about 60 year old, and then gradually declining due to the progressive loss of midbrain dopaminergic neurons. It has been suggested that the accumulation of neuromelanin and other byproducts of dopamine oxidation may contribute to the loss of SNc neurons in Parkinson's disease (PD) (see below).

In humans, SNc neurons are divided into three major groups, the dorsal α group, often referred to as the dorsal tier group (SNc-d), the densocellular β group, and the ventral γ group made up of cell columns that extend their dendrites dorsoventrally into the SNr up to the dorsal surface of the cerebral peduncle (**Figure 1**). These two groups are commonly recognized as the ventral tier neurons (SNc-v). There is strong evidence that dendrites of SNc-v neurons release dopamine into the SNr, thereby providing a source of local dopamine into the SN. One of the main neurochemical features that differentiate dorsal from ventral SNc neurons is the expression of

the calcium binding protein, calbindin D28K, which is more heavily expressed in SNc-d and VTA neurons than SNc-v cells (**Figure 1**). It has been hypothesized that this differential expression of calbindin confers to SNc-d and VTA neurons some neuroprotective properties in PD. Other neurochemical features that differentiate SNc-d/VTA neurons from SNc-v cells include the relatively high level of D2 dopamine receptors and higher expression of dopamine transporter (DAT) in the SNc-v group. Finally, VTA dopaminergic neurons co-express neuropeptides such as neurotensin and cholecystokinin, known to play important role in the regulation of dopamine release and function in the midbrain and striatum. Although the SNc is largely made up of dopaminergic neurons with very few, if any GABAergic interneurons, the VTA comprises a significant population of GABAergic cells that act as interneurons and provide extrinsic projections to the prefrontal cortex.

Efferent and Afferent Connections

Midbrain dopaminergic cell groups are the main sources of dopamine to cortical and subcortical telencephalic structures. In general, SNc neurons are recognized as the main sources of dopamine to the dorsal striatum (caudate nucleus and putamen), known as the nigrostriatal pathway, whereas the VTA contributes dopamine innervation to the ventral striatum (nucleus accumbens and olfactory tubercle) and cerebral cortex, known as the mesostriatal and mesocortical systems, respectively (**Figure 2**). The VTA and medial SNc neurons are also the main sources of dopamine innervation to the hippocampus and amygdala. It is noteworthy that the dopamine innervation of the cerebral cortex in rodents is confined to the prefrontal cortex, while in primates, it extends beyond prefrontal regions to include neocortical areas involved in sensorimotor processing. In addition to the striatum, extrastriatal basal ganglia nuclei, including the globus pallidus, the subthalamic nucleus (STN) and the SNr, also receive SNc dopaminergic inputs, which represent additional routes through which dopamine may influence basal ganglia functions (**Figure 2**). Dopaminergic inputs to the thalamus have also been demonstrated in primates, but the exact sources of this system remain unclear.

The main sources of inputs to ventral midbrain dopaminergic neurons include glutamatergic and cholinergic neurons in the brainstem pedunculopontine tegmental nucleus (PPN) as well as GABAergic neurons in the ventral striatum, ventral pallidum, and SNr. Additional, more modest, sources of afferents to the ventral midbrain include the prefrontal cortex, central amygdala, and superior colliculus that use glutamate, GABAergic inputs from the lateral habenula and ascending monoaminergic inputs from the raphe (serotonin) and the locus coeruleus (noradrenaline) (**Figure 2**).

Degeneration of Dopaminergic Cell Groups in PD

Midbrain dopaminergic neurons in the SNc and their corresponding axonal projections to the caudate nucleus and putamen (i.e., the nigrostriatal pathway) are severely affected in PD, while VTA neurons that project to the ventral striatum are relatively less damaged in this disease (**Figure 1**).

Dopamine plays a critical role in regulating striatal activity through stimulation of two main receptor subtypes (D1 or D2), which have opposite effects on striatal neurons. Because these receptors are largely segregated into two major populations of striatal projection neurons, their decreased activation in parkinsonism results in complex changes in the functional circuitry of the basal ganglia that are thought to underlie the main pathophysiological features of PD.

Dopaminergic neurons in the VTA and the related mesostriatal and mesocortical systems play an important

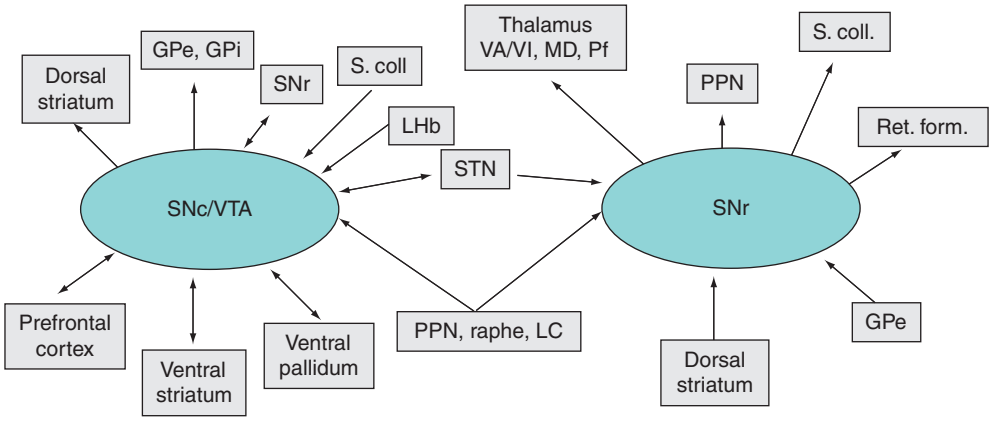

Figure 2 Diagram that summarizes the afferent and efferent connections of the SNc/VTA and SNr. For the sake of simplicity, some minor connections have been omitted. GPe, external globus pallidus; GPi, internal globus pallidus; LC, locus coeruleus; LHb, lateral habenula; MD, mediodorsal nucleus; Pf, parafascicular nucleus; PPN, pedunculopontine nucleus; Ret. Form., reticular formation; SNr, substantia nigra pars reticulata; S. coll., superior colliculus; VA/VL, ventral anterior/ventral lateral nucleus.

role in regulating limbic functions related to reward and motivational behaviors. These systems are the key mediators of neurochemical and pathophysiological changes in neural circuits that underlie addiction to drugs of abuse.

Physiological Roles of Dopaminergic Neurons

In addition to their obvious role in motor control, midbrain dopaminergic neurons are also involved in complex cognitive and limbic functions. Based on the seminal work achieved by Wolfram Schultz and colleagues in nonhuman primates, it is now well established that midbrain dopamine neurons play important roles in learning, cognition, and reward-related behaviors. Although these neurons do not respond to movements per se, they encode the rewarding aspects of environmental stimuli showing short phasic increases of activity in response to unconditioned stimuli such as food reward or following sensory conditioned reward-predicting stimuli. They also code for the discrepancy between the prediction and occurrence of reward, thereby providing a critical 'prediction error' signal to the striatum and the cerebral cortex, which constitutes a powerful teaching signal for behavior and learning. Because of these important physiological properties, pathological changes of dopamine neurons activity underlie the complex symptomatology of various neurological and psychiatric disturbances such as seen in PD, schizophrenia, attention deficit hyperactivity disorder, and drug addiction.

The SNr: An Output Structure of the Basal Ganglia

In contrast to the SNc, SNr neurons are much less abundant, more diffusely distributed and use GABA as neurotransmitter. They are located ventral to SNc neurons and give rise to thalamic and brainstem GABAergic outflow from the basal ganglia (**Figures 1** and **2**). The dorsal striatum is, by far, the most massive source of GABAergic inputs to these neurons, which also receive GABAergic influences from the external globus pallidus (GPe) and glutamatergic inputs from the STN. Other minor inputs to these neurons originate from the brainstem PPN (acetylcholine/glutamate), the raphe (serotonin), and the locus coeruleus (noradrenaline). In turn, the SNr provides significant GABAergic projections to the ventral motor and mediodorsal thalamus, the PPN, the superior colliculus, and the reticular formation. The SNr projection to the superior colliculus is an important regulator of saccadic eye movements (**Figure 2**).

Conclusions

The SN is a key structure in the central nervous system recognized for its important functions in motor, cognitive, and limbic behaviors. A deeper understanding of the etiology and the mechanisms that underlie the degeneration of SNc dopaminergic neurons in PD and the functional abnormalities of VTA neurons in drug addiction remain major challenges that face the scientific community for years to come.

Subthalamic Nucleus

D K Sierens, John H Stroger, Jr. Hospital of Cook County, Chicago, IL, USA

Glossary

Hemiballismus – Disorder caused by stroke or lesioning of the subthalamic nucleus on one side of the brain. Hemiballismus is clinically described as unilateral, large amplitude, involuntary proximal limb movements.

Parkinson's disease (PD) – Neurodegenerative disease first described by James Parkinson in 1817. PD is clinically described by bradykinesia, rest tremor, and rigidity.

Subthalamic nucleus deep brain stimulation (STN DBS) – The first case report of subthalamic nucleus deep brain stimulation was published in 1994 by A.L. Benabid. Deep brain stimulation is a high-frequency continuous electrical stimulation to the subthalamic nucleus through a surgically implanted device, which has been shown to improve motor symptoms in PD.

Definition and History

The subthalamic nucleus (STN) is part of the basal ganglia circuitry and one of the main regulators of motor function. The STN was first described by Jules Bernard Luys in 1865. It is also known as corpus luysi or Luys' body.

Anatomy

The STN is derived from the proliferative epithelium of the marginal layer of the subthalamus and is initially seen as part of the intermediate layer around 33–35 days of gestational age. The nucleus assumes its characteristic lens-shaped appearance between 48 and 51 days. The STN has approximately 560 000 cells in humans and the volume of the STN is 240 mm^3. It is located in the most caudal part of the diencephalon. The dimensions of the almond-shaped STN are approximately 10 mm *rostrocaudal*, 10.5 mm *mediolateral*, and 7 mm *dorsoventral*.

The STN is a relatively small, densely populated, biconcave lens-shaped nucleus located between the zona incerta (ZI) *dorsally* and the substantia nigra pars reticulata (SNr) *ventrally* in the upper midbrain. The posterior limb of the internal capsule is *anterior and lateral*. The medial lemniscus is *posterior*. The red nucleus and the third cranial nerve are *medial*.

More specifically, the *borders* of the STN can be described in much greater detail:

Dorsal

Dorsally, the STN is limited by a portion of the fasiciculus lenticularis (H_2) and the ZI, which separate this nucleus from the ventral thalamus. Pallido-thalamic projections originate from the globus pallidus, internal segment (GPi), which contain γ-aminobutyric acid (GABA), and initially constitute two separate bundles: fasciculus lenticularis (H_2) and the ansa lenticularis. These fibers merge in the Fields of Forel (H) and then ascend as a single bundle in the thalamic fasciculus (H_1) into the rostral part of the ventral lateral thalamus (see **Figure 1**).

Anterior and Lateral

The STN *anterior and lateral* borders are surrounded by the dense bundles of myelinated fibers of the posterior limb of the internal capsule which descend as the striae pedunculi interni (Str.pd.i) into the cerebral peduncle inferiorly.

Medial

Rostromedially, the STN borders the fields of Forel (H) and the thalamic fasciculus (H_1), which separates this nucleus from the mamillo-thalamic tract (T.mth) and the posterior aspect of the mamillary body also known as the nucleus postmammillaris hypothalami (Pm.h).

Caudally and medially, the STN borders the zona incerta (ZI) and the FasciculusQ (Sano), which separates the nucleus from the red nucleus dorsally and the third cranial nerve (III) ventrally.

Posterior

Posteriorly, the STN borders the zona incerta (ZI), which separates the nucleus from the radiations of the medial lemniscus also known as (Ra.prl) or Radiatio praeleminscalis and just posterior to those radiations is the medial lemniscus. The red nucleus also continues to rest *posterior and medial* to the STN.

The STN is subdivided into somatic motor, oculomotor, limbic, and associative *territories*.

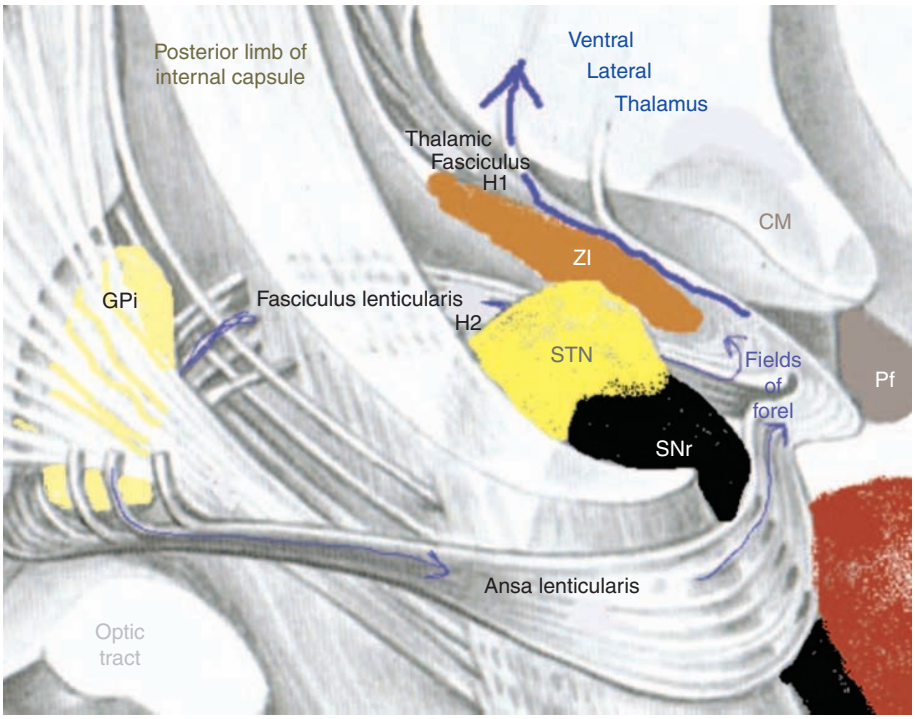

Figure 1

Somatomotor

The somatomotor territory is the largest territory of the STN, occupying two-thirds of the STN in the *dorsolateral* quadrant of the STN. Deep brain stimulation (DBS) electrodes should be placed in this region for maximal efficacy. Using microelectrode recordings in human clinical studies during surgery for DBS, this sensorimotor region is routinely mapped and identified when the contralateral body is manipulated to trigger firing of neurons that respond to either active, passive, or tremor movements. These neurons are called kinesthetic cells.

Associative

The associative territory and limbic territory share the other one-third of the STN. The associative territory is located in the *ventromedial* quadrant of the rostral STN. This territory receives input from the prefrontal cortex and frontal eye fields and projects to the SNr, which is involved in oculomotor control and cognitive aspects of motor behavior.

Limbic

The limbic territory is located in the *medial* tip of the rostral STN. This territory receives input from the medial prefrontal cortex and the anterior cingulate cortex. The limbic territory projects to the ventral and medial pallidum, which controls motivational and emotional aspects of motor behavior.

The *somatotopical* organization of the STN has been well documented. There is a distinct topographical representation of the leg, arm, and face. The leg area is located in the upper dorsal one-third and centro-*medial* portion. The face is located in the dorsal two-thirds and central portion. The arm is located in the dorsal two-thirds but in the *lateral* region of the STN (see **Figure 2**).

The *vascular supply* to the STN includes perforating branches of the anterior choroidal artery (pedunculosubthalamic arteries), posterior communicating artery, and the posteriormedial choroidal artery (lateral mesencephalosubthalamic arteries). When Cooper ligated the anterior choroidal artery to treat Parkinson's disease (PD) in 1953, the antiparkinsonian effects might have been in part related to the infarction of the STN.

STN Afferents

The STN receives inputs from *excitatory* glutamatergic projections from the cerebral primary motor cortex, parafascicular nucleus (Pf), and centromedian nucleus (CM) of the thalamus. *Inhibitory* GABA projections come from the globus pallidus, external segment (GPe). Dopaminergic projections come from the substantia nigra compacta (SNc). Cholinergic and serotonergic projections are from the pedunculopontine nucleus (PPN) and dorsal raphe nucleus (DRN) respectively.

STN Efferent Targets

STN neurons are glutamatergic projection neurons and they provide *excitatory* input to the GPe and GPi, and SNr.

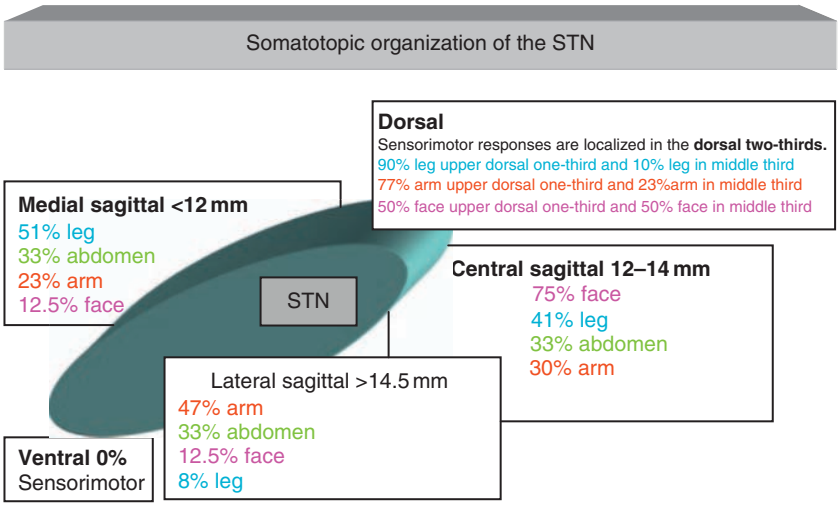

Figure 2

This makes the STN the only glutamatergic nucleus in the basal ganglia.

Physiology

The STN is a commonly used target for DBS in PD. Over 60 000 DBS cases have been performed worldwide using STN, Vim, and GPi as the physiological targets. Microelectrode recording (MER) is often used and this allows for physiological confirmation of the STN target and its borders. Under normal physiological conditions, the STN exhibits a regular pattern of discharges with intervals of bursting activity. In the parkinsonian state, the STN has a characteristic irregular spontaneous discharge pattern at a mean rate of 20–50 Hz. During MER of the STN, the cells should be assessed for the presence of movement-related activity by examining the contralateral extremities. The limbs should be moved rapidly with shoulder, elbow, wrist, hip, knee, and ankle abduction, adduction, internal and external rotation, flexion, extension, dorsi-flexion and plantar-flexion. Movement-related activity is found if the cells exhibit reproducible modulation of the cell discharge during passive movement. Movement-related activity confirms localization within the motor area of the STN located primarily in the *dorsolateral* portion of the nucleus.

Pathology

Surgical lesions of the STN in normal primates and mainly hemorrhagic lesions of the STN in humans are associated with contralateral hemiballismus and it therefore comes as no surprise that in PD patients, surgical lesions of the STN may also be associated with hemiballism. Hemiballism is characterized by irregular, coarse, violent movements of the proximal muscles of the limbs. It may be caused by a reduced glutamatergic excitatory drive of subthalamopallidal fibers, resulting in a reduced inhibitory activity of the pallidothalamic pathway, leading in turn to disinhibition of thalamocortical projections. This is partly supported by electrophysiological recordings in patients with hemiballism, where GPi firing rates were low (about 30 Hz) compared with those in PD and even levodopa (LD)-treated PD patients. However, altered firing patterns in these pathways as a result of STN lesions may play a more important role.

Deep Brain Stimulation

Levodopa remains the gold standard for the treatment of PD; however, long-term use of levodopa is associated with motor complications, including dyskinesias. There has been a new interest in functional neurosurgery such as DBS to alleviate the symptoms of PD. High-frequency STN stimulation improves motor function in PD patients. The precise mechanism(s) by which this occurs remains controversial.

The STN is targeted for DBS, using stereotactic coordinates and direct visualization using magnetic resonance imaging (MRI) with either T_2 or inversion recovery coronal and axial images. Using the standard 1.5 T MRI, the STN itself is generally not easily visualized and indirect localization can be used based on visualization of the red nucleus and its relationship to the STN. The STN is typically located approximately 11–12 mm lateral from

the midline, 2–4 mm posterior to the midcommisural point (MCP), and 4 mm below the anterior and posterior commissural (AC-PC) plane. The STN is obliquely oriented along the three anatomical axes. It is approximately 55° oblique to the frontal plane and 35° oblique to the sagittal plane and 20° oblique to the horizontal plane. The optimal approach to this almond-shaped nucleus is 60° from the AC-PC plane with a slight lateral to medial approach that will result in a longer trajectory through the STN.

Using MER, a typical trajectory through the brain will encounter the following structures: Caudate with insertional activity at less than 1–6 Hz, and then the anterior thalamus with low density spontaneously firing neurons followed by an electrically quiet ZI and fields of Forel (H_1) and (H_2). Just before entering into the dorsal border of the STN, there will be a sudden increase in background activity and border cells may be present. The STN will have lots of activity with high-frequency cells (20–50 Hz) with short pauses. As described earlier, the STN may have movement-responsive cells if the trajectory is in the dorsolateral quadrant of the STN representing the sensorimotor region. When the cell activity decreases, the base of the STN is reached and finally the SNr is approached with increasing background activity and higher frequency (50–120 Hz) regular firing rates.

After the STN is localized, a permanent DBS lead, which is a quadripolar electrode, is implanted and secured and connected to an internal pulse generator neurostimulator. This is a silver vanadium oxide battery housed in a titanium case, which allows for the programming of the deep brain stimulator.

Stimulating the STN in a parkinsonian patient induces improvements in contralateral tremor, rigidity, and bradykinesia. Occasionally, stimulation effects may be seen when stimulating near the border of the STN. These stimulation-induced effects may include contralateral muscle contractions, dysarthria, or conjugated gaze deviation if the *lateral* border is stimulated due to the spread to the internal capsule. Stimulation of the *medial* border may cause unilateral eye deviation from spread to the third cranial nerve (III). Contralateral paresthesias are demonstrated when the *posterior* border of the STN is stimulated (see **Figure 3**). Bilateral DBS of the STN can have behavioral and cognitive consequences such as personality changes, disinhibition, cognitive decline, acute depression, decline in verbal and working memory, impairments in executive functioning, attention, and verbal and visual learning. This is most probably due to interference with the basal ganglia-thalamocortical associative and limbic circuits. Hypersexuality, anxiety disorders, hallucinations, and suicide have also been reported.

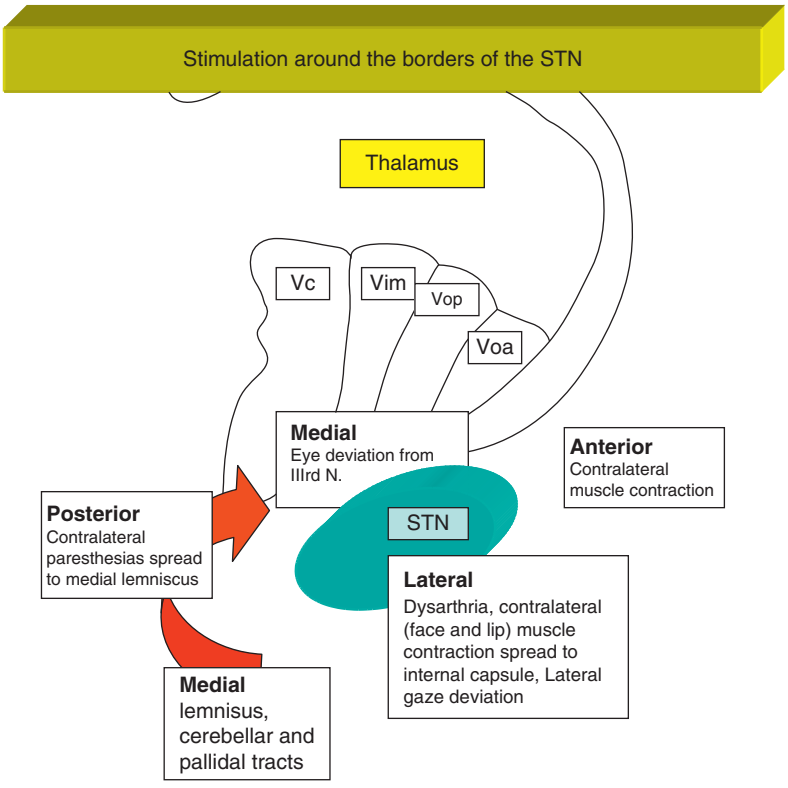

Figure 3

Conclusion

The STN is a critical component of the basal ganglia controlling not only motor function, but also cognition and affective behavior. Besides the treatment for PD, the STN is also being investigated at this time for the treatment of dystonia, tremor, and epilepsy.

Supranuclear Eye Movement Control

T Mizen, Rush University Medical Center, Chicago, IL, USA

Glossary

Oral dyskinesia – Abnormal, involuntary, aimless, repetitive movements affecting the tongue, lips, and jaw.

Oral stereotypies – Repetitive, aimless, patterned movements of the tongue, lips, and jaw.

Oromandibular dystonia – Sustained muscle contractions resulting in twisting repetitive movements and abnormal postures, producing lip retraction and grimacing, tongue rolling and thrusting, jaw closure with trismus, jaw opening or lateral deviation, and jaw jerks, sometimes generating teeth grinding noise (wakeful bruxism) and tremor.

Tardive dyskinesia – Term encompassing a variety of abnormal, involuntary movements following chronic exposure to dopamine receptor-blocking agents (e.g., antipsychotic drugs, antiemetic agents such as metoclopramide), commonly involving the lower facial musculature to justify the label "orobuccolinguomasticatory syndrome".

The cranial nerves control the eye muscles. There are six extraocular muscles innervated by cranial nerve 3, 4, and 6. The nuclei for these cranial nerves are located in the brainstem. The complex and precise array of eye movements that secure clear vision results from the interaction of a number of neural systems. Their combined output plays on the ocular motor nuclei in the brainstem. Thus the term supranuclear is appropriate to designate these systems. Input for the supranuclear control of eye

movements comes from the saccadic, the smooth pursuit, the vestibular, the optikokinetic, and the vergence systems. While the cranial nerves control eye muscles, the supranuclear areas control eye movements. The goal of the supranuclear control centers and the nuclei of the muscles is to provide the ocular motor system with the ability to attain a target and to maintain a target upon the fovea of the retina. The supranuclear system of eye movements is divided into the systems that perform saccades, smooth pursuit, and vergence, all of which work in concert to maintain an image of regard on the fovea. Additionally, the involuntary reflexes of the vestibular oculomotor system and optokinetic nystagmus are under the control of supranuclear centers.

Saccades are a fast eye movement to move the fovea rapidly to a target sensed in the peripheral visual field. A pulse of innervation provides a velocity command followed by a tonic pulse step discharge to maintain foveal fixation. These forces work against the viscous forces within the orbital tissues. Saccades can be either visually guided or volitional, controlled from the frontal eye fields (FEFs), and the parietal eye fields (PEFs). The PEF process visually guided saccades and the FEF process both volitional and visually guided saccades. Information is dispatched to the superior colliculus (SC) and then to the brainstem structures responsible for analyzing eye movement control. There is an ongoing balance between the pause and burst cells to allow eye movements to occur. An additional pathway through the caudate to the substantia nigra pars reticulata (SNPR) projects to the superior colliculus; discharges during fixation and subsequent pauses thus disinhibit SC burst neurons during voluntary and visually guided saccades.

From the FEF and the SC, fibers project to the contralateral paramedian reticular formation (PPRF) and the mesencephalon in the region of the rostral interstitial medial longitudinal fasciculus (riMLF). Horizontal saccades are generated from the contralateral FEF and SC, while vertical saccades originating in the riMLF require simultaneous action in both FEFs and SCs. The balance between the excitatory burst neurons and the inhibitory burst neurons allow saccades to occur. The abducens nucleus in the pons controls horizontal eye movements innervating the ipsilateral lateral rectus through cranial nerve 6, and via the medial longitudinal fasciculus, the MLF, the contralteral medial rectus subnucleus of cranial nerve 3 in the midbrain. Vertical gaze control originates in the riMLF requiring output to the nuclei of cranial nerves 3 and 4. Burst neurons subserving vertical and horizontal gaze are modulated by omnipause cells in the midline caudal pons.

Smooth pursuit is a slow eye movement, the purpose of which is to maintain an image of regard on the fovea once a saccade finds the object. Area V5 and V5a in the temporal occipital junction are involved to maintain smooth pursuit. Control is believed to be for ipsilateral smooth pursuit. Lesions in the area decrease the speed of smooth pursuit and the accuracy of saccades in the contralteral visual field. Fibers from V5 and V5a project to the ipsilateral pons, dorsal cerebellar vermis, and the cerebellar flocculus. The flocculus contributes to smooth pursuit and to vestibular involuntary eye movements.

The eye movement system of humans allows the eyes to move in opposite directions at the same time: convergence and divergence. The purpose of vergence eye movements is to maintain the image of regard on the fovea and to maintain stereopsis at near. Image disparity stimulates the vergence system. The exact supranuclear location of the vergence system is poorly identified. Vergence burst, vergence tonic, and vergence burst-tonic cells are located in the midbrain reticular formation, sending information to the medial and lateral rectus motor systems. Areas that may be involved in vergence include the posterior temporal, prestriate, and dorsal prefrontal cortex. The vergence system is also activated in the near triad of miosis, accommodation, and convergence, an involuntary reflex that can be volitionally suppressed or diminished following a variety of entities that inhibit cortical activity. Head trauma and processes that result in meningeal irritation can diminish the near triad.

The vestibuloocular reflex (VOR) is an involuntary reflex under the command of the semicircular canals. The purpose is to maintain an image on the fovea as the head rotates in the opposite direction. Otolith receptors are activated for both horizontal and vertical movements and are involved in a tilt reaction stimulated by gravity. Via the vestibular nerve signals are transmitted to the vestibular nucleus from which information is processed via several routes. For horizontal movements, information is directed to the area of the abducens nucleus and MLF. Primary and second order neurons work through additional ascending tracts, lateral to the MLF, transmitting vertical and torsional commands through the MLF and brachium conjunctivum to the nuclei of cranial nerve 3 and 4. There is a signal for the initial movement, an eye velocity position signal, and a tonic contraction signal to maintain target position. Signal coding occurs in the neural integrator, for saccades, pursuit, and optokinetic movements. For horizontal movements, the neural integrator is located in the medial vestibular and adjacent nucleus prepositus hypoglossi; for vertical and torsional movements, the integrator is located in the interstitial nucleus of Cajal of the rostral midbrain and vestibular nucleus. Visual input coordinates with VOR for low-frequency eye movements, balancing eye speed to head speed. Clinically, the VOR can be tested in a cooperative patient with distant fixation and rotation of the head in the vertical and horizontal plane. In the unconscious patient, the VOR can be driven through the use of the caloric response, with both warm and cold water infused into the ear.

Optikokinetic eye movements balance eye and head movements at low-frequency rotations. To maintain eye speed, the same as head speed at low frequency, the VOR activates and maintains fixation. The optikokinetic aids the VOR in keeping the eyes still during low-frequency stimulation. Optikokinetic slow phases occur reflexively by scenes that stimulate a large portion of retina. A slow phase to maintain fixation, similar to smooth pursuit, and an opposed quick phase represent optikokinetic nystagmus (OKN) The OKN is involuntary, but can be suppressed voluntarily with poor fixation or volitionally. Angular and translational eye movements are balanced by the involuntary vestibulo-ocular reflex and the optikokinetic system. The reflex is best observed when a large object subtending about 40° of the visual field is moved with a background scene moving in the opposite direction. The motion processing area of cerebral cortex is activated in all conjugate tracking mechanisms, the OKN, and the smooth pursuit system.

Surgery for Movement Disorders, Overview, Including History

A M Lozano, University of Toronto, Toronto, ON, Canada

Glossary

Deep Brain Stimulation (DBS) – A surgical procedure that is very effective in *treating Parkinson's disease*. The surgery includes the implantation of permanent electrodes in various parts of the brain through which continuous pulses of electricity are given through an implanted pacemaker to control the symptoms of Parkinson's disease.

Dopamine – A neurotransmitter (neural messenger) that is involved in numerous processes, including movement and mood regulation.

Dyskinesia – Abnormal muscle movements. May appear as a side effect of long-term drug treatment in Parkinson's disease and may worsen in response to stress.

Dystonia – Involuntary movements and prolonged muscle contraction, resulting in twisting body motions, tremor, and abnormal posture. These movements may involve the entire body or only an isolated area. Symptoms may even be 'task specific,' such as writer's cramp.

Parkinson's disease – Parkinson's disease (PD; paralysis agitans) is a *neurodegenerative disease*. The disease produces a progressive movement disorder characterized by tremor, rigidity (increased tone or stiffness in the muscles), *akinesia* (lack of spontaneous movement), and *bradykinesia* (slowness of movement), failing balance, and walking problems.

The history of neurosurgical procedures for movement disorders dates to the early twentieth century. The first surgeries involved cortical resections to treat chorea. A number of procedures predominantly directed at lesioning the corticospinal system to treat the tremor associated with Parkinson's disease (PD) followed. Beginning in the early 1940s, the realization that the basal ganglia were involved in the pathogenesis of movement disorders led to the exploration of various structures including the subthalamic area, the globus pallidus, and the thalamus to treat PD and dystonia. Until effective medications in the form of levodopa were available, neurosurgery played an important role in the treatment of PD. With the introduction of dopamine replacement and the realization of its striking clinical benefit in the 1960s, the role of neurosurgery for PD diminished considerably. There are now, however, a large number of Parkinson's patients who continue to be disabled by fluctuations in their motor function and who suffer adverse effects despite optimal medication therapy. With the introduction of deep brain stimulation (DBS) and the realization of its increased level of safety and efficacy, there has been a rediscovery of neurosurgery for movement disorders.

There have currently been ~40 000 patients with PD and other movement disorders treated with DBS. Stimulation is directed at treating motor fluctuations and the levodopa responsive components of PD. DBS can also be effective in treating levodopa induced dyskinesias through both a direct reduction in the propensity of dyskinesias and also because the procedures can be associated with a diminution in the requirement for drug. The use of DBS is now well established at most major neurosurgical centers. The mechanism of action is still not fully elucidated but is thought to be related to the neutralization or suppression of the pathological activity along the basal ganglia circuits.

A number of other experimental approaches to treat PD, including cellular transplantation and gene therapy, are in clinical trials. The outcomes of these experimental therapies will be available in the near future. The ongoing challenges for movement disorder surgery include how to treat the nondopaminergic, medication unresponsive components of PD such as cognitive dysfunction, psychiatric dysfunction, particularly depression, autonomic dysfunction, speech, and gait and posture problems. The second important challenge is that so far we have no means of slowing down or stopping the progression of the illness.

Sydenham's Chorea

F Cardoso, Internal Medicine Department, The Federal University of Minas Gerais, Belo Horizonte, MG, Brazil

Glossary

β-hemolytic *Streptococcus* – Strains of *Streptococcus* that have the ability to induce autoimmune reaction that cross-reacts with antigens of the brain, heart, joints, and skin.

Chorea – Abnormal involuntary movements that are brief, random, usually distal, and without purpose.
Epitopes – Antigens.
Jones criteria – Set of clinical and laboratory criteria used to diagnose rheumatic fever.

Definition and History

Sydenham's chorea (SC) is one of the major features of rheumatic fever (RF). 'Chorea' (derived from the Latin choreus meaning 'dance') refers to abnormal involuntary movements that are brief, random, usually distal, and without purpose. First described in the Middle Ages, the most common illness was perhaps a psychogenic movement disorder, but some cases were probably the postinfectious chorea known now as SC. Despite previous authors', including Paracelsus, having described rheumatic chorea earlier, Thomas Sydenham was the first to provide an accurate description of the condition.

Pathogenesis

SC is thought to result from an autoimmune response triggered by group A β-hemolytic *Streptococcus*, which induces the formation of antibodies cross-reactive with epitopes of the basal ganglia. According to this hypothesis, the antibasal ganglia antibodies cause dysfunction of the loops linking the striatum and frontal cortex. The current evidence supports the existence of these antibodies in virtually all patients with acute SC but their biological role is less certain. A few studies suggest that these antibodies are capable of inducing changes in the intraneuronal concentration of calcium. These findings support thus the notion that the pathogenesis of SC is related to molecular mimicry. There are also data demonstrating that the cell-based immunity is abnormal in patients with SC. The autoimmune nature of the condition is further supported by the observation of improvement of chorea with the use of steroids, as described later in this article. It remains unknown, however, what the predisposing factors to the development of RF and SC are. Not more than 2.5% of patients infected with group A β-hemolytic *Streptococcus* develop acute rheumatic fever (ARF), of whom just 25% have SC. Obvious candidates are genetic factors, but the studies so far have failed to identify which genes are relevant to the pathogenesis of SC.

Epidemiology

Up to the middle of the twentieth century, RF and SC were an important public health problem throughout the world, especially North America and Western Europe. With the development of antibiotics, the incidence of these conditions sharply declined. There are, however, large areas of the world, such as Latin America, Africa, and parts of Asia, where they remain common despite a trend toward reduction of their frequency. Nevertheless, recent studies show that SC is still the most common cause of chorea in children in North America. The usual age of onset is 9 years, being less common in children of less age and very rare, although it may occur, in adults. In most series, it is more common in girls, with a female/male predominance of 3/1.

Clinical Features and Diagnostic Criteria

From a clinical point of view, it is characterized by a combination of motor and nonmotor findings. The chorea in SC is usually generalized but hemichorea is found in 20% of patients. Muscle tone is invariably decreased; in up to 8% of patients in our series, this can be so severe that the subjects become unable to walk or even stand up (chorea paralytica). More recently, there is a controversy surrounding the presence of tics in patients with SC. Because of the similarity of chorea and motor tics, this question has been tackled by the investigation of vocal tics in SC. Studying a large cohort of our SC patients, an investigation at the Federal University of Minas Gerais was able to identify vocalizations in $<10\%$ of them. As there was an association with chorea of the face and lack of features typically seen in tics (e.g., premonitory sensations and ability to suppress them), it was concluded that tics are a rare occurrence in SC. There has also been a great interest in the association between behavioral abnormalities and SC. Several studies have shown that obsessive–compulsive disorder as well as attention deficit and hyperactive disorder is more commonly seen in SC than in controls. In fact, in a study at the Federal University of Minas Gerais, these conditions were diagnosed in, respectively, 23.2% and 30.4%, whereas these numbers for controls were 4% and 8%. Other behavioral abnormalities described in association with SC are irritability, trichotilomania, and psychosis. More recently, there has been an interest in investigating cognitive functioning in these patients. In the majority of patients, there is no abnormality with the exception of decreased phonetic verbal fluency, a finding already suspected by Gowers, who mentioned the 'disinclination to speak' presented by some of his patients back in the nineteenth century. Another recent investigation of our group has confirmed not only this finding, but also showed that 15% of patients have a more global dysexecutive syndrome, suggestive of a frontal–striatal dysfunction. In addition to neurological findings, cardiac valve dysfunction, especially mitral valve insufficiency, is found in up to 80% of patients, being the most important source of disability in SC. In all series of SC, arthritis is consistently less common, being diagnosed in not more than 25% of patients.

The current diagnostic criteria of SC are a modification of the Jones criteria: chorea with acute or subacute onset and lack of clinical and laboratory evidence of alternative

cause. The diagnosis is further supported by the presence of additional major or minor manifestations of RF. Recently, the first validated scale to rate SC has been published. The Universidade Federal de Minas Gerais (UFMG) Sydenham Chorea Rating Scale (USCRS) was designed to provide a detailed quantitative description of the performance of activities of daily living, behavioral abnormalities, and motor function of patients with SC. It comprises 27 items, and each one is scored from 0 (no symptom or sign) to 4 (severe disability or finding). It is important to emphasize that the USCRS is not intended to be used as a diagnostic tool but rather to assess patients already with an established diagnosis of SC.

Differential Diagnosis

SC accounts for virtually all cases of acute chorea in children. There are, however, rare causes, which should be ruled out. The most important ones are cerebral vascular disease and systemic lupus erythematosus (SLE). Stroke, not only of the subthalamus area, can cause chorea. Here are also reports of Moyamoya disease causing this movement disorder in children. Although SLE is a rare condition, which causes chorea in $<2\%$ of patients, it is the most important alternative cause to be ruled out in children with acute chorea. Other causes of chorea in children that should be remembered are encephalitis, acute disseminated encephalomyelitis, and Wilson's disease.

In adults, by far the most common cause of acute chorea is stroke. Diabetes mellitus type II, particularly among Asian patients, is an important cause of chorea. The mechanism is not clear but it seems to be related to microhemorrhages of the pallidum, which are visible on MRI scans. Other causes are infections, particularly AIDS and syphilis, hyperthyroidism, illicit drugs (amphetamines and cocaine), dopaminergic agents, and dopamine receptor blockers.

Diagnostic Workup

Children and young adults with chorea should undergo complete neurologic examination and diagnostic testing to assess the various causes of chorea, as there is no specific biological marker of SC. These are the tests helpful in the diagnostic workup of patients suspected to have rheumatic chorea: Tests of acute phase reactants such as erythrocyte sedimentation rate, C-reactive protein, leukocytosis; other blood tests like rheumatoid factor, mucoproteins, protein electrophoresis; and supporting evidence of preceding streptococcal infection (increased antistreptolysin-*O*, anti-DNAse-B, or other antistreptococcal antibodies; positive throat culture for group A *Streptococcus*; recent scarlet fever). These tests, however, are much less helpful in SC than in other forms of RF due to the usual long latency between the infection and onset of the movement disorder. Anti-DNase-B titers, however, may remain elevated up to 1 year after strep pharyngitis. Heart evaluation (i.e., doppler echocardiography) is mandatory, because the association of SC with carditis is found in up to 80% of patients. Serologic studies for SLE and primary antiphospholipid antibody syndrome must be ordered to rule out these conditions. Spinal fluid analysis is usually normal, but it may show a slight increased lymphocyte count. In general, neuroimaging will help to rule out vascular and other structural causes such as Moyamoya disease. CT scan of the brain invariably fails to display abnormalities. Similarly, head MRI is often normal, although there are case reports of reversible hyperintensity in the basal ganglia area. PET and SPECT imaging may prove to be useful tools in the evaluation, revealing transient increases in striatal metabolism during the acute phase of the illness seen in at least 60% of patients. This contrasts with other choreic disorders (such as Huntington's disease) that are associated with hypometabolism. Increasing interest is now directed to autoimmune markers that may be useful for diagnosis. The test of antineuronal antibodies, however, is not commercially available, being just performed for research purposes. Preliminary evidence, moreover, suggests that these antibodies are not specific to SC. Similarly, the low sensitivity and specificity of the alloantigen D8/17 render it unsuitable for the diagnosis of this condition.

Management

Management of SC is based on the use of medications to treat chorea as well as to prevent new *Streptococcus* infections. In some patients, chorea is mild and does not cause meaningful disability. Furthermore, after 1 year there is remission of the movement disorder in up to 75% of patients. There are instances, thus, where the use of antichoreic agents is not warranted. In patients where there is a need to control the chorea, valproate, at dosages usually employed to treat seizures, is the first choice agent. Although traditionally, dopamine receptor blockers have been the mainstay of control of chorea, currently they are regarded as second-line drugs. The reason for this is the observation that patients with SC are particularly susceptible to developing complications of neuroleptics such as drug-induced parkinsonism and acute dystonia. The current recommendation is to use steroids just in few selected patients who have failed to respond to or tolerate the aforementioned antichoreic agents. In these cases, the recommendation is intravenous methyl-prednisolone followed by oral prednisone. Secondary prophylaxis of *Streptococcus* infection is done with penicillin, or in patients with allergy, sulpha drugs. This has been shown to effectively decrease the risk of neurologic or cardiac problems

with additional streptococcal infections. The recommendation of the World Health Organization is to maintain the secondary prophylaxis up to age 21 years. In instances where the diagnosis of SC is made after this age, the policy is less clear.

Prognosis

There is a long-standing concept of SC as a benign condition, which invariably comes into spontaneous remission. However, contemporary work with careful prospective follow up of patients has shown a different picture. According to these studies, despite best treatment 25–50% of patients remain with active chorea after 2 years. More recently, we have also demonstrated that some of these patients also display cognitive abnormalities, particularly, dysexecutive syndrome. It is also clearly established that SC or even RF without chorea may cause basal ganglia dysfunction, which is silent but may lead to overtly clinical problems. Classical examples of this situation are chorea gravidarum and chorea induced by oral contraceptives. Additionally, one should bear in mind that the cardiac valve lesions are irreversible in most patients. In areas where RF and SC are still endemic, for cardiac surgery, such heart problems are a reason more important than coronary disease.

Synucleinopathies

K A Jellinger, Insitute of Clinical Neurobiology, Vienna, Austria

Glossary

Alzheimer disease – A neurodegenerative disease characterized by progressive cognitive deterioration together with declining activities of daily living and neuropsychiatric symptoms or behavioral changes.
Dementia with Lewy bodies – Second most common cause of dementia in the elderly, involving visual hallucinations and parkinsonism. Neuropathology is featured by widespread occurrence of Lewy bodies in brainstem and cerebral cortex associated with variable Alzheimer-type pathology.
Lewy body – Intracytoplasmic neuronal inclusion predominantly composed of misfolded α-synuclein, occurring in many areas of the nervous system.
Multiple system degeneration – A degenerative disorder of the central nervous system with parkinsonism, dysautonomic, and cerebellar symptoms. Neuropathological markers are α-synuclein-positive glial cytoplasmic inclusions in oligodendroglia.
Neurodegenerative disease – A disorder caused by the deterioration of certain neurons inducing their dysfunction and eventually bringing about their death.
Pantothenate kinase-associated neurodegeneration (Hallervorden–Spatz syndrome) – Rare autosomal-recessive disorder with dystonia, akinetic rigidity, and dementia, caused by mutation of the PANK2 gene on chromosome 20.
Parkinson disease – A degenerative disorder of the central nervous system that often impairs the sufferer's motor skills and speech.
Parkinson disease with dementia – A neurodegenerative disorder with extrapyramidal

motor dysfunctions and progressing cognitive impairment, caused by cortical Lewy body pathology and/or associated Alzheimer lesions.
Pure autonomic failure – Rare neurodegenerative disorder clinically featured by orthostatic hypotension and other autonomic failures, related to Lewy body pathology, predominantly in the peripheral autonomic system.
Synucleinopathies – A diverse group of neurodegenerative disorders sharing pathological aggregates of misfolded α-synuclein in neurons and glia with a wide spectrum of clinical syndromes.

Definition and History

The synucleinopathies are a diverse group of neurodegenerative disorders sharing common pathologic lesions composed of insoluble, misfolded αSyn protein that forms amyloid-like filamentous inclusions in selectively vulnerable populations of neurons and glia. The synucleinopathy diseases of the human nervous system are summarized in **Table 1**. αSyn, a member of the synuclein family of protein, was initially isolated from the electric plate of Torpedo californica and from rat brain and later as non-amyloid compound (NAC) of amyloid-rich plaques from Alzheimer disease (AD) brain. It is a natively unfolded 14.5 kD presynaptic phosphoprotein with potential for self-oligomerization and fibrillary aggregation under pathologic conditions. Its normal function remains elusive, but it may play important roles in synaptic plasticity and function. Recent improvement in the knowledge of αSyn was stimulated by the discovery of mutations in the SNCA (αSyn) gene (PARK1) on chromosome 4 and other PARK loci in familial forms of Parkinson's disease dementia (PD). Abnormally processed and hyperphosphorylated fibrillary αSyn – together with many other proteins – was demonstrated as a major component of Lewy Bodies (LBs), dystrophic neuritis, and astroglia in PD and glial cytoplasmic inclusions (GCIs) in oligodendroglia in multiple system atrophy (MSA). The histologic presence of insoluble aggregates of αSyn in these and related disorders has played an essential role in the diagnosis of neurodegenerative diseases during the last two decades.

Table 1 Synucleinopathies

1. Invariable forms (consistent occurrence of αSyn)
   - Sporadic Parkinson disease
   - Familial PD (αSyn, PARKIN mutations)
   - Incidental Lewy body disease (preclinical PD)
   - Rapid eye movement (REM) sleep behavior disorder (RSD)
   - Parkinson disease and dementia (PDD)
   - Dementia with Lewy bodies 'pure' form (no or little AD-pathology) LB variant of AD (LBV/AD)
   - Pure autonomic failure
   - Lewy body dysphagia
   - Multiple system atrophy
   - Pantothenate kinase-associated neurodegeneration (Hallervorden–Spatz syndrome)
2. Variable forms (inconsistent occurrence of αSyn)
   - Alzheimer disease (sporadic, familial)
   - Aging brain (with/without dementia)
   - Down syndrome
   - Frontotemporal lobe degeneration
   - Pick disease
   - Amyotrophic lateral sclerosis
   - Amyotrophic lateral sclerosis (ALS)-dementia complex on Guam
   - Progressive supranuclear palsy
   - Other tauopathies
   - Subacute sclerosing panencephalities
   - Ataxia telangiectasia
   - Meige syndrome
   - Gerstmann–Sträussler–Scheinker disease
   - Gaucher disease
   - Traumatic brain lesions

Pathogenesis/Pathophysiology

The etiology of synucleinopathies is thought to involve both genetic and environmental factors, but in most cases, nongenetic factors play a role, probably in interaction with susceptibility genes. Molecular interactions between environmental risk factors and genetic factors, for example, mutations in the αSyn gene, are implicated in the etiology of PD, dementia with Lewy bodies (DLB), MSA, and related disorders. Their pathogenesis has been related to a cascade of multiple noxious factors and events, including misfolded polymerized αSyn, phosphorylated at serine 129 that has a central role in dysregulating the dopamine synthesis and release, formation of free radicals, lipid peroxidation, oxidative and proteolytic stress, mitochondrial dysfunction and nuclear RNA deficits, protein–iron interaction, excitotoxicity from increased glutamatergic input, transcriptional dysregulation, disorders of calcium homeostasis, neuroinflammation, dysfunction of the ubiquitin–proteasome protein degradation system, impaired bioenergetics, and inhibition or loss of neuroprotective mechanisms and complex interaction between these and other factors that need to be carefully analyzed. Protofibrillary rather than fibrillary forms of αSyn have been shown to be cytotoxic, but αSyn containing LBs may be the structural manifestation of a cytoprotective mechanism to confine or eliminate toxic proteins. However, significant intracellular and neuritic protein aggregation may finally contribute to dysfunction and death of involved neurons. The question whether LBs and other αSyn aggregates are harmful or cytoprotective still remains unresolved. Although their formation may reflect

one of several response patterns by the central nervous system (CNS) to upstream dysregulation of αSyn metabolism, the αSyn pathway appears to be an essential factor for the selective multisystemic loss of neurons and glia in many synucleinopaties, for example, PD, Parkinson's disease dementia (PDD), DLB, and related disorders, showing widespread occurrence of LBs and dystrophic neurites with neuronal loss in many regions of the central, peripheral, and autonomic nervous system. They are associated with dysfunction of the dopaminergic nigrostriatal and many other neurotransmitter systems. It also appears to be a key pathway for selective loss of neurons, glia, and myelin in MSA, where αSyn-positive GCIs mainly in oligodendroglia are suitable morphologic markers. Although both clinically and pathologically related to PD, the working model of MSA as a primary glial disorder (oligodendrogliopathy) was strengthened by the finding of dysregulation in the metabolism of myelin basic protein and p25α (tubulin polymerization promoting protein), a CNS-specific phosphoprotein. This is suggested to cause degeneration of the oligodendroglia–myelin–axon–neuron complex associated with synucleinopathy, myelin dysfunction, and axonal damage leading to secondary neurodegeneration.

The pathophysiology of synucleinopathies is determined by the evolution pattern, distribution, and severity of αSyn pathology (LB and GCI density and distribution) and related parenchymal loss. The reliability of assessment of αSyn pathology, its dysfunction in various synucleinopathies, and their animal models have been reviewed recently. αSyn/LB predominance in brainstem is considered a marker for PD and their prominent occurrence in the cortex for PDD and DLB. In PD, DLB, and MSA-P (predominant parkinsonism, previously striato-nigral degeneration (SND)) and pantothenate kinase-associated neurodegeneration (PKAN) motor symptoms-like akinesia and rigidity are negatively correlated to neuron loss in substantia nigra and consecutive loss of tyrosin-hydroxylase and dopamine in striatum. In incidental Lewy body disease (ILBD), a precursor or preclinical form of PD, the lack of clinical symptoms is due to subthreshold αSyn pathology in various parts of CNS and sympathetic nerves. Cognitive decline is related either to abundant cortical αSyn/LB lesions, particularly in the limbic and mid-temporal regions or mixed αSyn and AD pathologies. Autonomic dysfunctions, such as in pure autonomic failure (PAF), PD, and MSA, are related to intensive αSyn/LB pathology in various parts of the central and peripheral autonomic system. However, in general, there is an imperfect correlation between αSyn/LB pathology and the clinical phenotype. Although the presence of LBs in brainstem and limbic cortex is suggestive of PD, PDD, and DLB, their mere presence – even in high numbers – does not reliably match extrapyramidal and cognitive impairment during lifetime. It remains a mystery as to which factors drive the expression of a more peripheral (PAF) or a more central (PD, DLB) versus a combined phenotype, as seen in some cases of sporadic (sPD) and familial Parkinson disease (fPD) with SCNA mutation. PKAN is a rare autosomal-recessive disorders with progressive dystonia, akinetic rigidity, optic atrophy, seizures, and dementia, caused by mutations of the pantothenate kinase 2 (PANK2) gene on chromosome 20. Neuropathology shows rust-brown discoloration of the globus pallidus and reticulata nigrae, neuronal loss, and numerous axonal spheroids in CNS and peripheral nervous system, associated with widespread αSyn-positive inclusions. Synuclein deposits in other diseases, like AD, tauopathies, etc., and in the central and autonomic nervous system of unremarkable aged individuals or those with dementia are not uncommon, but their pathophysiologic impact may be minimal or even nil compared to other pathologies.

Epidemiology/Risk Factors

The most common synucleinopathy is sPD with an annual prevalence of 48–69/1000 and standardized incidence rates of 8–18/100 000 person-years, its prevalence increasing from around 15% in persons aged 65 to 20–52% (age 75–85 years). PDD with incidence rates of 95–112/1000 pat-years and a cumulative prevalence between 48 and 83% after 15–20 years follow-up has a 4–6 times increased lifetime incidence rate compared to age-matched controls. DLB, with a reported prevalence of 0.3% over age 65 years is suggested to account for up to 10–22% of all dementia cases, thus being the second most common cause of dementia after AD. MSA is less common than PD with a prevalence of 1.9–4.9/100 000 and an incidence of 3/100 000 year^{-1}. Most of the other synucleinopathies are rare.

Risk factors

In addition to genetic factors, for example, mutations of SCNA/Parkin genes, aging, and occupational factors (exposure to pesticides, organic solvents, and heavy metals) have been implicated in the development of PD, while relations of increased PD risk with hypertension, hypercholesterolemia, and diabetes are discussed controversially. Smoking and caffein consumption, antioxidants, and increased dietary plasma urate may decrease the risk of PD. The genetic susceptibility and risk factors of most of the other synucleinopathies are hitherto unknown.

Clinical Features and Diagnostic Criteria

Several synucleinopathies, like PD, PDD, DLB, and SND, share common cardinal clinical features – rigidity, akinesia, rest tremor, and postural instability, and other motor (freezing, speach and neuroophthalmic dysfunctions) and

nonmotor disorders, in particular autonomic/dysautonomic, cognitive, and behavioral disorders that, in MSA-C are associated with cerebellar symptoms. Currently, PD is diagnosed upon the appearance of clinical symptoms when over 50–60% of nigral cells and striatal dopamine are lost. In DLB, parkinsonism is associated with visual hallucinations, fluctuating levels of consciousness, and cognitive impairment. Accepted clinical criteria for the diagnosis of probable PD, DLB, and MSA have a high sensitivity but only a moderate specificity, and for a definite diagnosis histopathologic confirmation is required. This also holds for the majority of other synucleinopathies, although modern neuroimaging may promote diagnostic possibilities, for example, in PD, MSA, and PKAN. PAF is featured by orthostatic hypotension and other dysautonomias, mainly related to αSyn/LB pathology in the peripheral autonomic system.

Differential Diagnosis

Parkinsonian disorders can be classified into four types: primary (idiopathic), secondary (acquired, symptomatic), heredodegenerative parkinsonism, and multiple system degeneration including parkinson-plus syndromes, but up to now, there are no definite clinical diagnostic criteria available for differentiating sPD from the various forms of parkinsonism. Although most clinical features have inadequate sensitivity, several of them, such as tremor, early gait abnormality, postural instability, pyramidal tract signs, response to levodopa, early olfactory dysfunctions (hyposmia), supported by (123)I-metaiodobenzylguanidine (MIBG)-cardiac scintigraphy studies and neuroimage techniques (transcranial sonography, functional magnetic resonance image (MRI), positron emission tomography (PET) and FP-CIT single photon emission computed tomography (SPECT), and increased iron content in midbrain in high field strength MRI) can be used to differentiate sPD from other parkinsonian disorders. Different putamen/nigra and putamen/caudate ratios of fluorodopa radioactivity, low cerebrospinal fluid (CSF) DOPA and DOPAC concentrations, and olfactory testing separate sPD from MSA.

Diagnostic Workup/Tests

The diagnosis of the various forms of synucleinopathies still relies on an exact medical and family history, an accurate examination of the patient and on the skills of the examiner. The use of ancillary tests (structural and functional neuroimaging, cardiovascular autonomic tests, neurophysiological investigations, and tests for biological markers) may be of help in the diagnostic workup of patients with synucleinopathies, but the results from many investigations are rarely specific and cost-effectiveness remains to be established. A possible exception is a positive genetic testing which allows the confirmation of rare forms, for example, monogenic autosomal dominant or recessive PD, rare forms of DLB, and PKAN. A number of biological or surrogate markers have been discussed: reduced cardiac MIBG uptake reflects cardiac sympathetic dysfunction in LB disease and MSA. Decreased αSyn and increased levels of DJ-1 in CSF, but increased αSyn expression in fibroblasts have been reported in sPD. Serum urate has been linked to clinical and radiographic progression in PD. Recent studies showed increased CSF 8-hydroxy-2-deoxyguanosine (8-OHdG) and glutathione levels, markers of oxidative damage, but reduced uric acid in sPD. CSF Aβ-42 and total tau levels are different between PD/PDD and DLB that shows significantly lower tau levels than AD, while DLB selectively shows increased Aβ-40. MIBG cardiac scintigraphy was superior to that of CSF markers in distinguishing DLB from AD. Increased CSF levels of neurofilament light chain and tau differentiate MSA-P from sPD, but cannot separate MSA-P and-C, while they are reduced in idiopathic late-onset olivo-ponto-cerebellar atrophy (OPCA).

Management

Current treatment of PD and related disorders, based on dopamine-replacement and dopaminergic agents, is well established but is burdened with adverse effects, and for this and other synucleinopathies, therapies that modify the inexorable progression of the disease are needed. To date, there are few symptomatic therapies available for the autonomic failure of MSA and PAF and practically none for their motor impairment. In patients with dementia, cholinesterase inhibitors may show some efficacy. Neuroprotective, neurorescue therapies and trials with neurotrophic factors have largely failed, while tissue implantation and gene therapeutic approaches are still in the investigative stages. Deep brain stimulation is most effective in patients that respond to levodopa. The future of neuro-gene therapy will depend on the development of gene therapy vectors capable of long-term expression, but will at best only partially address the underlying disease. A new therapeutic target would be αSyn influenced by protofibril activators, and the addition of protofibril-directed neurotherapeutics to the existing armamentarium may both extend the symptom-free stages of synucleinopathies and alleviate pathogenesis.

Prognosis

The natural history of synucleinopathies is variable. Several studies have shown that treating PD has changed its natural history, although the long-term effects of pharmacological and effective deep brain stimulation did not stop continuing progression of the disease. PD patients

have an increased risk of developing dementia with a mortality higher than that in individuals without PD, and the excess mortality increases with disease duration. DLB shows a more rapid progression and a prognosis worse than for PD and AD. Prognosis in MSA is even worse; most patients deteriorate rather rapidly and survival beyond 10 years after the disease onset is rarely seen. Most of the other synucleinopathies also have a poor prognosis because of a lack of efficient treatment options.

Glossary

6-Hydroxydopamine – 6-Hydroxydopamine, or 6-OHDA, is a neurotoxin used by neurobiologists to selectively kill dopaminergic and noradrenergic neurons in the brain. To this end, 6-OHDA must be injected in specific brain structures, where it enters neurons via the plasma membrane transporters for dopamine and noradrenaline (also called norepinephrine). The main use for 6-OHDA in neuroscience research is to produce models of Parkinson's disease in rats and mice.

Dopamine – Dopamine is a neurotransmitter occurring in a wide variety of animals, including both vertebrates and invertebrates. In the brain, it can activate five types of dopamine receptors – D1, D2, D3, D4, and D5, and their variants. Dopamine is produced in several areas of the brain, but the largest aggregates of dopamine-producing neurons are found in two midbrain nuclei named 'substantia nigra' and 'ventral tegmental area'. Dopamine is also a neurohormone released by the hypothalamus. Its main function as a hormone is to inhibit the release of prolactin from the anterior lobe of the pituitary. Severe dopamine deficiency in the striatum is the prime cause of parkinsonian motor symptoms (in particular, slowness of movement, poverty of movement, difficulty in movement initiation, resting tremor, rigidity).

Locus coeruleus – A nucleus in the brain stem involved in physiological responses to stress and behavioral arousal, and in the control of REM sleep. This nucleus is the principal site for synthesis of noradrenaline (also called norepinephrine) in the brain. Its name is derived from the Latin words 'coeruleus' (or 'caeruleus') and 'locus' meaning, literally, 'the blue spot' because of its somewhat azure appearance in unstained brain tissue (which is due to melanin granules). The axonal projections from this nucleus are widespread and highly ramified, reaching virtually all parts of the brain and spinal cord. The locus coeruleus is studied in relation to clinical depression, panic disorder, anxiety, and neurodegenerative diseases.

Nigrostriatal projection – Axon fibers that originate from neurons in the substantia nigra pars compacta and reach the striatum. This projection uses dopamine as its primary transmitter.

Raphe nuclei – The raphe nuclei (from the Greek word 'raffe', seam) are clusters of serotonin-containing neurons located along the midline in the brain stem (i.e., medulla oblongata, pons, and midbrain). Specific names of these nuclei are (in order from caudal to rostral), nucleus raphe obscurus, raphe magnus, raphe pontis, raphe pallidus, nucleus centralis superior, nucleus raphe dorsalis, nuclei linearis intermedius and linearis rostralis. These neurons have widespread and highly ramified projections that provide a serotonergic input to the entire brain (some nonserotonergic projections also arise from these nuclei, however). Serotonin is involved in a vast variety of cognitive and behavioral processes, and in the regulation of mood, sleep and wakefulness. Selective serotonin reuptake inhibitors (SSRI), which provide a treatment for depression, target the raphe nuclein and their projections.

Behavioral Studies

The first report on the behavioral effects of tail pinch was provided by Antelman and collaborators, who described a reproducible induction of eating, gnawing, and licking behavior by mild tail pinch in rats. This response was dependent on the integrity of the nigrostriatal dopamine

system and was maintained for the duration of the pinch, that is 20 s. Tail pinch was applied using a handheld hemostat and was described as nonnoxious because it did not evoke vocalization or other signs of distress. Since this first report, many rodent studies have utilized tail pinch as a way to induce transient behavioral arousal under standardized conditions. To apply the pinch for minutes (as opposed to seconds), a plastic or metal clip is fastened to the mid-distal portion of the rat tail.

Tail pinch has been extensively used in rats with unilateral 6-hydrodopamine (6-OHDA) lesions of the nigrostriatal pathway in order to transiently induce turning behavior in the direction ipsilateral to the lesion. This response is due to asymmetric activity in dopamine-dependent systems that control posture and locomotion. A particular application of the tail pinch stimulus is the Elevated Body Swing Test (EBST), which was developed for the behavioral assessment of unilaterally 6-OHDA-lesioned rats, but is now used also in other models of unilateral brain lesion. In the test, a rat is held ~3 cm above a table by a point 3 cm from the base of its tail. In 30 s, the number of left-biased swings and right-biased swings are counted. A normal rat does not exhibit side bias in the swinging behavior (50% swings towards each side), while a rat with a nearly complete unilateral nigrostriatal dopamine lesion shows a swinging bias in the direction contralateral to the lesion.

In Vivo Electrophysiology and Neurochemistry

In addition to its application in behavioral studies, the tail pinch stimulus has been extensively used in the neuroscience literature in order to assess whether specific categories of neurons respond to behavioral arousal. Tail pinch increases the firing rate of locus coeruleus neurons and of some neurons in the serotonergic raphe nuclei. The tail pinch stimulus readily enhances transmitter release and turnover in the terminal fields of ascending noradrenergic, serotonergic, and dopaminergic projections. The extent of this response may exhibit regional differences. In particular, the increase in dopamine and noradrenaline efflux induced by tail pinch is much more pronounced in the prefrontal cortex and nucleus accumbens than in the caudate-putamen.

Tardive Dystonia

A Rajput, University of Saskatchewan, Saskatoon, SK, Canada

Glossary

Drug-induced movement disorders – Includes parkinsonism, dystonia, tardive dyskinesias, and akathisia. Most though not all are due to dopamine-blocking medication. Some appear early (acute) while others are delayed (tardive). Treatment and prognosis are variable depending on the condition. More than one drug-induced movement disorder may be present at a time.

Dystonia – Involuntary twisting and turning movements caused by coactivation of agonist and antagonist muscles. The position may be fixed, affected by movements, and associated with jerky irregular tremor. Dystonia is due to dysfunction

of the basal ganglia. There are many different causes of dystonia.

Neuroleptic – Literally, 'that which grips the nerve.' These medications block the dopamine receptors and are effective in treating psychosis (and are often called 'antipsychotics'). Neuroleptic medications blocking the D2 dopamine receptors may cause drug-induced movement disorders, including acute dystonic reactions.

Tardive dystonia – Persistent dystonia that occurs typically after months to years of chronic dopaminergic blocking medication use. This condition is often uncomfortable and disabling. Retrocollis and trunk hyperextension are classic features. In contrast to idiopathic dystonia, tardive dystonia tends to improve with activity and is less responsive to sensory tricks. The overall prognosis is guarded; treatment includes stopping or switching medications. Symptomatic treatment with dopamine depleting agents or anticholinergics may be effective.

Definition and History

Chronic dystonic reactions were noted in the late 1950s. However, the term 'dystonia tarda' was first described by Keegan and Rajput in a single case in 1973 followed by Burke et al. who described a case series of 42 persons with tardive dystonia (TDyst) in 1982. An association between dopamine blocking agents and TDyst was noted, though causality was difficult to prove. Dopamine blocking agents were felt to play a causative role as the rate of dystonia was much greater than expected for sporadic or inherited dystonia.

The term tardive means 'delayed.' While TDyst typically occurs months to years after medication exposure, sometimes only a few days or weeks of exposure are enough to produce TDyst; rare cases have occurred after a single exposure to medication. Unlike acute dystonia, TDyst does not quickly resolve upon withdrawal of the causative agent.

Pathogenesis and Pathophysiology

Chronic dopamine receptor blockade is believed to underlie TDyst. While there is individual susceptibility, no consistent findings regarding dopamine receptor polymorphisms have been found. The biochemical basis appears different for tardive dyskinesias (TD); while anticholinergics tend to improve TDyst, they worsen TD.

Rarely, medications without dopamine-blocking properties have been linked to TDyst. Given the usual long latency before development of TDyst, it can be extremely difficult to establish a link between a nondopamine blocking medication and dystonic symptoms.

Epidemiology and Risk Factors

The risk of TDyst increases with longer duration of treatment. While more common after months to years of treatment (one study by Kiriakakis et al. report median 5 years and mean 6.2 years), there is no 'safe period' as TDyst may begin after a few days of medication or even after a single dose.

In a 1996 baseline study of drug-induced extrapyramidal syndromes among all psychiatric inpatients of the Netherlands Antilles, 194 patients were evaluated who were on or had used neuroleptics for the prior 3 months. The 13% prevalence of TDyst in this mostly chronic population was higher than that was previously reported. However, mild dystonia was included. If only moderate to severe dystonia cases were counted, the prevalence would be 2.9%, similar to what other studies have reported.

TDyst occurs at an earlier age than TD, which more often affects elderly females. Unlike acute dystonia, there is no marked decline in incidence after the age of 40 for TDyst as it may affect all age groups. Males with TDyst are about a decade (or more) younger than females. While some studies report no gender predilection, others report male to female ratios between 1.6 and 2.7. In a series of 100 cases (26 males, 74 females) with tardive syndromes from five movement disorders units in Spain, Orti-Pareja and colleagues reported 16% had TDyst. By comparison, 72% had orobuccolingual dyskinesias (TD). Unlike other tardive syndromes (dyskinesias, akathisia, and tremor), which had clear female predominance in this study, males and females had similar risk for TDyst.

One study reported an association with a history of acute dystonia with TDyst although the numbers are too small to definitively state that an acute dystonic reaction predisposes to TDyst.

A study by Yassa et al. focusing on severe TDyst and severe TD found prevalence rates of 1.4% and 2.0% in a combined inpatient and outpatient psychiatric population respectively. Only eight cases of severe TDyst were found, with a 3:1 male: female ratio. TDyst is often painful and distressing, while many patients with TD are unaware or only slightly bothered by it. Even in severe cases, only 60% of the TD cases were aware of their symptoms in contrast to all the TDyst cases. In this study, TDyst developed in a shorter time period with less total neuroleptic dose than TD.

Clinical Features and Diagnostic Criteria

TDyst may be indistinguishable from idiopathic torsion dystonia. In adults, the dystonia is more often focal or segmental, while in younger persons, it is more often generalized. The craniocervical region and upper limbs are the most commonly affected body parts. Retrocollis and trunk hyperextension are classic features of TDyst. Internal rotation of the arms, elbow extension, and wrist

flexion are seen in the upper limbs and are almost never seen in idiopathic dystonia. Lower limb dystonia is more commonly seen in young persons. Findings in the cranial musculature may be similar to the acute dystonic reactions, and occasionally intermittent oculogyric crisis has been reported.

Unlike idiopathic dystonia, TDyst tends to improve with action (including walking) and is generally less responsive to sensory tricks (*geste antagoniste*).

Onset of TDyst is insidious, with progression over weeks to months followed by stabilization. It is an often painful and disabling condition.

Patients may have concomitant TD (orobuccal lingual movements), tardive akathisia, or drug-induced parkinsonism.

Criteria to diagnose TDyst include:

1. duration for more than 1 month,
2. occurring during or within 3 months of stopping a neuroleptic,
3. secondary causes of dystonia have been ruled out,
4. negative family history of dystonia or documented exclusion of known mutations.

It is not necessary for dystonia to be the predominant movement disorder to diagnose TDyst.

Differential Diagnosis

The differential diagnosis for TDyst is more extensive than for acute dystonia. As noted above, idiopathic dystonia may be indistinguishable from TDyst. Genetic causes of dystonia, including DYT1 mutations should be considered in young persons. Unmasking of cases with genetic dystonia without clinical findings may also occur with neuroleptics. Secondary causes of dystonia should be considered. Wilson's disease, a reversible illness due to abnormal copper metabolism, should be excluded by 24 h urine copper, serum ceruloplasmin, and ophthalmological exam for Kayser–Fleischer rings. Brain MRI can exclude underlying structural causes. Young onset Parkinson's disease may present with dystonia. Dopa-responsive dystonia often has diurnal variation with improvement after rest.

Stiff person syndrome can cause painful trunk hyperextension with lumbar muscle hypertrophy and should be considered in the appropriate setting.

Psychogenic dystonia may also be considered in the differential diagnosis only if the clinical picture appears inconsistent with TDyst and appropriate investigations are negative.

Management

The mainstay of treatment is to remove the offending agent. Improvement is often delayed and incomplete. Judicious use of antipsychotic medications would also reduce the overall prevalence of TDyst.

Symptomatic treatment is often necessary. Anticholinergics and dopamine depleting agents are the two most common types of medications.

Anticholinergics including benztropine, trihexyphenidyl, and biperiden have been used with overall moderate success. The doses required may be extremely high and are less well tolerated by older adults. Adverse effects are common including dry eyes, dry mouth, constipation, urinary retention, confusion, blurred vision, and bradycardia. Anticholinergics may also improve drug-induced parkinsonism but worsen TD.

Dopamine depleting agents including tetrabenazine and reserpine are also used with good effect. Adverse effects from both medications include depression and hypotension. While tetrabenazine may rarely cause drug-induced parkinsonism, it does not cause TD.

Increasing the dose of the neuroleptic may temporarily improve the TDyst; however, it is not in the best long-term interest of the patient.

As a number of patients on neuroleptics have an underlying psychiatric illness requiring treatment, it may be impossible to stop neuroleptics entirely. In patients who require antipsychotic medications, switching to an atypical agent such as olanzapine or quetiapine is suggested. Both these drugs may cause improvement of the dystonia for several weeks; however, olanzapine itself may cause TDyst, and long term results of quetiapine are not available.

Clozapine is an atypical antipsychotic which may provide sustained benefit in TDyst. It is uncertain whether the benefit from clozapine is due to its anticholinergic properties, its 'loose' binding of dopamine receptors, or the fact that the offending agent has been removed. A rare but potentially fatal adverse effect is agranulocytosis, and blood work must be checked regularly.

Clozapine has also been reported to cause tardive oculogyric crisis; rapid withdrawal of clozapine may also cause severe dystonias and dyskinesias.

Medications that work on the GABAergic system such as benzodiazepines and baclofen have been used with variable success and are worth trying if there is no improvement or there are problems tolerating other medications. Occasionally dopamine agonists, amantadine, and clonidine have been helpful.

For focal dystonia, botulinum toxin injections into the affected muscles can be quite helpful. For severe refractory dystonia, bilateral deep brain stimulation (DBS) of the globus pallidus interna (GPi) significantly improved both motor and disability scores by at least 80% in six cases followed by Sako et al. for a mean of 21 months. Moreover, the psychiatric status remained stable in each case.

Prognosis

Unlike TD, this syndrome is less responsive to treatment and is often painful. Significant disability in severe cases of TDyst is not uncommon. In a study by Kiriakakis and

colleagues of 107 TDyst patients, there was only 14% remission over a mean follow-up of 8.5 years. Discontinuing neuroleptics increased the remission rate four-fold, while those on neuroleptics for 10 years or less were five times more likely to remit. Patients with TDyst on neuroleptics for more than 10 years have essentially no chance of remission.

In a follow-up study conducted in 2008 by van Harten and colleagues, in the 26 patients (mean age 53.3 years) with TDyst at baseline, 64% recovered, 20% persisted, and 16% had an intermittent course over a 9 year follow-up. The cumulative incidence of TDyst (in those without baseline TDyst) over 9 years of follow-up was 16.1% (27/168). Mean age was similar at 57.6 years, and this group did a bit better – 80% recovered, 8% had persistent dystonia, and 12% had an intermittent course (defined as anything other than TDyst at all assessments or TDyst absent at last assessment). The most common sites of involvement were the upper limbs, eyes, neck, and mouth. While they mentioned whether the patients were on a first generation antipsychotic or one of olanzapine, clozapine, or risperidone at each visit, the dosages were not given nor was any information regarding symptomatic treatments. The prognosis in this carefully followed population is better than what has previously been reported in TDyst.

Tardive Syndromes

R Wolf Gilbert and C Waters, Columbia University Medical Center, New York, NY, USA

Glossary

Dopamine – A neurotransmitter that functions in several areas in the brain, including the basal ganglia. It affects multiple brain functions including motor planning, reward, and attention. Once released, it interacts with the dopamine receptor to trigger its effects.

Neuroleptic – An antipsychotic medication that acts to change cognition or behavior.

Tardive akathisia – A disturbing sense of inner restlessness, with the outward manifestation of

semi-voluntary fidgety movements, that occurs as a chronic side effect of dopamine-blocking medications.
Tardive dyskinesia – Repetitive, stereotyped movements, most commonly of the mouth and tongue, that occur as a chronic side effect of dopamine-blocking medications.
Tardive dystonia – Sustained twisting movements, most commonly of the neck and trunk, that occur as a chronic side effect of dopamine-blocking medications.

Definition and History

In 1952, chlorpromazine (Thorazine) became the first dopamine-blocking agent used clinically in the treatment of psychosis. Four years after its release, the first case report of abnormal mouth movements as a side effect was published. The term 'tardive dyskinesia' was coined in 1964, as it became clear that the movements were the late effects of treatment.

Tardive syndromes are now understood to be a group of movement disorders that emerge after chronic treatment with centrally acting medications that block the dopamine receptor. There are three major classes of movements that can be seen in this setting: tardive dyskinesia, tardive dystonia, and tardive akathisia. Each has its own clinical features, natural history, prognosis, and treatment. Tardive dyskinesia refers to repetitive, stereotyped movements that most typically involve the mouth and tongue. Tardive dystonia refers to sustained twisting movements, most commonly of the neck and the trunk. Tardive akathisia refers to a disturbing sense of inner restlessness, with the outward manifestation of semivoluntary fidgety movements. Other types of movements attributed to dopamine blockade, such as tardive myoclonus, tardive tics, tardive chorea, and tardive tremor, have also been described. More than one of these conditions can exist in the same patient. Because these conditions can persist for years and can even be permanent and because they are caused by medications prescribed by physicians, they are a particularly problematic complication of therapy with dopamine-blocking agents.

Tardive syndromes must be distinguished from acute movement disorders that occur due to dopamine blockade, which are significantly more treatable and reversible. Acute dystonic reactions, including oculogyric crises, are responsive to antihistamines (such as diphenhydramine), anticholinergics (such as benztropine), and benzodiazepines (such as diazepam). Even if they are not treated, they always resolve over time after the cessation of the dopamine-blocking agent. Acute akathisia can be responsive to beta-blockers or anticholinergics and also resolves with the removal of the offending agent. Drug-induced parkinsonism is a common and well-described phenomenon, which can look identical to idiopathic Parkinson's disease (PD), but may be more symmetric in onset. Although it may take several months after neuroleptics are stopped for parkinsonism to resolve, it almost always does. If parkinsonism does not resolve, a diagnosis of idiopathic PD must be considered, as these agents may unmask the symptoms of PD. The existence of the diagnosis of tardive parkinsonism remains in question.

Dopamine-blocking medications include 'typical' antipsychotics such as chlorpromazine (Thorazine), thioridazine (Mellaril), trifluoperazine (Stelazine), and haloperidol (Haldol). The newer antipsychotic medications such as olanzapine (Zyprexa) and risperidone (Risperdal) have been referred to as 'atypical.' A lower risk of tardive syndromes has been linked to these drugs compared with the typical medications, although the risk is not zero. Ziprasidone (Geodon) and aripiprazole (Abilify) are newer, but have also been shown to cause tardive movements. The only truly atypical antipsychotics are quetiapine (Seroquel) and clozapine (Clozaril), although there are case reports of even these medications causing tardive syndromes. Antipsychotics are not the only type of medication that can cause dopamine blockade. Medications for nausea, including metoclopromide (Reglan) and prochlorperazine (Compazine), can also cause tardive syndromes. Interestingly, medications that act on the presynaptic dopamine system such as reserpine and tetrabenazine (TBZ) have not yet been shown to cause tardive syndromes.

Pathogenesis/Pathophysiology

The pathophysiology most accepted for tardive disorders is that with chronic use of dopamine-blocking agents, the dopamine receptors become oversensitized, leading to abnormal movements. The details of how that process occurs are not well understood. There are five known dopamine receptor subtypes, D1 through D5, which are present in various locations throughout the brain. Blockade of the D2 receptor is responsible for the tardive phenomenon. Agents that preferentially block other dopamine receptor subtypes are safer in this regard. One theory suggests that movements result from an imbalance between D1 and D2 signaling – with the blockade of the D2 receptor, D1 signaling is unchecked.

One classic feature of tardive syndromes is that they are more likely to start or become worse if the dopamine-blocking medications are stopped or reduced quickly, leading the oversensitized receptors to be released from their blockade. This also explains why increasing the dopamine-blocking medication can be used as a method to quickly suppress the tardive movements when they

start, although the suppressed symptoms may later reemerge and be more severe.

Other neurotransmitters, besides dopamine, such as acetylcholine, GABA, and glutamate have been implicated in the development of tardive movements. Theories include the disruption of the balance of dopamine and acetylcholine in the basal ganglia, direct damage to striatal cholinergic and/or GABAergic interneurons, insufficient GABAergic inhibition of dopamine release, or excessive glutamatergic stimulation. In addition, oxidative damage has been hypothesized to play a role. Treatments that counteract these abnormalities have been suggested and tested (see the Management section).

Epidemiology/Risk Factors

Incidence and prevalence of tardive dyskinesia vary widely between studies, due to the differences in assessment, the types of medications used, and the type of population under study, among other variables. Prevalence has been shown to range from 12.3% for psychiatric outpatients to 37.4% among psychiatric inpatients. In one study, the prevalence of tardive movements among patients in an outpatient psychiatric center was found to be as high as 44%.

In 1988, Kane et al. determined the incidence of tardive dyskinesia in the setting of first generation antipsychotics to be 5% per year, increasing to 19% by 4 years. The prevalence rate of tardive dyskinesia tends to stabilize around that time, as the remission rates equalize with rates of new cases. The rates in the population of over 55 years of age, however, were higher than 19%. In 1998, Woerner et al. studied a group of elderly neuroleptic naïve patients and found that the rates of tardive dyskinesia were 25%, 34%, and 53% after 1, 2, and 3 years of treatment respectively, leading to the conclusion that the elderly population is 3–5 times more susceptible to this condition.

The introduction of a new generation of antipsychotics brought with it the hope and possibility of lower rates of tardive syndromes. In 2008, Correll and Schenk conducted a meta-analysis comparing the rates of tardive due to first and second generation antipsychotics. Across all ages, first generation antipsychotics had an annual risk of tardive dyskinesia of 5.5%, while second generation antipsychotics had an annual risk of 3.9%. However, some individual studies showed annual rates of less than 1% for second generation antipsychotics. This variation between studies may reflect the inherent difficulty of screening patients properly for all the past exposures to first generation neuroleptics. The Correll and Schenk meta-analysis determined that the prevalence of tardive syndromes in adults was 13% for second generation antipsychotics and 32% for first generation medications. Rates of tardive dyskinesia in children are low. One study showed an annual rate of 0.35% for second generation medications.

It has been reported that schizophrenics never exposed to dopamine-blocking agents have a higher rate of spontaneous facial dyskinesia than the general population, and that this can confuse epidemiological studies. This assertion relies on accurate prior medication reporting, which is difficult to assess in the schizophrenic population.

Epidemiologic studies have revealed many interesting features of the tardive population. Age is a major risk factor for tardive syndromes. Incidence increases and remission rates decrease with age. Other risk factors include increased duration of exposure to medications, increased total dose administered over time, presence of alcoholism or preexisting brain damage, higher severity of psychiatric illness at baseline, and poor response to antipsychotic medication. In addition, trials of multiple different agents increase the risk over maintaining a single agent, although this risk factor is difficult to separate from the severity of psychiatric illness. Stopping and restarting the medications increases the risk as well. The development of acute or early symptoms from these medications may predispose an individual to the later development of tardive syndromes. Elderly patients on antipsychotics in the context of dementia develop tardive syndromes less frequently than those on antipsychotics for schizophrenia or affective disorders. Finally, gender is a risk factor, and elderly women have higher rates of tardive dyskinesia than elderly men.

The risk factor profile for tardive dystonia is somewhat different than tardive dyskinesia. Kang et al. showed in 1986 that in contrast to tardive dyskinesia, younger patients tend to have more severe tardive dystonia than older patients. In 1998, Kiriakakis et al. showed that tardive dystonia develops after a shorter exposure in men than in women.

Not all treated individuals with the same risk factor profile will behave similarly in their development of tardive syndromes. Genetic risk factors that may help to explain the diversity of response to these medications have begun to be identified. Polymorphisms in the dopamine D3 receptor, the serotonin 5-HT2C receptor, and the superoxide dismutase-2 enzyme have all been associated with increased risk of tardive dyskinesia.

Clinical Features and Diagnostic Criteria

The diagnostic criteria for tardive dyskinesias have been developed by the American Psychiatric Association Task Force on Tardive Dyskinesias. The movements should improve with an increase of the neuroleptic dose and worsen with a reduction or discontinuation of the medications. The movements should develop either while the patient is on neuroleptics or within a few weeks of discontinuing the medication. They should be present for at

least 4 weeks, after at least 3 months of total cumulative neuroleptic exposure. Although these are the guidelines, tardive symptoms have been reported to start months to years after the medication is stopped and after only a single dose of dopamine-blocking medications. In general, tardive dystonia is more likely to start after a briefer exposure to medication than tardive dyskinesia.

Tardive Dyskinesia

The most common and well described of the tardive syndromes is tardive dyskinesia. Classically, this movement disorder involves oro-buccal-lingual movements, including lip puckering, tongue popping, and lateral jaw movements. Breathing can also be affected, with repetitive gasping and respiratory dysrhythmia. Rhythmic abdominal and pelvic movements can also be seen. The repetitive flexion and extension of the fingers, known as 'piano-playing' fingers, is another manifestation. The flexion and extension of the toes can also occur. The movements are stereotyped, and this differentiates them from choreic movements, which are by definition, erratic and affect various parts of the body in a random, flowing manner. Tardive movements are typically suppressible to some degree.

Tardive Dystonia

Tardive dystonia presents most commonly as retrocollis, back arching, and internal rotation of the shoulders with flexion at the elbows. The dystonia often has a jerky quality, with sustained bursts of stereotyped movements. Blepharospasm and jaw dystonia are other common manifestations. Other forms of cervical dystonia are also possible such as anterocollis, laterocollis, or torticollis, but retrocollis is most often associated with tardive dystonia. Tardive dyskinesia may accompany dystonia. Unlike tardive dyskinesia, which is often not noticed by the patient, tardive dystonia is typically very distressing. The dystonia may be indistinguishable from idiopathic dystonia and accompanied by many of the same features, including sensory tricks. Dystonia tends to begin focally, and then to spread. Younger people are more likely to have generalized disease than older people. The head and the neck are most commonly affected first and are the most severely affected body parts.

Tardive Akathisia

Since akathisia is a well-described acute reaction to dopamine-blocking medications, it was not immediately recognized by the medical community that this phenomenon could also develop as a chronic side effect. In 1989, Burke et al. presented their experience with this disorder. They described the movements that the clinician sees, which are often volitional and are a reflection of the agitation, such as trunk rocking, knee abduction/adduction, marching in place, and leg crossing/uncrossing. The lower body is most often involved, although trunk rocking and complex hand movements can also be seen. Most patients with tardive akathisia also have tardive dyskinesia and/or tardive dystonia. Akathisia is probably the most distressing of the three major syndromes to the patient.

Other Tardive Disorders

In a study by Tominaga et al., 24% of patients taking neuroleptics for more than 3 months demonstrated postural myoclonus, documented by electromyogram (EMG). Clonazepam reduced these movements.

The withdrawal emergent syndrome causes chorea in the setting of an abrupt withdrawal of a neuroleptic. Although tardive dyskinesia is stereotyped and rhythmic, the chorea of this syndrome migrates from place to place without pattern. Withdrawal emergent syndrome occurs mostly in children and usually resolves completely with reinstatement of the dopamine-blocking agent and the institution of a slow taper. Motor and vocal tics have been reported as tardive phenomena. Tardive tremor is a rare phenomenon and refers to a rest and postural tremor that develops in a patient previously exposed to dopamine-blocking agents.

Differential Diagnosis and Diagnostic Work-up

The patterns of both tardive dyskinesia and tardive dystonia tend to be very characteristic, and an experienced clinician may strongly suspect the diagnosis even before obtaining a history of neuroleptic use. The suspicion may be so high that even if the patient is not aware of past neuroleptic use, a thorough investigation may reveal it. On the other hand, if other neurological features exist on examination, then an alternative explanation for the movements should be sought. There are no laboratory or imaging tests that can confirm tardive syndromes.

Tardive Dyskinesia

Differential diagnosis for tardive dyskinesia includes Huntington's disease, although unlike tardive dyskinesia, the choreic movements of Huntington's move from one part of the face to another, without a distinguishing pattern. Huntington's disease also involves the upper face, which is not present in tardive dyskinesia, unless it is complicated by tardive blepharospasm. Other causes of choreic mouth movements include hyperthyroidism and systemic lupus erythematosis. Idiopathic oromandibular dystonia can look like tardive dyskinesia as well, although these movements tend to have more of an effect on talking

and eating. In the right setting, edentulous dyskinesias must be considered. Parkinsonian tremor of the jaw can be confused with tardive and may be attributable to the use of dopamine-blocking agents or to PD itself. Other diagnoses to consider include facial tics, hemifacial spasm, myokymia, brainstem infarctions, neuroacanthocytosis, and epilepsy partialis continua.

Tardive Dystonia

It may be difficult to distinguish tardive dystonia from idiopathic dystonia. Inherited dystonias, dopamine-responsive dystonias, and Wilson's disease should be considered in the younger population.

Tardive Akathisia

Tardive akathisia can be difficult to distinguish from an agitated depression, which may be the reason the dopamine-blocking agent was given in the first place. Distinguishing these two conditions is important as they have opposite treatments; akathisia requires the removal of the dopamine agonist, whereas agitated depression may require an increased dose. Restless leg syndrome may resemble tardive akathisia, although it is typically present only at night and only involves the legs.

Management

Tardive Dyskinesia

As tardive syndromes can be difficult to treat, the clinician's focus should always be on prevention, by avoiding or minimizing exposure to dopamine-blocking agents. Dopamine-blocking agents should be reserved for patients with appropriate problems, and generalists and neurologists might benefit from a psychiatric consultation on alternative options to these agents. The lowest dose of the drug should be used. The treatment plan should be periodically reassessed to see if the dopamine-blocking agent is still needed. The patient should be periodically examined to determine if tardive symptoms are present. It is generally advised that frequent initiation and withdrawal of the medications should be avoided.

If the patient is on a dopamine-blocking agent when the tardive movements begin, the first plan of action should be to slowly titrate the patient off of the medication if possible. Stopping the medication too quickly can exacerbate the disorder. If the patient is dependent on neuroleptics because of a psychiatric condition, the patient can be switched to clozapine. Although there are case reports that suggest that clozapine causes tardive syndromes, in virtually all these reports, the patient had prior exposure to other neuroleptics. Regardless, if there is a risk of tardive syndromes with clozapine, it is very low. Clozapine, however, is associated with a 1% risk of agranulocytosis and requires weekly blood draws for monitoring. It is therefore not an ideal medication for many patients.

The literature remains unclear as to whether clozapine treats tardive dyskinesia or is just the neuroleptic of choice to avoid the syndrome. In most studies, clozapine had a beneficial effect on movements, but these tended to return when clozapine was stopped. A minority of patients had sustained improvement. Clozapine likely suppresses tardive movements successfully until the natural history of the condition plays out and improvement or remission is achieved.

If the movements persist despite stopping the dopamine-blocking agent, a number of other strategies can be tried. Tetrabenazine (TBZ) and reserpine are dopamine-depleting agents, which work as vesicular monoamine transporter (VMAT) inhibitors. VMAT normally transports norepinephrine, serotonin, and dopamine into presynaptic vesicles. If the transporter is inhibited, the neurotransmitters are not protected and are degraded by monoamine oxidase (MAO) and cathechol-*O*-methyl transferase (COMT), thereby leading to dopamine depletion. This class of medicine has been used for other hyperkinetic disorders such as chorea, hemiballismus, and tics. TBZ has some dopamine receptor blocking action, but this mechanism appears to be clinically inconsequential, since tardive dyskinesia has not been reported with the use of this drug. α-Methyl-*para*-tyrosine (AMT) is a tyrosine hydroxylase inhibitor and can also be useful in tardive syndromes by decreasing the dopamine availability. It is a milder agent than TBZ or reserpine and normally is effective only if it is added either to one of these agents or to a neuroleptic. Combinations of TBZ and AMT are more effective at controlling these movements than each alone. Combining reserpine and AMT, however, may cause excessive hypotension.

Recently, the Food and Drug Administration (FDA) approved TBZ for the treatment of chorea in Huntington's disease, and it is now available in the USA. Prior to this, only certain movement disorder centers had access to this medication, and patients were required to pay out of pocket for it. Depression and parkinsonism are serious side effects of TBZ and reserpine, which limit their use in predisposed individuals. All patients exposed to TBZ must be followed with vigilance for subtle emergence of depressive signs. Whereas tardive dyskinesia has not been described with TBZ, the overall population exposed to this drug chronically remains relatively small, and since it is used to treat patients with hyperkinetic disorders, the emergence of tardive dyskinsesia may be difficult to distinguish from the underlying disorder being treated (Huntington's disease, tics). For this reason, consultation with movement disorder specialists may be particularly useful when patients are treated with TBZ.

A vast number of other medications have been tried with varying degrees of success. Most of the studies that

report benefit were conducted on very small populations. In addition, very few were randomized, double-blinded, case-controlled and placebo-controlled studies, and are therefore hard to interpret. Cholinergic medications were not successful, although anticholinergic medications seem to make tardive dyskinesia worse. Modifiers of the GABA system such as baclofen, valproic acid, and benzodiazepines all showed mixed results in various trials. Although trial results of lithium have been mixed, recent evidence suggests that lithium may confer protection from tardive phenomena, reducing the risk of onset of tardive dyskinesia as well as improving the outcome of tardive dyskinesia when it occurs. Although the data from these various trials may be unclear, a small percentage of patients appear to derive benefit from these medications. In clinical practice, it is therefore prudent to try benzodiazepines, valproic acid, baclofen, and lithium when faced with a patient who has failed the dopamine-depleting agents.

Other medications that have been tried in mostly non-randomized studies include amantadine, calcium channel blockers, branched-chain amino acids, gabapentin, and a combination of acetazolamide and thiamine. The results of these studies are difficult to interpret because of trial design. The antioxidant Vitamin E has been subjected to multiple trials with some promising results. More recently, double-blind, placebo-controlled studies of melatonin, the combination of naltrexone and clonazepam, Vitamin B6, piracetam, and levetiracetam were conducted, all showing efficacy. However, these studies were typically done in small groups of patients for short periods of time. Botulinum toxin has been tried with some promising results.

The fact that so many different medications with varying mechanisms of action have been tried for this condition indicates that the field has yet to find a truly effective treatment. Larger trials are needed to further examine the effects of drugs found promising in smaller trials.

The clinician should always remember that if the movements are not bothersome to the patient, they do not need to be treated, besides the removal of the offending agent. If, on the other hand, the tardive movements are very severe and cannot be tolerated, restarting a neuroleptic should work to control the movements in the short term, although there is a real danger that, in the long run, this will worsen the movements.

Tardive Dystonia

Unfortunately, tardive dystonia is harder to treat than tardive dyskinesia and spontaneous remissions occur less often. Many of the same principles outlined for the treatment of tardive dyskinesia hold true. If possible, the neuroleptic should be tapered off very slowly and clozapine should be the neuroleptic of choice. In 1982, Burke et al. showed a 68% improvement with TBZ. Clonazepam may also offer relief.

There are some treatment options that are unique to tardive dystonia. Burke et al. showed in 1982 that anticholinergics that are effective in idiopathic dystonia improved tardive dystonia in 39% of patients, although they may worsen tardive dyskinesia. Botox injections can be helpful if the dystonia is isolated to a few injectable muscles.

Pallidotomy and thalamotomy were demonstrated to be effective for the treatment of tardive dystonia in some small case series. The first case report of deep brain stimulation for the treatment of tardive dystonia was published in 2001. Electrodes were placed into both the globus pallidus pars interna (GPi) and the ventral intermediate (VIM) thalamus. Only the stimulation of the GPi was effective in reducing the patient's dystonia. Since then, this finding has been repeated in a number of case reports and case series.

Tardive Akathisia

This syndrome may be the hardest of the three main syndromes to treat. A study by Burke et al., 1989, showed TBZ and reserpine to be the most effective medications in this condition, producing improvement in 87% and 58% of patients treated. Benzodiazepines may be useful as well.

Prognosis

Tardive Dyskinesia

There is an exceedingly wide variation in reported remission rates in the published literature, from 0% to 92%. Remission rates are difficult to calculate, as many patients with this condition continue to take neuroleptics, which as discussed earlier, can suppress the movements in the short term. Remission rates also vary by age, as it is well recognized that younger people have higher remission rates than the elderly. Finally, the length of follow up of the study is crucial, as tardive syndromes can wax and wane in their presentation. Wegner and Kane reevaluated patients previously determined to have undergone remission of their tardive dyskinesia. All of the five patients studied had persistence of abnormal movements.

In 2001, Fernandez et al., examined the natural history of tardive dyskinesia in an inpatient psychiatric facility over the course of 14 years. Of the 53 patients that were followed, 19% worsened, 15% stayed the same, 4% improved, and 62% had resolution of symptoms. These results were in the setting of ongoing neurolepticuse. However, patients with the most improvement in their tardive symptoms tended to have worse parkinsonism. Other studies have shown that complete recovery is unusual, but that the majority of patients have substantial improvement with time.

Tardive Dystonia and Akathisia

Kiriakakis et al. showed in their 1998 study that remission rates for tardive dystonia were 14%, over a follow-up period of 8.5 years. Interestingly, patients with less than 10 years of exposure to neuroleptics had a 5 times greater chance of remission than those with greater than 10 years of exposure. In 1989, Burke et al. showed remission rates of 33% in tardive akathisia.

The tardive movement disorders are a collection of difficult-to-treat syndromes that result from exposure to dopamine-blocking agents. Although prevention of exposure to these medications is the best way to avoid these syndromes, this is not always possible. The syndromes may remit, but often do not. TBZ is the most effective drug to date and has recently been approved in the USA. The side effect of depression, however, makes it a poor choice for many psychiatric patients. Multiple other medications have been tried for these conditions, but none has convincingly shown a benefit. A number of small trials of various compounds have recently been conducted which have shown some promise. Larger trials of these medications are necessary to investigate their potential as treatments for this difficult array of diseases.

I Litvan, University of Louisville School of Medicine, Louisville, KY, USA

Glossary

Alternative splicing – Modification of a mRNA transcript due to exclusion and/or rearrangement of exons.
Apraxia – Loss of the ability to carry out learned purposeful movements, despite having the physical ability to perform them.

Atypical parkinsonian disorders – Parkinsonian disorders that differ from Parkinson's disease as patients exhibit features such as rapid progression, poor or transient response to dopaminergic therapy, early falls, oculomotor abnormalities, early autonomic failure, pyramidal and cerebellar signs, hallucinations, early cognitive impairment, apraxia, and alien hand syndrome.

Dystonia – Abnormal movement characterized by sustained muscle contraction, leading to twisting, abnormal postures, or repetitive movements.
Freezing – Manifestation of akinesia characterized by sudden incapacity to continue moving or to start a movement.
Neurodegeneration – Pathogenic process, usually of unknown or genetic etiology, that leads to progressive cell loss in specific neuronal populations, with consequent loss of previous normal functions.
Oculogyric crisis – Dystonic movement in which the eyes deviate tonically, usually upwards.
Parkinsonism – Clinical syndrome characterized by bradykinesia and at least one of the following features: rest tremor, rigidity, or postural instability.
Pseudobulbar palsy – Dysfunction of lower cranial nerves responsible for swallowing and speech, caused by lesions in the pathways that connect higher cortical centers and the nuclei localized in the medulla (bulbar). It mimics a bulbar palsy, but lower cranial nerve nuclei are preserved.
Supranuclear gaze palsy – Oculomotor abnormalities originating in cortical or subcortical oculomotor centers or linking pathways with oculomotor nuclei in the brainstem. Because the oculomotor nuclei are preserved, the oculocephalic reflex is intact.

Definition

Neurodegenerative disorders are primary disorders of the central nervous system (CNS) in which there is progressive neuronal loss. They are grouped depending on neuropathological characteristics, particularly the proteins present in the specific inclusions. In neurodegenerative causes of parkinsonism, the major component of the intracellular inclusions can be α-synuclein, tau protein, or TDP-43, leading to their classification as α-synucleinopathies, tauopathies, and TDP-43opathies. Although there are clinical features that may suggest the diagnosis, differentiation of tauopathies from α-synucleinopathies and TDP-43opathies is not always possible on clinical grounds and definite diagnosis relies on neuropathology.

The three major tauopathies that present as movement disorders are progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), and frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17). Other tauopathies are listed in **Table 1**. Most occur sporadically, but some can be inherited, such as FTDP-17. Some disorders do not have a 'pure' tau pathology, such as Alzheimer's disease (AD) (**Table 2**).

The Normal Tau Protein

Tau is a cytoskeletal phosphoprotein codified by the MAPT gene in the chromosome 17q21. It promotes microtubule polymerization and stability, playing a fundamental role in axoplasmatic transport, axonal growth, neuronal polarity, and neuronal integrity. It may also regulate intracellular signal transduction, development, and viability of the neurons.

In the normal adult brain, there are six isoforms of tau protein that result from alternative splicing of the MAPT gene. A microtubule-binding domain is present in exons 9, 10, 11, and 12. The alternative splicing of exon 10 gives rise to the 3R and the 4R isoforms, respectively, with three and four microtubule-binding domains. Additionally, the alternative splicing of exons 2 and 3 leads to three N isoforms. The normal brain has a ratio of 3R/4R isoforms of ~1:1. **Figure 1**

Table 1 Tauopathies – clinical entities

- Progressive Supranuclear Palsy
- Corticobasal ganglionic degeneration
- Lytico-Bodig disease (or amyotrophic lateral sclerosis and parkinsonism-dementia complex of Guam)
- Guadeloupean Parkinsonism
- Postencephalitic Parkinsonism
- Pallido-nigro-luysial degeneration
- Pick's disease
- FTDP-17
- Argyrophilic grain disease
- Neurofibrillary tangle dementia/tangle only dementia
- Progressive subcortical gliosis
- Diffuse neurofibrillary tangles with calcification
- Sporadic multisystem tauopathy with dementia

Table 2 Diseases with tau-positive neurofibrillary inclusions, but in which these are not the main pathological feature

Disease	*Predominant neuropathologic feature*
Alzheimer's disease	Amyloid deposition
Down's syndrome	
Dementia pugilistica	
Familial British dementia	
Familial Danish dementia	
Creutzfeldt–Jacob disease	Prionic protein deposition
Gerstmann–Sträussler–Scheinker disease	
Prion protein cerebral amyloid angiopathy	
Niemann–Pick type C	Glycolipids inclusions
Pantothenate kinase-2 deficiency	Iron containing pigments

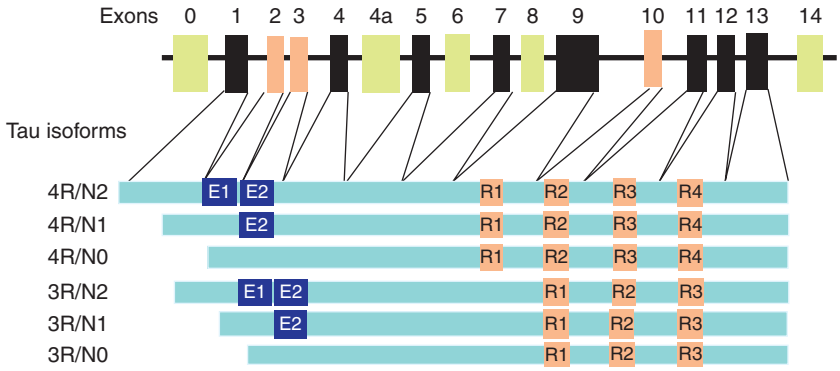

Figure 1 The MAPT gene and the six tau isoforms. The MAPT gene contains 16 exons (E). Alternative splicing of E2, E3, and E10 produces the six isoforms. Exons 9–12 encode microtubule-binding repeats (R1 to R4). Alternative splicing of E10 produces the 3R and 4R tau isoforms and alternative splicing of E2 and E3 produces the N0, N1, and N2 isoforms. Exon 3 is always co-expressed with exon 2, explaining why only three isoforms result from alternative splicing of these two exons. E6, E8, and E4a are not transcribed in human CNS. Reproduced from Forman MS, Lee VMY, and Trojanowski JQ (2000) New insights into genetic and molecular mechanisms of brain degeneration in tauopathies. *Journal of Chemical Neuroanatomy* 20: 225–244, with permission from Elsevier.

shows the six different tau isoforms and their relationship with the alternative splicing of exons 2, 3, and 10.

Tau protein undergoes posttranslational modifications, including phosphorylation, glycosylation, glycation, ubiquitination, truncation, and nitration, that determine its functional state.

Tau Pathology in Tauopathies

The tau-positive intracellular inclusions are composed of insoluble fibrillary aggregates of hyperphosphorylated tau. The abnormal hyperphosphorylated tau protein may form two kinds of filaments: the paired helical filaments (PHF), with a periodic helical twist, and the straight filaments (SF), that lack the helical periodicity. The various tauopathies accumulate different kinds or proportion of filaments, which constitutes an important ultrastructural differential marker (**Table 3**). In addition, the ratio of tau isoforms in the insoluble aggregates is specific for different tauopathies, allowing the biochemical classification as 3R, 4R, and 3R–4R tauopathies (**Table 4**).

The neuropathological heterogeneity of tauopathies is also reflected in the intracellular location and type of the inclusions (**Table 5**), the vulnerable cell types that are affected (**Table 5**), and the anatomical distribution of the lesions in the CNS (**Table 6**). This diversity is not understood at the present time and may be related to the predominant tau isoform or interaction with still unknown specific cofactors.

Mechanisms of Neurodegeneration in Tauopathies

The mechanisms that lead to neurodegeneration in tauopathies are still largely unknown. The tau protein is thought to play an important role along with genetic, epigenetic, and environmental factors that may influence the clinical and pathological manifestations.

Table 3 Ultrastructure of tau inclusions in tauopathies and AD

	PHF	*SF*
AD	+++ (width 8–20 nm, twist: 80 nm)	±
PSP	±	+++ (15–18 nm)
CBD	++	++
Pick disease	++ (width 15–28 nm; twist:130–180 nm)	++ (10–15 nm)
Argyrophilic grain disease	–	+++ (9–18 nm)
Lytico-Bodig disease	+++	±
Postencephalitic parkinsonism	+++	±

Table 4 Biochemical classification of Tauopathies

4R tauopathies	*3R and 4R tauopathies*	*3R tauopathies*
• PSP • CBD • Argyrophilic grain disease • GP • Sporadic multisystem tauopathy with dementia • Pallido-nigral-luysial atrophy • Neurofibrillary degeneration of CA2	• AD • Postencephalitic parkinsonism • Lytico-Bodig disease • Amyotrophic lateral sclerosis and parkinsonism-dementia complex of Kii peninsula of Japan • Neurofibrillary tangle dementia • Diffuse neurofibrillary tangles with calcification	• Pick disease

Table 5 Typical tau-positive inclusions in tauopathies and AD

	Neurons		*Glial cells*	
	Cell body	*Neuronal processes*	*Astrocytes*	*Oligodendrocytes*
AD	Flame-shaped neurofibrillary tangles	Neuropil threads, neuritic plaques	No glial pathology	
PSP	Globose neurofibrillary tangles, balloned cells (uncommon)	Neuropil threads (sparse)	Tufted astrocytes, thorn-shaped astrocytes	Coiled bodies threads
CBD	Achromatic ballooned cells, neurofibrillary tangles	Neuropil threads (numerous)	Astrocytic plaques	Coiled bodies threads
Pick's disease	Pick's bodies, Pick's cells (ballooned neurons)	Neuropil threads (variable)	Glial pathology is less prominent than neuronal Thorn-shaped astrocytes	 Coiled bodies
Argyrophilic grain disease	Pretangle neurons, balloned neurons	Argyrophilic grains	Bush-like astrocytes, thin astrocytic plaques	Coiled bodies
Lytico-Bodig disease	Neurofibrillary tangles, Hirano bodies	Neuropil threads (sparse)	Granular hazy inclusions	Coiled bodies (sparse)
Postencephalytic parkinsonism	Neurofibrillary tangles		Cytoplasmatic inclusions, astrocytic tufts	

Table 6 Anatomical distribuition of tau pathology in different tauopathies

Disease	*Cortex*	*Subcortical structures*
PSP	Frontal lobe: precentral and premotor areas	Pallidum, subthalamic nucleus, substantia nigra, striatum, oculomotor complex, periaqueductal grey matter, superior colliculi, basis pontis, dentate nucleus
CBD	Asymmetric involvement of frontal and temporal lobes (mainly pre- and postcentral regions)	Substantia nigra, basal ganglia, brainstem nuclei
Pick's disease	Frontal and anterior temporal lobes, Dentate gyrus (granule cells), subiculum, entorhinal cortex (pyramidal cells)	Amygdala, external pallidum, substantia nigra, locus ceruleus, pontine nuclei
Argyrophilic grain disease	CA1, Entorhinal and transentorhinal cortex	Amygdala, hypothalamic lateral tuberal nuclei
Lytico-Bodig disease	Hippocampus, frontal and temporal lobes	Substantia nigra, locus ceruleus, hypothalamus (thalamus, basal ganglia)
Postencephalitic parkinsonism	Hippocampus, Insular cortex, frontal and temporal lobes	Substantia nigra, locus ceruleus, brainstem
Multisystem tauopathy with dementia	Frontal, temporal, and parietal neocortex	Basal ganglia, brainstem nuclei

Genetic Factors

The discovery of MAPT mutations in the most common familial tauopathy – FTDP-17, and their biochemical and pathogenic consequences, widened the knowledge about pathogenic mechanisms. There are around 40 mutations described since 1998. Mutations are clustered around the microtubule-binding domains and two types can be identified: mutations that decrease the ability of the tau protein to bind to microtubules and mutations that change the ratio of 3R/4R isoforms. Most mutations appear to affect the alternative splicing of exon 10 (**Figure 2**) with consequent alteration of the ratio of 3R to 4R tau isoforms.

The neuropathology of FTDP-17 is highly heterogeneous and can mimic the specific neuropathology of different sporadic tauopathies. The isoform that accumulates, the cellular type in which tau accumulation occurs and its subcellular topography are highly dependent on the nature and position of tau mutation.

FTDP-17 also can present clinically as any of the sporadic tauopathies. **Table 7** gives some examples of tau mutations and illustrates the heterogeneity in biochemical, neuropathological, and clinical phenotypes.

The H1/H1 haplotype has been identified as a genetic risk factor for the development of some of the 4R tauopathies such as PSP, CBD, and possibly also Guadeloupean parkinsonism (GP) and pallido-nigro-luysial degeneration (PNLD). This haplotype includes several polymorphisms that are in linkage desequilibrium in a genetic region that includes the MAPT gene. Two independent single nucleotide polymorphisms of MAPT

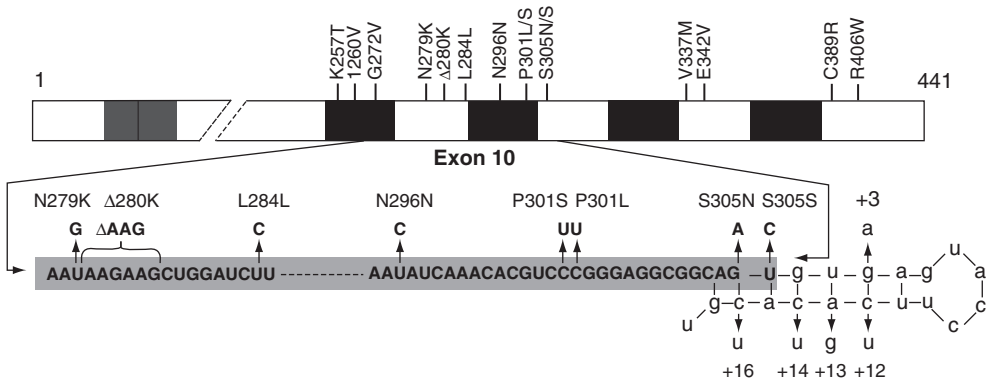

Figure 2 Schematic representation of MAPT mutations described in FTDP-17. The majority of MAPT mutations have been found in exons 9–13. The longest tau isoform is shown. Black boxes represent microtubule-binding domains. The second microtubule-binding domain is codified by exon 10, which is subject to posttranslational alternative splicing. Part of the pre-mRNA transcript that corresponds to exon 10 and downstream intron is detailed and mutations in this region are shown. A significant percentage if mutations occur in a stem-loop structure in the pre-mRNA transcribed at the downstrem end of exon 10 that regulates splicing of the exon 10 transcript. The lower case nucleotides correspond to intronic nucleotids. Reproduced from Lee VM, Goedert M, and Trojanowski JQ (2001) Neurodegenerative tauopathies. *Annu Rev Neurosci* 24: 1121–1159.

Table 7 Tau mutations and the heterogeneity of biochemical, neuropathological, and clinical phenotypes, mimicking sporadic tauopathies

Exon	*Mutation*	*Biochemical/neuropathological phenotype*	*Clinical phenotype*
1	R5L	4R > 3R, subcortical	PSP
1	R5H	4R > 3R, widespread	Late-onset dementia
9	I260V	4R only	FTD
9	G272V	4R = 3R, Pick bodies	Pick's
9	K257T	3R > 4R, Pick bodies	Pick's
9	L266V	Cortical/subcortical 3R = 4R, Pick-like pathology	Early-onset FTDP
10	N279K	Widespread, 4R > 3R*	FTDP, PSP-like
10	_280K	3R > 4R	FTD
10	L284L	4R > 3R	Presenile FTDP
10	P301L	4R > 3R, mini-Pick-like bodies (4R) and glial inclusions (3R)	FTDP
10	P301S	Widespread, 4R > 3R	Early-onset FTDP; CBD-like; supranuclear gaze palsy
10	N296N (ESS site)	CBD-like 4R ? 3R	CBD-like or FTDP
10	N296H	Cortical and subcortical: 4R?3R	FTDP
10–1	S305S	4R > 3R	FTDP or PSP-like
10–2	S305N	4R > 3R	FTDP
+ 11	T–C	4R > 3R, brainstem	FTDP with MR
+ 12	C–T	Pure 4R aggregates and 4R > 3R soluble	FTDP
+ 13	A–G	4R > 3R	FTD
+ 14	C–U	4R > 3R	DDPAC
+ 16	C–T	CBD-like 4R > 3R	FTDP or PSP-like
+ 19	C–G	3R soluble > 4R: no stable aggregates	FTDP
+ 29	G–A	3R soluble > 4R or 3R = 4R: no stable aggregates	FTDP
11	S320F	4R > 3R, Pick path. No N03R	Early Pick's
11	L315R	4R = 3R, Pick-like inclusions. No N03R	FTD, incomplete penetrance
12	V337M	4R = 3R, all six isoforms	FTD, paranoid and antisocial
12	E342V	Picks path, 4R > 3R; 4R0N ↑, 4RN1 and 4RN2 ↓	Pick-like
12	K369I	Pick's, severe temporal atrophy	Pick's
12	Q336R	3R and 4R: ratio not determined	Pick's
12	S352L,homozygous	Not determined; 4R present	Recessive, respiratory failure
13	G389R (GGG > AGG)	3R = 4R, Pick's	Pick-like
13	G389R (GGG > AGG0)	Not determined	Pick body-like inclusions and widespread tau filaments

gene have been shown to influence the risk for developing Guam neurodegeneration. It is thought that these polymorphisms might influence exon 10 splicing.

It is suggested that the Val380Leu polymorphism of PARK2 gene may be protective for the development of sporadic or familial PSP.

Epigenetic Factors

Whether hyperphosphorylation is the cause or a consequence of tau protein instability is not yet known, but it seems to play a role in tau accumulation. There is also a putative role of unbound tau in the destabilization of the microtubule network, with consequent disruption of axonal transport.

Environmental and Toxic Factors

Studies on patients with GP support the role of mitochondrial dysfunction in neurodegeneration, two epidemiologic studies show significant exposure to tropical plants, such as *Annona muricata* (corossol, soursop), that contain high levels of mitochondrial enzyme complex I inhibitors. Annonacin, one of the toxic compounds has been shown to induce nigral and striatal neuronal degeneration in rats. Mitochondrial involvement with decreased complex I activity has also been demonstrated in cell lines expressing mitochondrial genes from PSP patients. There are markers of oxidative injury in specific brain regions in PSP patients, and oxidative stress has been proposed to result in kinase activation and consequent hyperphosphorylation.

These studies favor the role of mitochondrial dysfunction, environmental toxins, and oxidative stress in the pathogenesis of tauopathies.

Clinical Manifestations

Parkinsonism and dementia are the main clinical syndromes that characterize the tauopathies. Some have more prominent parkinsonism while others have more cognitive and behavioral impairment, but in later stages both usually coexist. The parkinsonism is characterized by an akinetic-rigid syndrome, usually without rest tremor, and mostly unresponsive to levodopa; dementia is usually of frontotemporal type (FTD). Typical features may help us identify a specific disorder.

The clinical picture of FTDP-17 includes frontal dementia, parkinsonism, dystonia, as shown in the sporadic tauopathies. Apart from a positive familial history and a younger age at onset, these tauopathies are not clinically nor pathologically distinguishable from the sporadic diseases. Molecular genetic analyses are required for the diagnosis.

Tauopathies with a Predominant Parkinsonian Syndrome

Progressive supranuclear palsy

PSP is a 4R tauopathy also known as Steele–Richardson–Olszewsky syndrome, honoring those who first described this disease in 1964. It is the most common sporadic tauopathy, accounting for 5% of parkinsonian patients seen in a movement disorder clinic. Its age of onset is usually in the sixties, and typically presents insidiously with early postural instability with falls within the first year of symptom onset, a predominantly axial, symmetrical and levodopa unresponsive akinetic-rigid syndrome, supranuclear gaze palsy mainly affecting vertical gaze, pseudobulbar palsy, and frontal cognitive and behavioral features. This typical phenotype is known as the Richardson's syndrome (RS). Frontal cognitive impairment, with marked executive dysfunction and apathy, is frequent. Validated clinical diagnostic criteria are highly specific for PSP tau pathology. Although these criteria have high sensitivity to the classical syndrome, they are much less sensitive to diagnose the atypical variants of the disease such as PSP – parkinsonism (when parkinsonism is preponderant and other classical features are missing), pure akinesia with freezing of gait, isolated FTD and corticobasal syndrome. The neuropathological differences in these variants are mostly quantitative and topographic, but some differences in isoform composition of tau fibrillary lesions have been described.

Corticobasal degeneration

CBD is also a 4R tauopathy originally described by Rebeiz and coworkers in 1967. It accounts for 1% of parkinsonian patients seen in a Movement Disorders Clinic. Age at onset is, on average, in the sixties, and there are two main clinical presentations: the classical lateralized corticobasal syndrome and a dementia syndrome. In the classical phenotype, both cortical and motor symptoms are unilateral or markedly asymmetric. The most common initial symptom is an asymmetrical progressive clumsiness and difficulty using one limb, usually the arm, related to apraxia, dystonia, rigidity, and less commonly alien limb. The dementia phenotype is characterized by early development of severe frontotemporal dementia usually accompanied by incontinence, pyramidal signs, bilateral parkinsonism, and followed then by a full-blown dementia with added cortical features (memory, attention, language, and frontal behavior disturbances). This cognitive phenotype tends to develop in the absence of motor symptoms.

Lytico-bodig disease

The Lytico-bodig disease was previously known as Guamanian amyotrophic lateral sclerosis/parkinsonism-dementia complex. It is an endemic 3R–4R tauopathy found in the indigenous Chamorro population at the island of Guam on the Western Pacific. Several environmental factors, such as plant neurotoxins, including the

one that exists in the cycad seeds (*Cycas micronesica*), have been proposed to explain the high prevalence and geographical clustering. Phenotype correlates with age at onset: youngest patients present with amyotrophic lateral sclerosis; oldest patients predominantly develop dementia; and parkinsonism is the prominent feature in middle age individuals. In all forms of disease, more than half (56%) of patients have a retinal pigment epitheliopathy that is also present in 16% of Chamorros.

Guadeloupean parkinsonism

GP occurs on the French West Indian island of Guadeloup and accounts for two-thirds of parkinsonian patients in that geographical location. The clustering of this disease has been associated with exposure to alkaloid toxins contained in fruits of the *Annonaceae* family. Two main syndromes characterized by both atypical parkinsonism with early postural instability and dementia have been described: one with supranuclear gaze palsy that resembles the RS and another one, without oculomotor abnormalities, that was named GP-dementia complex. Classical PSP can be distinguished from the Guadeloupean PSP-like phenotype by the presence of autonomic dysfunction, hallucinations, rapid eye movement (REM) sleep behavior disorder, and tremor (usually postural) in more than half of patients. Both phenotypes share identical neuropsychological and neuroimaging profiles. Brain MRI shows enlargement of the third and lateral ventricles and hypointense signals of basal ganglia, particularly substantia nigra but also putamen, globus pallidum and red nucleus, and midbrain atrophy, particularly in PSP-like syndromes.

Postencephalitic parkinsonism

Postencephalitic parkinsonism is a late complication of encephalitis lethargica, also known as 'sleep sickness,' first described by von Economo after the World War I. Influenza A virus has long been suspected as a cause. The most prominent clinical characteristics are: young onset, levodopa-responsive parkinsonism, slow progression over more than 10 years, oculogyric crisis and previous history of encephalitis. Nowadays, with the disappearance of encephalitis lethargica, the diagnosis of postencephalitic parkinsonism is unlikely.

Pallido-nigro-luysial degeneration

PNLD is a rare 4R tauopathy that involves the globus pallidus (pallido), the sustantia nigra (nigro), and the subthalamic nucleus of luys (luysial). Clinically, it is characterized by a slowly progressive akinetic-rigid syndrome, postural instability and vertical supranuclear gaze palsy, mimicking PSP. However, the timing of the features is different in PSP and PNLD: age at onset is on average 10 years younger and the initial signs are usually gait and handwriting disturbances. Dementia is absent even in advanced stages. Some investigators suggest that PNLD may be a clinical and pathological variant of PSP.

Tauopathies with Predominant Dementia Syndrome

Pick's disease

Pick's disease is a 3R tauopathy that was first described in 1892 by Arnold Pick. The term Pick's disease is usually applied to the cases of dementia with Pick's bodies. It accounts for 0.4–6.0% of all dementias. Onset is usually before age 65 years, and patients initially present with prominent FTD features. Parkinsonism is usually a late feature. Neuroimaging shows marked circumscribed frontal and/or anterior temporal atrophy. Fluorodeoxyglucose PET scan shows frontal and temporal hypometabolism.

Argyrophilic grain disease

Argyrophilic grain disease is a 4R tauopathy that accounts for 5% of all cases of dementia. Clinically, it is different from the above described FTD, as predicted by the more restrictive distribuition of tau pathology in mesial temporal and limbic regions. It is a late-onset dementia with mean age of onset of 75–80 years. The most common presenting symptoms are memory disturbances and personality changes, followed by delusions (mostly of persecution), dysphoria, and apathy. There are no other cognitive or sensory-motor functions remarkably affected. Clinicopathological studies have shown that it is overrepresented in the amnestic type mild cognitive impairment.

Other tauopathies presenting with dementia

Neurofibrillary tangle dementia or tangle only dementia is a sporadic subset of a very late-onset dementia, mainly in females over age 80 years. It is suggested to be a variant of AD occurring in the oldest-old.

Diffuse neurofibrillary tangles with calcification or Kosaka–Shibayama disease, has rarely been described in the literature, almost always in Japanese patients. Clinical phenotype is defined as an overlapping syndrome comprising memory changes, disorientation, dressing apraxia, and perseveration, like in AD, plus FTD. Parkinsonism is the most prominent accompanying motor feature. CT/MRI scan shows a localized temporal or temporofrontal atrophy with pronounced basal ganglia calcification.

Progressive subcortical dementia is a rare form of dementia with age of onset in the fifties, clinically characterized by abnormal behavior, cognitive impairment, and parkinsonism.

Sporadic multisystem tauopathy with dementia is a rare 4R tauopathy characterized by FTD with severe temporal atrophy and mild frontal and parietal atrophy. The clinical syndrome is not clearly defined.

Treatment

There are no current effective treatments for the tauopathies. Physical, occupational, and speech therapies to improve the quality of life and help prevent complications are the mainstays of treatment. Trials with inhibitors of

GSK3β such as lithium and valproic acid to slow disease progression are underway. In a near future, therapeutic approaches will probably focus on the modulation of hypothesized pathogenic mechanisms, such as regulation of alternative splicing, inhibition of tau aggregation and/or hyperphosphorylation, enhancement of mitochondrial metabolism, or induction of neurotrophic factors. Dopaminergic agents may be considered for the parkinsonian features, although these disorders are less likely responsive to levodopa than Parkinson's disease; monitoring for adverse effects on cognition and behavior is necessary.

Conclusion

Tauopathies are neurodegenerative disorders pathologically defined by the presence of intracellular tau-positive inclusions and clinically characterized by dementia and/or parkinsonism. Different tauopathies have specific clinical and neuropathological features, but significant overlap exists. Tau mutations leading to hyperphosphorylation have a significant a role in neurodegeneration. Clinical and pathological heterogeneity in familial tauopathies show that additional epigenetic and environmental factors probably play a role. Pathogenesis is far from being completely understood in the sporadic diseases. Tauopathies are a heterogeneous group of neurodegenerative disorders characterized by tau-positive inclusions. Definitive diagnosis is based in specific neuropathological features. Clinically, they present with atypical parkinsonism or dementia, both usually present in later stages. There is a significant clinical overlap between the different tauopathies. This heterogeneity and the clinical and neuropathological overlap are not understood at present time. MAPT mutations, posttranslation hyperphosphorylation of tau, oxidative stress, and mitochondrial dysfunction are thought to play a role, but other genetic, epigenetic and environmental factors are yet to be discovered. This huge complexity suggests that the pathogenesis is far from being completely understood, and hampers the development of specific neuroprotective strategies.

Glossary

Collimator – A device that filters a beam of rays so that only those traveling parallel to a specified direction are allowed to go through.

Gamma knife – A method of radiation therapy in which gamma radiation from multiple sources in a spherical distribution converge in a small target region. This method has been used for thalamotomy as an alternative method to the classic stereotactic surgical technique.

Microelectrode recording – A method of recording brain cells through a very fine electrode so that individual neurons can be recorded.

Radiofrequency coagulation – Targeted coagulation or lesioning of tissue by heat production resulting from high- (radio-) frequency electrical activity through a special electrode.
Thalamotomy – Stereotactic ablation of specific thalamic nuclei, primarily the ventral intermediate nucleus (Vim), for the treatment of movement disorders, particularly tremor.

Definition and History

Thalamotomy is ablation of pallidal receiving (ventral oral, Vo) and cerebellar receiving nuclei of the thalamus (nucleus ventral intermediate, Vim) for the treatment of movement disorders. It was first introduced by Hassler, who reasoned that the improvement in Parkinson's disease (PD) following lesions of the pallidum might also be gained following lesions of Vo, which receives input from the pallidum. Using microelectrode recordings, the area posterior to Vop, which was identified as the cerebellar receiving zone (Vim), was later found to have rhythmic bursting activity close to the frequency of tremor. Vim then became the thalamotomy target of choice for tremor of all types. The use of this operation has decreased significantly with the advent of deep brain stimulation (DBS) for the treatment of tremor.

Stereotactic Surgical Technique

Radiologic and physiologic landmarks are used to accurately localize the target for ablative procedures. Many surgeons employ radiologic localization of the anterior commissure (AC), posterior commissure (PC), and of the border between the capsule and thalamus, using CT or MRI scans. The radiologic estimate of location is refined, before radiofrequency lesioning, by microelectrode recording, semimicroelectrode recording, or by macrostimulation. The relative efficacy and safety of these different techniques have not been examined systematically.

Microelectrode recording in the ventral caudal nucleus (Vc), posterior to Vim, reveals sensory cells responding to sensory stimulation in small, well-defined, receptive fields. There is a well-described mediolateral somatotopy within Vc, proceeding from representation of oral structures medially to leg laterally. In Vim, neuronal firing is related to passive joint movement (deep sensory cells) or to active movement (voluntary cells), or to both (combined cells). Stimulation in Vc will evoke somatic sensations. Stimulation in Vim may produce brief movements or alter ongoing tremor or dystonia. An analysis of the locations of tremor cells suggests that the optimal target for thalamotomy is located 2 mm anterior to Vc and 3 mm above the ACPC line.

Targets in thalamotomy have been placed among deep sensory cells anterior to the cutaneous sensory cells and sites at which hand somatic sensory cells can be recorded. Lesions have also been made in the region where electrical stimulation produces effects on tremor and anterior to the region where cutaneous sensations are evoked.

Lesions are made by the technique of radiofrequency coagulation using an electrode with a 1.1 mm outer diameter and a 3 mm exposed tip and a thermister at the tip of the electrode (TM electrode, Radionics Inc., Burlington, MA). Temperature is held constant at 60 °C over a 1-min interval and then increased in 5–10 °C steps during subsequent 1-min intervals to a level of approximately 80 °C. Neurologic examination is carried out throughout coagulation and stresses function of adjacent structures such as cutaneous sensory, pyramidal, and cerebellar function, plus speech.

Randomized Controlled Trial of Vim Thalamotomy Versus Vim-DBS

A recent trial compared Vim thalamotomy with DBS in patients with Parkinson's tremor (PT) ($n = 45$), or essential tremor (ET) ($n = 13$), or intention tremor ($n = 10$). Across all types of tremor, functional status was improved in significantly more patients following Vim-DBS (54%, 18/33) than thalamotomy (24%, 8/34). Overall, tremor was abolished or a minimal residual was left in 30/33 (90%) of patients treated with Vim-DBS and 27/34 (79%) of patients treated with thalamotomy. Overall, significantly more patients (16/34) had complications postthalamotomy than following Vim-DBS stimulation (6/33).

Prospective, Uncontrolled Studies of Thalamotomy

The American Academy of Neurology recommendation regarding safety and efficacy of thalamotomy for PT was based upon a systematic evaluation of the literature. Overall, inexperienced centers had less success and more complications. Contraindications were cognitive, medical, or psychiatric conditions and abnormal imaging studies including focal lesions or atrophy greater than expected for age. Patients with advanced age derived less benefit.

For thalamotomy, 18 articles were found in this study, but only four studies met the study criteria. Thalamotomy was recommended as effective and safe for asymmetric, severe, medically intractable PT, particularly for the tremor variant of PD. This was a positive recommendation based on the results of prospective studies with historical controls.

It was judged possibly effective for the treatment of dyskinesias and rigidity, but not for micrographia, bradykinesia, or difficulties of gait or speech. Thalamotomy on the other hand was felt to be effective for the treatment of tremor but to be associated with a high incidence of speech and swallowing difficulty. Therefore a class D negative recommendation was made for bilateral thalamotomy; Vim-DBS was recommended on the second side.

Clinical series of thalamotomy for ET report that the majority of patients have a significant reduction in tremor. Complete cessation or slight residual tremor was reported in 68–83% of cases, while moderate reductions in tremor were reported in the remainder. Most patients were able to discontinue their pharmacological therapy, and many were able to return to work.

Studies of patients with intention tremor of different etiologies show complete abolition or significant reduction in 44–82% of patients.

Complications of Thalamotomy

Complications from stereotactic surgery can arise from infection or intracranial hemorrhage. Infection of pin sites and meningitis have been reported in about 1% of stereotactic surgeries. Hemorrhages occur in 1–6% of procedures. Hemorrhages may occur at the lesion site or at cortical sites resulting in intracerebral or subdural hematomas. The risk of radiologically defined hemorrhage during functional stereotactic procedures employing coagulation is 9/57 (17%) overall, and 5/23 (22%) for Vim thalamotomy.

Functional deficits account for most of the postoperative complications in thalamotomy. In a series of 60 patients with ET, PT, or cerebellar tremor, functional deficits in the immediate postoperative period were reported in 58% of patients. These transient deficits included weakness (34%), dysarthria (29%), ataxia (8%), dystonia (5%), and sensory deficits (3%). Transient deficits may have occurred from edema surrounding the acute lesion site. Functional deficits persisted in 23% but were generally mild and did not increase disability.

Radiosurgical Thalamotomy

The use of MR imaging to provide radiologic localization has led to the development of stereotactic radiosurgical ablation. The majority of stereotactic gamma knife procedures are carried out with a 50% iso-dose plan using 4-mm collimators. Lesions with a volume of approximately 250 mm^3 are created. The lesion placement is estimated from the usual location of Vim in relation to the AC and PC and the internal capsule.

In the largest of these series, MRI-guided gamma knife procedures (4 mm collimator, 110–165 Gy, 50% isodose line at the medial edge of the internal capsule) were carried out in 34 patients with PT at high risk for standard stereotactic procedures. Good to excellent results were found in 78–56%, depending upon the dose, and no complications were reported at minimum follow-up of 5 months (median 28 months).

In contrast to this series is a report of nine complications encountered at Emory University among an estimated 118 patients with gamma knife ablations for movement disorders carried out at a nearby medical center. Complications included weakness or paresis ($n = 3$), visual loss, speech/bulbar symptoms ($n = 3$), and dysphagia-aspiration pneumonia-death ($n = 1$). The conservative interpretation of these results is that gamma knife is indicated for thalamotomy in patients whose high surgical risk precludes a microelectrode-guided, radio-frequency procedure.

Theta Burst TMS

Y Z Huang, Chang Gung Memorial Hospital and Chang Gung University College of Medicine, Taipei, Taiwan
J C Rothwell, Institute of Neurology, University College London, London, UK

Glossary

Active motor threshold (AMT) – The minimum stimulation intensity over the motor hot-spot that could elicit an MEP of not less than 200 μV in 5 out of 10 trials during a voluntary contraction of the contralateral target muscle.
Resting motor threshold (RMT) – The minimum stimulation intensity over the motor hot-spot that could elicit an MEP of not less than 50 μV in 5 out of 10 trials.

Definition and History

Transcranial magnetic stimulation (TMS) is a noninvasive and painless method of stimulating the brain. It uses a magnetic field to carry a conventional electrical stimulation pulse across the barrier of the skull and scalp where it activates axons of neurones in the cerebral cortex and the underlying white matter. In animal experiments, there is a wealth of evidence that repeated stimulation of neural pathways in the cortex can change effectiveness of the synaptic connections within those pathways. This leads to long term potentiation or depression of transmission (LTP or LTD) that can last from hours to days or weeks, and is thought to be a fundamental process for learning and memory as well as in the reorganization that occurs after neural damage.

TMS machines are now available that allow us to stimulate human cortex repeatedly (rTMS) and produce effects that are thought to be analogous to those observed in animal preparations. Thus, rTMS of motor cortex can increase or decrease cortical excitability for up to an hour or more after the end of stimulation. Since the effects are influenced by drugs that interfere with transmission at NMDA receptors (which are an essential component of many forms of LTP/LTD), they are likely to involve changes in synaptic transmission in cortical circuits. Given the potential role of such synaptic 'plasticity' in reorganization of the CNS after damage, there has been an upsurge of interest in the possibility of using such interventions to treat brain diseases such as depression, stroke, tinnitus, and others.

Initial experiments with rTMS used regular stimulation at a range of frequencies from 0.2 to 20 Hz with up to 2000 pulses in total. The effects are readily observed on motor, visual, parietal, and other areas of the cortex using physiological measures of cortical excitability or behavioral testing. However, they are often variable and last for a relatively short period of time. In addition, one of the most popular protocols, 1 Hz stimulation with 1000+ pulses, takes 10–20 min to apply and employs relatively high intensities of stimulation (>100% threshold for eliciting hand movement from the motor cortex: resting motor threshold, RMT) which can be uncomfortable, particularly if given over frontal or temporal areas of the scalp due to the contraction that each pulse produces in underlying scalp muscles.

Theta Burst Stimulation

Theta burst stimulation (TBS) is a modification of the regular rTMS protocols and was developed in order to

replicate some of the more powerful LTP/LTD conditioning protocols used in animal experiments, which were themselves based on the physiological pattern of neuronal firing found in the hippocampus.

The basic element of TBS is a short burst of high frequency stimulation that is repeated 5 times per second (5 Hz: the theta frequency in EEG terminology). In humans, this initially consisted of a three-pulse burst at 50 Hz given in every 200 ms (**Figure 1**). Because of safety concerns, the initial stimulus intensity was low, at 80% active motor threshold (AMT for stimulation of the hand area of motor cortex). TBS in humans was first introduced by Huang et al. in an article describing its effects on the hand area of the motor cortex that was published in 2005. However, more recently, other authors have experimented with modifying the number of pulses, the rate at which they are applied, and the intensity of stimulation.

Given the possibility that TBS interacts with natural processes of synaptic plasticity, there has been an increasing interest in applying TBS as a therapy in a number of disease states. Although few studies have been published, TBS has been found to be safe in stroke, tinnitus, and depression, but there are no formal large scale trials as to efficacy.

The Effect of TBS

The effect of TBS relies on the pattern that is given. A regular series of bursts at 5 Hz (continuous TBS, cTBS) tends to depress the cortical excitability, whereas if there are gaps in the stimulation (e.g., 2 s stimulation, 8 s pause followed by 2 s stimulation, etc.: intermittent TBS, iTBS), then excitability may be potentiated. The duration of the effect depends on the total number of stimuli applied: 300 pulses may last for 20 min, whereas 600 pulses may last for 40 min (**Figure 2**). Both these protocols are effective in many different areas of the brain, including the primary and secondary motor cortices, visual cortex, and even the cerebellum. The advantage of TBS is the speed of application since 600 pulses of cTBS takes only 40 s to apply. In addition, the low stimulus intensity makes the protocol less likely to cause scalp muscle contraction. Recent work has shown that the effects of TBS can be further prolonged if several sessions of TBS are given at intervals of 20 min or so.

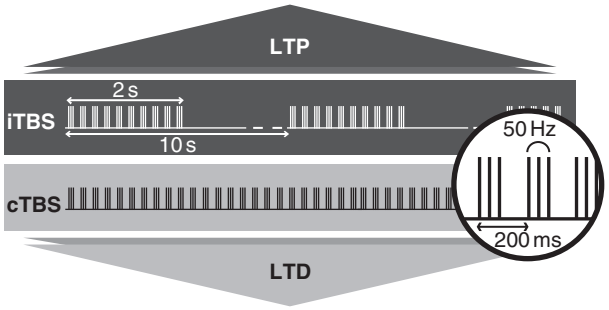

Figure 1 When short trains of TBS are given intermittently (e.g., iTBS), the LTP-like effect is induced. On the contrary, when bursts are given every 200 ms continuously (e.g., cTBS), the LTD-like effect is induced.

The Mechanism of TBS

Although the precise mechanism of TBS remains unclear, it seems clear that the effects are caused by changes in excitability of the cortical circuits rather than at any other level in the CNS. The evidence for this comes from experiments on the motor cortex. Stimulation with a suprathreshold TMS pulse evokes a series of high frequency volleys of activity in the axons of the corticospinal tract that are caused by the synaptic bombardment of pyramidal neurones in the grey matter. These volleys can be recorded directly in human patients who have had electrodes implanted in the spinal epidural space for relief of pain. The fact that the number and amplitude of the volleys change after TBS protocols indicates that TBS has affected the excitability of intracortical circuits. The most likely mechanism is thought to be through processes involving synaptic plasticity. This is because the effects of TBS are dependent on the NMDA receptor, which is a critical receptor for plasticity induction. Memantine, a NMDA antagonist, blocked both the facilitatory effect of iTBS and the suppressive effect of cTBS, while the partial NMDA agonist D-Cycloserine reversed the facilitatory effect of iTBS into inhibition.

Effect of Brain Activity on TBS

The response to TBS depends on the amount of activity in the stimulated area before, during, or even after TBS has been applied. This has been demonstrated most clearly in

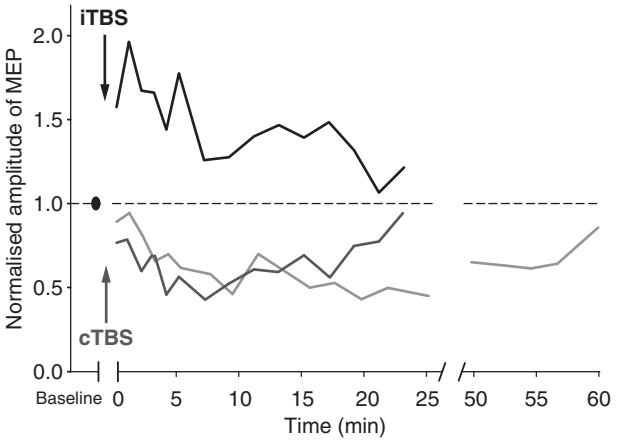

Figure 2 cTBS for 20 or 40 s suppress the size of motor evoked potentials (MEPs) for 20 or 60 min, respectively (gray lines), whereas iTBS for 190 s facilitates MEPs for ~20 min (black line).

the motor cortex. Huang and colleagues showed that mild tonic contraction (10–20% of maximum contraction) of the target muscle during iTBS or cTBS conditioning abolishes almost all the aftereffects of cTBS and iTBS. Similarly contraction immediately after conditioning for 1 min enhances the effect of iTBS, and converts the suppressive effect of cTBS into a facilitation effect. Contraction at 10 min after cTBS had no long lasting effect. Gentner and colleagues found that cTBS of 20 s produced mild enhancement, instead of depression of the corticospinal excitability, unless it was conditioned by voluntary contraction of sufficient duration (5 min). The stimulus intensity of TBS is usually referenced to the AMT. This implies that before TBS is applied, subjects are required to contract the target muscle for ~3–5 min to complete the assessment of AMT. They suggested that this preactivation might be crucial to produce the excitability depressing effect of a 20 s period of cTBS. A similar requirement for isometric contraction was not noted for cTBS of 40 s. Moreover, Iezzi and colleagues demonstrated that a brief sequence of phasic finger movements before TBS converted the facilitatory effect of iTBS to suppressive and the suppressive effect of cTBS to facilitatory. These data imply that the state of the cortex plays a crucial role in determining the response to TBS and is a factor that must be considered when applying to patient groups, particularly if used as a therapy.

Conclusion

In conclusion, theta burst rTMS is capable of modulating cortical excitability for up to an hour, possibly through changing the excitability of synaptic mechanisms. This technique has advantages over classic regular pulse rTMS including speed of delivery and low intensity of stimulation. This makes TBS an attractive form of stimulation to use in the experimental and particularly the clinical setting, where ease and speed of administration is of great importance.

Tics

K J Black, Washington University School of Medicine, St. Louis, MO, USA

Glossary

CBIT (Comprehensive Behavioral Intervention for Tics) – A behavioral therapy for tics based on habit reversal therapy.

Coprolalia – The repetitive utterance of socially inappropriate words or short phrases as a complex vocal tic.

Echolalia – Repeating the words of another person.

Echopraxia – Mimicking the gestures of another person.
Exposure and response prevention (E/RP) – A behavior therapy method used in the treatment of obsessive–compulsive disorder in which sustained volitional suppression of the manifest behavior (compulsions) produces diminution in the frequency both of compulsions and of the uncomfortable premonitory event (obsessions).

Definition and History

Tics are brief, nonrhythmic, stereotyped abnormal movements that most often affect the head, neck, and shoulders. Traditionally tics have been divided in a 2×2 fashion into simple and complex tics and motor and vocal (or, phonic) tics. These points are perhaps defined more clearly with examples (**Table 1**).

Tics that do not fit easily into this rubric include dystonic tics and sensory tics (discussed in the Clinical Features section). One comment that needs to be highlighted early is that coprolalia – perhaps the most well-known type of tic – is in fact relatively uncommon.

As vocal tics are just motor tics of the muscles of respiration and phonation, many experts feel that the motor/vocal division is arbitrary. Supporting this view are the observations that subjects with vocal tics usually have motor tics at other times in life and have elevated rates of motor tics in family members. Nevertheless, the division is of historical importance and figures in the currently accepted nosology of primary tic disorders. Interestingly, contemporaneous commentary on a well-documented historical figure who clearly had tics presaged several current topics in debate and research on tics. Samuel Johnson, the author of the first widely accepted dictionary of the English language, described his tics once as 'involuntary' and another time as 'a bad habit.' Some of his peers ascribed his movements and noises to a psychological disturbance; others thought that it was a sequela of rheumatic fever. The volitional or involuntary character of tics, their relationship to habit formation and to cognitive and affective symptoms, and the question of shared features with rheumatic chorea are all areas of intense current interest or debate.

Table 1 Examples of tics

	Simple	*Complex*
Motor	Forceful blinks, eyebrow raising, head shaking, shrugging, finger tapping, tensing of abdominal muscles, kicking	Touching the face or objects or other people, echopraxia, orchestrated sequences of simple tics
Vocal	Sniffing, humming, throat clearing, coughing, squealing, forceful nasal exhalations	Saying word fragments or words or short phrases, echolalia, palilalia (repeating one's one words)

Pathogenesis/Pathophysiology

Published research on the pathophysiology of tics has grown at an ever-faster rate in the past 30 years. Only a few notable results will fit within the text of this article. Surprisingly, little is known about the causes or pathophysiology of transient tics, although these are much more common. Most of the information that follows comes from research on people with chronic tic disorders.

Tic disorders are highly heritable, with monozygotic twin concordance much higher than concordance in dizygotic twin pairs. Although recent large, collaborative genetic studies have found probable linkage, no specific gene has yet been associated with a primary tic disorder.

Tics appear most commonly in the prepubertal period, peak in severity around ages 9–12, and on average wane thereafter. Although most youth with chronic tics still have tics when examined as adults, some do not even notice their tics, and only about a third of them have tics that bother them enough to seek continuing medical care. Thus, abnormalities in neurodevelopment are thought to be crucial in the development and maintenance of tics. Consistent with this hypothesis, a fascinating recent study showed that correlation of activity among various brain regions at rest showed a pattern in cognitively normal adolescent tic subjects that was seen in tic-free control subjects who were 4–5 years younger.

Tics are about 5 times more likely to occur in boys than in girls. This clue may relate to known differences in the rate of cortical maturation in boys and girls, or to androgen-sensitive brain regions during prenatal development. Male and female patients with chronic tic disorders differ in the volume of specific cortical regions as assessed by in vivo MRI volumetry.

Several brain regions differ in volume in patients with chronic tics compared with age-matched controls. One of the most compelling such findings is that caudate volume measured in childhood inversely predicts the severity of both tics and compulsions in adolescence. Thus, possible injury to brain cells by chronic or severe tics cannot explain the entire association of caudate volume with tics. More likely, some pathophysiological process produces reduction in caudate volume and leads to tics, obsessions, and compulsions in tic patients.

One possible relevant pathology has been recently discovered in histological studies of the small number of

Tourette syndrome (TS) patients with brain material available from autopsy who were carefully characterized clinically during life. Striatal interneurons that stain positive for parvalbumin are significantly fewer in the striatum and external pallidum from TS brains, but significantly increased in the internal pallidum. A defect in the migration of these cells during brain development has been proposed as one possible mechanism for these findings.

Mink has drawn attention to the common role of the basal ganglia in selecting some behaviors at the expense of suppressing others. He proposed that tics could reflect focal thalamocortical disinhibition. This disinhibition would be produced by a diminished firing of selected clusters of inhibitory basal ganglia output cells in the internal pallidum or the analogous substantia nigra pars reticulata (GPi/SNr), nuclei that normally provide a 'brake' on thalamocortical output. The model proposes that these clusters of GPi/SNr are abnormally inhibited by clusters of striatal neurons (specifically, matrisomes) that are firing excessively and out of context. Variability over time in which matrisomes are more active would be reflected by changes in which tics are manifest over time. The Mink model also provides a link to the dopamine system by proposing that dopamine would reinforce the abnormal activity in these circuits over time.

Numerous studies of the dopaminergic system have been prompted by the response of tics to dopamine antagonist medications. Postsynaptic D2 receptor binding is normal, but studies increasingly suggest a reduction in presynaptic dopaminergic markers in ventral striatum. These studies include positron emission tomography (PET) and single-photon emission computed tomography (SPECT) studies of levodopa uptake and dopamine production, of the VMAT2 site in mesostriatal dopaminergic neurons, and of the dopamine reuptake site, plus PET studies consistent with greater striatal dopamine release in response to intravenous amphetamine. A cognitive-pharmacological interaction functional MRI (fMRI) study examined nonmotor areas of brain and found several regions with a dopamine-sensitive abnormality in brain activity in response to a working memory task, despite normal task performance.

At rest, subjects with tic disorders show higher activity, measured as regional blood flow or metabolism, in primary sensorimotor cortex (possibly a nonspecific marker of increased movement) and a reduction in activity in striatum, perhaps especially ventral striatum. The spontaneous correlation of brain activity at rest between different anatomically defined brain regions also differs in TS from that seen in control subjects. The urge to tic has been associated with an increased brain activity in the right caudate nucleus and in anterior cingulate cortex, supplementary motor area, and insula.

Cognitive tasks intended to probe striatal circuits have been examined using neuropsychological methods and fMRI. Although declarative memory and sensorimotor task learning are normal in patients with chronic tics, habit learning assessed by a 'weather prediction' task was significantly impaired, and the impairment correlated with the severity of tics. Thus, habit learning may be specifically abnormal and may contribute to the persistence of tics.

Deficient habit learning relates to a model of tic maintenance that posits that tics can reduce preceding discomfort (see section on Clinical features), and this reinforces tics (i.e., maintains the likelihood that they will persist). This model has explanatory power in relation to certain behavioral observations and the efficacy of habit reversal therapy (see section on Treatment). However, critics of this theory observe that many children with tics report neither premonitory sensations nor a sense of relief on ticcing. This observation could mean either that the premonitory sensations are an epiphenomenon and not central to tic genesis or (as this author prefers) that children can tic long before they are able to notice or verbalize the relationship of tics to premonitory sensations.

In this connection, it is interesting to note that when a person suppresses tics by effort in the natural world, such suppression is often for relatively brief periods of time (e.g., while a physician looks directly at the person, or during a job interview). In such settings, a rebound effect often occurs when tic suppression is no longer needed, that is, tic frequency increases above the presuppression rate. By contrast, no rebound is observed after tic suppression is sustained for a much longer duration ($\geq$90 min) during a professionally conducted session of exposure and response prevention (E/RP). In fact, E/RP clearly diminishes ticcing and the urge to tic even after overt patient observation ends and the patient is instructed that it is now okay to tic. However, these observations occur in such very different settings as not to indicate discordance. Presumably, the key difference is that the E/RP session is long enough that the patient habituates to the discomfort engendered by not ticcing, so that by the end of the session a tic no longer reinforces the urge to tic. The tic at this point would tend to extinguish or become less frequent.

Another theory of tic genesis derives from Peterson and Leckman's observation of the timing of tics, with tics tending to cluster in what are called bouts of tics. On a longer time scale, patients also tend to have clusters of days or months with greater tic frequency and severity. A recent review by Leckman and colleagues discusses this observation on a smaller time scale, in relation to the periodic discharge of neurons in frontal-striatal circuits.

Epidemiology/Risk Factors

Until relatively recently, tics were thought to be uncommon. However, now several independent, competent

epidemiological studies have examined tic prevalence in children, and they agree remarkably well that chronic tics (lasting at least a year) are present in about 3% of all children ages ~5–15 years. Transient tics are even more common. Lifetime prevalence of transient tics is hard to determine with certainty; the very definition means that the odds of observing them in an individual who will ever have them is lower than for chronic tics. However, extrapolating from several cross-sectional studies, probably as many as 30% of the population will have tics for a month or two but will be tic-free before a year passes.

Tics occur around the world in people of diverse ethnic and racial backgrounds. However, the relative prevalence of tics across cultures is not clear. Two American studies have found a significantly higher rate of tics in African-American children compared with white children. However, it is difficult to reconcile this result with the observation that few black children are diagnosed with tics or attend lay groups for tic disorders. Conceivably, the disparity is entirely the result of inequitable access to health care. Alternatively, differences could exist in whether mild tics are taken to indicate disease, or in the actual rate of tics in different groups. Both studies alluded to above diagnosed tics using parental report or a lay interviewer, and there may be cultural differences in the description or identification of tics. One large, unpublished study in South Africa found extremely low prevalence of tics in the Xhosa population.

There are a few known risk factors for tics other than age and male sex. Tics are very heritable. Discordant monozygotic twin pairs have been reported, but one study used a national referral campaign to find such pairs for a brain imaging study, and found only 5 pairs. Even then, all 10 twins had tics, but in each pair one twin had more severe tics than the other. Tics are much more common in children with learning disabilities.

Some environmental factors are known to be related to tic production. If one monozygotic twin was smaller at birth or had greater birth complications (e.g., forceps delivery) than his or her co-twin, tics tend to be more severe in the twin with more complications. More recently, maternal smoking during pregnancy was associated with a greater likelihood of tics.

Clinical Features and Diagnostic Criteria

Tics were described briefly in the first section of this article as discrete, intermittent, brief, nonrhythmic, stereotyped abnormal movements. Blinking, throat clearing, touching objects, and saying words are typical tics that exemplify the traditional orthogonal categories of motor versus phonic (vocal) tics and simple versus complex tics. Complex tics occasionally predominate the clinical picture in chronic tic patients, but in such cases the possibility of obsessive–compulsive disorder (OCD) without tics must be maintained in mind. Generally, patients with chronic tics have a mixture of simple and complex tics or simple tics alone. Outside the simple/complex and motor/vocal paradigm, phenomena that have been described as tics include sensory tics and dystonic tics.

Most adults with tics (about three fourths) report uncomfortable premonitory sensations, sometimes called sensory tics, just prior to motor or vocal tics. Often this is a focal discomfort such as a scratchy throat before a loud harrumph, or itchy eyes before a pair of forceful, brief blinks. Other preceding phenomena are less localized or less purely sensory. Examples include akathisia-like discomfort or detection of sharp corners in the peripheral visual field. These phenomena and their relationship to tics are reminiscent of the link between obsessions and compulsions. Some historical writers on tics even called compulsions 'mental tics.' However, typically premonitory phenomena before tics are sensory in nature, whereas obsessions are generally cognitive, imaginal, or affective.

The description 'dystonic tics' is most appropriate in less common cases such as a man who presented for treatment of blepharospasm. His eye movements resembled those of primary eyelid dystonia, with forceful eye closures sustained for several seconds at a time and a sensory trick. However, the patient reported that the blepharospasm had been present for 2 years, disappeared for 5 years, and reappeared 3 years before. He also had lifelong simple tics that had come and gone over the years, and he could suppress the blepharospasm temporarily upon request. Dystonic tics are also sometimes diagnosed for the more common situation of a patient some of whose tics are longer than brief movements, like pressing a heel against the floor for 1–2 s or twisting the head to one side for a similar duration. These might perhaps be more accurately called 'tonic tics.'

Typically, tics change over time in anatomic location, frequency, type, complexity, and severity. This is in fact a defining feature of the Tourette Syndrome Study Group (TSSG) criteria for tic disorders.

Tics most commonly involve the head and upper body, for reasons that are unknown. One possibility is that a disproportionate fraction of the mammalian brain is devoted to control of muscles that are used in social communication, including gesture, eye contact, contextual facial expression, affect, and prosody in addition to language. A rodent model that has been proposed as relevant to tics is the so-called syntactical chain grooming, describing stereotyped sequences of rostral body behaviors.

Like nearly all movement disorders, tic severity worsens with emotional stress and anxiety. In school-aged children, September and the return to school often mark a period of worsened symptoms. However, the fluctuation of tic severity in response to other environmental variables is remarkable and also helps distinguish tics from other abnormal movements. For instance, many patients

report that tics improve when they are engaged in purposeful activity, either concentration-requiring activity such as vocal performance or surgery, or physical activity such as running. Several patients describe an impression that they have a certain amount of mental energy that 'has to' express itself either as purposeful activity or as tics. Although unlikely as a pathophysiological explanation, this description has heuristic value in understanding many patients' fluctuating severity in different activities.

Tics are not volitional in the usual sense of being a desired, intended action. However, tics can be suppressed with an effort of will. The perception of volition varies but when people are paying attention to their tics, they are most often experienced as an inevitable capitulation to an almost irresistible urge. Probably fewer than 10% of adults with tics describe them as truly involuntary (e.g., 'look at that, my arm just moved'), and most children with tics use words such as 'I do this' or 'I have to blink.' This sense of volition is an important feature, when present, in distinguishing tics from other movement disorders. On the other hand, many patients report that tics are so common that they are often ticcing without thinking about the tic or even noticing it.

The ability to suppress tics can be substantially affected by providing rewards carefully timed to follow short periods of successful tic suppression (differential reinforcement of zero-rate ticcing). Like the ringing bell of Pavlov's experiments, these rewards can be paired with neutral stimuli (like a purple light) until a conditioned response develops so that even without any direct instruction to suppress tics, tics are less frequent when the purple light is illuminated. These experimental results suggest one mechanism by which tics may become more frequent in one environment (like home) compared with another (like a school bus).

There is no universally accepted definition of tics. Two sets of diagnostic criteria for idiopathic tic disorders are widely accepted: the DSM-IV-TR criteria and the TSSG criteria. Although minor differences exist, in fact both criteria sets identify essentially the same patients. For TS, for instance, both definitions require motor and vocal tics that begin in childhood or adolescence, occur many times a day for most of a year, and for which a specific neurological or systemic cause cannot be identified.

Interestingly, although the diagnostic criteria now focus exclusively on tics, most tic patients who come to the doctor's office have other neurological or psychiatric symptoms.

Differential Diagnosis

Tics are distinguished from other abnormal movements by several clinical features. Most importantly, tics are stereotyped. In other words, across relatively long intervals of time, a few tics are preferentially repeated and become somewhat predictable in character to the observer. Someone with chorea may be 'that man who is continually moving,' whereas someone with tics may be 'that man who blinks and shakes his head.' However, tics are nonrhythmic, which separates them not only from tremor but also from other stereotypies such as typical tardive dyskinesia, akathisia, or the agitation of anxiety or major depression. Tics are generally brief, discrete movements, in contrast to the more sustained postures of dystonia. The patient characteristically can suppress tics for a period of time, whereas myoclonus is not suppressible (and involves much briefer movements). Finally, in contrast to most other involuntary movements, tics more often than not are sensed as volitional (discussed in the section on Clinical features).

Tics are classified as primary if no specific illness is identified as causing them. Primary tic disorders include transient tic disorder, chronic tic disorder (motor or vocal), and TS (motor and vocal tics). Schlaggar and Mink discuss several causes of secondary tic disorders, including developmental or degenerative illnesses and focal brain lesions. However, these are uncommon.

Diagnostic Workup/Tests

If the patient is developing normally and has normal cognition, the physical examination is normal except for the tics, and the patient meets the diagnostic criteria for a primary tic disorder (including age of onset), there is no compelling reason to perform further laboratory or radiologic testing. This is especially true when the tics have persisted for many years without other evidence of impairment. Wilson's disease and carbon monoxide poisoning may be the most treatable and serious secondary causes.

Management

More than 20 different classes of treatments have produced positive results in at least one double-blind, randomized controlled trial. However, the first important question in management is whether treatment is necessary at all. Factors to consider in that judgment include impairment in school or work, social life, self-esteem, or relationships with parents, spouse, or close others. Often reassurance and education suffice. Education as to the side effects and the likely maximum benefit is also useful; no known tic treatment suppresses more than about 50–75% of symptoms on average. Expectations need to be managed.

A second treatment principle is to identify which symptoms are most problematic at present. Many patients present for management of (say) TS, yet obsessions or hyperactivity or anger outbursts are the more compelling clinical concern. Since the management of all of these is ameliorative rather than curative, one can start by treating the most severe or most impairing symptom.

The nonspecific management of chronic tics can be valuable. This can include referral to the Tourette Syndrome Association, neuropsychological evaluation and treatment if school or work function is impaired, and consultation regarding legal protections at school or in the workplace.

Only two drugs are approved by the US FDA for the management of a tic disorder (haloperidol and pimozide), and neither is currently recommended as first-line treatment for most patients. The most efficacious treatments for tics according to replicated studies include newer antipsychotics such as risperidone, ziprasidone, olanzapine, and aripiprazole, and habit reversal therapy, now dubbed Comprehensive Behavioral Intervention for Tics (CBIT) for Comprehensive Behavioral Management for Tics. Clonidine may be one of the most widely prescribed medications for tics. Several recent articles review medications with proven antitic efficacy.

A number of newer treatments are in early testing but show some evidence of efficacy. These include midline repetitive transcranial magnetic stimulation, and deep brain stimulation in the thalamus (centromedian-parafascicular nuclei) or in the GPi. In monitoring and judging the efficacy of any treatment, it is important to remember that tics usually improve and worsen spontaneously over time. Additionally, patients are most likely to begin a new treatment when symptoms are at their worst. These factors combine to make judging the benefit difficult in most patients. Thus, randomized controlled trials are essential for testing any new treatment.

Prognosis

On average, patients improve after about age 12 in terms of tic frequency and severity. Most patients even with fairly severe symptoms in childhood will have substantially reduced tic frequency and severity as adults. Symptom severity in childhood does not accurately predict severity as an adult. However, individual patients can have variable courses.

Tics, Complex

D Shprecher and R Kurlan, University of Rochester, Rochester, NY, USA

Glossary

Autistic spectrum disorders – Neurodevelopmental disorders characterized by impaired socialization and communication skills with stereotyped or restricted patterns of interest or behavior.
Coprolalia – Involuntary utterance of profanities.
Deep brain stimulation – Treatment of movement disorders which applies electric current to basal ganglia or thalamic targets via surgically implanted leads.
Encephalopathy – A disturbance of consciousness caused by medical illness, infection, or drug toxicity.
Rett syndrome – A neurodegenerative disorder with typical onset in childhood, commonly accompanied by loss of motor and social skills, seizures, and stereotypies.
Tourette syndrome – A developmental neuropsychiatric disorder characterized by the onset of both motor and vocal tics in childhood, lasting longer than 1 year.

Definition and History

The Tourette Syndrome Classification Study Group defines tics as brief movements (motor tics) or sounds produced by the movement of air through the mouth, nose, or throat (vocal tics). As a movement disorders phenomenological category, tics are characterized by not being constantly present (unless very severe), occurring out of a background of a normal motor activity, often mimicking normal movements, lacking in rhythmicity, varying in intensity, often changing in quality, and having some element of temporary voluntary suppressibility. Patients with tics often recognize an urge to execute the tics and a feeling of relief after their tics.

Clinical Features and Diagnostic Criteria

Both motor and vocal tics can be divided into simple and complex types. Complex motor tics are distinct, coordinated patterns of sequential movements. They may appear purposeful, as if performing a voluntary action, such as tapping, touching, punching, kicking, hopping, or smelling. Other examples include copropraxia (obscene gestures) and echopraxia (mimicking the movements of others). A repetitive coordinated sequence of simple tics (e.g., facial grimace with head jerk, shoulder shrug, and arm jerk) may not appear purposeful and would be considered to represent a form of complex tics.

A complex vocal tic has linguistic meaning, consisting of a partial word (syllables), word, or phrase. Examples include coprolalia (obscene or insulting words often truncated such as 'fu-'), echolalia (repeating the words of others), and palilalia (repeating one's own words such as 'How are you today, today, today?'). Like simple tics, complex tics are often associated with premonitory sensations and irresistible urges.

Complex tics must be distinguished from stereotypies, which are seen in patients with autistic spectrum disorders, mental retardation, Rett syndrome, psychosis, encephalopathies, and congenital blindness and deafness. Contrary to complex tics, stereotypies tend to be more repetitive and continual (e.g., body rocking, hand flapping), or vocalization (e.g., moaning, yelling) occurring over and over for prolonged periods of time. Stereotypies are not known to be associated with premonitory sensations and may be more difficult to suppress than tics.

Since tics and obsessive-compulsive disorder commonly occur together, it may be difficult to distinguish complex motor tics and compulsions. Contrary to tics, compulsions are performed in response to an obsession (e.g., hand washing to prevent contamination), to ward off future problems (e.g., counting to prevent harm to a loved one), to reduce anxiety, or according to certain rules. This latter rule-based (ritualistic) quality is characteristic of compulsions. Examples of rules include a certain number of times, in a certain order, equally on both sides of the body ('evening up'), or a certain time of day (e.g., morning or bedtime rituals). In our experience, some specific actions have the qualities of both tics and compulsions, and it is impossible to distinguish the two phenomena. We use the term 'compulsive tic' or 'compultic' for these overlap behaviors. We have also found that some complex motor tics have impulsive, socially inappropriate qualities and use the term 'impulsive tic' or 'impultic' for these actions. Examples of impulsive tics include hitting others, self-injury, touching a hot stove, and stepping into oncoming traffic. Some actions have mixed tic, compulsive, and impulsive qualities (e.g., pushing or hitting someone after they coughed to avoid contamination) and could be considered 'compulsive/impulsive tics.'

As discussed elsewhere in this encyclopedia, Tourette's syndrome (TS) is the primary tic disorder, and is characterized by childhood onset of chronic motor and vocal tics. In individual patients, tics can be simple, complex, or

of both types. It is very unusual to see complex tics in the absence of simple tics, often helping to clarify the phenomenology of a complex action. Although coprolalia is the feature of TS most responsible for the notoriety of the condition, we find this feature only rarely (~1–2%) in our TS patients. Some patients have only internal, nonverbalized, obscene words, thoughts, or images, termed 'mental coprolalia.' In our experience, the secondary causes of tic disorders are usually associated with simple rather than complex tics.

Pathogenesis

Information on the course, pathogenesis, and the treatment of tics is provided in the Chapter 'Simple Tics.'

Management

Complex motor and vocal tics tend to produce greater disability in patients than do simple tics, and therefore, their presence often signifies the need for tic-suppressing therapy. For debilitating and dangerous complex tics, such as loud coprolalia or self-mutilating tics, we tend to initiate medication therapy with an antipsychotic drug in order to achieve more rapid and predictable control. Intramuscular or intralaryngeal injections of botulinum toxin may reduce some disabling complex motor or vocal tics respectively. Some TS patients with self-harming behaviors have not tolerated deep brain stimulation surgery due to self-induced damage to the equipment or infection related to constant picking at the operative sites. Surgical anterior cingulotomy can be considered for patients with medication refractory self-harming behavior. For patients with complex phenomenology (e.g., compulsive tics, impulsive tics, compulsive/impulsive tics), a combination of tic-suppressing medications, obsessive-compulsive disorder therapies (e.g., cognitive behavioral therapy, selective serotonin reuptake inhibitors), and impulse control therapies (e.g., behavior therapy, stimulants, mood stabilizers) may be needed for optimum control.

Tics, Simple

D Shprecher and R Kurlan, University of Rochester, Rochester, NY, USA

Glossary

Deep brain stimulation – Treatment of movement disorders which applies electric current to basal ganglia or thalamic targets via surgically implanted leads.

Huntington disease – A neurodegenerative genetic disorder characterized by movement disorders, cognitive deficits, and psychiatric disturbances.

Neuroacanthocytosis – A neurodegenerative genetic disorder characterized by thorny appearing red blood cells ('acanthocytes') and often accompanied by involuntary movements including chorea or tics.

Definition and History

The Tourette Syndrome Classification Study Group defines tics as brief movements (motor tics) or sounds produced by the movement of air through the mouth, nose, or throat (vocal tics). As a movement disorders phenomenological category, tics are characterized by not being constantly present (unless very severe), occurring out of a background of normal motor activity, often mimicking normal movements, lacking in rhythmicity, varying in intensity, often changing in quality, and having some element of temporary voluntary suppressibility. Patients with tics typically express an urge to have their tics and relief after making the movement or sound.

Pathogenesis

The neurobiological basis for tics remains largely unknown. There is substantial evidence for the importance of hereditary factors in Tourette syndrome (TS), but no specific gene locus has been identified. The observed response to dopamine receptor antagonist medications in concert with the finding of reduced levels of the dopamine metabolite homovanillic acid in the cerebrospinal fluid (CSF) of patients with TS suggested an underlying state of postsynaptic dopamine receptor supersensitivity. More recently, neuroimaging studies have suggested the presence of reduced tonic synaptic levels of dopamine and increased phasic release of dopamine in the basal ganglia. Other neuroimaging investigations have yielded conflicting information about whether or not there is an increase in presynaptic dopamine transporters or excessive dopaminergic innervation. Overall, there appears to be a dysfunction of inhibitory activities in corticostriatal circuits, perhaps allowing the expression of unwanted motor programs as tics.

Clinical Features and Diagnostic Criteria

Both motor and vocal tics can be divided into simple and complex types. Simple motor tics are abrupt, sudden, and brief movements occurring in single and isolated fashion. Some of the more common examples include an eye blink or wink, a head jerk, a shoulder shrug, or a dart of the eyes. Some simple motor tics have a slower, often twisting or tightening quality and have been termed 'dystonic tics' because of their resemblance to dystonia. Common examples of dystonic tics include facial grimacing, torticollis-like head/neck twisting, blepharospasm-like prolonged forceful eye closure, and abdominal muscle tensing.

Simple vocal tics consist of inarticulate noises or sounds that are produced by the movement of air through the mouth, nose, or throat. Thus, a clicking noise produced by knocking the teeth together, for example, would be considered a motor tic and not a vocal tic. Common simple vocal tics include throat clearing, sniffing, snorting, and grunting. Both simple motor (especially dystonic) tics and vocal tics are commonly associated with a premonitory sensation, sometimes referred to as a 'sensory tic.' Such sensations are typically uncomfortable and localized at the site of a tic (e.g., in the throat for vocal tics). Patients often describe a need to tic in order to relieve the abnormal sensation, but it inevitably returns to induce more tics.

Simple motor tics must be distinguished from myoclonic and choreic jerks, which tend not to be repetitive in the same location like tics. Simple motor tics are often accompanied by complex motortics, allowing them to be identified based on 'the company they keep.' Contrary to torsion dystonia, dystonic tics occur in abrupt bursts of movements, are not continuous, and tend to produce abnormal postures for a shorter time period. Dystonic tics are usually associated with more typical motor tic jerks, revealing the nature of the movement disorder.

TS is defined by the presence of chronic (at least 1 year) motor and vocal tics, with onset in childhood or adolescence. When only one type of tic is present, the diagnoses of Chronic Motor Tic Disorder (CMTD) or Chronic Vocal Tic Disorder (CVTD) are used. TS, CMTD, and CVTD are considered to represent a spectrum of primary tic disorders, thought to occur on a largely genetic or idiopathic basis. It should be pointed out that since the movement of air needed to produce a vocal tic involves the contraction of muscles in the mouth, pharynx, larynx, or diaphragm, the distinction between motor and vocal tics per se probably does not reflect neurobiological differences and largely exists from historical perceptions. With this consideration, most clinicians view TS, CMTD, and CVTD as the same condition.

Epidemiological studies indicate that at least transient tics occur commonly in the course of childhood development, possibly resulting from the process of normal basal ganglia synaptogenesis. The term 'physiological tics' has been applied to this phenomenon. Tics can be seen in the setting of a wide variety of conditions linked to abnormal brain development or cerebral damage, and these cases are referred to as 'secondary tic disorders.' Included are mental retardation, autism, pervasive developmental disorder, neuroacanthocytosis, Huntington's disease, encephalitis, and traumatic brain injury. Tics may be a manifestation of tardive dyskinesia or withdrawal-emergent dyskinesia related to chronic antipsychotic drug use. A variety of medications (e.g., carbamazepine, levodopa, calcium channel antagonists) have been reported to induce tics. Secondary tic disorders are usually evident by the presence of neurological signs in addition to tics.

In TS patients, tics have their onset usually around age 6–7 years. They tend to follow a waxing and waning course of severity, with exacerbations and remissions occurring over periods of weeks or a few months. Tics often occur in

waves, with one set of tics being replaced by another set over time. Some patients have a few persistent tic types throughout the different waves. Tic severity tends to peak around age 10–12 years. In about two thirds of cases, tics either fully resolve or substantially lessen as TS patients grow into adulthood, so the ultimate prognosis is usually good.

Management

When tics are disabling in causing social embarrassment, discomfort or interference with daily activities, tic-suppressing medications are available. Most clinicians start with the alpha-agonist drug guanfacine (0.5–4 mg per day; h.s. or b.i.d.). If there is inadequate response or problems with tolerability, one can either switch to or add an antipsychotic medication. The atypical antipsychotics risperidone (0.25–16 mg per day) or aripiprazole (5–30 mg per day) are the most commonly prescribed. Classical neuroleptic antipsychotics such as haloperidol (0.5–10 mg per day), pimozide (0.5–10 mg per day), or fluphenazine (0.5–20 mg per day) may be of value. Other tic-suppressing agents to consider include clonazepam (0.5–10 mg per day) and tetrabenazine (25–200 mg per day). Local intramuscular injections of botulinum toxin may be helpful when there is a small number of disabling motor tics. Deep brain stimulation surgical therapy has been reported to benefit some patients with severe, medication-refractory tics, but the best anatomical target and proper subject selection criteria remain to be determined as does the overall efficacy and safety of this approach.

Tocopherol Transfer Protein and Ataxia with Vitamin E Deficiency

H J Kayden, New York University School of Medicine, New York, NY, USA
D Manor, Case Western Reserve University, Cleveland, OH, USA

Glossary

Abetalipoproteinemia – An autosomal recessive disease due to mutations in the microsomal triglyceride transfer protein, characterized clinically by peripheral neuropathy, ataxia, acanthocytosis, retinitis pigmentosa, and steatorrhea, and treated with vitamin E supplementation.

Microsomal triglyceride transfer protein – A protein which catalyzes the transport of triglyceride, cholesteryl ester, and phospholipids from phospholipid surfaces. It is isolated as a soluble protein from the lumen of the microsomal fraction of liver and intestine.

***RRR*-α-tocopherol** – A form of vitamin E, which is extracted from plants; also known as α-tocopherol or vitamin E.

***TTPA* gene** – The gene that encodes the α-tocopherol transfer protein, αTTP.

Definition and History

The term vitamin E refers to a family of plant-derived neutral lipids. The different forms of vitamin E are distinguished from each other by the pattern of methylation on the chromanol ring (α vs. β vs. γ vs. δ), the saturation level of the phytil side-chain (tocopherols vs. tocotrienols), and the stereochemical configuration of three chiral carbon centers (*S* vs. *R* configuration for each center). Vitamin E supplements sold over-the-counter typically contain a synthetic mixture of tocopherols, whereas 'natural source' vitamin E extracted from plants contains primarily *RRR*-α-tocopherol. Regardless of intake composition, only *RRR*-α-tocopherol accumulates in plasma and tissues at significant levels, while other forms of the vitamin are degraded in the liver and excreted in urine. This remarkably efficient discrimination between different forms of vitamin E has led to the common definition of *RRR*-α-tocopherol as the 'biologically active' form of vitamin E. In clinical analyses, the terms 'vitamin E' and 'α-tocopherol' are used synonymously.

The essential role of α-tocopherol in preserving normal neurologic function is demonstrated by the occurrence of acquired and hereditary disorders that cause vitamin E deficiency. Most instructive are the observations that genetic mutations in the *TTPA* gene (encoding the α-tocopherol transfer protein, αTTP) result in low to absent plasma and tissue levels of vitamin E accompanied by neurologic abnormalities, especially ataxia.

The first indications of the critical neuroprotective role of vitamin E in humans were observed in patients with the hereditary disease abetalipoproteinemia. In this autosomal recessive disorder, mutations in the microsomal triglyceride transfer protein (MTTP) impair the assembly of apolipoprotein B-containing particles, i.e., chylomicrons, very low density lipoproteins (VLDLs) and low density lipoproteins (LDLs). These defects result in inability of the patients to absorb dietary fat (including fat-soluble vitamins), and to circulate lipids from the liver to peripheral tissues. By the second decade of life, neurologic abnormalities such as progressive peripheral neuropathy and spinocerebellar ataxia appeared; other clinical features included acanthocytes, retinitis pigmentosa, and a celiac-like malabsorption syndrome. Since specific laboratory determinations of vitamin E levels were not commonly performed at the time, early patients were diagnosed as subjects with Friedreich's ataxia. Closer analyses of plasma and tissue lipid profile revealed extremely low or non-detectable levels of vitamin E. When patients received supplementation with extremely high doses of vitamin E, the neurologic abnormalities could be ameliorated. Furthermore, it was found that supplementation at infancy protected patients from developing the debilitating neurologic symptoms associated with this syndrome.

Interest in vitamin E biology intensified when patients diagnosed with 'Friedreich's ataxia' were found to have exquisitely low plasma levels of α-tocopherol, despite having intact fat absorption and normal lipid profile. The availability of deuterium-labeled forms of vitamin E allowed investigation and consequently the 'mapping' of the physiological routes of vitamin E after ingestion. Thus, it was established that isomer composition of postprandial vitamin E mirrors that of intake, and that discrimination in favor of *RRR*-α-tocopherol occurs only later, during hepatic incorporation of vitamin E into VLDL and LDL. Patients diagnosed with the so-called 'variant Friedreich ataxia' were investigated by several groups. The recognition that a large number of affected individuals were from defined geographical locations such as the Mediterranean basin – specifically Tunisia, stimulated intense search for hereditary abnormalities. The high incidents of consanguinity coupled with a high birth rate made many patients in these areas available for studies of heritability patterns and for the identification of the molecular 'culprit' behind the syndrome.

Laboratory studies previously have identified a protein isolated from rat liver extracts that bound α-tocopherol with high affinity and catalyzed the transfer of the vitamin between membranes – the α-tocopherol transfer protein (αTTP). Once the rat liver protein was purified to homogeneity and sequenced, its mRNA was genetically cloned; the human transcript encoding αTTP was cloned shortly thereafter, and the *TTPA* gene mapped to the q13 region of human chromosome 8. Further studies in cultured cells established that αTTP facilitates the secretion of α-tocopherol from hepatocytes to lipoprotein acceptors outside the cell. Specifically, TTP is thought to catalyze the intracellular transport of the vitamin from lysosomes to the site of secretion in the plasma membrane. The syndrome characterized by ataxia coupled to vitamin E deficiency due to mutations in the *TTPA* gene was originally termed familial isolated vitamin E deficiency (FIVE). The term ataxia with vitamin E deficiency (AVED) was later coined, and is more commonly used at present. AVED

and FIVE describe the same disorder, and are therefore synonymous.

The importance of αTTP in regulating vitamin E status is also underscored by mice models in which expression of αTTP is disrupted (αTTP knock-out or $\alpha TTP^{-/-}$ mice). These animals are particularly useful in analyzing changes in the brain under states of vitamin E deficiency, especially in the cerebellum. As expected, $\alpha TTP^{-/-}$ mice exhibit high lipid peroxidation products in the brain, especially in degenerating neurons. As $\alpha TTP^{-/-}$ mice age, they display the classical neurological symptoms associated with AVED. Interestingly, postmortem analyses revealed increased expression levels of αTTP in cerebellar Purkinje cells in brains of patients suffering from oxidative-stress-related diseases such as Down syndrome and AVED.

Pathogenesis/Pathophysiology

Multiple mutations in the *TTPA* gene have been described in AVED patients. These genetic changes result in a αTTP protein that is either compromised with regard to its biochemical activities, or is missing altogether. As a result, vitamin E is not incorporated into liver-assembled lipoproteins, and is not distributed to peripheral tissues. While all nonhepatic tissues in AVED patients become depleted of vitamin E, the central nervous system appears to be especially sensitive, and degeneration of neuronal tissue ensues early in life, followed by progressive ataxia. The presence of multiple genetic alterations in the *TTPA* gene accounts for the wide variety of clinical syndromes presented by affected individuals, ranging from severe ataxia apparent at early childhood, to mild symptoms that manifest only after the second decade of life. The pathogenic scenarios may involve altered activity of αTTP that is expressed in the central nervous system, especially in the cerebellum. The function of brain-αTTP is presently not known.

Epidemiology

Heritable mutations in the *TTPA* gene are very rare, with fewer than 100 cases reported to date. The disease is inherited in an autosomal recessive pattern. In the reported cases, over 22 different mutations in the *TTPA* gene have been described. Some mutations arise from nucleotide deletions or insertions that cause incorrect initiation or termination of transcription or shifts in the translation reading frame. Such drastic changes in αTTP's primary structure often cause severe, early-onset form of the pathological disorder. Other mutations result from single amino acid substitutions that produce a full-length protein with compromised activity. Such missense mutations can affect TTP activity in different ways, leading to various clinical phenotypes ranging from mild, late-onset ataxia, to the most debilitating, early-onset variant of the disease. In most cases, the effect of a specific mutation on TTP's biochemical activity in vitro correlates to the clinical severity presented by the patient carrying the mutation(s). It should be noted, however, that some mutations do not alter TTP's activity in tocopherol binding and transfer, yet they impart clinical vitamin E deficiency on human carriers. The molecular-level bases of these observations are still not known.

Clinical Features

It is important to note that comprehensive neurological examination by itself is not sufficient for distinguishing between clinical consequences of vitamin E deficiency and other forms of cerebellar ataxias (e.g., Friedreich's ataxia). Neurological symptoms usually appear between early childhood and late teens. Patients initially present with progressive ataxia and clumsiness of the hands, loss of deep tendon reflexes, dysarthria, and gait disturbances. In some cases, these symptoms may be accompanied by head titubation, loss of visual acuity, positive Babinski sign, and cardiomyopathy.

Differential Diagnosis

The neurological symptoms characteristics of vitamin E deficiency are similar to those presented in other unrelated disorders. Friedreich's ataxia patients present with similar symptoms, but do not exhibit diminished plasma vitamin E levels. Fat malabsorption disorders such as abetalipoproteinemia, cystic fibrosis and short bowel syndrome are accompanied by vitamin E deficiency, but abetalipoproteinemia is uniquely characterized by an abnormal lipid–lipoprotein profile.

Diagnostic Workup

Clinical neurologic examination, including electrophysiologic evaluation may aid in diagnosis, but resultant findings cannot specifically implicate vitamin E deficiency. Neurologic evaluation must be accompanied by analytical determination of plasma vitamin E and lipid profile (levels of HDL, LDL, VLDL, cholesterol, and triglycerides in plasma after 12 h fast). Molecular sequencing of the *TTPA* gene is the ultimate diagnostic tool, but may not be readily available.

Management

Patients carrying mutations in the αTTP should be supplemented with high doses of vitamin E throughout their life. Plasma vitamin E levels should be monitored routinely, and maintained at the high-normal range.

Prognosis

Routine, high-dose supplementation with vitamin E ameliorates, overcomes, and protects against the pathological consequences of mutations in TTP. If diagnosed early, supplementation with vitamin E can reverse some of the neurologic features of the disease.

Summary

Available information supports special awareness in Movement Disorder clinics to possible AVED diagnosis in any patient presenting with spinocerebellar ataxia. Plasma vitamin E levels should be determined in such patients. This is especially critical in light of the profound efficacy of supplemental vitamin E therapy for this disorder.

Torsin A

R H Walker, James J. Peters VA Medical Center, Bronx, NY, USA; Mount Sinai School of Medicine, New York, NY, USA

Glossary

Caenorhabditis elegans – A nematode used in laboratory genetic studies.
Chaperone proteins – Cellular housekeeping proteins with functions such as protein quality control, protein folding, degradation, protein complex assembly, cytoskeletal regulation, and vesicular transport.
Dystonia – A hyperkinetic movement disorder characterized by abnormal sustained postures and repetitive movements.
Inclusion bodies – Aggregations of proteins within cells, usually indicative of a pathological process.

Definition

TorsinA is a 332 amino acid protein encoded by the *DYT1* or *TORA* gene, located on chromosome 9q34. Homologues of human torsinA are found in rat, mouse, zebrafish, *Drosophila*, and *Caenorhabditis elegans*, suggesting an evolutionarily important function. TorsinA is found throughout the brain and in various organs including liver, kidney, and muscle.

TorsinB is encoded by the gene *TOR1B*, located adjacent to the *DYT1* gene, which has 70% homology to torsinA. In the nervous system, it has similar, although not identical, localization to torsinA, but does not appear to functionally compensate for mutation of torsinA.

Mutations of the *DYT1* gene are responsible for one of the commonest forms of autosomal dominantly-inherited child-onset dystonia, DYT1 dystonia. To date only one

dystonia-causing mutation has been identified, namely a GAG deletion in exon 5, which results in loss of a glutamic acid at either position 302 or 303, near the carboxy terminus of the protein (ΔE-torsinA). Other mutations initially postulated to cause dystonia, such as the 18-base pair deletion, have not been unequivocally shown to cause the disease.

About 30% of the carriers of a single mutant copy of the *DYT* gene will develop dystonia. The typical phenotype is the onset of dystonia in a limb during mid-late childhood, with generalization during adolescence. Adult-onset focal dystonia is rarely associated with mutations of torsinA, especially when the disorder develops after the age of 26 years, but occasionally may be seen below this age. The penetrance of the mutation appears to be influenced by a single nucleotide polymorphism at position 216. When histidine is present rather than aspartic acid on the nonmutant allele, penetrance is significantly reduced. The presence of aspartic acid on the mutant allele appears to be associated with increased likelihood of developing the disease. As these effects were not absolute, it is very likely that other genetic or possibly environmental factors influence the disease manifestation.

The lack of prominent neuropathological abnormalities in the *postmortem* tissue of humans with DYT1 dystonia, in concert with clinical observations, strongly suggests a functional role for torsinA, for example, related to neurotransmitter release.

Localization

TorsinA appears to be present in all neurons in normal brain in all mammalian species examined (mouse, rat, macaque, and human), but not, under normal circumstances, in glia. Reports of torsinA being present in higher amounts in dopaminergic neurons of the substantia nigra pars compacta (SNc) are likely due to the large size of these neurons, as immunohistochemical labeling using antibodies to torsinA demonstrates prominent labeling in all areas of high neuronal density and/or size such as cerebellar Purkinje cells, neurons of the pontine nuclei, and the pyramidal cell layer of the hippocampus. Double-labeling immunohistochemical studies showed that torsinA was present in the vast majority of neuronal types throughout the brain, and in particular in projection neurons and interneurons of the striatum.

TorsinA is present in neuronal cell bodies, where it is localized in the lumen of the endoplasmic reticulum (ER), and in the space between the inner and outer membranes of the nuclear envelope. The 19 amino acid hydrophobic domain near the N-terminus may serve to anchor torsinA to the membrane. This position may put torsinA in a unique position to fulfill functions related both to the nuclear envelope and to cytoskeletal components. In the nuclear envelope, torsinA appears to interact with lamina-associated polypeptide 1 (LAP1), and in the ER, it interacts with the homologous, luminal domain-like LAP1 (Lull1), both of which may be its substrates. In addition, torsinA is present in synaptic terminals of axons and dendrites, suggesting a role in neurotransmitter function.

In cell cultures overexpressing ΔE-torsinA, the protein relocalizes from the ER to the nuclear envelope where it forms whorled aggregations containing several nuclear envelope proteins. This has been a consistent finding from a number of different laboratories, and it is hypothesized that somehow, maybe due to an abnormal function, the mutant protein gets trapped in the nuclear envelope. This effect appears to be specific to neurons rather than other cell types, consistent with the absence of symptomatology outside the nervous system, despite the widespread presence of torsinA in many organs. It remains unclear whether the protein accumulations found in cell culture studies are related to the inclusion bodies reported in the brainstem of some torsinA transgenic mouse models or in a small number of human *postmortem* brains with DYT1 dystonia, and whether they are related to the disease pathogenesis, as is true of other disorders involving mutation of nuclear envelope proteins.

Mutant, but not wild-type, torsinA is degraded by the proteasome system, which handles abnormal and misfolded proteins, and has a shorter half-life as compared to the wild-type.

Potential Functions

Chaperone Function

The function of torsinA is suggested by its homology to the AAA + superfamily of proteins (ATP-ases associated with a variety of cellular activities). Having a single ATP-binding site, it is classified as a member of the Class 2-type HSP100/Clp subfamily. Many of these proteins are chaperone proteins with cellular housekeeping functions such as protein quality control, protein folding, degradation, protein complex assembly, cytoskeletal regulation, and vesicular transport. Energy to drive these reactions comes from binding and hydrolysis of ATP. TorsinA has been shown to bind ATP, but the functional significance of this is not yet known, and this is not affected by the mutation. The mutation does not affect the Walker A and B sequences which are highly evolutionarily conserved and are likely to play a significant role in function. The Walker A domain binds ATP, while the Walker B domain is responsible for ATP hydrolysis. The carboxy terminus, where the ΔE mutation is located, forms a helical subdomain that in general appears to be important for the functions of the AAA + protein superfamily.

The GAG deletion does not cause any major changes in biochemical properties or protein conformation.

TorsinA forms hexamers, and it is hypothesized that the dominant negative effect of the mutation is due to an effect of the mutant form when it is complexed with normal protein in hetero-oligomers. As the carboxy terminus is important for these interactions, it is likely that the mutation in this region will affect interactions with other proteins in the oligomer.

A number of studies support a chaperone-type role for torsinA; however, the relationship of this function to the development of dystonia is not known. TorsinA has been found to be upregulated in a number of studies of cell cultures and animal models in response to a variety of stresses, including hypoxia/ischemia, oxidative stress, and serum deprivation, consistent with a role as a chaperone protein. Oxidative stress, but not other stresses, resulted in the redistribution of torsinA to inclusions on the nuclear envelope, and a small increase in molecular weight.

A role in enhancing protein degradation was suggested by the finding that overexpression of normal torsinA can reduce aggregates in cell culture because of mutant α-synuclein overexpression. Similar results were found in the nematode *C. elegans,* in a model of protein aggregation due to trinucleotide repeat expansions. In these organisms, when torsinA was overexpressed, a reduction in protein aggregation was found. Overexpression of wild-type torsinA in *C. elegans* also protected dopaminergic neurons from neurodegeneration caused by the neurotoxin 6-hydroxydopamine. This protective effect was lost when either ΔE-torsinA or a combination of mutant and wild-type protein was expressed. Cell culture studies in which mutant ε-sarcoglycan, the gene that causes inherited myoclonus-dystonia, was coexpressed with torsinA suggested that torsinA was able to facilitate clearance and breakdown of the abnormal protein.

TorsinA was found to alter the transcription of several members of the heat shock protein family, an effect which was not affected by ΔE-torsinA. This would argue against impaired chaperone functions causing dystonia.

Using immunohistochemical methods, a decrease in torsinA in the entopeduncular nucleus (rat homologue of globus pallidus internal segment) was seen in rats that had undergone unilateral dopamine depletion and then treatment with levodopa to render them dyskinetic. This decrease was seen only in animals that developed dyskinesias, and it remains unknown whether this was a primary or secondary effect. TorsinA immunolabeling was not altered in several rodent models of dystonia.

Cytoskeletal Functions

There is significant evidence for a role of torsinA in the development of the cytoskeleton. This is supported by the finding of an increase in the levels of protein (and also of torsinB) during prenatal and early postnatal periods, particularly during periods of dendrite and synapse formation.

The *C. elegans* homologue of torsinA, OOC-5, is involved in nuclear rotation of the nuclear-centrosome complex during embyrogenesis, and mutations affecting this protein result in polarity defects of embryos.

In cell cultures, torsinA associates with the retain cytoskeletal proteins kinesin light chain and vimentin, and plays a role in neurite outgrowth and cell adhesion. TorsinA appears to be transported down the axons to synapses by anterograde transport in association with kinesin. TorsinA also interacts with tau, a microtubule-associated protein that contributes to the development of polarity and neurite development. ΔE-torsinA interferes with cytoskeletal events, and it may thus interfere with neuronal development and synapse formation. Wild-type torsinA, when overexpressed, appears to inhibit neurite outgrowth, while cells with the mutant form develop abnormally long neurites and growth cones.

Neurotransmitter-Related Functions

TorsinA may regulate the distribution of membrane-associated proteins, such as the dopamine transporter. Studies of protein interactions found that torsinA bound to SNAP-25, which is required for vesicle docking, and interacted with synaptotagmin. Overexpression of both wild-type and ΔE-torsinA interfered with synaptic vesicle recycling but in opposite ways. ΔE-torsinA appeared to enhance membrane recycling, but caused mislocalization of synaptic vesicle proteins. Human fibroblasts from patients with DYT1 dystonia showed a reduction in secretory function, which, intriguingly, could be blocked by small interfering RNA (siRNA).

In *C. elegans*, overexpression of torsinA resulted in downregulation of the dopamine transporter, which is responsible for the uptake of dopamine into neurons. The vesicular monoamine transporter (VMAT2), important in packaging of dopamine into vesicles for synaptic release, has been found in the whorled aggregations associated with the nuclear envelope found in cells in culture that overexpress mutant torsinA.

Electrophysiological studies of slices from one line of transgenic mice overexpressing human ΔE-torsinA found an alteration in responses to dopamine of striatal large cholinergic interneurons, mediated by dopamine D2 receptors. The neurons showed an excitatory response rather than an inhibitory response following D2 receptor activation, because of increased inhibition of the N-type calcium channels that resulted in a reduction of the after-hyperpolarization. This would result in increased acetylcholine release from these interneurons that play a major role in regulation of striatal efferents. This finding implies an overactivity of these striatal interneurons in dystonia,

and may be of clinical relevance and significance as anticholinergic drugs have long been a mainstay of antidystonic therapy.

Transgenic Animal Models

A number of transgenic mouse models have been generated to try and understand the pathogenesis of DYT1 dystonia. TorsinA appears to be critical for the development as mice without the mouse *DYT1* gene or with two mutant copies die soon after birth.

Other studies have examined the effect of overexpression of the mutant form of human torsinA. The methodology for producing mouse models varies, including the use of different insertion sites and promoters. In some cases, lines overexpressing ΔE-torsinA were compared with animals overexpressing normal human torsinA. Findings have been somewhat heterogeneous and in general disappointing in either shedding light upon the pathophysiology of DYT1 dystonia, or as a potential tool for novel therapies. One limitation of some of the mouse studies has been the time frame. As DYT1 dystonia tends to manifest during childhood and evolve during adolescence, it is important to study mice at corresponding ages, which has not always been done. Abnormalities in only a proportion of mice, corresponding, perhaps coincidentally, to the penetrance of disease in human carriers were only apparent in the reports from one laboratory. This transgenic mouse model was the only one with a severely hyperkinetic phenotype, manifested as marked motor hyperactivity, and dystonic neck and limb posturing. In lines from other laboratories, by employing other methodologies, motor deficits were more subtle and showed a mixture of hypo- and hyperkinetic features with motor incoordination, in some cases with impaired learning; however, these lines may be more stable and the findings more reproducible.

Examination of striatal tissue for dopamine neurochemistry demonstrated heterogeneous results, showing variably either increased or decreased turnover. In addition, one line showed abnormally decreased dopamine release following amphetamine administration, in the absence of other abnormalities of dopamine neurotransmission such as tissue levels or transporter binding. Serotonin levels and its metabolite 5-HIAA were reported to be increased in the brainstem in one model.

Neuropathological findings in ΔE-torsinA transgenic mice have been subtle and variable. No signs of gross neuroanatomical changes or frank neurodegeneration have ever been reported, but in some models abnormalities of the nuclear membrane were seen, similar to those found in cell cultures, or intracellular inclusions in the brainstem containing torsinA, nuclear envelope proteins, and ubiquitin-related proteins. These were found both in the mice overexpressing ΔE-torsinA, and to a lesser extent in those overexpressing human wild-type torsinA.

Studies of TorsinA in Humans

Studies of neuropathological tissue from patients with Parkinson's disease demonstrated the presence of torsinA in Lewy bodies in the SNc. Tissue from patients with trinucleotide repeat disorders, including Huntington's disease, Huntington's disease-like 2, and spinocerebellar ataxia 3, also found immunoreactivity to torsinA localized to the intranuclear inclusion bodies typical of these disorders, which characteristically comprise ubiquitin, the causative mutant protein and various other proteins.

Neuropathological studies of a very small number of brains of patients with DYT1 dystonia did not show any gross abnormalities or areas of neuronal loss, although dopaminergic neurons of the SNc appeared to be larger and closer together. The neuropathological findings in brains of patients with varying forms of dystonia, prior to the discovery of the *DYT1* gene, are heterogeneous.

Examination of selected regions (SNc, striatum, neocortex, cerebellum) in a single case of DYT1 dystonia did not disclose any abnormalities. Neuronal inclusions in the pedunculopontine nucleus were reported in a small series of DYT1 dystonia cases. These inclusion bodies were immunoreactive for torsinA, lamin A/C, and ubiquitin. Lamin A/C proteins are also associated with the nuclear envelope, while the presence of ubiquitin suggests that there was degradation of abnormal proteins via the ubiquitin–proteasome system.

Summary

The identification of torsinA as the cause of DYT1 dystonia was a major breakthrough in the field. Ten years later we understood more about the functions of this protein; however, a lot remains to be discovered regarding exactly how and where it malfunctions to cause the brain dysfunction which results in the appearance of dystonia in only a proportion of carriers of the mutation.

Tottering Mouse - a Definition

W D Atchison, Michigan State University, East Lansing, MI, USA

Glossary

Absence seizure – Brief, recurring seizures that are characterized by loss of alertness. The seizure often presents as a vacant stare by which the patient appears to be 'absent.' There is no recollection of the seizure after its occurrence (post-ictally). Absence seizures are occasionally accompanied by involuntary muscle movements.

Ataxia – Ataxia is a neurological sign consisting of lack of coordination of voluntary movements, especially with respect to ambulation. It typically presents as a staggering, or wobbling gait, or instability while walking/standing.

Cerebellum – The 'hindbrain.' This distinct brain region is directly associated with coordination of movement. More recently, it has been implicated in other functions such as cognition as well.

Dystonia – Involuntary muscle movements, which may be repetitive and sustained. They can result in aberrant limb movement or positioning, or disturbed body posture.

$GABA_A$ receptor – The principal inhibitory receptor in the mammalian brain. $GABA_A$ receptors are made up of five subunits, and typically involve combinations of three types of subunits, $\alpha\beta\gamma$ are the most commonly occurring combination. However, several other subunit subtypes can also substitute for γ; often this involves a δ subunit, or other less-abundant units. $GABA_A$ receptors are ligand-gated, and respond to the amino acid transmitter GABA. When activated, the receptor gates an intrinsic ion channel selective for Cl^-. For the most part, the transmembrane $[Cl^-]$ gradient favors Cl^- leaving the cell. Thus, $GABA_A$ receptors typically move the membrane potential away from the action potential firing threshold, that is, hyperpolarize.

P/Q-type Ca channel – Also known now as Cav2.1. P/Q-type Ca channels are a member of the high voltage-activated class of channels, meaning that strong depolarizations from the resting potential are needed to induce activation of the channel. These channels were originally described in cerebellar Purkinje cells where they occur in high abundance (~80%). Hence, they are named P-type channels to signify their Purkinje cell origin. So-called Q-type channels arise as a splice variant of P-type. Both comprise an $\alpha 1$, β, and $\alpha_2\delta$ subunit, where the pore-forming subunit α_{1A} is distinct from other Ca channel phenotype $\alpha 1$ subunits. P/Q-type channels are blocked with high affinity by a peptide toxin isolated from the venom of the funnel web spider (*Agelenopsis aperta* – agatoxin IVA). P/Q-type channels couple to many physiological functions, but are best known for participating in the regulation of release of chemical neurotransmitters.

Purkinje cell – The sole 'outflow' path from the cerebellar cortex to other brain regions. Purkinje cells have an extremely extensive dendritic arborization. They are themselves inhibitory, but receive both inhibitory and excitatory input. The latter includes both an intrinsic and external pathway in the cerebellum. The intrinsic pathway is mediated by the parallel fibers of the cerebellar granule cells. The extrinsic pathway derives from the inferior olive, and is known as the climbing fibers.

Vestibule – A region of ion channel proteins located at the internal and external hydrophilic and external region of the channel. The vestibule is charged with an appropriate charge so that it attracts the type of ion (i.e., cation) that permeates the channel. Having a vestibule improves ion channel function by facilitating ion entry when the channel is activated.

Voltage-gated ion channel – A transmembrane protein responsible for passage of ions into or out of the cell. The channel 'opens,' or is gated by a change in the transmembrane potential. Voltage-gated ion channels are typically relatively selective for the permeant ion, and ion transport occurs in the absence of input of cellular energy.

Introduction

'Tottering' refers to one of a series of naturally occurring mutations in mice in the pore-forming (α_1) subunit of a specific subtype of voltage-gated calcium channel (Cav). The *tottering* (*tg*) (B6.D2-Cacna1atg/J) genotype is an inherited autosomal recessive mutation on chromosome 8 in the gene encoding the α_{1A} subunit gene (e.g., *CACNA1A*) of the P/Q type (Cav2.1) Ca^{2+} channel. This type of Ca^{2+} channel is ubiquitously expressed throughout the central and peripheral nervous system, but effects of *tg* are not uniformly directed at all neurons. Regions with high density of P/Q-type channels have more prominent pathophysiology. P/Q-type channels are extensively expressed in the cerebellum. This is especially true in the Purkinje cells, where these channels were first described, and are the sole output cells from the cerebellar cortex. Cerebellar dysfunction likely contributes substantively to the motor dysfunction. *Tg* encodes a single amino acid substitution (proline to leucine, both of which are nonpolar and hydrophobic) in the S5–S4 extracellular region of repeat domain II of the α_{1A} subunit protein. This site is located near the so-called 'outer vestibule' of the pore of the channel. The mutation affects the functional properties and likely the expression of the Cav2.1 channel and presumably results in the observed pathophysiology; however, other proteins are also affected in the *tg* mice. Whether their alterations occur specifically as a result of the deficiency in the Cav2.1 channels is yet unknown.

Behavioral Phenotype

The *tg* mutation causes a delayed-onset neurological disorder that is characterized by ataxia, episodes of dystonia, and myoclonic motor seizures. The latter resemble absence epilepsy in humans. The ataxia and episodic dystonia have been associated with dysfunction in the cerebellum. However, these two signs appear to be dissociated in that surgical resection of the cerebellar vermis prevents the dystonic attacks without appreciably affecting the ataxia. The absence-like seizures exhibit aberrant EEG responses, and can be attenuated using conventional antiseizure treatment for petit mal seizures.

The onset of the *tg* phenotype is delayed. Absence epilepsy and motor dystonia appear 3–4 weeks postnatally. This may reflect maturation of processes that depend on the P/Q-type Ca^{2+} channel, but for which other Ca^{2+} channel phenotypes can substitute prior to developmental shift. The behavioral responses have been attributed to impairment of excitatory glutamatergic transmission at synapses between cerebellar granule cells and Purkinje cells – the so-called 'parallel fiber' synapses. However, other proteins are also affected in *tg* mice.

Cellular Consequences of *tg* Mutation

P/Q-type Ca^{2+} channels were first described in cerebellar Purkinje cells, where they occur in high abundance. They are found throughout the cerebellum, including the granule as well as Purkinje cells. P/Q-type Ca channels contribute to control of a number of critical neuronal functions. Among these are neurotransmitter release, regulation of transcription, and $[Ca^{2+}]$ regulation within the nucleus. As a result of *tg* mutation, those functions that depend on P/Q-type channels are affected. P/Q-type channels typically coexist with other subtypes of Cav – typically Cav2.2 (N-type), Cav2.3 (R-type), or Cav1.2 (L-type). The purpose of this redundancy is unknown, as is the basis for a particular combination of overlapping channel phenotypes. Several studies have examined physiological responses of *tg* mice to characterize the phenotype. Rather subtle changes occur in function of P/Q-type channels in Purkinje cells of *tg* mice. These include reduction (~40%) in whole cell current density, and alteration of current inactivation (the ability to sustain current amplitude) following prolonged depolarization.

Effects on P/Q-type Ca^{2+} channels are not the only proteins whose expression is altered in the *tg* mice. However, the extent to which other protein alterations contribute to the phenotype is yet unknown. One important alteration is in the expression of receptors for the inhibitory neurotransmitter GABA. *Tg* mice have a reduced expression of certain $GABA_A$ receptor subunits found specifically at cerebellar granule cells, namely the α6 and δ subunits. This effect could have profound effects on granule cell excitability and contribute to the abnormal glutamatergic transmission along the parallel fibers – the axons of cerebellar granule cells – observed in *tg* mice. Another protein whose expression is significantly altered in *tg* phenotype is tyrosine hydroxylase, the rate limiting step in the synthesis of catecholamines.

Compensation for Lack of Cav2.1 Function

When the P/Q-type channel is mutated, the relative contribution of other types of Ca^{2+} channels increases, presumably in a pleiotropic response to try to maintain the critical functions. For example, at hippocampal and cerebellar parallel fiber synapses, release of the neurotransmitter glutamate normally exhibits a high dependance on P/Q-type Ca^{2+} channels. However, in *tg* mice, the N-type (Cav2.2) channels assume control of secretion. Conversely, L-type (Cav1.2) Ca^{2+} channels are upregulated in the cerebellum and basal forebrain of *tg* mice, and stereotypic behavior can be induced by the L-type channel dihydropyridine agonist BayK 8644, whereas no such effect

occurred in wild-type (*wt*) mice. Moreover, L-type Ca channel α_{1C} subunit mRNA was upregulated in Purkinje cells of *tg* mice, suggesting that the L-type phenotype was now either newly present, or unmasked in these animals. L-type channels may not be as involved in transmitter release as compared to other processes including neuronal plasticity or membrane excitability.

In the peripheral somatic nervous system, P/Q-type Ca^{2+} channels are the primary regulators of acetylcholine (ACh) release at mammalian neuromuscular junctions, so their dysfunction might be expected to result in neuromuscular weakness. However, *tg* mice have no significant neuromuscular impairment, despite their obvious gait abnormality. Several subtle effects on neuromuscular transmission do occur mostly related to release at high rates of stimulation. In adult *tg* mice, N- and R-type (Cav2.3) channels become responsible for ACh release. Thus, other types of Cav are upregulated in the *tg* mutants; the other channel types are relatively effective in maintaining normal function. This compensatory response is a property seen at synapses in several of the naturally occurring mutations and transgenic strains of mice with alterations in P/Q-type Ca^{2+} channels.

Other Tottering Loci

Two naturally occurring variants of the *tg* genotype have recently been identified and characterized; both arise as spontaneous mutations in the *Cacnala* gene. One is semidominant, and arises in the tottering-5J allele (*Tg-5J*), while the other is recessive and occurs on the tottering-4J allele (*tg-4J*). In the *Tg-5J* mutation, there is a shift from positively charged and conserved arginine to an uncharged glutamine, while in the *tg-4J* mutant, the switch is from a valine to alanine, both of which are nonpolar and hydrophobic. Both mutations caused functional changes that were unique from those seen in mice with other *tg* alleles. Similarly, the typical triad of behavioral manifestations seen in *tg* mice are recapitulated in *tg-4J*, whereas *Tg-5J* homozygotes are typically lethal. Ataxia is present in the heterozygotes, but appears to be distinct from that of other *tg* loci; it is characterized by a shaky gait with the hind limbs splayed laterally from the body. The characteristic spike-wave discharge pattern associated with *absence* seizures in the other mutants is not observed, so *absence* seizures are not associated with this mutation. Also, dyskinesia is not seen in *Tg-5J* heterozygotes.

Several other naturally occurring mutations in the α_{1A} subunit have been identified. These include '*leaner*' and '*rolling Nagoya*,' both of which occur as a result of a single locus on the gene encoding for the α_{1A} subunit. They either affect the expression or functional properties of the encoded channels. While the overall site of the mutation is similar, and motor dysfunction occurs with each mutation, the phenotypes of these genotypes vary considerably from that of *tg* both in terms of pattern and severity. In conjunction with *tg*, these mutations have been used as models to study naturally occurring spontaneous mutations in the Cav2.1 α_{1A} subunit, such as those responsible for spinocerebellar ataxia (SCA)6, familial hemiplegic migraine (FHM), and episode ataxia (EA) in humans.

Tourette Syndrome

D S Wolf and H S Singer, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Glossary

Compulsions – Repetitive, purposeful behaviors usually performed in response to an obsession, or according to certain rules, or in a repetitive fashion.
Coprolalia – The uncontrollable and excessive use of foul or obscene language.
Echolalia – Pathologically repeating (echoing) the words of another person.
Neuroleptics – Antipsychotic medications.
Obsessions – Recurrent ideas, thoughts, or impulsions that intrude on conscious thought and are persistent and unwelcome.
Palilalia – Pathologically repeating one's own words.
Stereotypies – Involuntary, repetitive, and rhythmic movements that have a predictable pattern and location, seem purposeful but serve no obvious function, tend to be prolonged and are able to be suppressed.
Tics – Involuntary, sudden, rapid, repetitive, nonrhythmic stereotyped movements, or vocalizations.

Definition and History

Tourette syndrome (TS) is named after the French physician Georges Gilles de la Tourette who, in 1885, reported nine patients with chronic, involuntary motor, and phonic tics. These patients also experienced a variety of neuropsychiatric problems such as obsessive–compulsive and anxiety symptoms. Since that time there have been numerous advances, from genetics to therapeutics, although we are far from fully understanding this complex disorder. Here, we aim to provide the reader with an overview of TS.

Pathogenesis and Pathophysiology

Genetics

The precise pattern of transmission and the identification of a gene responsible for TS remain elusive. Studies of monozygotic twins provide the strongest support for a genetic disorder, with an 86% concordance rate with chronic tic disorder compared with 20% in dizygotic twins. A multifactorial inheritance with at least one major locus seems likely. Genetic linkage, cytogenetics, candidate gene studies, and molecular genetic studies have been used to identify the genetic site. Linkage analyses have suggested multiple chromosomal locations, but no reproducible locus or convergence of findings. An association with SLITRK1 has not been confirmed and linkage to a marker on chromosome 2p23.2 requires further investigation. Although susceptibility loci have been identified in TS, it is possible that no causative gene has been identified because of phenotypic heterogeneity. The possible effects of genomic imprinting (sex of the transmitting parent may affect the clinical phenotype), bilineal transmission (genetic contribution from both sides of the family), genetic heterogeneity, and gene–environment interactions further complicate the understanding of TS genetics. Epigenetic risk factors that have been examined include timing of perinatal care, severity of mother's nausea and vomiting during the pregnancy, low birth weight, Apgar score at 5 min, thimerosal exposure, nonspecific maternal emotional stress, and prenatal maternal smoking. Still other investigators have suggested that TS is not genetic but rather represents a common disorder in the general population.

Neurobiology

Understanding of the cortico–striatal–thalamocortical (CSTC) circuits has provided a unifying framework for understanding the interconnected relationships that exist between TS and its comorbid psychiatric disorders. The supplementary motor cortex and its projections to the putamen are believed to play a role in motor tics. The oculomotor circuit, possibly influencing ocular tics, begins principally in the frontal eye fields and connects to the central region of the caudate. Other circuits, such as the dorsolateral prefrontal circuit link Brodmann's area 9 and 10 with the dorsolateral head of the caudate and appear to be involved with 'executive functions' (flexibility, organization, constructional strategy, verbal and design fluency) and 'motor planning' (sequential and alternating – reciprocal motor tasks). Obsessive–compulsive disorders (OCD) have been linked to the lateral orbitofrontal circuit originating in the inferior lateral prefrontal cortex and projecting to the ventral medial caudate. Lastly, the anterior cingulate gyrus projections to the ventral striatum, with additional input from the amygdala, hippocampus, medial orbitofrontal cortex, entorhinal and perirhinal cortex have been linked to a variety of behavioral problems.

Although direct and indirect evidence suggests that the components of the CSTC are involved in the expression of tic disorders, identification of the primary site of abnormality (frontal cortex, striatum, midbrain) remains an active area of research. Cortical dysfunction may play a primary role in TS. Many children with TS have executive dysfunction, and volumetric MRI studies have shown larger dorsolateral prefrontal regions in children with TS, but significantly smaller volumes in adults with the disorder. Examinations of white matter have shown increased cortical white matter in the right frontal lobe and decreased white matter in the deep left frontal region in children with TS, and midsagittal measurements have shown variable changes in the size of the corpus callosum. DT-MRI studies in TS demonstrated lower fractional anisotropy of the corpus callosum, suggesting reduced white matter connectivity in this interhemispheric pathway.

Functional imaging, using glucose metabolism and blood flow studies, has identified abnormalities within the basal ganglia and cortical areas in patients with TS. Positron emission tomography (PET) showed bilateral and symmetrical increases or decreases of glucose utilization within the basal ganglia and decreased activity in frontal, cingulate, and insular cortices. Hypoperfusion of basal ganglia has been found through cerebral blood flow examination by single photon emission computed tomography (SPECT). Comparison study using 'perfusion imaging' in children with chronic motor tics and TS showed decreased perfusion primarily affecting the left hemisphere in the TS group, although the differences were thought to be related to comorbidities rather than tics. Regional blood flows were found to be significantly lower in the left caudate, cingulum, right cerebellum, and right and left dorsolateral prefrontal regions in children with TS when compared with controls; a correlation between motor tic severity and blood flow was not detected, but there was a positive correlation between the severity of vocal tics and several regions. Functional neuroimaging of tics using event-related PET combined with time-synchronized videotaping showed numerous brain regions significantly correlated with tic occurrence including medial and lateral premotor cortices, anterior cingulate cortex, dorsolateral–rostral prefrontal cortex, inferior parietal cortex, putamen, caudate, primary motor cortex, the Broca's area, superior temporal gyrus, insula, and claustrum. Which of these regions accounts for initiation, rather than execution, of motor and vocal behaviors, remains unknown.

The presence of dopaminergic, glutamatergic, GABAergic, serotoninergic, cholinergic, noradrenergic, and opioid systems within the CSTC circuits raises the possibility that various transmitters may be involved in the pathophysiology of TS. Because many transmitter systems are interrelated in the production of complex actions, it is indeed possible, if not probable, that imbalances exist within several transmitter systems.

Dopamine dysfunction continues to receive attention as playing a primary role in TS because of its therapeutic response to neuroleptics and the results from various nuclear imaging protocols, CSF, and post-mortem studies. There are increases in the number of dopamine receptors, high concentrations of dopamine transporters, and increased intrasynaptic dopamine release within the striatum. An association has been identified between a polymorphism of the dopamine transporter gene DAT *Dde*I and TS. One unifying hypothesis is that an overactive dopamine transporter results in the increase of phasic dopamine release that, in turn, results in a hyperresponsive spike-dependent dopaminergic system in the prefrontal cortex. This hypothesis is supported by clinical findings including (1) the exacerbation of tics by stimulant medication, likely secondary to enhanced dopamine release; (2) tic exacerbation by events shown to increase phasic bursts of dopamine, such as stress, anxiety and medications; and (3) tic suppression with very low doses of dopamine agonists, likely due to presynaptic reduction of phasic dopamine release.

Other neurotransmitter systems have been implicated as well. Glutamate plays an essential role in pathways of CSTC circuit. Reduced levels of glutamate have been identified in the globus pallidus interna, globus pallidus externa, and substantia nigra pars reticulata of four TS brains. Serotonin interacts with the CSTC circuit via fibers projecting from the median raphe to the basal ganglia and cortex. Decreased levels of serotonin and tryptophan were noted in serum samples of children with TS. Levels of 5-HIAA, a serotonin metabolite, were lower in the CSF and basal ganglia of TS subjects, but were normal in cortical tissue.

Epidemiology

TS affects people world-wide and its common features are evident in all cultures and races. The prevalence of tics in childhood is about 6 to 12% (range 4–24%). The precise prevalence of TS is unknown, with estimates ranging from 1 to 10/1000 children and adolescents. If mild cases that may not be identified are included, the prevalence can rise to 10–30/1000 children and adolescents. TS is more common in males than in females (more than 3:1), and the mean age of onset is typically between 5 and 7 years, with most developing tics before their teenage years. Children with autistic spectrum disorders including Asperger syndrome and fragile-X have a high incidence of TS, but it is unrelated to the severity of autistic symptoms.

Clinical Presentation

Tics, the cardinal features of TS, are involuntary, sudden, rapid, repetitive, nonrhythmic stereotyped movements or

vocalizations. Tics may take a variety of forms, with different durations and degrees of complexity. Simple motor tics are rapid movements that often involve only one muscle group (e.g., eye blink, head jerk, shoulder shrug). Complex motor tics may involve a cluster of simple movements or a more coordinated sequence of movements. These can be nonpurposeful (facial or body contortions) or can be integrated into more purposeful movements (e.g., touching, jumping, obscene gestures). Sterotypies and compulsions are often confused with the complex motor tics of TS. Stereotypic movements, such as head nodding, rocking and arm flapping/waving, tend to appear before age 3 years, involve a fixed and prolonged movement and stop abruptly with distractions. Compulsions, such as touching or tapping, occur in association with other obsessive–compulsive symptoms and are often preceded by a conscious desire to perform the action in a particular way or number of times, or until it feels 'just right.' Vocal tics can also be simple (e.g. sniffing, grunting, yelping, and throat-clearing) or complex (syllables, phrases, echolalia, palilalia, or coprolalia). Although coprolalia is one of the most distressing and recognized symptoms of TS, it occurs in only about 10% of patients.

The frequency of tics is quite variable. Tics are commonly exacerbated during periods of anticipation, anxiety, anger, or fatigue. It is controversial whether tic severity worsens during times of perceived life stress. In one study of children with TS, higher scores on the Daily Life Stressors Scale correlated positively with the total tic score on the Yale Global Tic Severity Scale. In another study, however, only a minority of patients indicated that changes in tic severity (over the course of 1 week) correlated with stressful events. Tics may also worsen during inquiries about specific movements or after the observation of a movement or sound (echophenomena). They decrease in frequency when the person is absorbed in activities, concentrating, or asleep. However, polysomnograms of people with TS have shown an increased rate of tics during rapid eye moments (REM) sleep. Patients can actively suppress tics; usually associated with a growing inner tension that resolves when the tic happens. Premonitory sensations, often described as an urge, impulse, tension, pressure, or itch may take place before a motor or phonic tic typically localized to discrete anatomical regions. In TS, premonitory sensations occur in about 90% of adults, but only in 37% of young children. Misdiagnoses of tics are common: eye blinking tics are often thought to represent eye problems and throat clearing or involuntary sniffing tics attributed to sinusitis or allergic conditions.

Tic Disorders

The diagnosis of a tic disorder is based solely on the historical features and a clinical examination confirming their presence and ruling out other conditions. There is currently no blood test, brain scan, or genetic screen to assist in diagnosis. TS represents only one entity in a spectrum of tic disorders. A classification system endorsed by the Tourette Syndrome Association defines tics as 'transient' (present for <12 months) or 'chronic' (present for more than 12 months).

The mildest and most common tic disorder is transient tic disorder, found in about 24% of school children. There is no way to predict whether an individual will have resolution of tics, addition of other tics, or persistence of tics; thus, the use of the term tic disorder – 'diagnosis deferred' is preferred for individuals with ongoing tics present for <1 year. 'Diagnosis deferred' is included, since it is impossible to predict whether an individual's tics will persist for the requisite 1-year time interval required for a 'chronic' designation or fall into the transient category. Chronic (motor or phonic) tic disorder requires that the tics be either entirely motor or, less commonly, vocal.

Formal criteria for the diagnosis of TS is similar to Tourette disorder, as outlined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, except for minor differences. Requirements for TS according to the Tourette Syndrome Classification Study Group are as follows: the presence of multiple motor and at least one vocal tic (not necessarily concurrently); a waxing and waning course with tics evolving in a progressive manner; the presence of tic symptoms for at least 1 year; the onset of symptoms before age 21; the absence of a precipitating illness (e.g., encephalitis, stroke, or degenerative disease) or medication; and the observation of tics by a knowledgeable individual. The DSM-IV-TR criteria for Tourette disorder requires that tic-free intervals not be greater than three consecutive months and reduce the age of onset to <18 years.

Tourette-like (or secondary) disorder includes tic syndromes that do not meet the formal criteria for TS; for example, tics associated with a variety of acute and chronic neurological disorders including head injury, stroke, cardiac surgery with by-pass and hypothermia, peripheral trauma, infectious disease, medications and degenerative disorders including neuroacanthocytosis, Huntington's disease, Creutzfeldt–Jakob disease, and pantothenate kinase deficiency. Although the diagnosis is controversial, also included in this category are children with the abrupt onset and repeated rapid worsening/exacerbation of tics associated and with evidence of group A β hemolytic streptococcal infections, known as PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection). 'Tardive' Tourettism is the de novo appearance of motor and vocal tics in patients being withdrawn from chronic neuroleptic treatment. Adult onset tic disorders have been reported and are often associated with potential environmental triggers, severe symptoms, greater social morbidity, and a poorer response to medications.

Neuropsychiatric Comorbidities

Multiple psychopathologies are associated with TS, and their clinical impact can be more significant than the tics. For example, the quality of life is predicted by the coexisting conditions such as ADHD and OCD rather than tic severity. Further, the presence of a child with TS in the home, especially one with a behavioral comorbidity, has a significant negative impact on parents. It is essential that the physician caring for an individual with TS should be aware of associated psychiatric disorders and differentiate them from tics.

Obsessive–compulsive disorder

Obsessive–compulsive behaviors are common in individuals with TS. Obsessions are recurrent ideas, thoughts, or impulsions that intrude on conscious thought and are persistent and unwelcome. Compulsions are repetitive, purposeful behaviors usually performed in response to an obsession, or according to certain rules, or in a repetitive fashion. Obsessive–compulsive behavior becomes a disorder when these activities cause marked distress, occupy inordinate time, or have a significant impact on normal function or relationships. The incidence of obsessive–compulsive behavior in TS is typically reported to be in the range of 45%, though some studies report up to 89%. Compulsive behaviors emerge during adolescence, typically several years after the onset of tics. A genetic association between OCD and TS has been identified.

The obsessive–compulsive symptoms in persons with OCD alone appear different as compared to those with OCD and TS. In patients with TS, obsessive–compulsive behaviors usually include a need for order and 'symmetry' and typically involve arranging, ordering, hoarding, touching, tapping, rubbing, counting, checking for errors, and 'evening-up' rituals.

Attention-deficit hyperactivity disorder

Attention-deficit hyperactivity disorder (ADHD) is defined by impulsivity, hyperactivity, and a decreased ability to maintain attention to a degree that impairs function. Approximately, 50% of TS cases in a referral population are affected by ADHD. ADHD typically precedes the onset of tics by 2–3 years in TS patients, beginning at age 4–5 years. The severity of ADHD in children with tics, rather than the severity of tics themselves, predicts the behavioral and social problems. In children with TS, ADHD is the primary contributing factor in impairments of school performance. The existence of a genetic relationship between TS and ADHD remains unclear. Studies showed that children with ADHD are more likely to have a family history and increased incidence of tics while others suggest that ADHD is not genetically related to TS.

Anxiety and depression

Several studies have found an increased incidence of anxiety and depression in patients with TS. A history of mood disorder of any type (based on DSM-IIR criteria) was found in 76% of children and adolescents with TS evaluated in a psychiatric specialty clinic, and 64% met criteria for any type of nonobsessive–compulsive anxiety disorder. Separation anxiety, agoraphobia, and panic disorder are all more common in TS patients. Severe anxiety was found in 25% of patients with TS and found that 17–23% were clinically depressed. Bipolar disorder was also over-represented in a community sample of TS patients. Depressive symptoms were more severe in TS patients who were female, older (adults), and who had echo phenomena (echolalia or echopraxia). It remains unclear, however, whether depressive symptoms are related to the severity of tics. Ratings on the Yale Children's Global Stress Index directly correlated with clinician depression ratings in children and adolescents with TS and/or OCD and this population also experienced more psychosocial stress than controls.

Other problems

Many other behavioral disorders have been associated with TS. Migraine headaches are observed more frequently in patients with TS compared with the general population. On the basis of migraine questionnaires, 25% of patients with TS have migraine, exceeding the general estimates of migraines in adults and in children. Problems associated with sleep have been reported in up to 50% of children and young adults with TS. The most difficulties are in falling and staying asleep and parasomnias. Polysomnographic studies have shown multiple abnormalities including disturbed sleep quality with increased sleep latency, reduced sleep efficiency, prolonged wakefulness after sleep onset, and altered slow-wave sleep. Tics can be seen in all sleep stages, along with frequent arousals, periodic limb movements, and sleep apnea. It is also known, however, that associated neuropsychiatric comorbidities, such as ADHD and anxiety can contribute to the sleep deficits. There is significant clinical and pathological overlap between patients with TS and restless-legs syndrome. Both desire to move the limbs in association with a preceding urge or sensation, worsen over the course of the day; occur with sleep, and share pathological associations with dopamine and frontal-striatal cortical circuits. A study of children with TS in a French-Canadian population demonstrated that 10% had restless-legs syndrome. Furthermore, the true prevalence of restless leg syndrome may be underestimated because of confusion with ADHD, complex tics, and compulsions. Rage attacks and difficulty with aggression have been described in patients with TS.

Treatment

Treatment of TS should be individualized based on the analysis of tics, presence of comorbiddisorders, assessment of severity, as well as the resulting impairment and the support system available. Prioritization based on the degree of impairment is an important guide for the treatment of TS patients with comorbidities. Reassurance and education of families about TS, its predicted outcome, and underlying pathophysiologic mechanisms are essential and often beneficial in permitting a conservative course.

Nonpharmacological Treatments

Behavioral treatments (conditioning techniques, massed negative practice, awareness training, habit reversal, relaxation training, biofeedback, and hypnosis) have been proposed as complementary and alternative therapeutic approaches, but their efficacy is not well evaluated. Habit reversal training substantially improved tics as compared to a supportive therapy group, with the beneficial effect persisting to follow-up 10 months later. In a small cohort study, habit reversal therapy also reduced the severity of vocal tics. Scientific evidence is scant for the use of dietary therapies, including vitamins, protein supplementation and elimination diets, or acupuncture.

Pharmacotherapy

As there is no cure for tics, all pharmacotherapy must be regarded as symptomatic therapy. Typically, medication is recommended if there are significant psychosocial disturbances (bullying, interference with schooling) or physical harm secondary to the tics. If a tic-suppressing drug is indicated, a two-tiered approach is recommended: (1) nonneuroleptic drugs for mild tics and (2) typical or atypical neuroleptics for more severe tics. Although multiple medications are used for tic suppression, the only FDA approved drugs are haloperidol and pimozide. The goal of treatment is not to completely suppress all motor and phonic tics, but to reduce to a level in which they no longer cause substantial psychosocial or physical disturbance.

Tier one drugs include clonidine, guanfacine, baclofen, and clonazepam. Both clonidine and guanfacine are α-2-adrenergic receptor agonists, primarily acting on presynaptic receptors to regulate norepinephrine release. The efficacy of anticonvulsants is unclear: the use of levetiracetam is controversial and topiramate has been beneficial in case reports.

In tier two, classic neuroleptics, such as D2 dopamine receptor antagonists, are effective tic-suppressing drugs, but side effects may restrict their use. Pimozide or fluphenazine have a lower occurrence of side effects and are preferable to haloperidol. The atypical neuroleptics (risperidone, olanzapine, ziprasidone, quetiapine) have the potential for fewer extrapyramidal side effects, likely due to a greater affinity for 5-HT2 receptors than for D2 receptors. Risperidone has been examined in randomized double-blind trials and shows efficacy against tics. Although several neurosurgical approaches have been tried, evidence that deep brain stimulation may be beneficial is accumulating.

Prognosis

The history and evolution of tics in TS remains poorly understood. Tics persisting into adulthood do not differ from those in children. Tics have a waxing and waning course. The outcome of TS is no longer thought to be lifelong, but remains quite variable, with some patients experiencing a spontaneous remission or marked improvement independent of tic-suppressing medication. In a study of 58 young adults, tics virtually disappeared in 26%, diminished considerably in 46%, remained stable in 14%, and increased in 14%. Investigations have suggested that maximum tic severity occurs between ages 8 and 12 years, and is then followed by a steady decline in symptoms. In a longitudinal study of patients first seen as children and reevaluated in adulthood, tic disability and severity were significantly reduced over time. Interestingly, 90% of patients still had some tics documented on videotape including half of those who thought they were tic-free. The severity of tics early in the course of TS is not a good predictor of later tic severity. People with chronic tic disorder and coexisting disorders are more impaired than those chronic tics alone.

Conclusion

TS remains a challenge for both the clinician and researcher. For the treating physician, patients have complex intertwined neuropsychiatric problems that can be challenging to treat. For researchers, numerous questions remain about the genetics, neuroimmunology, and neurobiology of TS.

Tourette Syndrome: Animal Models

N R Swerdlow and M Weber, University of California, San Diego, CA, USA

Glossary

Animal model – An experimental paradigm in laboratory animals designed to understand issues of relevance to human biology, e.g., anatomy, physiology, pathophysiology, and therapeutics.
Deep brain stimulation – A therapeutic modality achieved by delivering controlled electrical current to selective brain regions to reduce symptoms of specific brain disorders.
Nucleus accumbens – Literally, 'the nucleus that leans against the septum': a specialized region of the ventral striatum that is the forebrain terminal field of the mesolimbic dopamine system, and which is heavily innervated by limbic-associated cortical and subcortical regions.
Sensorimotor gating – The automatic inhibition of motor responses by a weak sensory event, operationalized in the laboratory by prepulse inhibition of the startle reflex.
Tic – A rapid, repetitive, nonrhythmic stereotyped motor, phonic, or sensory event, generated either involuntarily or in capitulation to a state of psychic or somatic discomfort.
Tourette syndrome – A tic disorder of childhood onset, characterized by multiple motor and at least one phonic tic, and typically accompanied by premonitory urges or sensory tics.

Introduction

Perhaps the most important point to understand about animal models of Tourette syndrome (TS) is that there are no adequate examples. Anyone who has experienced TS personally or is a clinician or family member involved with TS subjects knows that the symptoms of TS are far too complex and far too 'human' to be captured in the twitching of a mutant mouse or the sniffing of a rat. For the majority of individuals with TS, tics are preceded or accompanied by premonitory sensory or psychic urges that have only recently been quantified by reliable self-rating instruments in humans. These attributes of tics cannot be measured in infrahumans, even by the most sophisticated laboratory apparatus. Likewise, there are complex social and family dynamic aspects to TS that shape the expression of tics and their psychological consequences, and these features cannot be modeled in laboratory animals. Added to this, TS is a heterogeneous syndrome, with many phenotypic variations and combinations of comorbidities, and no single 'model' could possibly capture this diversity. Several investigators have written about the pitfalls of trying to develop animal models of TS or most other neuropsychiatric disorders and have argued that the most appropriate uses of animal models in neuropsychiatry are to develop and test hypotheses about the biology of brain function. In this context, animal models can lead to discoveries on neuroanatomy, neurochemistry, neuropharmacology, neurodevelopment, or genetics and

may help to suggest etiologies or treatments of disorders affecting the brain. The quest for homology in animal models is generally misguided, and as Millan aptly writes, these are 'models for, not of,' brain disorders.

Good animal models are nonetheless important, and perhaps indispensable, to understand TS and other complex brain disorders. At a basic level, animal models teach us about the organization of forebrain neural circuitries and how genes and the environment interact to regulate their development, organization, and ongoing function. Even if we posit a notion now broadly dismissed – that TS is a disorder of very simple genetics – we will never understand TS simply by finding TS genes. As Landis and Insel suggest, 'we cannot hope to understand how genomic variation influences behavior without understanding how genomic variation influences neural circuitry.'

We and others have previously written about the value of animal models and their predictive and construct validity in relationship with TS and other disorders. Predicting effective treatments and understanding their mechanisms of action have clearly been valuable for animal models of brain disorders. Animal models have also been important for testing constructs for the etiologies of disorders like TS. Here, we will describe the state of several models that may be informative about TS-related treatments and the pathogenesis of TS.

Models Related to Therapeutic Insights

Therapeutic approaches to TS include medications, behavioral therapy, and in extreme cases, neurosurgery. Animal models are being used to advance each of these approaches.

A New Target for TS Drug Development

It is generally believed that central abnormalities of dopamine (DA) function contribute to the pathogenesis of TS, or at least, to the mode of therapeutic action of anti-TS treatments. Neuroimaging studies suggest both DAergic hyperinnervation and volumetric reduction in the ventral striatum/nucleus accumbens (NAC) in TS, within a region that regulates sensorimotor gating processes that are deficient in TS, and which may also serve as a target for therapeutic effects of deep brain stimulation (DBS) in TS. Drugs that block D2-family (D2,3,4) receptors (e.g., haloperidol and pimozide) reduce tic severity; it has been hypothesized that these drugs exert at least some of their therapeutic effects via D3 receptor antagonism, while their major side effects, including extrapyramidal effects and hyperprolactinaemia, reflect widespread forebrain D2 receptor antagonism. Compared to D2 receptors, D3 receptors have a much localized expression, with very high levels in the NAC. It is thus conceivable that drugs that selectively antagonize D3 receptors might target a restricted forebrain field, and thereby offer a preferable therapeutic index.

Several studies have demonstrated the ability of D3 agonists (as well as D2 agonists and mixed D2/D1 agonists) to reproduce in rats the loss of sensorimotor gating detected in TS patients. More recently, we demonstrated that this model can be used to identify novel compounds that act as selective, functional D3 antagonists. While it is clearly premature to suggest that functional D3 antagonists will offer therapeutic benefit in TS, there is reason to believe that they might selectively oppose DA hyperfunction in TS within a relatively restricted forebrain DA field that is linked closely to identified pathology in TS. Further, they might also be relatively free from the adverse effects of existing neuroleptic agents. One advantage of the sensorimotor gating model in TS drug discovery is that it can be studied in humans in advance of clinical trials; we anticipate that future D3 antagonists will be studied in clinically normal humans to test the ability of these compounds to oppose effects of D3 agonists on sensorimotor gating, and in TS subjects, to test their ability to normalize sensorimotor gating after acute challenge. A similar strategy appears to be showing promising results in studies of fragile X syndrome. In some disorders, sensorimotor gating deficits are exhibited not only by affected probands, but also by asymptomatic first-degree relatives; this allows the use of healthy, medication-free relatives, rather than more complex patients, in early phase drug development for compounds designed to normalize disorder-related gating deficits. Studies of gating deficits in TS relatives should clarify whether this strategy could be applied toward TS drug development.

Neural Mechanisms of Habit Reversal Therapy (HRT) and Relationships to Therapeutic Effects in TS

One approach to treating TS involves therapies, including HRT, that are designed to help patients systematically 'unlearn' tics, or to learn competing response to tics. The utility of these therapies in TS was suggested by the effectiveness of related therapies in the treatment of obsessive compulsive disorder (OCD), and the fact that symptom reduction in OCD after behavior therapy is accompanied by the normalization of metabolic patterns within corticostriato–pallidothalamic (CSPT) circuitry. Controlled studies have now demonstrated the efficacy of these treatments in TS. While it is not likely that animal models will be useful for predicting the effectiveness of HRT or other behavioral therapies for TS, animal models can be quite valuable for elucidating the neural basis of implicit learning within CSPT circuitry, and potentially predicting pharmacological strategies for

augmenting HRT-induced tic suppression; similar strategies are being used in attempts to produce the pharmacological augmentation of extinction in the treatment of phobias.

Studies combining behavioral and electrophysiological measures in rats have identified probabilistic response patterns within specific caudate cell types that may be a neural substrate of 'habit' formation, 'switching' in advance of the behavioral changes that follow shifting reinforcement contingencies. The caudate and prefrontal cortex appear to respond differently to these reinforcement shifts, and to contribute differently to the subsequent behavioral change. For example, one focus of animal models of operant behavior has been the neural adaptations responsible for the shift from response acquisition, in which behavior is controlled by an expectation of the future consequences of that behavior, to habit formation, when behavior is relatively insensitive to the reduction in reward. During acquisition, responses (and their underlying neural circuitries) are plastic and easily shaped by reward contingencies; with sustained practice, responses become controlled by more complex contingencies, and the underlying neural substrates appear to diversify among distributed corticostriatal circuits. Ultimately, these types of animal models may help us understand which circuits are most culpable in disorders where habits 'stick' and may help predict what neurochemical levers will be most effective at making this circuitry amenable to response 'unlearning.' Importantly, the neurobiology of habit formation will have relevance to disorders well beyond disorders of overt tics and compulsions, perhaps including substance dependence and eating disorders, among others.

Our group is exploring a different approach to develop an animal model to understand the neural basis for therapeutic responses to HRT. In TS patients, positive responses to HRT correlate significantly ($p < 0.02$–0.008) with both deficient inhibitory priming and excessive facilitatory priming in a visuospatial priming (VSP) paradigm. Conceivably, this linkage between VSP deficits and treatment response in TS may reflect a common underlying circuitry that would make this measure particularly sensitive to predicting therapeutic potential in novel compounds. We are currently developing a VSP task suitable for rats using a 5-hole operant chamber, with the goal of using this model for both to understand the neural basis for VSP abnormalities in TS, and to predict therapeutic efficacy of novel compounds.

Animal Models for Understanding the Neural Consequences and Therapeutic Mechanisms of DBS in TS

Electrical DBS is an effective therapy in relieving some symptoms of Parkinson's disease and dystonia, and its use in treating psychiatric disorders such as OCD is being investigated in large studies. A small number of limited case series have identified both therapeutic effects and morbidities associated with the use of DBS in TS patients. The optimal stimulation sites and parameters for therapeutic effects in TS are still unclear, as are the mechanisms of action. In these areas, animal models may help inform clinicians, who can then be left to grapple with the more difficult ethical issues associated with this potential therapeutic modality.

Animal models used to understand DBS range from in vitro studies of membrane responses to electrical stimulation, to studies of intact neural circuits in both infrahuman primates and rodents. Tremblay and colleagues have studied basal ganglia subterritories responsible for the genesis and suppression of abnormal movements in infrahuman primates. Stereotyped motor responses (e.g., licking) stimulated in monkeys after microinfusion of the GABA antagonist, bicuculline, into basal ganglia regions are evaluated after systematic variations of electrical stimulation within specific portions of basal ganglia output circuitry. These studies identify both sites where DBS leads to cessation of generated abnormal movements, and sites where stimulation triggers significant adverse effects. Electrophysiological studies of DBS in rodents have primarily targeted nuclei associated with therapeutic effects in Parkinson's disease, but more recently, Grace and colleagues have been studying the effects of NAC DBS on circuitry of more relevance to TS and OCD, including the orbitofrontal cortex and more 'limbic' thalamocortical connections.

Models Related to Pathophysiological and Etiological Insights

The predominant pathophysiological constructs implicated in the etiology of TS include some combination of genetics, neurodevelopment, and autoimmune-induced neuropathology. As it stands, there is little agreement on, or compelling empirical evidence for, specific mechanisms underlying any of these constructs. Nonetheless, animal models are being used to explicate features of general relevance to genetic, neurodevelopmental, or immunologic etiologies of TS.

Animal Models of TS Genetics

Genetic models have been used in several ways to understand TS. First, a number of candidate genes of TS have been identified in human studies, though replication of many findings remains elusive. In some cases, such as the dopamine transporter (DAT) genes, mutant mouse models exist and are being studied to understand the physiological, neurochemical, and behavioral impact of DAT perturbations. For example, DAT knockout mice exhibit hyperactivity and sensorimotor gating deficits and have been used to model pathology in numerous

disorders, including schizophrenia, bipolar disorder, attention deficit disorder, and TS. As a predictive model for TS therapeutics, this mouse clearly has failings: for example, clozapine normalizes gating in DAT knockout mice but is not an effective anti-tic medication, and neither is valproate, which can normalize hyperactivity in this mouse. On the other hand, studies of gating deficits in DAT knockout mice have shown that they can be opposed by drugs that target the norepinephrine transporter; this model has some appeal in TS, where – unlike many other disorders – symptoms of a proposed underlying hyperdopaminergic state can be controlled effectively in many patients by drugs (e.g., clonidine, guanfacine) that target noradrenergic transmission. Thus, studies of a model based on this TS candidate gene might help us to understand the basis for therapeutic medication effects in TS.

Another use of genetic models to understand TS has focused on the neural basis for heritable gating deficits, like those exhibited by TS patients. Here, the glaring omission in logic is that gating deficits in TS have not yet been demonstrated to be heritable. Nonetheless, as they clearly distinguish individuals with the TS diagnosis from those without the TS diagnosis, they at least appear to be associated with the larger heritable phenotype. Freudenberg, Schwabe, and colleagues have demonstrated that selective breeding for low levels of sensorimotor gating results in substrains that not only 'breed true' for reduced gating, but also exhibit perseverative cognitive and motor patterns. Understanding the neural basis of these heritable phenotypes will at least yield some testable hypotheses for the neural basis of gating deficits and cognitive or motor disturbances in TS. Along this line of inquiry, we have reported that heritable differences in the ability of DA agonists to disrupt sensorimotor gating in rats are associated with differences in key elements of DA-linked signal transduction pathways in the NAC, and with highly significant differences ($p < 10^{-7} - 10^{-18}$) in the expression of a number of DA-linked genes in this same region. By pursuing these models, we hope to identify targets within DA signaling pathways that might serve as novel therapeutic targets in TS.

Neurodevelopmental Abnormalities in Parvalbumin-Positive GABAergic Neurons

Evolving hypotheses in TS (as well as other disorders) suggest that either genetic events, or epigenetic events, or both lead to aberrant forebrain development by altering neuronal migratory patterns within specific cell populations, including the parvalbumin (PV)-positive GABAergic neurons. Abnormal distributions of PV+ cells in cortical and subcortical regions in schizophrenia and TS have been interpreted to suggest a developmental delay or arrest in the early rostral migration of these cells, and shifts in these distributions will certainly alter the dynamics of CSPT circuits. Some of these patterns of abnormally-distributed or regionally reduced cortical and striatal PV+ cells can be recreated in animal models ranging from isolation rearing to focal cortical ischemia, and models are being developed to understand the impact of such regional and distributed circuit changes on the expression of tics and other symptoms.

Models of Autoimmune Pathology in TS

A hypothesis that has created great interest, intense study, and some degree of controversy links TS and related conditions to autoimmune mechanisms triggered by group A beta-hemolytic streptococcus or other pathogens. 'Definitive' studies are regularly published that either support or fail to support this hypothesis. Undeterred by this disagreement, many groups are pursuing animal models of relevance to the 'immune hypothesis' of TS. Three groups have reported evidence that infusion of sera from TS patients into the striatum of rats triggered the expression of TS like behaviors, including repetitive stereotyped movements and vocalizations; in one report, some of these behaviors were elicited by intrastriatal infusion of immunoglobulins isolated from TS sera, and in another report, behaviors were opposed by intrastriatal implantation of rat neural stem cells. Others have failed to detect these behavioral effects after intrastriatal infusion of TS sera, prompting the difficult search for methodological differences that might account for these contradictory reports. Of course, others have also failed to detect differences in autoantibodies in sera from controls, TS subjects, and patients with pediatric autoimmune neuropsychiatric disorders associated with Streptococcus (PANDAS).

Future Directions

Animal models are being used to understand evolving therapeutic avenues in TS, including pharmacotherapy, HRT, and DBS, and to clarify biological principles associated with the primary etiological constructs of TS. The utility of animal models in TS has been limited by the dearth of definitive findings emerging from neuropathological, neuroimaging, and neuroimmune studies of TS patients. These problems are due in part to the clinical and diagnostic complexities of this disorder and to the concentrated effort placed on other scientific endeavors, including many studies designed to identify TS genes. In parallel to the development of clinical research, animal models for TS are highly informative on issues related to the structure and function of the brain. These studies provide insights into the biological factors that control behavior, and the regulation and dysregulation of this control by genes and the environment.

Transplantation

M B Newman, L P Kelly, and R A E Bakay, Rush University Medical Center, Chicago, IL, USA

Glossary

Human embryonic stem cells – Primitive undifferentiated cells derived from the inner cell mass of the blastocyst of a preimplanted embryo that can divide for long periods without differentiating and can develop into cells or tissue from the three primary germ layers.

Pluripotent – The ability of cells to give rise to various cells or tissue types of the body, except embryonic tissue.

Stem cells – Unspecialized cells that are capable of self-renewal through cell division and have the potential to be induced (differentiate) into specific cells of an organ or tissue with a particular function.

Definition and History

In the context of Movement Disorders therapy, cell transplantation can be defined as a surgical procedure in which human cells or tissue are implanted into a specific site(s) in the brain to relieve the symptoms or stop the progression of the movement disorders in a patient by either

repairing, regenerating, or restoring function to the defective area(s). The first recorded neural tissue transplants dates back to the late 1800s, when W.G. Thompson transplanted frontal cortical tissue from felines into the brain of canines. Surprisingly, some animals and grafts, he believed, survived for seven weeks, which encouraged him and other investigators to move forward in this field of study.

Early on high quality investigations were also performed by Elizabeth Dunn (1917), Le Gros Clark (1940) and R.M. May (1955). However, not until after the early 1970's did this field begin to grow with euthanasia and with the support of the scientific and medical communities. This slow start may have been related to the work of the prominent histologist Santiago Ramón y Cajal (1852–1934), who was convinced by his own research that central nervous system tissues are 'fixed and immutable' and cannot regenerate. However, eventually this hypothesis came into question, as researchers demonstrated axonal sprouting in damaged brain areas and survival of transplanted neural tissue grafts in the 1970s, thus marking the era of a new research field that would develop expeditiously neural transplantation.

Rationale for Cell Transplantation in Movement Disorders

Unlike other neurosurgical interventions for movement disorders, in which there are accepted guidelines for patients undergoing such surgeries, cell transplantation guidelines have not been established, as this is developing therapy, and patients receiving cell transplants are considered on a case by case basis. In this discussion, Parkinson's Disease (PD) is used as the disease of reference, because most clinical trials for cell transplantation have been performed in PD patients and deep brain stimulation (DBS) is the treatment of choice when drug therapy fails in PD patients. While several factors have motivated the need for neurosurgical intervention, the strict criteria for these surgeries tend to exclude a large number of patients. Statistical reviews have approximated that only 2% of PD patients evaluated are considered suitable for DBS, of the subthalamic nucleus. Consequently, cell transplantation may be the suitable alternative for patients not meeting the standards for DBS surgery.

DBS therapy has two additional criteria, the disease should be present for at least five years and there should not be any significant cognitive impairment in patients with PD. This modality also results in excluding a large subset of patients. Although the 5 year set point is to ensure the diagnosis is correct and the restriction on cognitive impairment is to confirm compliance and tolerance with surgical or postoperative procedures, this may be to extensive of await for cell therapy and earlier intervention may prove to be more beneficial. The premise of cell therapy is to stop the progression of the disease and the patient should have less cognitive impairments in the earlier stages of the disease vs. later stages.

Another factor instrumental in the development of neurosurgical and cell transplantation therapies for movement disorders is the inadequacy of oral medication, such as low or variable efficacy, low tolerability, intolerable side effects, and nondisease specific drugs, like those for dystonia and essential tremors. Patients are considered for neurosurgery when oral medication fails to relieve symptoms or when the side effects are so insufferable that the medication cannot be tolerated. In general, cell transplantation would allow more patients with PD to be treated overall compared to the other treatment modalities. The combination of medication, DBS, and cell therapy is a possible alternative for movement disorders not responding to one specific treatment alone. Co-therapies may be useful with a multifaceted disorder, such as Huntington's disease (HD), which has a complex pathology with several cell types included in the disease process. Therefore, the first criterion for cell transplantation is a meticulous and comprehensive understanding of the disease's pathology, which includes affected areas, cell type(s) and pathway (**Figure 1**). While we have focused on PD, similar arguments can be made for other movement disorders. Thus, cell therapy will likely be applicable to more patients than any other neurosurgical treatment.

Cell Transplantation for Movement Disorders

No longer is cell transplantation considered science fiction for the treatment of CNS disorders. In fact, on January 23, 2009 Genron Corp. (Menlo Park, CA) received the first approval for the transplantation of human embryonic stem cells (hESCs) from the FDA. In their application Genron states they will direct the hESCs to spinal cord progenitor cells and transplant these cells into patients with a complete spinal cord injury. Since the first human fetal tissue transplants in PD patients and the isolation of hESCs, there has been tremendous controversy surrounding their use for research and clinically. Although the ban on the use of non-Federally approved hESCs in research supported by Federal monies (grants) was lifted in March 2009, the ethical controversy and the previous 7-year ban compelled scientists to acquire other sources of pluripotent stem cells. Stem cells have now been isolated and characterized from several human tissues/organs, including bone marrow, umbilical cord blood, peripheral blood, skin, adipose, most major organs, and tumors. However, these cells do vary in their ability to differentiate into a cell or multiple cell types, even when cultured with similar methods for induction.

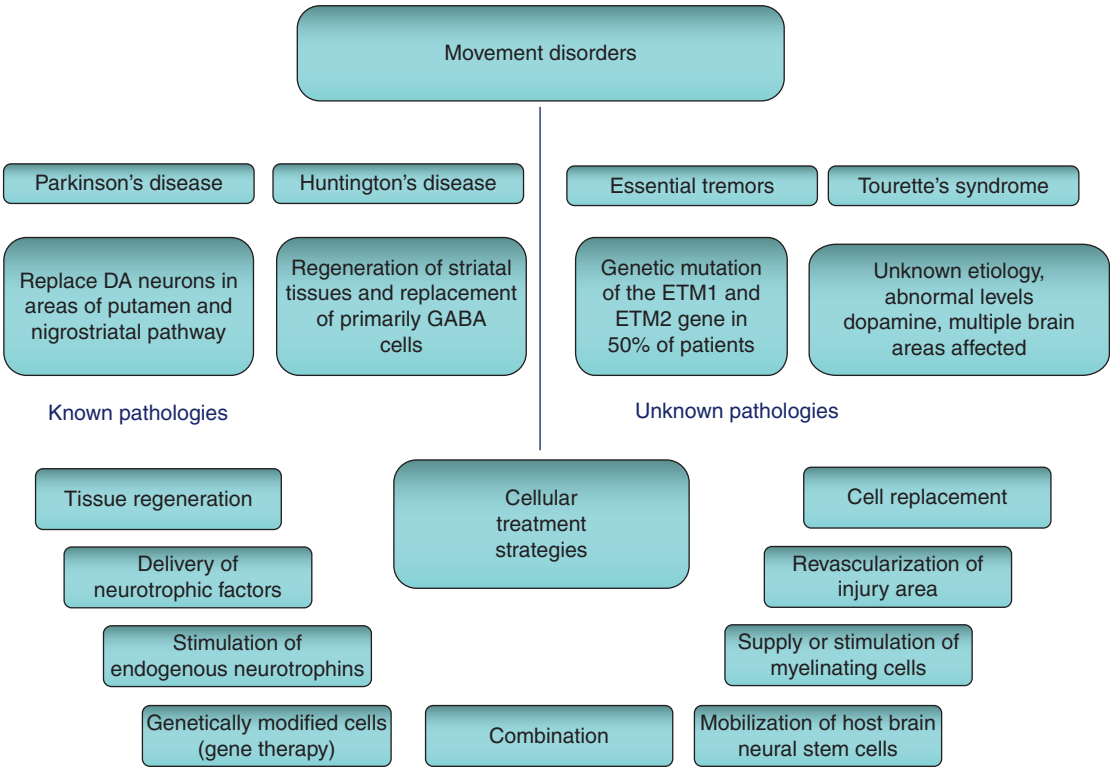

Figure 1 The schematic represents the multiple strategies of cell therapy that may be applicable to movement disorders, overall. However, the pathology of the disorder needs to be well understood before the cellular therapy is selected. Depending on the disease different strategies may be chosen, and a greater therapeutic benefit may realized by combining two or more treatment strategies, resulting in a synergistic effect. The combination of treatment strategies may be actually be necessary. For example there is a genetic mutation, damage to striatal tissue, and a loss of GABAminergic cells in HD in which a single cell type and a single strategy simply would not be enough to overcome this complex disorder. More than likely a HD patient would benefit from gene therapy, cell replacement, and neurotrophic factor support. GABA, gamma-aminobytyric acid; ETMI1 & 2, essential tremor.

Brief History of Cell Transplantation

The earliest report of fetal tissue for transplantation was in 1904, by Elizabeth Dunn from the University of Chicago who showed the survival of fetal grafts in adult animals. However, like other significant research contributions there was a long interval, approximately 85 years, before human fetal tissue was again used in transplantation of the CNS. In the 1980s, a brief flurry of enthusiasm occurred over adrenal medullary cell transplants to the caudate nucleus, but replicate studies of original observations were less impressive in light of serious operative–postoperative morbidity. Lindvall and colleagues (1989) were the first to report the successful transplantation of human fetal ventral mesencephalic tissue into the putamen of PD patients and to show graft survival with dopamine synthesis by positron emission tomography (PET). Clinical trials using improved protocols for achieving fetal dopaminergic neurons from mesencephalon tissue helped provide 'proof of principal' that cellular regeneration can be a viable treatment. Over 600 PD patients have now received human fetal ventral dopaminergic mesencephalic tissue transplants and the successes of these transplants are being evaluated clinically, through PET scans and at autopsy.

Pivotal Trials in Parkinson's Disease

Two central clinical trials for patients with PD occurred in the early 2000s. Freed and colleagues (2001) were the first to include a surgical control group in their clinical PD trial for cell transplantation. This was a double-blind, sham surgery-controlled study, with patients between the ages of 34 and 75 that were either transplanted with cultured mesencephalic tissue from four embryos or they received sham surgery (with a hole drilled in the skill, but the dura is not penetrated), and no immunosuppression treatment was administered. The results indicated the younger population had significant beneficial improvements as analyzed with scores from Unified Parkinson's Disease Rating Scale and the Schwab and England Scale. A new type of off-stage dyskinesias also recurred in 15% of the patients after the first year. A more recent analysis of this data set revealed that the early-stage-disease patients actually had improvements in motor function, and not necessarily the 'younger' patients.

The second PD clinical trial by Freeman and colleagues (2003) was a randomized placebo-controlled study, in which the transplanted recipients were randomized to receive either a 'low dose' (one donor per side) or 'high

dose' (four donors per side) of fetal dopaminergic tissue that were transplanted into the postcommissural putamen. Significant improvements in motor function were seen in the group that received four donors per side at 6 months after transplantation, but this benefit was short lived. However, the role in discontinuation of cyclosporine, an immunosuppressant, may have played in the loss of these improvements is unsettled. There have been no reported clinical studies that have tested the affects of withdraw or continuation of immunosuppression therapy for the long- or short-term outcome of movement function. However, post hoc stratification based on disease severity demonstrated a treatment effect with patients receiving four donors per side, which showed motor improvements at 2 years in milder (stage of disease) patients. More importantly, 56% of transplanted patients developed off-stage dyskinesias that persisted following withdrawal of dopaminergic medication. In addition, there was significant striatal fluoro-dopa uptake following the transplants and robust graft survival was observed postmortem in both studies.

Although both trials failed to achieve their primary outcome measure, the lessons from these two pivotal placebo-controlled trials should be applied to future trials, and other issues that were brought forth should be addressed before moving forward with additional larger trials. Most importantly, the studies demonstrated the necessity of utilizing sham surgery controls in testing all reconstructive therapies. Subsequently, the off-time dyskinesias generated by the grafts in both studies must be better understood before cell transplant trials go forward, especially because there does not appear to be a dose-related phenomena, as the dyskinesias occurred in patients that received both 'low' and 'high' doses of dopaminergic tissue. Furthermore, the withdrawal of the immunosuppressant was followed by a loss of benefits or a further loss in motor function, which generates the possibility that graft rejection may be a subclinical process. However, the patients in Freed's study were not administered an immunosuppressant and some patients showed improvements and the grafts were present at autopsy. The role of the immune system's interaction with the CNS in graft rejection or in cell transplantation, in general, is not well known. In addition, some donor solid tissue grafts (as opposed to suspension grafts/cells) may contain mesenchymal vasculature that may induce a stronger immunologic response from the graft's recipient, which can considerably influence the graft's survival, the interaction of the graft with the host tissue, and the overall host immune response. Recent autopsy studies of grafts over 10-year posttransplantation demonstrated classic lewy body degenerative changes in some of the transplanted cells suggesting possible transfer of the pathology to the graft cells.

Although there has been considerable controversy over the results from open clinical trials, with some studies reporting beneficial outcomes, others reporting innervation of graft and host tissue, while other studies showed limited behavioral recovery with untoward effects, and still others reported only effects in certain subpopulations of patients, the overall findings are still considered promising and research in this area is moving forward. Given the limited availability of fetal tissue and the ethical implications in using this tissue, other sources, particularly stem cells, are being investigated for the clinical use in cell transplantation for movement disorders.

Cell Transplantation Studies in Huntington's Disease

Several clinical trials using cell transplantation for the second major movement disorder, HD, have also been performed. Although these started much later than PD trials, the first HD clinical trial was reported in 1990 from Mexico, with others taking place even later in California, Cuba, the United Kingdom, and Czechoslovakia, in which fetal striatal tissue was transplanted into the striatum of patients without reports of any major complications. There were also reports of recipients with graft survival, as measured by MRI, within the striatum with no disruption of surrounding tissue and some cognitive improvements symptoms associated with HD were noted. However, there were no reports of cortical or subcortical improvements in these patients, which was likely due to the location of transplanted tissue and the lack of cell migration from the graft. Unlike in PD, tissue repair in other brain regions besides the striatum is imperative for the treatment of HD. The pathology of HD is widespread and characterized by affecting numerous areas within the brain, with initial atrophy of the caudate nucleus and putamen, where there is the loss of γ-aminobutyric acid (GABA)-mediated medium spiny neurons, and a secondary degeneration of globus pallidus, frontal cortex, thalamus, locus ceruleus, and subthalamic nucleus, which is due to the loss of pre- and postsynaptic neurons. Therefore, the transplantation of either fetal tissue or cells only to the striatal region may be insufficient to produce the needed improvements, given degeneration occurs in multiple brain areas, and cell transplants may need to correspond with these multiple sites. The clinical trials for HD have used the fetal tissue that came from elective abortions and spontaneously aborted fetuses, as in the PD studies. However, the tissue collected and transplanted typically is from the lateral ganglionic eminence, which is where most medium spiny neurons are derived. There were a few more clinical trials in the early 2000s, and results of some transplants have been reported postmortem. However, there has been no evidence of the fetal tissue grafts stopping or slowing down the progression of HD and a lack of graft integration with host parenchyma in patients has been reported by several scientist, which could be responsible for the in

consistant results thus far. In addition, the same ethical concerns and the lack of available fetal tissue for transplantation that plagues PD research, also affects HD research. This is true for all movement disorders that would benefit from fetal tissue or fetal cell suspension grafts, which further necessitates the need and search for alternative sources of pluripotent stem cells.

Together these findings suggest that a reliable and consistent source of human stem cells that are standardized along with improved methods of cell engraftment and graft survival are important factors in minimizing the variability of transplantation outcomes. In addition, a more thorough understanding of the immune system's capabilities and the interactions of graft and host tissues with immunosuppression is required to advance the future of cell therapies in movement disorders.

Beyond Cell Replacement Transplantation – To Repair, Regenerate, Restore, or Arrest Progression

Therapeutic effects and the survival of grafted cells are influenced by several factors; however, as discussed, there are no established criteria for cell-based therapies. **Table 1** provides a broad set of criteria we feel are important concerning cell therapies, and has been assembled from eminent reviews and prominent original scientific articles (see Further Reading). While the definition of cell therapy has changed considerably over the years, one thing that has not changed is the cell(s) utilized is highly dependent on the type of disease. Furthermore, what once was a rather simple definition of a 'stem cell' has become complex, as our characterization and study of these cells has grown. There is still unanimous agreement on the two main properties a cell must possess to be classified a 'stem cell.' First, a stem cell must be able to self-renew, that is during cell division they must produce at least one identical daughter cell. Second, at some point during one of their cell divisions one cell must further differentiate into one or more cell types, depending on their linage. In addition, a clear understanding of the terms embryonic stem cells (ESC), neural stem cells (NSCs), and neural progenitor cells (NPC) is required when discussing cell transplantation for movement disorders, because the majority of transplants discussed are concerned with the CNS and these cells have typically been used in the hope that they will integrate and communicate with the host tissue. Briefly and for the purpose of this article: (1) ESCs are from embryonic tissue and are pluripotent – meaning they will give rise to derivatives from each of the three primary germ layers, can establish a stem cell line without the use of immortalizing agents, can be propagated as a homogeneous culture, symmetrically amplified for an extended period while maintaining stability, and will develop normally when returned to a developing organism; (2) NSCs are multipotent stem cells, meaning they are more restricted in the types of cells they may give rise to, they can differentiate into one of the three neural cell types, can be expanded (self-renew) to produce clinically significant

Table 1 Criteria for cell transplantations in movement disorders

Identification of movement disorder
Complete pathology
- (a) Stage of disorder/disease of recipient
- (b) Affected areas in brain identified
- (c) Identification of pathway(s)
- (d) Degree of tissue damage

Selection of cell type(s) for transplantation
Source of cells
- (a) Source of cells known and accessible
- (b) Cells and source free of infections, diseases, and mutations
- (c) Purity of cells or purity of multiple cell types
- (d) Cells need to be consistent and renewable
- (e) Stage, maturity, and age of cells known or identified

Properties of cells once selected
- (a) Cells before grafting can be induced into required phenotype(s)
- (b) Cells differentiate to appropriate phenotype(s) upon grafting
- (c) Cells have the potential to differentiate according to host environment
- (d) Population of cells is sufficient
- (e) Cells can proliferate into needed quantities
- (f) Cells remain terminally differentiated – do not revert back to early cell stage
- (g) No potential for tumorigenicity of grafted cells

Selection of transplantation strategy
- (a) Replacement of single cell type in one or multiple brain areas
- (b) Replacement of multiple cell types in one or multiple brain areas
- (c) Transplantation of cells that produce neurotrophic or growth factor(s)
- (d) The delivery of cells to stimulate endogenous neurotrophic or growth factors, cytokines, proteins, etc.
- (e) The delivery of cells to stimulate endogenous neural stem cells
- (f) Delivery of genetically modified neural stem cells to the host that will replace damaged cells
- (g) Delivery of genetically modified cells that will produce neurotrophic or growth factors
- (h) A combination of strategies
- (i) Co-therapies – cell transplantation with therapeutic drugs, neurosurgical procedure, or gene therapy

Additional issues to consider
- (a) The selection and use of immunosuppressant drugs
- (b) Immune matching between host and donor – genotyping
- (c) Influence of culturing conditions before transplantation
- (d) Transplanted cells' ability to respond to endogenous signals
- (e) Transplanted cells' ability to integrate and form functional connection within host environment
- (f) Atypical circuit reconstruction
- (g) Standardization or reproducibility of transplants
- (h) Cost of cell transplantation procedure
- (i) Cost of clinical trials

Note: Depending on the particular disease or disorder more specific issues may arise. Individual recipient issues that may effect choice and utilization of cell-based therapy also need be recognized.

numbers of cells for transplantation, and they are cultivated from the brain at either the embryonic or the adult stage or these may be derived from ESCs; (3) NPCs have the same origin of NSCs and are typically derived from NSCs, but they have a more restricted repertoire.

There are several cell transplantation strategies that have been investigated in addition to the replacement of loss or dead cells; however, replacement of homogenous cells is still a viable approach for certain movement disorders. The current strategies are: (1) the replacement of specific cell types in a specific area or areas of the brain, such as dopaminergic neurons into the striatum for PD, (2) the replacement of multiple cell types and transplantation of cells into specific areas within the brain, as in HD, (3) the transplantation of cell that produce growth or neurotrophic factor(s) that are known to aid in repair or recovery of damaged tissue (instead of ones that produce and release neurotransmitters) and can be delivered to single or multiple areas of the brain, (4) the delivery of cells targeted to stimulate the endogenous neurotrophins and neurotrophic growth factors, proteins, or cytokines that aid in the repair of damaged tissue, (5) the delivery of cells targeted to stimulate the endogenous NSCs to proliferate and/or repair damage tissue, (6) the use of gene therapy by the delivery of genetically modified NSCs to the host that will replace damaged cells and/or delivery of genetically modified cells that will produce neurotrophic growth factors, (7) induced pluripotent stem (iPS) cells is a newer technology that uses cells extracted from adult tissue and induces them into embryonic-like stem cells; in this strategy a person's own cells may be used and made into iPS cells that could be directed to the cell type(s) needed and transplanted into target area(s) of the brain, and (8) a combination of strategies may be used, which may prove to be the most successful transplantation strategy. Most of these same strategies can apply to systems outside of the CNS. Cells that are transplanted in the brain are not isolated from affecting other systems that are not involved with the movement disorder. In fact, for most movement disorders, there is the potential for systems outside the CNS to aid in repairing the disorder. For example, the bone marrow continually releases stem cells into peripheral blood when needed. Cells transplanted into the brain could be programmed to home to the bone marrow to stimulate new stem cells that would migrate to the injured brain area to aid in the repair. Because these stem cells are from the host's bone marrow signaling and communication within the brain would be effortless and these cells would pass the body's immune defenses leaving only the transplanted cells for the host's immunological response as a concern. In addition, immune rejection would not be a concern when iPS cells, derived from the patient, are used for transplantation. Patient-specific stem cell therapies may be the direction for future cell transplantation in movement disorders. However, those movement disorders caused by a gene mutation would not be eligible for patient-specific stem cells transplants, because the mutation would still be present in the gene of the individual cells.

Single or multiple cell types transplantations?

Furthermore, single or two or more cell transplantation strategies may be necessary depending on the movement disorder identified. A single cell type might not be able to perform all the functions required of a particular disorder, and more than a single cell type would be necessary. More than likely greater therapeutic benefits would be realized from a transplantation strategy that provides a synergistic approach. For example, when cells are co-transplanted with other cell types or cells that produce growth factors there would be a combination of factors at work thus creating a synergistic effect. The transplanted cells may be releasing the needed neurotransmitter for movement, while the growth factors are aiding in repairing the damage tissue. This type of synergistic effect has been observed in clinical and preclinical studies. Meyer and colleagues (1995) co-transplanted fetal ventral mesencephalic dopaminergic neurons with embryonic striatal cells, in a PD trial, and observed that the co-grafted cells survived and integrated within the host tissue. In preclinical studies, the survival enhancement of grafted cells has been achieved when cells were co-treated with glial-derived neurotrophic factor (GDNF), and when the grafted dopamine neurons were co-transplanted with testis-derived sertoli cells. Thus, the utilization of more than one transplantation strategy may allow for a synergistic environment, which may prove to be more beneficial for movement disorder patients and their recovery.

The transplantation strategies outlined on the surface seem relatively uncomplicated, but when considering the best therapy for movement disorders that will not only treat the symptoms, but also repair the damage and stop the progression, there are multitudes of factors to consider. While the transplantation of a cell type(s) into the target site is straightforward, complications emerge when the target site(s) is not the site where most of the damaged tissue is located or where the cells are needed the most. As in the case of PD, the most damage occurs from the loss of dopaminergic neurons in the substantia nigra and these neurons' axons project to the striatum where dopamine is released and controls motor functions. The striatal tissue would be the more beneficial site to transplant dopamine replacement cells that will release the dopamine once transplanted. Here we know three factors of this disease: the pathology, the cell type to use, and the area in the brain in which to transplant. However, while this strategy has worked well in animal models and has shown potential in PD patients, progression of the disease is not stopped. We know from other animal models of disease that tissue regeneration does occur and this might be what is needed to stop the progression in PD; that is to regenerate the substantia nigra tissue and its pathway to the striatum. In animal

models of stroke, when neural-induced human SCs or ESCs are transplanted directly into the infarct area, regeneration of the damaged tissue and improvement in motor functions are seen. Published studies have suggested that the transplanted human NSCs may be assisting (stimulating) endogenous SCs, neurotrophic factors, cytokines, or other endogenous factors that are aiding in repairing the damaged tissue. Because of the inherent difficulty in measuring and verifying in vivo secondary actions, this supposition has not been fully proven, but is highly suggestive as a mechanism of action in producing regeneration of the damaged tissue. The enhancement of any biological function, by co-factors, that the transplanted cells stimulate or provide support for could be one of the first clinical treatments.

Engineered cells

Similar to the transplanted cells stimulating endogenous factors is the transplantation of engineered cells, which is a relatively new and exciting area of research especially for movement disorders. There have been a few clinical trials with neurotrophic factors, such as glial cell line-derived neurotrophic factor (GNDF) for PD, HD, and progressive supranuclear palsy, brain-derived neurotrophic factor (BDNF) for HD, and the cytokine granulocyte colony stimulating factor for Amyotrophic Lateral Sclerosis. However, most of these clinical studies had significant problems related to the delivery method employed, in which implantation of a catheter was used to target an area of brain and the infusion pump was placed under the skin. With gene therapy, the cells can be engineered to produce and release protein(s), neurotrophic or neurotrophin factor (s), or an essential amino acid that is lacking. There have been two clinical studies for Alzheimer's disease that use gene therapy to deliver human nerve growth factor to the basal forebrain. The first clinical trial for advanced PD, using the strategy of gene therapy, was the delivery of glutamate decarboxylase (GAD) by viral vector infusion to the subthalamic nucleus. Phase I study has been completed for safety and Phase II study has been started for safety and efficacy with reports thus far showing promise. Other Phase I trials have been or are being conducted for PD using adeno-associated virus as the vector and delivering either human aromatic L-amino acid decarboxylase or neurturin, which is structurally related to GDNF. There are numerous advantages to delivery of neurotrophic factors using this method of gene therapy. These include: no catheters to implant, no concerns for refilling infusion pumps, no threat of infections from external/internal catheter, long-term treatment cost should be less due fewer office visits, and the viral vectors can be implanted directly into deficient brain areas or different vectors can be implanted into appropriate areas within the brain.

There are unique concerns for any one of the strategies chosen, and there are general concerns that apply to the methods of cell transplantation. General concerns consist mostly of the concentration of cells, neurotrophic factors or other factors used, the assurance that the correct area(s) of the individual brain is reached, the acceptance of the grafts or vectors by the host system, the mechanism selected for the gene therapy or transduction method of the cells, what long-term effects this method may have on the host system, and whether cells or neurotrophic factors remain localized or become dispersed and the effects this may have on the host. Taken together with the issues that must be considered for surgery and for the patients' health, what seems to be a simple transplant is in fact very complex. The need for cell transplantation guidelines, criteria, protocols, and an open exchange of vital information between clinical trials and research is seriously needed.

New Directions

There is a genuine potential for cell therapy, in the near future, to treat or possibly cure age-related diseases and even the most debilitating movement disorders and neurodegenerative diseases. While the etiology of the disease or disorder may not be known, cell transplantation could be the provisional therapeutic strategy that improves the symptoms until the underlying cause of the disorder is found, progression is stopped and regeneration or replacement of the damaged tissue occurs. Successful cell and organ transplantations are increasing yearly, however, the number of patients needing or waiting for treatment is much greater than our current resources allow. Movement disorders is one of the major health problems and one that has led scientists and physicians to focus on new techniques, new cell sources, ways to create standardize protocols, and on means of bringing new treatments to the clinic quickly, safely, and efficiently. There are new technologies that could assist with ensuring the safety of cell transplantations such as epigenetic analysis, gene profiling, and proteomics. These technologies, as well as others, should be used whenever possible to assure safe procedures are used and to avoid clinical adversities.

Tremor

R J Elble, Southern Illinois University School of Medicine, Springfield, IL, USA

Glossary

Action tremor – Tremor that occurs during any voluntary contraction of skeletal muscle.
Intention tremor – Crescendo tremor that occurs when a limb or other body part approaches a target.
Isometric tremor – Tremor that occurs during a muscle contraction against a rigid stationary object.
Kinetic tremor – Tremor that occurs during a voluntary movement.
Postural tremor – Tremor that occurs during an attempt to hold a body part motionless against the force of gravity.
Rest tremor – Tremor that occurs when skeletal muscle contraction is neither intended nor necessary.
Tremor – An involuntary oscillatory movement of a body part.

Definition and Classification of Tremor

Tremor is an involuntary oscillation of a body part. Tremor is categorized as rest, postural, kinetic, isometric, or action tremor according to whether the tremor occurs during voluntary muscle activation, steady posture, or movement (**Table 1**). The term static tremor (tremor at rest or in steady posture) is no longer used because of its ambiguous definition and usage.

The classification schema in **Table 1** is often expanded to include subtypes of tremor with unique characteristics. For example, pill-rolling rest tremor is a rest tremor in which the fingers and wrist move in a manner reminiscent of a rhythmic voluntary manipulation of small objects or pills in the hand, and is a hallmark of idiopathic Parkinson's disease. Some kinetic tremors are called task specific or focal, because they are solely limited to a specific task, movement, or body part. Postural tremors may be limited to or greatly exacerbated by specific postures, and these tremors are sometimes referred to as position-specific or position-sensitive postural tremors.

Several tools are available for the electrophysiologic quantification and characterization of tremor. Miniature accelerometers, gyroscopic angular velocity transducers, and video photogrammetry are useful in measuring the motion of a body part. Pen motion during writing and drawing can be quantified with commercially available digitizing tablets that are used in computer graphics.

Table 1 Classification of tremor

Type of tremor	*Definition*	*Example circumstances*
Rest tremor	Occurs when skeletal muscle contraction is neither intended nor necessary	The patient is recumbent on a bed or seated on a couch, with the body part supported. Tremor is often enhanced by the performance of cognitive tasks or motor tasks with other body parts, and it is often suppressed, at least temporarily, by voluntary muscle contraction
Postural tremor	Occurs in an attempt to hold a body part motionless against the force of gravity	Extending the upper limbs horizontally, pointing at objects, sitting erectly without support for the upper body, protruding the tongue
Kinetic tremor	Occurs during a voluntary movement	Finger–nose–finger testing, heel–knee–shin testing, reaching, writing, drawing, pouring water into a cup, drinking from a cup, eating with utensils, speaking
Intention tremor	Crescendo tremor that occurs when a limb or other body part approaches a target; generally greater when the movement to a target is visually guided	Finger–nose–finger testing, heel–knee–shin testing, reaching, writing, drawing, pouring water into a cup, drinking from a cup, eating with utensils
Isometric tremor	Occurs during a muscle contraction against a rigid stationary object	Pushing against a wall, flexing the wrist against a table, making a fist
Action tremor	Occurs during any voluntary contraction of skeletal muscle	Any combination of postural, kinetic, and isometric tremors

Muscle activity is measured electromyographically, using skin electrodes for gross motor activity and needle electrodes for single motor-unit activity. Motion transducer signals and electromyographic signals are recorded digitally with a computer and analyzed with spectral (Fourier) techniques. With these methods, tremor amplitude and frequency are easily quantified, and coherence (linear correlation squared) between any two digitized signals is also readily computed. These methods are also useful in quantifying the effect of mass (inertial) loading on tremor frequency (see Physiologic Tremor section) and the effect of distraction and voluntary rhythmic motor tasks on tremor amplitude and frequency (see Psychogenic Tremor section).

Physiologic Tremor

Physiologic tremor consists of two distinct oscillations: mechanical reflex and central neurogenic. All normal people exhibit the *mechanical-reflex component*, which is a passive mechanical oscillation that occurs in response to irregularities in subtetanic motor-unit firing and to the ejection of blood at cardiac systole. The cardioballistic forcing accounts for nearly all of physiologic tremor at rest. The frequency and amplitude of mechanical-reflex tremor are governed by the underdamped inertial, viscous, and elastic properties of the body. Consequently, normal elbow tremor has a frequency 3–5 Hz that is lower than the frequency (7–10 Hz) of wrist tremor, because the forearm has much greater inertia than the hand as a whole. Similarly, the fingers have even less inertia, and therefore, the frequency of metacarpophalangeal joint tremor is 17–30 Hz. Voluntary co-contraction of the muscles about a joint produces a slight increase in tremor frequency due to the increased joint stiffness. Conversely, a gradual relaxation of the joint causes the frequency of mechanical-reflex tremor to fall.

Under normal circumstances, the response of somatosensory receptors (e.g., muscle spindles) to the mechanical oscillations of physiologic tremor is too weak to entrain motoneurons at the frequency of tremor. Consequently, the electromyogram (EMG) exhibits a normal interference pattern, with no evidence of motor-unit entrainment at the tremor frequency. Additional limb inertia I decreases tremor frequency, and additional stiffness K increases frequency according to the equation $\omega = \sqrt{K/I}$. Limb ischemia sufficient to suppress the stretch reflex causes a slight reduction in normal mechanical-reflex tremor. Therefore, the stretch reflex appears to contribute little to the control of physiologic postural tremor. However, the reflex-induced modulation of EMG increases when perturbations to the limb increase the amplitude of mechanical oscillation or when stretch-reflex gain is enhanced by fatigue, anxiety, thyrotoxicosis, or β-adrenergic drugs. The increased participation of the stretch reflex is associated with increased tremor amplitude, and the resulting tremor is referred to as *enhanced physiologic tremor*. Enhanced physiologic tremor is primarily an enhanced mechanical-reflex oscillation, because the frequency of tremor is proportional to the square root of the stiffness and inversely proportional to the square root of the inertia ($\omega = \sqrt{K/I}$). However, greater central-neurogenic tremor may also occur, as in patients taking tricyclic antidepressants.

In contrast to normal mechanical-reflex tremor, the *central-neurogenic component* of physiologic tremor is always associated with a modulation of motor-unit activity at 8–12 Hz, even when this tremor is much smaller than

Table 2 Properties of tremor in healthy people

	Mechanical reflex	*Enhanced mechanical reflex*	*Central neurogenic*
Amplitude	Invisible or barely visible, not disabling	Less than 1 cm, may be disabling	Invisible or barely visible, not disabling
Frequency	A function of joint stiffness and inertia. Reduced by adding inertia to the limb	A function of joint stiffness and inertia. Reduced by adding inertia to the limb. Influenced by reflex arc length	8–12 Hz, does not vary with limb inertia or reflex arc length
Electromyogram	No motor-unit entrainment or synchronization	Motor-unit entrainment at the frequency of tremor	Motor-unit entrainment at 8–12 Hz
Treatment	Robotic aids	Robotic aids, β-adrenergic blockers	Robotic aids, β-adrenergic blockers

the mechanical-reflex oscillation. Participating motor units are entrained at 8–12 Hz, regardless of their mean firing frequency. Furthermore, the frequency of central-neurogenic tremor exhibits little or no change when inertial or elastic loads are attached to the limb, and the frequency of central-neurogenic tremor is independent of stretch-reflex loop time and muscle twitch properties. There is now fairly convincing evidence that the central-neurogenic tremor originates from an oscillation in the cerebello-thalamo-cortical loop.

Intention Tremor

Gordon Holmes noted that cerebellar 'tremor, which is sometimes apparent during the whole range of movement, is usually more prominent toward its end.' Holmes observed that 'the irregular oscillations in the intended direction result from failure of uniform deceleration, but this is complicated by secondary or correcting jerks when the object has not been accurately reached in the first attempt.' Consequently, distinguishing tremor from other features of ataxia (dysmetria, overshoot) is difficult and somewhat arbitrary in patients with cerebellar lesions.

The frequency of cerebellar tremor is commonly in the range of 3–5 Hz and is influenced by reflex arc length and by the inertia and stiffness of the body part. This influence of reflex dynamics and limb mechanics on tremor frequency is consistent with the notion that cerebellar tremor emerges from abnormal mechanical-reflex oscillation in somatosensory long-loop reflex pathways.

Intention tremor in the ipsilateral extremities occurs with lesions in the deep cerebellar nuclei or in their outflow tracts to the contralateral ventrolateral thalamus via the superior cerebellar peduncle. Thach and colleagues performed selective muscimol injections in the deep cerebellar nuclei of monkeys and found that inhibition of interpositus (globose emboliform in man) is the critical nuclear lesion in the production of tremor.

Normal limb movements toward a target are decelerated with a burst of antagonist muscle contraction so that the target is reached with little or no overshoot (dysmetria). This anticipatory deceleration is an example of feedforward motor control and is accomplished by cerebro-bulbo-cerebello-thalamo-cortical pathways. Loss of cerebellar feedforward control leads to delayed and inappropriately sized antagonist activity, resulting in target overshoot and limb oscillation. The cerebellum, based on prior experience (motor learning), is capable of predicting the amount and timing of deceleration (antagonist contraction) needed to land precisely on target. Cerebellar tremor appears to be due to an excessive reliance on feedback control, which results in abnormal mechanical-reflex oscillation in segmental and 'long-loop' transcortical and transcerebellar sensorimotor feedback pathways. The amplification of this oscillation by excitatory thalamocortical loops seems likely and would explain the dramatic reduction in cerebellar tremor that occurs with ventrolateral thalamotomy and deep brain stimulation (DBS).

Holmes Tremor (Rubral Tremor)

Holmes tremor is a striking combination of 2–5-Hz rest, postural, and intention tremor of an extremity. This unusual tremor is caused by lesions in the vicinity of the red nucleus: an observation that led to the name rubral tremor. However, isolated lesions in the red nucleus are not tremorogenic, and animal studies and clinicopathological studies in man have shown that combined damage to the neighboring cerebellothalamic and nigrostriatal fiber tracts is required. Consequently, Holmes tremor has become the preferred name for this tremor.

Holmes tremor usually begins weeks to months after brainstem trauma or stroke, and therefore, compensatory or secondary changes in nervous system function probably participate in tremorogenesis. Olivary hypertrophic degeneration is frequently present in patients with rubral tremor, due to the interruption of cerebello-olivary fibers. Thus, olivocerebellar oscillation may also play a role in tremorogenesis.

Reduced striatal ^{18}F-fluorodopa uptake is found in some patients with Holmes tremor. This finding explains why levodopa and dopaminergic agonists are occasionally beneficial. However, additional studies are needed to

determine if rubral tremor is merely a combination of parkinsonian rest and cerebellar intention tremors, or if rest tremor is produced by some other mechanism. Holmes tremor has been described in patients with cerebellar stroke and no apparent damage to the nigrostriatal pathway, and rest tremor and Holmes tremor have been reported in patients with thalamic strokes. Consequently, the rest tremor in some cases may be primarily due to compensatory changes in motor networks and is not the direct result of nigrostriatal deficiency. This notion is in keeping with the observation that other signs of parkinsonism are usually absent in patients with Holmes tremor.

Holmes tremor responds to stereotactic thalamotomy and DBS in ventralis intermedius (Vim), but its response to pharmacotherapy is usually nil. There have been no controlled trials, but there have been anecdotal reports of patients responding to dopaminergic drugs, clonazepam, propranolol, and levetiracetam.

Tremor Associated with Ventrolateral Thalamic Lesions

The development of tremor subsequent to a thalamic stroke has been known since the writings of Dejerine and Roussy in 1906, but the occurrence of tremor without other motor and sensory signs is rare. Lee and Marsden reviewed the published reports of 33 patients with movement disorders following isolated thalamic lesions. Only seven patients exhibited tremor in repose, posture, or movement, and all these patients had coexistent dystonia. However, there are case reports of rest tremor, intention tremor, and Holmes tremor following small ventrolateral strokes.

The development of tremor subsequent to a ventrolateral thalamic stroke seems paradoxical when one considers the efficacy of ventrolateral thalamotomy and DBS in the treatment of most forms of tremor. Of course, surgical thalamotomy and DBS are far more selective than thalamic infarction, and tremor following thalamic infarction is admittedly rare. In most instances, tremor developed weeks or months after thalamic infarction, and this delay suggests that neuroplasticity and network reorganization play an important role in tremorogenesis. The loss of cerebello-thalamo-cortical influence might lead to the excessive participation of cerebellobulbospinal loops, or surviving corticothalamic loops could become overactive, resulting in tremor. Furthermore, the extension of an infarct into the neighboring H fields of Forel could damage cerebellothalamic and nigrostriatal fibers, thus producing a variety of tremors.

Palatal Tremor (Palatal Myoclonus)

Palatal tremor was originally categorized as a form of myoclonus, but its rhythmicity clearly establishes that it is a form of tremor. In this condition, there is a repetitive elevation of the soft palate at 1–3 Hz. There are two forms of palatal tremor, symptomatic and essential, which differ clinically and pathophysiologically. *Essential palatal tremor* usually causes an annoying ear click but no other neurological signs or symptoms. The palatal movement and ear click are produced by a rhythmic contraction of the tensor veli palatini and are suppressed with botulinum toxin injection into the tensor veli palatini. Essential palatal myoclonus is not associated with the structural abnormalities of the brain. *Symptomatic palatal tremor* is produced primarily by a rhythmic contraction of the levator veli palatini and is frequently accompanied by synchronous movements of the eyes, face, pharynx, larynx, and diaphragm, and less commonly by movements of the extremities. It is usually associated with other signs of brainstem or cerebellar damage. It rarely causes ear clicks and is otherwise an asymptomatic sign of brainstem or cerebellar damage.

Symptomatic palatal tremor is produced by lesions, usually vascular, in the dentato-olivary pathway, which causes the secondary hypertrophic degeneration of the inferior olive. This olivary hypertrophy is visible with magnetic resonance imaging (MRI). The occurrence of olivary hypertrophy and palatal myoclonus usually follows a stroke by several weeks or more, although microscopic vacuolization of olivary neurons can be seen within 12–20 days.

The superior cerebellar peduncle contains dentate and globose-emboliform axons that project to the contralateral olive directly and indirectly, via several midbrain nuclei that include the parvocellular red nucleus. The nuclear axons in the indirect pathway are excitatory, while the axons in the direct pathway are inhibitory (GABAergic). These GABAergic neurons synapse near the electrotonic synapses between dendrites of olivary neurons, and the activation of GABAergic synapses probably decreases the coupling between olivary neurons. Since lesions in the superior cerebellar peduncle and dentate produce olivary hypertrophy, it seems likely that the loss of the direct pathway plays a major role in the pathophysiology of this condition. The loss of this pathway could produce increased neuronal coupling and could cause the olivary neurons to fire rhythmically at 1–3 Hz. However, this olivary hypothesis of palatal tremor is unproven and will probably remain so until a suitable animal model is developed and studied.

Essential Tremor and Familial Tremor

In classic essential tremor (ET), the upper limbs (>95% of patients), and less commonly, the head (at least 34%), face/jaw (~7%), voice (~12%), tongue (~30%), trunk (~5%), and lower limbs (~30%) exhibit a mixed postural and kinetic tremor without other neurologic abnormalities.

Patients with advanced ET exhibit intention tremor and impaired tandem walking. ET seems to be dominantly inherited in many large families, but there is increasing suspicion that polygenic inheritance (multiple genetic risk factors) may be more common than true autosomal dominant inheritance. A gene for ET has not been identified despite linkage studies of many large families with apparent autosomal dominant inheritance. In the cases of clear autosomal dominant inheritance, the term familial tremor is often used, but the characteristics of the tremor are the same as ET. Pharmacologic and electrophysiologic abnormalities are suggested by the variable response to ethanol, β-adrenergic blockers, primidone, and topiramate. The elucidation of these abnormalities, probably, will not occur until the underlying genetic defects or risk genes have been identified.

The fundamental electrophysiologic abnormality of ET is an abnormal entrainment of motor-unit firing at the frequency of tremor, which is typically 4–8 Hz. Many observations suggest that motor-unit entrainment emerges from oscillation in thalamocortical and olivocerebellar pathways. Lesions of the cerebellum, basis pontis, and thalamus have abolished or reduced ET. These observations are consistent with the notion that ET depends critically on the corticospinal tract and on cerebellar pathways projecting via the ventrolateral thalamus (Vim) to motor cortex. Louis and coworkers have found abnormally high numbers of axonal torpedoes in the deep cerebellar white matter and reduced numbers of Purkinje cells in the cerebellar cortex of patients with ET. PET studies of patients with ET revealed increased olivary glucose utilization and increased blood flow in the cerebellum, red nucleus, and thalamus. Finally, harmaline and related β-carboline alkaloids enhance the inhibition-rebound properties of olivary neurons and other neurons, causing increased rhythmicity and neuronal entrainment. The tremor produced by harmaline resembles ET.

Primidone, topiramate, and propranolol reduce tremor in many patients. Response to one does not predict response to the others, and their mechanisms of action in tremor reduction are unclear (see Beta Blockers, Essential Tremor).

Stereotactic thalamotomy and DBS in Vim are beneficial in the treatment of ET, but they are also beneficial in the treatment of Parkinson, cerebellar, rubral, and task-specific tremors. Vim receives inputs from the contralateral cerebellar nuclei and possibly from ascending somatosensory pathways, and it makes abundant reciprocal connections with motor cortex, from which tremor-correlated electroencephalogram (EEG) activity has been recorded. The Vim thalamocortical loop could amplify tremor of any origin.

Patients with ET and with ET combined with Parkinson's disease have responded to DBS in the subthalamus (STN). The critical target in this anatomically compact area is unclear, but is possibly the neighboring H field of Forel, which carries cerebellar and somatosensory afferents to the ventrolateral thalamus. Thalamic and subthalamic DBS probably suppress tremor by driving motor circuits at high frequencies to prevent pathologic low-frequency tremorogenic neuronal firing.

Parkinson Tremor

Rest tremor in the upper or lower extremities is the most specific feature of Parkinson's disease. Action tremor is common and is often an asymptomatic 8–12 Hz tremor, indistinguishable from an enhanced central-neurogenic component of physiologic tremor. Disabling action tremor is usually a re-emergent rest tremor or a coexistent ET. Recent magnetoencephalography (MEG) data by Timmermann and coworkers suggest that the 4–6 Hz oscillation of rest tremor is a subharmonic of the 8–12 Hz oscillation in sensorimotor cortex. Both forms of tremor have neurophysiological properties that are consistent with a central source of oscillation.

The principal site of tremorogenic oscillation is unknown. The cortical–basal ganglia–thalamocortical loop is prone to oscillation when dopaminergic nigrostriatal input is lost. Recent PET studies revealed an inverse correlation between presynaptic raphe 5-HT_{1A} binding and tremor severity, suggesting that the degeneration of the raphe nuclei may contribute to the expression of Parkinson rest tremor. Recordings during stereotactic surgery in Parkinson's disease reveal oscillatory neuronal firing in the ventrolateral thalamus, globus pallidus, and STN. Tremor-related oscillation in lateral premotor cortex, cingulate motor area, supplementary motor area, somatosensory cortex, and thalamus has been demonstrated with MEG.

The cerebellum is active in patients with Parkinson tremor, and MEG activity from the cerebellum is correlated with tremor in EMG and sensorimotor cortex. However, the cerebellum appears to be active in all forms of tremor, and the cerebellum is not necessary for the production of rest tremor.

Vim is the most effective stereotactic surgical site for treating Parkinson tremor, even though Vim receives inputs from cerebellum and ascending spinal sensory tracts and only a sparse input from the internal pallidum. The destruction of the posteroventrolateral internal pallidum or the STN is an effective treatment for tremor, but the thalamic receiving nucleus of the internal pallidum, ventralis oralis posterior (Vop), is not an effective target. These paradoxical surgical and anatomical data can be reconciled, to some extent, by noting that Vim and Vop are not completely segregated, and both nuclei project to and receive considerable input from supplementary and primary motor cortices. These over-lapping

corticothalamocortical projections could facilitate the entrainment of the pallidothalamic and cerebellothalamic pathways. Furthermore, spinothalamic inputs to VL overlap with the cerebellothalamic projections in Vim, and therefore, this thalamic nucleus could easily become entrained by any tremor, through sensory and cerebellar inputs. Finally, amplification within the thalamocortical loop in Parkinson's disease could contribute to the tremorogenic oscillation and entrainment of neurons throughout the cortical-basal ganglia-thalamocortical loop. Vim thalamotomy may simply preclude this amplification more effectively than Vop thalamotomy, because Vim projects more abundantly to motor cortex and receives somatosensory feedback from the periphery.

This discussion of Parkinson tremor illustrates the difficulty and perhaps futility in ascribing the origin of any tremor to a single nucleus of oscillating neurons. In Parkinson tremor, all parts of the cortical-basal ganglia-thalamocortical loop are involved, facilitated perhaps by their intrinsic oscillatory properties and interconnections. There is increasing evidence that Parkinson tremor emerges from the altered dynamics of this loop such that lesions in many locations are capable of suppressing tremor.

Neuropathic Tremor

Patients with acquired and hereditary peripheral neuropathies occasionally exhibit symptomatic 3–10Hz action tremors. Some patients with hereditary neuropathy have tremor that is indistinguishable from 6- to 8-Hz ET. Other patients exhibit an abnormal mechanical-reflex tremor that resembles enhanced physiologic tremor or cerebellar tremor. The frequency and amplitude of many neuropathic tremors bear little or no relationship to the degree of sensorimotor loss or the velocity of nerve conduction. Therefore, compensatory changes in the central nervous system, in response to distorted sensory input, are possibly tremorogenic. The cerebellum, in particular, has been implicated, but the details are far from clear. Central reorganization in response to altered peripheral sensorimotor function is hypothesized to cause the rare heterogeneous tremors that occur weeks to months after peripheral nerve trauma.

Focal, Dystonic, and Task-specific Tremors

Patients with *primary writing tremor* exhibit severe tremor during the act of writing, but there is no tremor during other activities. Isolated *tremors of the voice, chin, tongue, head, and smile* have also been described. These focal and task-specific tremors are analogous to focal and task-specific dystonias, and the prevailing opinion is that these focal and task-specific tremors are tremor-predominant dystonias with little or no dystonic posturing. Dystonic muscle contractions are commonly tremulous.

Orthostatic Tremor

Orthostatic tremor is an unusual postural tremor that develops in the lower extremities and torso within seconds of assuming erect stance, producing a sensation of unsteadiness. Electromyography of the lower extremities and torso reveals rhythmic bursts of motor-unit activity at 14–18 Hz, which is a uniquely high tremor frequency. This activity begins almost immediately upon standing and is usually symptomatic to the patient, but barely visible to the examiner. With continued standing, the frequency of body tremor may change into a 7–9 Hz subharmonic oscillation that is more symptomatic and visible. The same synchronous tremor occurs in the upper limbs if the upper limbs are used for support while standing (e.g., leaning on a table).

Patients may benefit from clonazepam, primidone, gabapentin, and possibly dopaminergic medications, but the response is often disappointing. The patient's complaints often exceed the visible signs of unsteadiness and tremor, and the disabling sensation of unsteadiness may be due to the tremulous disruption of somatosensory feedback.

A central source of oscillation is certain, given the high tremor frequency and synchrony of oscillation among the involved body parts. No other tremor exhibits bilateral synchrony in the upper and lower limbs.

The anatomy of this oscillator is unknown. Oscillation in the cranial musculature has been demonstrated, and therefore, a supraspinal source of oscillation is certain. Like many other tremors, orthostatic tremor is associated with increased cerebellar blood flow as measured with $H_2{}^{15}O$ PET, and the phase of orthostatic tremor is reset by transcranial electrical stimulation over the posterior fossa, but not by transcranial magnetic stimulation over the motor cortex. Thus, the cerebellum and bulbospinal pathways appear to play an important role in tremorogenesis.

Cortical Tremor (Rhythmic Cortical Myoclonus)

Cortical tremor is an irregular 7–14 Hz action tremor that resembles ET and occurs in patients with cortical myoclonus. Many patients also exhibit major motor seizures and myoclonus, and have a family history of these disorders with tremor. The tremor in asterixis is probably a form of cortical tremor, and therefore, cortical tremor is common in patients with metabolic encephalopathies. Enhanced C-reflexes and giant sensory evoked potentials

occur in many patients and are consistent with the presence of enhanced cortical excitability. An EEG transient preceding the EMG bursts of cortical tremor has been demonstrated with EEG back averaging. Therefore, cortical tremor is actually a rhythmic cortical myoclonus at 7–14 Hz. Clonazepam and other medications for cortical myoclonus are often beneficial (see Cortical Myoclonus).

Drug-induced Tremor

Many drugs produce parkinsonian rest tremor (neuroleptics, metoclopramide, dopamine-depleting drugs), action tremor (β-adrenergic agonists, valproic acid, lithium, thyroxin, tricyclic antidepressants, and methylxanthines), and combinations of rest, postural, and kinetic tremors (lithium, amiodarone, and valproate). Parkinsonian tremor is produced by dopaminergic blockade (neuroleptics, metoclopramide) or depletion (reserpine). Extrapyramidal toxicity underlies amiodarone-induced tremor, and enhanced mechanical-reflex oscillation occurs with β-adrenergic agonists, valproic acid, lithium, thyroxin, tricyclic antidepressants, and methylxanthines. Enhanced cortical irritability is considered the primary mechanism underlying lithium and valproate-induced tremors. Amiodarone- and lithium-induced tremors are particularly noteworthy, because they are occasionally irreversible. Persistent lithium-induced tremor and ataxia are caused by neuronal loss and gliosis of the cerebellar cortex and dentate nuclei.

Drug-induced tremor must be distinguished from an undiagnosed tremor disorder (e.g., ET, Parkinson's disease) that is exacerbated by a drug. A complete withdrawal of the drug and long-term follow-up are often needed to make this determination.

Psychogenic Tremor

There are two basic types of psychogenic tremor: co-contraction type and coherent type. These two forms of psychogenic tremor are equally common, and electrophysiology is useful in their diagnosis.

In the co-contraction type, patients consciously or subconsciously coactivate the muscles of the affected body part. In the hands, one typically sees a 7–10 Hz tremor that is independent (not synchronous) of tremor in the contralateral limb. This tremor is associated with an abnormally increased tone that is produced by the coactivation of the forearm muscles. A passive manipulation of the wrist reveals that the amplitude of tremor is proportional to the degree of coactivation ('coactivation sign'), and the tremor stops during interruptions in coactivation.

The coherent type is produced by a conscious or subconscious rhythmic movement of the affected joint. The tremor frequency is usually about 6 Hz or less, because voluntary rhythmic movement at higher frequencies is extremely difficult and exhausting. People with this form of psychogenic tremor cannot rhythmically move the same or contralateral extremity at a different frequency, except at subharmonics of the tremor frequency. Attempts to do so result in an abrupt change in the tremor frequency to the frequency of voluntary movement (entrainment), or the tremor abruptly stops during the voluntary movement. During entrainment, the tremor and voluntary movement become synchronous (coherent).

Glossary

Familial tremor – This term for inherited tremor is often used interchangeably with 'essential tremor (ET),' or combined as in 'familial ET'; however, ET cases with no clear tremor family history are well reported (generally 30% of study cohorts), and a positive family history is not required for ET diagnosis, so this frequently used term does not capture a current movement disorders entity.
Intention tremor – Intention tremor implies a distinct increase in tremor amplitude at the endpoints of targeted visually guided movements; this is a subtype of kinetic tremor by Movement Disorders Society consensus definitions.
Kinetic tremor – Tremor occurring with any type of voluntary movement including nontargeted, visually guided or nonvisually guided.
Physiological tremor – Tremor that occurs normally in any area/joint that can oscillate, and may enhance in many conditions (medications, pregnancy, metabolic disorders) or situations (anxiety, stress); the low amplitude high frequency (8–12 Hz) upper extremity form, especially enhanced physiological tremor, can be indistinguishable from mild ET.
Postural tremor – Tremor occurring with voluntarily held postures against gravity.

Definition and History

Tremor descriptions date back to Ecclesiastes XII:3, and ancient India and Egypt. Galen's writings specifically describe kinetic tremor. The term 'essential tremor' (ET) was developed in the 1800s to describe kinetic, usually familial tremor; the medical term 'essential' indicated unknown cause.

Tremor is an involuntary rhythmic oscillatory movement. ET is defined as persistent bilateral hand/arm tremor occurring with voluntary action or posture. The head/neck (most commonly), voice, legs, or other areas may also be affected. Head tremor without limb tremor is accepted as ET, although this definition remains uncertain as isolated head tremor is a manifestation of cervical dystonia among other disorders. Definite, probable, possible ET categories are used in research, not clinically. Duration over 3 years, positive family history, and positive alcohol response are considered supporting criteria.

This deceptively simple definition belies the diagnostic challenges. Mild or even severe ET is often incorrectly dismissed as normal aging. The old conception of tremor as a trait rather than a treatable pathologic state persists in ET families and the medical community. Tremor self-reporting and community diagnosis rates are notoriously low. These issues impact all ET aspects, from epidemiology to management.

Tremor Characteristics

Kinetic tremor is the most recognized ET form. Postural tremor may also define ET. Intention tremor implies an amplitude increase at targeted movement endpoints; this kinetic tremor subtype occurs in ET, but is not required for diagnosis. Tremor amplitude may vary with posture or movement trajectory. Frequency ranges from 4 to 12 Hz, typically 4–8 Hz, especially in older individuals and with tremor progression.

Rest tremor without Parkinson's disease (PD) occurs in ET, notably in long-standing severe ET: rest tremor is less severe than kinetic/postural.

ET is usually slowly progressive. Longstanding mild hand tremor may rapidly change into significant ET later in life. Tremor can progress in amplitude, plus spread to more areas. While current definitions stress bilateral tremor, severity may be asymmetric, and many ET descriptions note unilateral onset with subsequent spread to both upper extremities.

Severity and Disability

ET tremor severity may vary by day or hour, and can create significant disability. Kinetic limb tremor can compromise eating, drinking, and handwriting (**Figure 1**). Vocal tremor may limit communication or social activities. Even mild limb tremor affects work skills, causing job loss or preventing promotions. Functional impairments, from objective skill change to social embarrassment, are important factors in ET treatment decisions.

Age of Onset and Family History

ET manifests at any age, including childhood and (rarely) infancy. In population-based studies, onset peaks in later decades. Patients often reported the age tremor became

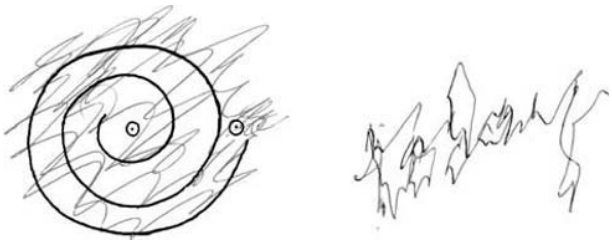

Figure 1 Writing sample from an ET research participant on maximum medical therapy for tremor. Attempt to draw within the lines of a spiral figure using right (dominant) hand, and write 'today.'

bothersome as age of onset, noting 'nervousness' or mild tremor from a younger age. Familial ET has generally earlier onset than sporadic, but onset varies widely within families. About 60% of ET subjects self-report positive tremor family history.

Exacerbating and Remitting Factors

Tremor increases with stress, fatigue, anxiety, and excitement. Caffeine may increase tremor, although a formal study of caffeine in ET showed no effect.

Ethanol ameliorates tremor in up to 75% of ET patients. Alcohol response is heterogeneous within families. Ethanol likely decreases tremor through a central mechanism. The effect, while more common than in other disorders, is not sensitive or specific enough for diagnosis.

Nontremor Features

ET is defined as a monosymptomatic tremor disorder. Still, some nontremor signs are long recognized. ET causes measurable, sometimes significant balance and gait impairments, independent of tremor site (head or not) and severity. Alcohol ingestion improves, not worsens, ET gait.

Minimal parkinsonian signs without PD are frequently reported – mild tone changes, cogwheel rigidity, and mild arm swing decrease. Severe kinetic tremor may break up fine motor tasks.

Controversial ET Subsets

Attempts to subclassify ET using tremor characteristics, treatment responses, and family history combinations have not yielded consistent categories, reinforcing the concept of ET as one clinical entity. However, dividing ET into classic and 'complicated,' usually ET/parkinsonism or ET/dystonia, dates back to at least the 1800s. Associations with dystonia and parkinsonism pervade ET genetics, pathophysiology, and diagnosis. Many argue for focusing on monosymptomatic classic ET to best move research forward. Alternatively, nontremor characteristics or ET subsets may indicate the range of underlying ET pathophysiology. Current evidence favors separating ET from dystonia and considering ET/parkinsonism within ET, but this is far from a consensus view. Sections below discuss classic ET, with relevant data on dystonia and parkinsonism.

The Evolving Range of ET

Cognition and mood

Cognitive symptoms in ET are increasingly recognized. Most reports focus on mild cognitive impairment, particularly in executive function and memory. Deficits closely overlap with observations in PD. One group reported increased dementia incidence and prevalence in ET, particularly tremor onset at the age of 65 and above. The extent and frequency of cognitive impairment in ET remain unclear.

Mood disorders may reflect primary ET neuropathology, secondary reaction to tremor, or shared predispositions for ET and other distinct disorders. Higher anxiety scores, harm avoidance, and social phobia rates are reported in ET versus controls. Strikingly, these findings are independent of tremor severity. Depression may be frequently comorbid in ET, as in PD.

Executive dysfunction, apathy, and depression, each predict poorer perceived health status in ET. Social phobia correlates with disability level. Thus, understanding cognitive and mood disorders in ET is crucial to improving treatment outcomes.

Special senses

ET subjects in one cohort had higher hearing disability than PD or controls. In another, hearing-impaired subjects were 30% more likely to have ET than controls. Families with coinherited sensorineural hearing loss and ET are reported.

Unlike in PD, olfaction is usually normal in ET. Olfaction testing scores in ET, even ET with rest tremor, are higher than in PD. However, one group observed mild olfactory deficits in ET versus controls, an intriguing, but disputed finding.

Potential comorbid conditions

Most proposed associations of ET with other common conditions have not held up. Currently, restless legs syndrome and migraine are each strongly associated with ET in isolated prospective studies. There are reports of clearly coinherited ET and migraine.

There are case series describing frequent ET within Klinefelter's syndrome. A recent controlled study observed a strong association between Klinefelter's syndrome and self-reported tremor. A high rate of intention tremor is also reported in XYY males.

Epidemiology

Prevalence, Incidence, and Mortality

The reported ET prevalence range is huge, narrowing to 0.4–4% when confined to community-based studies that specify ET definition. The highest estimates occur when neurologists directly examine all subjects – 4% at the age of 40 and above and up to 22% at the age of 95 and above.

Incidence and mortality data are scarce. One retrospective study (US) reported 23.7 cases per 100 000. The only prospective study (Spain) observed 616 cases per 100 000 person-years; the higher number is likely due to undiagnosed cases missed retrospectively. ET is assumed to have no impact on lifespan; however, limited prospective data suggest a mildly elevated mortality risk in ET.

Age and Gender

Age is an ET risk factor; prevalence increases with increased age.

ET prevalence and incidence are roughly equal in men and women, although some studies observe a higher prevalence in men. Voice and head tremor occur more often in women. Some studies report an association between childhood onset and male gender.

Ethnicity

ET is reported in many ethnic groups worldwide. Widely variable methodologies hinder comparisons across studies. Very few studies report on different ethnicities within a geographic population. A large Singaporean study observed higher ET prevalence in ethnic Indians than Chinese, and no Malay ET cases. A US survey (23 842 persons, 49% black, 50% white) found a slightly higher age-adjusted prevalence ratio for ET in whites versus blacks. One other US study observed some tremor characteristic differences between small groups of white, African–American and Hispanic ET subjects, and higher odds of ET in Hispanics.

Environmental Risks

Data on ET environmental risks are limited. One case-control study observed an association between ET and agricultural work; however, unlike in PD, a correlation between pesticides and ET is not observed. Blood lead concentrations were higher on average in ET versus controls in two small studies.

Mean log blood concentrations of the β-carboline alkaloid harmane were higher in ET than controls in one cohort. β-Carbolines are endogenous in brain; exogenous sources include dietary meats. Elevated plasma harmane levels are also reported in PD and alcoholism. Tobacco smoke is a β-carboline source, and plasma norharman is elevated in smokers. However, one group reported lower ET incident risk among heavy smokers and an inverse association between ET and smoking level. Harmaline toxin model use (below) lends importance to clarifying β-carbolines' roles, if any, in ET.

Genetics

There is varied and convincing evidence that much of ET is inherited in an autosomal dominant fashion. Twin studies support a large role of genes over environment in ET. In one study, pairwise concordance in monozygotic twins (0.60) was about double than that in dizygotic twins (0.27). In another, including only probable and definite ET cases, concordance rates were 0.93 monozygotic and 0.29 dizygotic, putting the heritability for potential ET development at up to 99%.

There are three distinct reported susceptibility loci linked to autosomal dominant ET: ETM1, chromosome 3q13, identified in Icelandic families with definite classic ET; ETM2, 2p24, first linked in a US family; and a 6p23 region linked in North American families with ET and dystonia, but not families with classic ET alone. More loci await identification: ETM1 and ETM2 have been excluded in other genetically informative families.

The first reported ET-associated genetic variation, 828C→G in the HS1 binding protein 3 gene (*HS1-BP3*), is within ETM2. Subsequent negative data argue for a restricted role (close linkage disequilibrium with a causative mutation) or no association.

Within ETM1, the dopamine D3 receptor gene (*DRD3*) 312A→G variant was associated with the age of onset and disease severity in French and US samples. Several replication studies did not observe an association between *DRD3* variants and ET risk or onset age, or linkage with *DRD3* in ET families. *DRD3* is probably not involved in ET genetic pathophysiology.

A recent genome-wide analysis observed association with markers in the leucine-rich repeat neuronal 6A gene (*LINGO1*) using an Icelandic plus multiple confirmatory ET cohorts. LINGO1 has possible links to ET cerebellar pathology (see text below).

Several candidate mutations were considered based on ET phenotypic overlaps. Fragile X associated tremor ataxia syndrome causes intention tremor, gait ataxia, and parkinsonism. However, studies show no role for the *FMR1* premutation in ET. Spinocerebellar ataxia type 12 (SCA-12) presents with kinetic tremor; indeed, affected SCA-12 family members are often initially misdiagnosed as ET. Kinetic tremor occurs less frequently in other SCAs. ET cohort screens have not yielded unexpected SCA mutation rates. Linkage to DYT1 (autosomal dominant dystonia) was negative in two independent studies, and the dystonia-causative 946–948delGAG deletion was absent in other ET families.

There are reports of ET (not PD) phenotypes observed with PD-causative *LRRK2* (encoding leucine-rich repeat kinase 2/dardarin), *SNCA*, and *parkin* mutations; however, these observations do not occur in larger ET surveys. ET/parkinsonism is reported in some kindreds, while PD and ET are linked to separate loci in others. One study observed an association between the length of a mixed dinucleotide repeat sequence (REP1) in *SNCA* (α-synuclein gene) and both ET and PD. However, we detected only a mild association for REP1 allele lengths with ET in our US cohort. The only other reported ET *SNCA* study did not observe an association between ET risk and *SNCA* haplotypes.

Inherent ET features complicate genetic studies. High age-related prevalence and multiple susceptibility loci both increase possible phenocopies. Inaccurate tremor and family history self-reporting impact phenotype assignments. Current data still indicate that clinically defined ET is a genetically heterogeneous disorder: multiple genetic loci contribute to similar phenotypes.

Pathophysiology

Electrophysiological data support a central tremor generator in ET. Early speculation on ET neuropathology suggested cerebellum and basal ganglia. The current consensus strongly favors cerebellar pathway dysfunction, but evidence continues to implicate both. Until recently, neuropathology data were surprisingly scarce.

Intention tremor, while not always present, is a classic cerebellar finding. ET gait abnormality is similar to cerebellar-based ataxia. Some authors see the pattern of cognitive findings in ET as evidence for cerebello-thalamo-cerebral dysfunction. Functional imaging ET studies show increased activation of and metabolism in cerebellar pathways, most consistently cerebellar cortex and red nucleus. An olivocerebellar tremor generator remains the popular hypothesis based on the preponderance of data.

Anatomical imaging techniques argue against gross cerebellar degeneration, but suggest cerebellar damage. Gross brain pathology is generally normal; however, most ET cases have cerebellar neuropathology including Purkinje cell loss and torpedos.

Other data suggest ties to basal ganglia disorders. Although dystonia is a classic ET exclusion criterion, the 6p23-linked families have affected members with tremor and dystonia or ET without dystonia. Rest tremor and mild parkinsonian signs are accepted in ET. Overlaps between ET and PD cognitive deficit patterns argue for similar underlying neuroanatomy.

A significant minority of ET cases is reported with Lewy bodies (non-PD distribution, locus ceruleus). α-Synuclein is the major component of Lewy neurites and bodies, the PD pathological hallmarks. *SNCA* variants represent a biologically plausible way to confer altered α-synuclein disease susceptibility; however, ET genetic studies yield mixed results (see earlier text). One pathological series reported locus ceruleus degeneration in noncerebellar ET but no significant difference in Lewy body pathology between ET and controls.

A phenotypic continuum of dystonia, ET, and parkinsonism may reflect the relative degree and type of underlying cerebellar versus brainstem/basal ganglia pathology, in completely distinct or mechanistically related disorders. The strongest ET data implicate cerebellar dysfunction but, taken together, recent findings demonstrate that ET may be pathologically as well as genetically heterogeneous.

Model Systems

There is no clear ET animal model. γ-Aminobutyric acid A receptor α1 knockout mice have alcohol-responsive tremor and cerebellar dysfunction; however, there are no corresponding genetic mutations in human ET.

Harmaline toxicity in mammals is a cerebellar tremor model; however, studies indicate direct effects on basal ganglia as well. Harmaline acts on many different neurotransmitter and ion channel systems, with unknown primary tremorogenic mechanism. Screening ET therapeutics against harmaline rodent models yields mixed results. Propranolol, ethanol, and 1-octanol improve harmaline tremor, but primidone does not. Mefloquine suppresses harmaline tremor in mice, but not humans. Harmaline model data should be interpreted cautiously.

Differential Diagnosis

Other Causes of Similar Tremor

Some level of involuntary oscillation, physiological tremor, is normal. It may be impossible to distinguish mild ET from enhanced physiological tremor. This is of limited clinical concern, but crucial for research. Electrophysiological data from young individuals at risk for ET support the concept that mild ET and physiological tremor are distinct entities; physiological tremor is not a precursor of ET.

Many drugs can cause or exacerbate ET-like tremor, including antidepressants, antiepileptics, antiarrhythmics, immunosuppressants, chemotherapeutics, hormones, antiasthma agents, and stimulants. Common causes (high percentage of tremor in users) include lithium, valproic acid, amiodarone, tacrolimus, and β-adrenoceptor agonists. Withdrawal of drug may be necessary to distinguish between medication-induced tremor and exacerbated ET. If this is not practical, the time line for tremor versus

medication is crucial, and supporting ET criteria (e.g., family history) may be useful.

Multiple systemic metabolic disorders cause tremor. Hyperthyroidism is particularly common, especially in older populations. Thyrotoxicosis often causes tremor indistinguishable from enhanced physiological tremor, and thus, mild ET.

Isolated action-specific tremors such as primary writing tremor and orthostatic tremor are considered separate from ET.

Misdiagnoses Versus Clinical Overlaps

Psychogenic disorders and ET

Tremor is a common purely psychogenic entity. Sudden onset, disappearance with distraction, and spontaneous remissions favor a psychogenic tremor diagnosis. However, ET patients may present with ET symptoms plus psychosomatic overlay. Clearly defining which symptoms represent ET versus psychogenic is critical to successful treatment. Our center has successfully treated ET with medications or even surgery while addressing psychosomatiform symptoms with psychology (panic-like tremor attacks), physical therapy (knee-buckling, cautious gait), and speech therapy (nonphysiological voice changes).

Diagnostic controversies: Dystonia and PD

ET is a misdiagnosis in up to 30–50% of cases (depending on ET definition). The most common alternative diagnoses are PD and dystonia. Conversely, ET is frequently misdiagnosed as PD.

Nonclassic ET with dystonia is currently thought to represent dystonia (although see Genetics and Pathophysiology above). In contrast, ET plus PD, PD/ET misdiagnoses, and disputed ET/parkinsonism subsets are all possibilities. Views on dystonia, parkinsonism, and ET will likely shift with future data.

There are numerous reports of ET preceding PD onset, and higher than expected frequencies of ET in PD patients' relatives and PD patients themselves, but the data are inconclusive. Whether ET/parkinsonism subsets exist will be debated until defining biomarkers are available. Current practice accepts ET with mild parkinsonism as ET, but recognizes patients can have both ET and PD. Diagnoses of ET, parkinsonism, and PD will necessarily overlap and should be skeptically, frequently reassessed.

Diagnostic Work up

The interview includes tremor characteristics, tremorogenic medication exposures, treatment responses, and functional impact. Probing for full duration may reveal longstanding 'nervousness.' Nonresponse to dopaminergic agents helps uncover PD misdiagnosis. Family history includes specific questions for ET, tremor, PD, and dystonia. Clinical and family history for alcoholism are prudent to distinguish mild self-medication with alcohol from abuse.

Tremor examination includes rest, postures (arms outstretched and wing-beating, knee extended/ankle dorsiflexed), and action (finger-to-nose, foot floor-to-hand, jaw clench, head turn). Writing and drawing are key exam components. ET spirals and writing demonstrate tremor but not micrographia. Bias of kinetic/postural tremor over milder rest tremor also distinguishes ET from PD. Voice is assessed with speaking and sustained vowel sounds.

Tremor rating scales provide reproducible exam structures, albeit subjective and nonlinear ones. Interrater reliability is good for upper extremity tremor but poor for writing/drawing. An objective tremor measurement like digitized spiral analysis may, therefore, be of particular value. Detailed electrophysiological tremor characterization may best classify ET versus others, but is impractical in most settings.

Attention to nontremor features is important. Tandem gait testing best reveals ET-related imbalance. A check for unrelated conditions (e.g., peripheral neuropathy) that further impair balance helps assess functional severity of gait impairment. Questioning for neuropsychiatric and cognitive symptoms, and consideration of formal neuropsychologic testing, are recommended.

Abnormal posturing of the head/neck, scalloping hands, or any other dystonia signs is exclusionary for ET. Use of a geste antagonistique (sensory trick) argues for dystonic head tremor, not ET.

A possible ET diagnosis generally assumes toxic/metabolic conditions are eliminated. Laboratory and other tests may eliminate alternative causes of nonclassic presentations, such as sensory ataxia, Wilson's disease, and stroke-induced tremor. There are no tests for ET, a clinical diagnosis. There are no ET genetic tests, and features vary widely within families; there are no prognostic algorithms for at risk subjects.

Management

There are no ET disease-modifying agents. Treatment plans center on weighing ET functional impact against tremor suppression treatment downsides. Management, therefore, requires attention to patient and family education. Education about clinical diagnoses is also crucial; many patients carry a misdiagnosis for years.

Tremor Suppression

Medications

Primidone and propranolol

Propranolol and primidone are the most widely used tremor suppressants, and the only level A evidence agents for ET. Both can reduce limb tremor by 60% or more, but

each is effective in ~50% of cases. Response of vocal tremor to either agent is mixed at best.

Primidone is well tolerated chronically, but can produce acute severe vertigo, nausea, ataxia, and confusion at initial doses of 50 mg or more. To avoid: start primidone at an extremely low dose, 12.5 or 25 mg, at bedtime for a week, and increase slowly to effect, intolerance, or a low initial 150 mg dose. Further increases can split doses two or three times a day, biasing larger doses to evening to avoid sedation. Maximum dose is 250 mg three times a day, with little symptomatic gain over 250 mg twice a day.

Long acting (LA) propranolol may be more effective than short acting. Start at 80 mg LA once a day or 10 mg a day for short acting, then slowly increase as needed and tolerated. Most patients benefit at 120 mg a day or lower. Side effects often relate to lowered pulse rate and blood pressure: fatigue, orthostatic hypotension. Patients should be altered to infrequent, but possible side effects of depression and impotency. Relative contraindications include heart block, heart failure, asthma, and diabetes mellitus.

Primidone and propranolol appear equally effective compared to placebo. They are frequently combined to increase tremor suppression, although combination efficacy is untested. There is no evidence for choosing one over the other to start. Given the range of propranolol contraindications, primidone may be easier initially (with care to avoid acute side effects). Propranolol's anxiolytic or antihypertensive effects may add benefit. Because ET treatments are not disease modifying, intermittent medication use to suppress tremor only when needed is an option. Short acting propranolol may be particularly effective in this setting.

Other Available Agents

Interestingly, no other β-blocker has Level A evidence for tremor suppression, despite numerous studies. β-Blockers at Level B or C include atenolol, sotalol, and nadolol. Metoprolol was a preferred alternative to propranolol, but class I data on its effectiveness are conflicting. Pindolol may actually cause tremor.

Topiramate may be effective. Adverse effects of topiramate include altered cognition. Study doses were ~300 mg total a day; many patients respond at much lower doses. Gabapentin also has Level B evidence, although with some contradictory results. There is a recent small positive report on pregabulin, now in active clinical trials.

Alprazolam is a Level B agent. Benzodiazepines may be most helpful in ET with anxiety; however, benzodiazepines worsen imbalance. Clonazepam has Level C evidence, but its long half-life is sometimes preferred.

There are numerous reports of medications improving ET tremor, with no or contradictory expanded data. For example, carbonic anhydrase inhibitors are no longer recommended in ET.

Experimental Therapeutics

The alcohol 1-octanol and dimethoxymethyl-diphenyl-barbituric acid (T2000) each improved tremor in small double-blind placebo-controlled trials. The antiepileptic carisbamate is also being tested in ET.

Ethanol

Ethanol often dampens tremor, as many patients discover; given dependency issues and other side effects, this is not a viable treatment recommendation. Most of the limited direct evidence shows no increased alcohol abuse in ET compared to the general population, although this is a recurring concern. Thus, while ethanol is not recommended as a treatment, there is no compelling reason to discourage its moderate use.

Botulinum Toxin

ET vocal tremor can be treated with botulinum toxin chemodenervation. Vocal tremor may involve a wide range of muscles; thus, flexible fiberoptic laryngoscopic exam is recommended. Efficacy varies; 40–65% show objective improvement, but up to 80% experience subjective improvement. Head tremor may also respond well to botulinum toxin. Potential side effects include dysphagia and neck weakness. Note while botulinum toxin is often used and may have a marked impact, it is a Level C agent based on aggregate data.

Botulinum toxin for upper extremity tremor yields mixed results, limited by hand and arm weakness.

Deep Brain Stimulation and Stereotactic Lesion Surgery

Thalamic deep brain stimulation (DBS) and stereotactic lesion surgeries effectively reduce limb tremor. Surgery is generally reserved for refractory tremor, when treatment benefit outweighs surgical risks. Both procedures yield immediate and sustained benefits. The established target is the thalamic ventral intermediate nucleus; new data suggest zona incerta DBS is as or more effective. DBS is now preferred over thalamotomy due to somewhat fewer side effects and stimulator adjustability, but there is little compelling evidence for one procedure over the other. Bilateral procedures control tremor in both upper extremities; there is no clear evidence for synergistic effects after bilateral procedures. There are case reports of bilateral thalamic DBS providing excellent benefit for ET vocal and head tremor, but results are mixed.

Surgical procedures carry a low risk of severe adverse events like stroke and hemorrhage. Long-term safety is generally good. Long-term side effects including dysphagia and imbalance are particular issues in bilateral procedures. These may be ameliorated in DBS with stimulator adjustment. There are few data on possible long-term nonmotor benefits or side effects.

Other Modalities

Occupational therapy, including weighted utensils and computer mouse tremor-suppression devices, is of anecdotal benefit. Physical therapy can address functional mobility and balance deficits. Walking is strongly recommended for maintaining balance. Both medication and nonmedication modalities can be effective for mood disturbances.

Tremor, Essential: Genetics

J J Higgins, Weill Cornell Medical College, NY, USA

Definition and History

Tremor is defined as a rhythmic oscillation of the upper extremities, or other body part, that is present at rest, the performance of an action, or during the maintenance of a posture. In addition, modern clinicians describe tremors by their oscillation frequency, aggravating factors, associated medical conditions, family history, and clinical findings on a neurological examination. These features are used to classify different types of tremor as physiological, essential, dystonic, parkinsonian, cerebellar, basal ganglia, palatal, neuropathic, toxic, or psychogenic tremor.

Tremor was recognized as a malady by the ancient Indians, Egyptians, Hebrews, Greeks, and Romans.

The distinction between a resting and action tremor is credited to the Greek physician, Galen of Pergamon, who lived between 130 and 200 AD. It was not until 1836 that C. F. Most recognized that tremor could be inherited. Half a century later, Charles L. Dana, an American physician, described the clinical characteristics and the inheritance pattern of the common type of tremor that we presently know today as hereditary or familial tremor. Two Italian medical professors, Pietro Burresi and Edoardo Maragliono, introduced the adjective 'essential' to the medical literature in 1874 and 1879, respectively. The term gained popularity at the turn of the twentieth century to delineate essential tremor (ET) from other types of tremors by its inherited, constitutional, and monosymptomatic nature.

Epidemiology

ET is a common movement disorder with prevalence rates ranging from 3.1% to 4.8% in epidemiological studies conducted between 2003 and 2005. The estimated incidence of ET is 17.5 cases per 100 000 persons annually with a higher adjusted rate of 616 cases per 100 000 persons annually in populations over the age 65. Frequency estimates of the familial aggregation of ET vary between 17% and 100%. First-degree relatives of individuals with ET have a higher risk of developing the disorder at an early age. Epidemiological studies show an association between ET and exposure to certain environmental factors such as the β-carboline alkaloids.

Clinical Features and Diagnostic Criteria

The cardinal clinical feature of ET is the presence of a postural tremor in the upper extremities with an oscillation frequency of 6–12 Hz. Other neurological abnormalities are absent in ET. A tremor is present in both upper limbs in ~95% of patients. The head (34%), tongue (30%), lower limbs (30%), voice (12%), face (5%), and trunk (5%), are involved less commonly. ET is a progressive disorder that often interferes with the quality of life by causing a functional impairment in daily living activities, social functioning, and employment.

The assignment of the correct phenotype in genetic studies is difficult because there are no validated clinical tests or scales to diagnose ET. Misdiagnoses are common because the clinical characteristics of tremor are not specific to ET. Tremor can be the presenting sign in other neurological conditions such as Parkinson's disease (PD), hereditary spinocerebellar ataxias (SCAs), dystonia, and the fragile X-associated tremor/ataxia syndrome (FXTAS). The rating scales clinicians use to evaluate ET include the criteria developed by the Tremor Investigator Group (TRIG), National Institutes of Health Essential Tremor Consortium, the Consensus Statement on Tremor by the Movement Disorder Society, and the Washington Heights-Inwood Genetic Study of ET (WHIGET). The affected phenotype in genetic studies is assigned to individuals with abnormal action tremor of both upper limbs or an isolated head tremor in the absence of abnormal posturing, dystonia, and other neurological signs. The hand tremor must be rhythmic and present in multiple activities with an amplitude of at least 1–2 cm. The accuracy of genetic studies may improve by incorporating quantitative measurements such as motion transducers into the clinical rating scales.

Inheritance

ET occurs as a sporadic or an inherited trait. The variable concordance rates between 60% and 93% in monozygotic twins with ET suggest that genetic, as well as environmental factors are operational in the pathogenesis of the disorder. An autosomal dominant (AD) pattern of inheritance is often seen in family pedigrees with ET. Transmission of ET to offspring is more than 50% that is expected for a dominantly inherited mutant allele. Incorrect phenotyping or genetic heterogeneity may explain the high ratio of affected to unaffected offspring. The disease penetrance of ET may be incomplete even at advanced ages.

Family Linkage Studies

Genetic studies on families where ET is presumably inherited as an AD trait find a high likelihood of linkage between ET and genetic loci on chromosome 3q13 (ETM1), 2p22–p25 (ETM2), and 6p23 (ETM3). The ETM1 and ETM2 loci have been excluded or have not reached statistical significance for genetic linkage in at least 13 large families with ET from the United States, Italy, and Tajikistan. Two candidate genes in the ETM1 and ETM2 regions that are involved in dopamine signaling and regulation, the *dopamine D3 receptor gene* (*DRD3*) and the *hematopoietic-specific protein 1 binding protein 3 gene* (*HS1BP3*), are identified as potential causes of ET, but are not confirmed in other studies. Genetic mutations are not found in the coding regions of 15 genes within the ETM3 candidate region. The search for a specific genetic cause for ET has been difficult due to confounding factors such as genetic heterogeneity and the presence of other conditions that mimic ET (i.e., phenocopies).

ETM1

In 1997, the ETM1 susceptibility locus for ET was mapped to chromosome 3q13 in 75 affected individuals from 16 Icelandic families. A variant (serine-9-glycine) in one of the genes [*dopamine D3 receptor gene* (*DRD3*)] within the ETM1 region is associated with ET in French and American families. Individuals homozygous for the *DRD3*

gene variant (glycine-9) are reported to have an earlier onset and a more severe ET phenotype. Experiments using cultured human embryonic kidney cells transduced with the glycine-9 *DRD3* gene variant show a greater dopamine affinity, an increased dopamine-mediated cyclic adenosine monophosphate (cAMP) response, and a prolonged mitogen-associated protein kinase signal. The *DRD3* variants reported in American and French families are not associated with ET in other family cohorts from the United States, Italy, Latvia, or Singapore. The relationship between *DRD3* homozygosity and an earlier age of ET onset and severity was not confirmed in other studies.

ETM2

In 1997, the ETM2 susceptibility locus for ET was mapped to chromosome 2p25–p22 in a large American family of Czech descent with 15 affected individuals in four generations. Genetic association studies in American, Singaporean, and Korean populations show that the ETM2 locus is in linkage disequilibrium with a disease gene for ET. A heterozygous polymorphism (alanine-265-glycine) in a gene within the candidate region, the *hematopoietic-specific protein 1 binding protein 3 gene* (*HS1BP3*), is associated with ET in 16.4% of 73 singleton families from the United States. This finding was not confirmed in other studies.

ETM3

In 2006, a third susceptibility locus for ET, ETM3, was mapped to chromosome 6p23 in one large North American family with 14 affected individuals in five generations with tremor and a form of dystonia called writer's cramp. An additional genetic disorder, malignant hyperthermia susceptibility, caused by a missense mutation in the *ryanodine receptor 1 gene* (*RYR1*) was also present in this family pedigree. This trait segregated independently from the tremor and dystonia phenotype. A second family with a pure ET phenotype was marginally linked to the same locus. Sequencing the coding regions of the 15 genes within the ETM3 candidate region did not identify mutations.

Cytogenetics

Tremor has been associated with numerical abnormalities and mutations of the X and Y chromosomes. Supernumerary X and Y chromosomes such as in the XXYY syndrome are associated with psychomotor retardation and a tremor that resembles ET. Men older than the age 50 who carry a *fragile X mental retardation 1 gene* (*FMR1*) premutation have tremor, gait ataxia, and executive cognitive deficits (i.e., the FXTAS). Intellectually disabled boys with the fragile X syndrome and *FMR1* gene mutations are not uniformly affected with tremor.

Candidate Gene Association Studies

Alcohol Dehydrogenase Genes

The ingestion of alcohol relieves tremor in two thirds of ET patients. This observation led investigators to research the possible association between alcohol dehydrogenase genotypes and ET. A study conducted in Spain that analyzed the relationship between the alcohol dehydrogenase 1B, β-polypeptide (*ADH2*) gene, and ET demonstrated no differences in the frequencies of *ADH2* genotypes and alleles between ET patients who did not drink alcohol and those who reported improvement with alcohol use.

PD Genes

James Parkinson alluded to the similarities between ET and PD in his original description titled the 'Shaking Palsy' in 1817. Some individuals have bilateral, postural tremor before they develop PD. The PD tremor differs from ET by its long latency of onset. There is no delay in the onset of tremor in ET upon the assumption of the arms in the horizontal position. Neuropathological evidence suggests that alpha synuclein-positive Lewy bodies are present in both ET and PD, but the substantia nigra is not involved in ET. These observations led to studies analyzing the association between ET and the genes that are involved in PD including the *parkin*, *α-synuclein*, *leucine-rich repeat kinase 2 (LRRK2)*, and the *cytochrome P450, subfamily IID, polypeptide 6 (CYP2D6)* genes. None of these genes are consistently associated with the ET phenotype.

Mitochondrial Genes

Mitochondria are subcellular organelles that are critical for oxidative phosphorylation and diverse neuronal signaling events. Mitochondria have an independent circular genome that encodes for five multisubunit complexes (complex I–V) involved in these processes. Electrons from Kreb cycle intermediates feed into complex I or II, and are transferred to complex III, then to complex IV, and finally to oxygen. The electrochemical gradient generated across the inner mitochondrial membrane by electron transport is ultimately utilized by complex V to produce energy in the form of adenosine triphosphate (ATP). The mitochondrial 'vicious cycle' theory hypothesizes that neurodegeneration occurs as a result of the accumulation of reactive oxygen species such as hydrogen peroxide and hydroxyl radicals, which in turn induces mutations in mitochondrial DNA. These mutations then lead to further oxidative phosphorylation dysfunction. This theory and the presence of a high burden of mitochondrial

DNA deletions in the substantia nigra of individuals with PD were the basis for a study that compared the mitochondrial DNA of nine patients with familial ET and six controls. Deletions in various mitochondrial genes including the *16S ribosomal RNA gene* (*16S rRNA*), and complex I [*nicotinamide adenine dinucleotide dehydrogenase subunit 1 gene* (*ND1*), and *nicotinamide adenine dinucleotide dehydrogenase subunit 2 gene* (*ND2*)], complex III, complex IV [*cytochrome c oxidase subunit II gene* (*COII*)], and complex V [*adenosine triphosphate synthase subunit ATPase 6* (*ATPase 6*), and *adenosine triphosphate synthase subunit ATPase 8* (*ATPase 8*)] region genes were identified in these patients. Deletions were not observed in the D-loop or in a complex IV gene [cytochrome c oxidase subunit I (COII)] in the ET patients. Currently, there is no definitive in vivo experimental evidence to support the mitochondrial vicious cycle theory. Thus, it is unclear if mitochondrial DNA deletions are directly involved in the pathogenesis of ET.

Genetics of ET 'Plus' Syndromes

The diagnosis of ET is complicated by the coexistence of phenocopies and other genetic disorders such as dystonia (*torsin-A* gene), X-linked spinobulbar muscular atrophy type I (*androgen receptor gene*), SCA types 2, 3, and 12 (*ataxin 2, ataxin 3,* and *beta subunit of the protein phosphatase 2* genes), and the FXTAS (*FMR1*). Genetic studies have not identified a specific link between these genes and individuals with ET as an isolated neurologic condition. ET-like tremor has been described in other genetic disorders including hereditary peripheral neuropathies such as Charcot–Marie-Tooth disease due to mutations in the *connexin 32,* and *peripheral myelin protein 22* genes.

Genetic and Biochemical Animal Models of ET

γ-Aminobutyric $acid_A$ receptor alpha 1 knockout transgenic mice (*gabra*1 −/−) exhibit a postural and kinetic tremor that is responsive to alcohol ingestion. This ET-like phenotype suggests that gamma-aminobutyric acid neural transmission has a role in the pathogenesis of ET. However, mutations in the human *GABRA1* gene are not found in individuals with ET.

Ecogenetics

Studies suggest that ET results from interactions between genes and the environment. Experimental data generated over four decades show that laboratory animals exposed to the β-carboline alkaloids (e.g., harmaline, harmane) exhibit a tremor similar to ET. β-Carbolines are a class of indole alkaloids which are structurally similar and biosynthetically derived from L-tryptophan, a serotonin precursor. The sources of dietary beta-carbolines are from plant-derived foods (e.g., wheat, barley, rice, and corn), beverages (wine, beer, whisky, and sake), and tobacco. Measurements of blood harmane levels in sporadic and familial cases of ET suggest that these chemicals exacerbate or even cause ET especially when there is a family history of the disorder. Blood lead levels and genetic variants in an enzyme involved in lead metabolism, delta aminolevulinic acid dehydratase, have been associated with the presence of ET in humans. Genetic variants in *glutathione-S-transferase* genes, polymorphic enzymes that participate in the metabolism of carcinogens (including those of tobacco smoke) and pesticides, are more frequent in individuals with ET.

Tremor, Holmes

S H Mehta and K D Sethi, Medical College of Georgia, Augusta, GA, USA

Glossary

Bradykinesia – Slowness of movement.
[18F]-fluorodopa PET – Positron emission tomography (PET) scan using [18F]-fluorodopa as radioactive ligand to evaluate presynaptic dopaminergic function.
Thalamotomy – Permanent lesioning of the thalalmic nuclei as a treatment for tremor.
Tremor – Repetitive, rhythmic oscillation of a body region caused by contraction of opposing muscle groups.

Definition and History

In 1904, Gordon Holmes described nine patients with different etiologies (vascular and tumors) all having a characteristic tremor. Since his was one of the first descriptions, the tremor has been eponymously named as 'Holmes tremor.' Although, the literature is abundant with various terms such as midbrain tremor, rubral tremor, and myorhythmia, which have been used interchangeably, the term Holmes tremor (HT) is preferred to describe this specific tremor syndrome. This tremor can also be a part of a larger syndrome associated with additional signs and symptoms such as ataxia, nystagmus and ophthalmoplegia, bradykinesia, and apathy. Some characteristics of HT include

1. A tremor of a low frequency usually less than 4.5 Hz, mostly unilateral.
2. Tremor is usually of a large amplitude and has a certain irregularity to it. It is more prominently seen with action, although may be present at rest and with posture as well.
3. There is considerable delay in the onset of the tremor compared with the timing of the original insult (from weeks to months).
4. Tremor cannot be controlled by volition and only increases in severity with the attempt. It also abates during sleep.

Pathophysiology of the Tremor

It is widely accepted that HT is a symptomatic tremor, that is, secondary to a lesion. In HT, the lesions usually involve the brainstem/cerebellar and thalamic regions mostly affecting the cerebello-thalamo-cortical and dentato-rubro-olivary pathways, and the dysfunction of the nigrostriatal system may account for the rest component. Even in his original monograph, Holmes postulated that the tremor was due to the interruption of the cerebello-rubrothalamic pathways and that when the lesion was caudal to the decussation of the pathway, it resulted in an ipsilateral tremor and when rostral, a contralateral tremor. A positron emission tomography (PET) study of six patients with HT secondary to a contralateral peduncular lesion showed a significantly decreased [18F]-fluorodopa uptake in the striatum, suggestive of nigrostriatal dysfunction. Also, MRI and dopamine transporter SPECT scan in a patient with the classic HT secondary to midbrain cavernous angioma showed damage to the cerebellorubro-thalamic and nigrostriatal pathways. This also suggests a possible pathophysiological interplay between the two pathways in the production of this distinct tremor. Since the typical rest tremor from basal ganglia dysfunction usually improves with voluntary activity, Deuschl and Bergman have hypothesized that once the ipsilateral cerebellum also becomes involved, the rest tremor spills over to voluntary activity producing the high-amplitude characteristic HT. Also, the frequency of HT (~4 Hz) is typically less than the Parkinson disease rest tremor (~6 Hz) possibly because of the influence of the cerebellar circuits over the basal ganglia, which are also disrupted.

Any lesion that disrupts the aforementioned pathways can produce a HT. Some of the different lesions reported to cause a HT include tumors, vascular insults (i.e., stroke, AVMs), hemorrhages, CNS infections including abscesses, multiple sclerosis, and iatrogenic causes (i.e., surgery/gamma-knife procedures or radiation injury) damaging the midbrain, among others. Hence, the diagnostic workup in a patient with HT is directed at detecting the lesion that caused the tremor.

Management

Since HT is typically secondary to an underlying lesion, it is important to identify the underlying cause, because if the insult is reversible, tremor may have a very favorable prognosis and however if the damage is permanent, that may not always be the case, that is, demyelination secondary to multiple sclerosis.

Medical management to symptomatically treat the tremor involves the use of levodopa, anticholinergics,

and clonazepam with some response. Others have also tried propranolol, dopamine agonists, and valproate with mixed results. Although, only isolated cases of levodopa-responsive HT (~15) have been found in the literature, it may be prudent to try levodopa as a first choice medication in the treatment of HT before resorting to other medications or invasive procedures. Ferlazzo et al. report a case of successful treatment of HT secondary to head injury with levetiracetam. Reports of HT responding to dopamine agonists such as pramipexole and cabergoline also exist in the literature. Hallett et al. treated six patients with isoniazid in a double-blind, placebo-controlled, crossover trial and found improvement in the severe postural cerebellar outflow tremor, suggesting that isoniazid may have a role in the treatment of cerebellar outflow tremor.

In the recent years, surgical treatment of HT with either lesioning or stimulation (DBS) has been employed with success. Many groups have noted improvement of HT in selected patients following stimulation or lesioning of the nucleus ventrointermedius (Vim) of the thalamus as well as with pallidotomy or stimulation. A recent review of the literature comparing outcomes of thalamotomy to DBS in patients with tremor secondary to multiple sclerosis showed that both thalamotomy and thalamic DBS were comparable procedures for tremor suppression. However, functional improvement was seen only in 47.8% of those who underwent thalamotomy, as opposed to 85.2% of those who had DBS. Earlier reports of Vim stimulation suggested more improvement of the distal contralateral extremity tremor with little effect on the proximal tremor. This relatively resistant nature of the tremor to single targets prompted investigators to combine to Vim stimulation with other DBS targets or lesions in patients with Holmes' tremor. Authors have reported a synergistic improvement of the tremor when combining Vim DBS with subthalamic nucleus DBS, globus pallidus interna pallidotomy, or ventralis oralis anterior (Voa)/posterior (Vop) pallidal receiving area stimulation. However, Lim et al. did not observe any additive effect with simultaneous multiple target DBS stimulation in two patients (one with MS-related tremor and one with post-stroke tremor).

Given the limited efficacy of thalamic DBS in alleviating proximal tremor in Holmes' tremor, other targets for stimulation have been explored. Plaha et al. performed bilateral stimulation of the caudal zona incerta (cZI) in patients with Holmes' tremor and found significant amelioration of both the distal and proximal limb tremor. However, further studies to evaluate cZI are necessary before concluding its efficacy as a potential therapeutic target for DBS.

Tremor: Drug-induced

J C Morgan, S H Mehta, and K D Sethi, Medical College of Georgia, Augusta, GA, USA

Glossary

Intention tremor – A terminal kinetic tremor that increases in amplitude near the target.
Postural tremor – Tremor that occurs with the arms outstretched.
Rest tremor – Tremor that occurs in a limb when fully supported and typically improves with action.
Tremor – Rhythmic or semirhythmic oscillation of one or more body parts.

Tremor is a common movement disorder. While there are numerous causes of tremor, drug-induced tremor is relatively common and frequently easy to treat by stopping the causative medication. The multiple causes of tremor and the high prevalence of tremor, especially in the elderly, sometimes makes it difficult to determine if a drug is responsible for a patient's tremor. Polypharmacy also makes it difficult to identify a single drug as causative. This discussion focuses on several drugs commonly associated with the induction or exacerbation of tremors.

The major drugs associated with tremor are listed in **Tables 1** and **2**. Different drugs can cause different types of tremors varying from resting (neuroleptics) to postural (central stimulants and numerous other drugs) to kinetic (ethanol and lithium) tremors. While most drug-induced tremor occurs in the context of current use of a medication, tremor can also emerge or continue after withdrawing the drug (ethanol withdrawal, tardive tremor related to chronic drug treatment that may persist after withdrawal). In addition, comorbidities can significantly influence the expression of drug-induced tremor. For example, renal failure is known to exacerbate metoclopramide-induced tremor. Typically, drug-induced tremors are rapid in onset and dramatically improve or resolve with discontinuing the offending drug.

Antiarrhythmics

Amiodarone, mexelitine, and procainamide are all reported to cause tremor, but amiodarone-related tremor is the most commonly encountered in practice. Amiodarone-induced tremor is reported to occur in about one-third of patients on the drug, and the tremor is characterized as a postural and kinetic tremor in the 6–10 Hz range. Keeping the dose of the drug in the low range (200 mg day^{-1}) appears to provide good arrhythmia control while minimizing the risk of tremor. Stopping the causative drug usually resolves the tremor, and in patients who cannot stop the medication safely, propranolol appears helpful. Amiodarone can cause thyroid dysfunction (both hypo- and hyperthyroidism), so it is important to exclude secondary hyperthyroidism in a patient with tremor on this drug.

Antibiotics/Antivirals/Antifungals

Antibiotics, antivirals, and antifungals are widely prescribed, but there are very few reports of tremor secondary to these drugs. Trimethoprim-sulfamethoxazole (TMP-SMX) is reported to cause significant resting and postural tremor in AIDS patients undergoing treatment of *Pneumocystis carinii* pneumonia. The mechanism of TMP-SMX-induced tremor is unknown, although tremor may relate indirectly to reduced catecholamine and indolamine synthesis through inhibition of dihydrofolate reductase.

The antiviral drugs vidarabine (Ara-A) and acyclovir are associated with tremors in patients being treated for herpetic infections or undergoing bone marrow transplant. Acyclovir-related tremors often occur in the elderly and in those with renal failure. The movement disorder is typically self-limited, resolving within several days to a week after discontinuing the drug.

Antifungal agents like amphotericin B, ketoconazole, and fluconazole are also rarely reported to cause tremors.

Antidepressants/Mood Stabilizers

Tricyclic antidepressants (TCAs) are widely used for numerous conditions including depression, headaches, and neuropathic pain. The development or exacerbation of existing tremor is a known side-effect of these drugs. While clinically significant tremor interfering with activities of daily living is uncommon with these drugs, most patients have at least some postural tremor evident on neurophysiological recording. The tremor can improve over time on therapy and in the event that the movement disorder is problematic and the patient cannot use an alternative drug, β-adrenergic blocking agents may be helpful.

Selective serotonin reuptake inhibitors (SSRIs) are widely used to treat anxiety, depression, and multiple other conditions. SSRI-induced tremor is probably the most common movement disorder induced by these

Table 1 Major drugs which induce or exacerbate tremors

Drug class	*Major tremorogenic drugs*
Antiarrhythmics	Amiodarone
Antibiotics/antivirals	Trimethoprim/sulfamethoxazole (TMP-SMX)
Antidepressants/mood stabilizers	Lithium, SSRIs, TCAs
Antiepileptics	Valproic acid (VPA)
Bronchodilators	Albuterol, salmeterol
Chemotherapeutics	α-Interferon, tamoxifen, thalidomide
Drugs of abuse	Alcohol, cocaine, nicotine
Gastrointestinal drugs	Cimetidine, metoclopramide
Hormones	Epinephrine, thyroxine
Immunosuppressants	Cyclosporine, tacrolimus (FK-506)
Methylxanthines	Theophylline, caffeine
Neuroleptics	Haloperidol, thioridazine

SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants; MDMA, 3,4-methylenedioxymethamphemtamine or 'Ecstasy'

Table 2 Drugs that cause resting, postural, and action/intention tremors

Major category	*Typical examples*
Resting	
Antibiotics/antivirals/antifungals	Trimethoprim/sulfamethoxazole (TMP-SMX)
Antidepressants/mood stabilizers	SSRIs, lithium
Antiepileptics	Valproic acid (VPA)
Chemotherapeutics	Thalidomide
Drugs of abuse	Cocaine, ethanol, MDMA
Gastrointestinal drugs	Metoclopramide
Neuroleptics/dopamine depleters	Haloperidol, thioridazine, cinnarizine reserpine, tetrabenazine
Postural	
Antiarrhythmics	Amiodarone
Antidepressants/mood stabilizers	Amitriptyline, lithium, SSRIs
Antiepileptics	Valproic acid (VPA)
Bronchodilators	Albuterol, salmeterol
Chemotherapeutics	Tamoxifen, Ara-C, ifosfamide
Drugs of abuse	Cocaine, ethanol, nicotine
Gastrointestinal drugs	Metoclopramide, cimetidine
Hormones	epinephrine, thyroxine
Immunosuppressants	Tacrolimus, cyclosporine, α-interferon
Methylxanthines	Theophylline, caffeine
Neuroleptics/dopamine depleters	Haloperidol, thioridazine, cinnarizine reserpine, tetrabenazine
Intention	
Antibiotics/antivirals/antifungals	Vidarabine
Antidepressants/mood stablilizers	Lithium
Bronchodilators	Albuterol, salmeterol
Chemotherapeutics	Ara-C, ifosfamide
Drugs of abuse	Ethanol
Hormones	Epinephrine
Immunosuppressants	Tacrolimus, cyclosporine

drugs, and it is estimated that new-onset tremor occurs in ~20% of SSRI-treated patients. In a study with fluoxetine, tremor emerged at a mean latency of 54 days at an average dose of 26 mg day^{-1} and the tremor frequency was typically 6–12 Hz. The tremor was typically postural in nature, although on occasion, resting and kinetic tremor developed. In half of the SSRI-treated patients with tremor, the movement disorder remitted within 1 month after discontinuing fluoxetine, while in the remaining patients, the tremor persisted for at least 15 months. Tremor can also occur as part of SSRI withdrawal, especially in patients discontinuing SSRIs with short half-lives.

Tremor is the most common movement disorder due to lithium. While the true prevalence of lithium-induced tremor is unknown, an average of 27% of 1000 patients in several studies developed tremors that were thought to be due to the drug. One study found that 32% of patients felt that their tremor resulted in noncompliance and some disability. For the majority of patients, however, the tremor is mild and not disabling. Men and the elderly may have a higher risk of developing tremor on chronic lithium therapy.

The tremor induced by lithium is typically between 8 and 12 Hz, falling into the category of enhanced physiological tremor and affecting mainly the hands. It can occur over a range of lithium levels and other medications, especially antidepressants and valproate, can exacerbate lithium-related tremor. Treatment involves dose reduction if the underlying medical or psychiatric condition permits. Another alternative treatment is a switch to another medication such as lamotrigine. In the event that the lithium cannot be decreased or replaced, the addition of propranolol or primidone can be helpful.

Antiepileptics

Valproic acid (VPA) is widely used for migraine prophylaxis, epilepsy, and bipolar disorder. Tremor due to this drug is one of the most common drug-induced tremors in clinical practice. The clinical and electrophysiological features of VPA-induced tremor resemble essential tremor, and VPA may induce tremor in people who never had tremor before or it can exacerbate underlying tremor conditions. Whereas 25% of patients exposed to VPA complain of tremor, up to 80% of patients show evidence of tremor on accelerometry recordings. The tremor is typically kinetic and postural, although rest tremor may occur. The hands are predominantly affected, but head and truncal tremor also occur. The tremor appears dose-related and dose reduction can improve VPA-induced tremor, usually within several weeks. If dose reduction is not possible, then propranolol, amantadine, or acetazolamide appear to provide benefit for VPA-induced tremor.

There are few reports of tremor with other AEDs. In fact, multiple AEDs, including primidone, carbamazepine, gabapentin, and topiramate are often useful in treating essential and other forms of tremor.

Bronchodilators

Albuterol (salbutamol) is a β_2-adrenergic agonist widely prescribed for chronic obstructive pulmonary disease (COPD) and asthma and one of the most common drugs causing drug-induced tremor. In large clinical trials, 7–20% of patients complained of tremor due to inhaled albuterol with similar numbers of patients complaining of tremor due to inhaled isoproterenol (14%). Tremor and other side effects appear dose related with β_2-agonists. Salmeterol, a newer β_2-agonist with a significantly longer half-life, can also cause tremors. While the exact mechanism for tremor induction by β_2-agonists is unknown, there is some evidence that these drugs act through a peripheral mechanism at the level of the muscle. Tolerance develops with continued use of β_2-agonists and the tremor may occur more often with oral versus inhaled therapy.

Chemotherapeutics

There are some reports of tremor associated with chemotherapy, but most standard chemotherapic agents are not associated with pronounced tremor. Tamoxifen is an antiestrogenic agent used in the treatment of breast cancer, and in early studies, the dose-limiting toxic effects of tamoxifen included tremor. Thalidomide caused tremor in 36% (10/28) of patients when used alone and in 30% (12/40) of patients receiving combination therapy with dexamethasone in one multiple myeloma clinical trial. Tremors associated with thalidomide therapy are mild and reversible. Cytarabine (Ara-C) is used to treat various cancers and can cause intention tremor, perhaps due to damage to cerebellar Purkinje cells. Ifosfamide, vincristine, and cisplatin are also rarely associated with tremors.

Drugs of Abuse

Ethanol is reported to cause multiple forms of tremor, including postural tremor as an acute/transient disorder when discontinuing ethanol use, a 'metabolic tremor' associated with alcoholic liver disease, a 3 Hz leg tremor in the context of alcoholic cerebellar degeneration, and rarely parkinsonism associated with intoxication or withdrawal. In addition, as a withdrawal syndrome, approximately one-half of 100 alcoholics who did not use ethanol for 3 weeks or more had postural tremor, although the tremor was associated with functional disability in only 17%. Propranolol appears to provide significant benefit in this setting.

Smoking is associated with an increase in tremor amplitude by at least twofold over all frequencies. In another study, cigarette smoking increased tremor significantly independent of age, gender, and anxiety levels. This effect was documented using electrophysiology and it appears that the effect is due to nicotine.

3,4-Methylenedioxymethamphemtamine (MDMA or 'Ecstasy'), cocaine, and amphetamine derivatives are reported to cause tremor. Cocaine can cause resting tremor and parkinsonism and the tremor may not remit even after 3 months of abstinence.

Gastrointestinal Drugs

Metoclopramide is a dopamine-receptor blocking agent that remains in relatively widespread use for gastroesophageal reflux disease and gastroparesis. Metoclopramide-induced movement disorders (tremor, orobuccolingual dyskinesia, parkinsonism) are very common in the tertiary setting in our experience. This drug can induce a Parkinsonian tremor, an essential-like tremor that responds to ethanol, or tardive tremor. Metoclopramide-induced parkinsonism and tremor appears more common in patients with renal failure and the dose should be lowered in these patients. Metoclopramide may cause tremor by acting as a cholinomimetic tremorogen or due to its dopamine-receptor blocking properties.

Cimetidine (a histamine H2 receptor antagonist) was shown to exacerbate tremors in three patients in one report. Bismuth salt toxicity can cause an encephalopathy with myoclonus, ataxia and tremor.

Hormones

Excess thyroid hormone in hyperthyroidism or in the setting of ingesting excess levothyroxine can cause tremor. In one study of elderly patients with hyperthyroidism, 36% had clinical signs of tremor. Tremor is frequently noted in children or adults who overdose on levothyroxine. It appears that the peak tremor frequency in thyrotoxicosis is the same as that of physiological tremor in healthy subjects; however, the power of thyrotoxic tremor is increased. Thyrotoxic tremor responds to both β-adrenoreceptor blockade by nadolol as well as treatment of the thyrotoxicosis by carbimazole.

Epinephrine and norepinephrine are associated with tremor in patients with pheochromocytomas. Epinephrine and norepinephrine have been extensively studied in humans and appear to act by enhancing physiological tremor at the level of the muscle. Interestingly, tremor

was noted as a side effect in *all* children injected with an epinephrine injectable (for patients at risk for anaphylaxis) in one study.

Immunosupressants/Immunomodulators

Calcineurin inhibitors such as cyclosporine and FK-506 (tacrolimus) are widely used in immunosuppressive transplant regimens and in autoimmune disorders. Postural tremor is reported in up to 40% of patients on cyclosporine with intention tremor being less frequent. The tremor typically is mild and generalized in nature and higher blood levels of cyclosporine are correlated with tremor. Tremor is frequently preexistent due to hepatic or renal failure and polypharmacy in most patients. Cyclosporine can also rarely cause parkinsonism with rest tremor.

FK-506 (tacrolimus) is also commonly used in immunosuppressive regimens and was associated with tremor in the first reports of neurological toxicity related to the drug following liver transplantation. Tremor was observed in 8 of 22 pediatric liver transplant patients on FK-506 and occurred in 10 of 44 patients undergoing orthotopic liver transplantation in another study. The tremor associated with FK-506 therapy in the latter 10 patients was severe and affected the hands, interfering with handwriting and worsening with action, but improving with dose reduction. Tremor was also associated with FK-506 therapy in rheumatoid arthritis and in treatment of fistulas related to Crohn's disease.

Tremor was actually the major neurological side effect in a trial of α-interferon for metastatic melanoma. Significantly increased action tremor occurred in 22% of patients in this trial and facial myorhythmia was also reported in one patient on the drug.

Methylxanthines

Methylxanthines include theophylline, aminophylline, and caffeine. Theophylline and aminophylline are typically used in the treatment of COPD and asthma. Caffeine is widely consumed throughout the world. Aminophylline and theophylline treatment leads to increased patient complaints of tremor, not quite reaching statistical significance in a recent meta-analysis of these drugs in acute COPD exacerbation, but aminophylline does increase tremor power on accelerometry when given to patients with essential tremor. In contrast to these reports, there is evidence that theophylline (an adenosine antagonist) may improve essential tremor as much as propranolol.

Studies on caffeine and tremor have demonstrated that 2% of normal controls complained of tremor when drinking coffee. Essential tremor and Parkinson's disease patients complained that coffee worsened their tremors in 8% and 6% of patients, respectively. However, an oral caffeine dose of 325 mg did not increase physiological, Parkinsonian or essential tremor in formal clinical studies. Other accelerometry studies have shown that 450 mg day^{-1} of caffeine appears to increase finger tremor in the fasting state. In another accelerometry study, a caffeine dose equal to two or three cups of coffee increased whole-arm tremor in normal subjects.

Antipsychotics and Dopamine-Depleting Agents

Antipsychotics or neuroleptics (dopamine-receptor blocking agents) can cause resting and postural tremors. Tremor occurs most frequently as a part of drug-induced parkinsonism with these drugs, and rest tremor generally develops several days or weeks after introduction or dosage increase of antipyschotics. Tardive tremor that occurs after prolonged antipsychotic therapy with persistence even after withdrawal of the drug has been reported, although its existence as a nosographic category has been debated. Parkinsonism with tremor that continues after withdrawal of an antipsychotic in an elderly or middle-aged subject is more likely due to the unmasking of Parkinson's disease that was preclinical at the time of antipsychotic exposure. Tremor associated with drug-induced parkinsonism was particularly frequent with older typical antipsychotics affecting 35–60% of treated patients. Tremor typically began asymmetrically in one arm, similar to Parkinson's disease, although bilateral tremor is also a frequent presentation. Exposures to fluphenazine (piperzaine group) or thioridazine (piperadine group) have been reported to cause drug-induced parkinsonism more frequently than chlorpromazine (aliphatic group). Newer generation antipsychotics are associated with lower frequencies of drug-induced parkinsonism, but the potential problem exists with all available antipsychotic agents that work through dopamine-receptor blockade.

The vestibular sedatives cinnarizine and flunarizine are not prescribed in the United States; however, they are frequently associated with drug-induced parkinsonism and postural/rest tremor in treated patients. The dopamine-depleting agents, reserpine, methyldopa, and tetrabenazine, are also reported to cause tremor.

Other Miscellaneous Drugs

While most β-blockers typically ameliorate various forms of tremor, pindolol, is known to cause tremor in various settings. The tremor is mostly postural and action in nature, about 7 Hz and is usually self-limited after

Table 3 Therapy of the most common drug-related tremors

Drug	*Treatment*
Albuterol	Reduce frequency or discontinue use longer-acting inhaled β-agonist may help
Amiodarone	Screen for hyperthyroidism, reduce dose to 200 mg day^{-1} if possible, β-blocker may help
Amitriptyline/ TCAs	Allow time to see if tremor will improve discontinue use or switch to an SSRI, β-blocker may help
Caffeine	Reduce caffeine intake
Cyclosporine	Avoid toxic states and consider reducing dose, try another immunosuppressive agent
Ethanol	Abstinence β-blockers
Lithium	Check drug levels, reduce dose change medications (valproate, lamotrigine, etc.) β-blocker therapy (may worsen depression)
Metoclopramide	Discontinue use and observe consider using erythromycin for gastroparesis observe for signs of parkinsonism
Nicotine	Stop using all forms of tobacco or nicotine gum
SSRIs	Wait to see if tremor improves over time reduce dose if depression allows β-blockers (may worsen depression)
Tacrolimus (FK-506)	Reduce dose try another immunosuppressive agent
Valproic acid	Reduce dose change to another antiepileptic or mood stabilizer β-blockers

stopping the drug. This drug may cause tremor due to its partial β-agonist activity, unlike other β-blockers.

Various reports have documented tremor in patients taking ephedrine, pseudoephedrine, and phenylpropanolamine in over the counter cold preparations or when used as appetite suppressants. The tremorogenic effect of these drugs is likely due to their sympathomimetic effects. Ephedrine and phenylpropanolamine are no longer available in the United States, but pseudoephedrine remains in widespread use.

Central stimulants like amphetamines, methyphenidate, and dexedrine are also known to cause tremors in some treated patients.

Treatment Strategies

Ideally a drug-induced tremor should be treated with withdrawal of the causative agent. In many instances, however, the underlying medical, psychiatric, or neurological condition requires the use of the tremorgenic drug and in these cases other treatments must be added to the tremorgenic drug.

Table 3 lists the most widely prescribed and used tremorogenic drugs in the United States today and briefly details treatment of tremor related to these drugs. It is important to remember that many drugs exacerbate underlying tremors and an underlying cause for tremor (psychogenic tremor, essential tremor, Parkinson's disease) should be considered in each patient.

Trinucleotide Repeat Disorders

C M Everett, Royal London Hospital, London, UK

Glossary

Condensed chromatin – DNA that is tightly packaged in chromatin inaccessible to transcription factors. Generally, genes present within condensed chromatin are silenced. Various histone modifications are associated with condensed chromatin, for example, deacetylated histone H3/4 and histone H3 methylated at lys^9 residue.
CBP – CREB binding protein, CREB – cAMP response element binding protein; both components of a common transcription activator pathway.

Huntington's Disease (HD)

Definition and History

HD is an autosomal dominant (AD) disorder, described by George Huntington in 1872. The HD locus was localized to chromosome 4p in 1983. The causative mutation identified in 1993 is an unstable expanded CAG repeat in exon 1 of the *Huntingtin* (*IT15*/*Htt*) gene.

Pathogenesis

The expanded CAG trinucleotide repeat is translated into a polyglutamine (polyQ) tract at the N-terminus of the Htt protein. The CAG repeat is unstable expanding between successive generations, particularly with paternal transmission, resulting in a more severe and earlier disease: a phenomenon known as anticipation. Pathogenesis is complex involving multiple cellular processes. The primary pathological changes are seen in the striatal medium-sized spiny neurons and in layers V and VI of the neocortex. Common to all the polyQ repeat diseases is a toxic gain of function of the mutant polyQ containing protein and deposition of ubiquitinated neuronal intranuclear inclusions (NIIs) – in HD formed by the self association of N-terminal mutant Htt. NIIs may be directly toxic to the cell but may represent a clearance mechanism for misfolded proteins and components of the ubiquitin-proteosome pathway are found associated with inclusions. Mutant-expanded Htt itself interacts with multiple cellular proteins, including transcription factors such as CBP, which may result in gene repression and cellular toxicity. Apoptosis is important in polyQ disease neurodegeneration.

Epidemiology

The prevalence of HD is ~4–8/100 000 in Europe and North America. The *Htt* gene usually contains 8–39 repeats; 37 or more repeats are found in patients, suggesting variable penetrance in the overlap range; 40–50 are found in middle age onset (90–95% of cases); >60 usually results in juvenile HD.

Clinical Features and Diagnostic Criteria

HD typically develops in adulthood with a progressive personality change, cognitive decline, and chorea. Psychiatric features such as depression may predate the movement disorder. Additional features include extrapyramidal signs such as rigidity, bradykinesia, tremor, myoclonus, and dystonia as well as pyramidal signs and ataxia. Difficulty in initiating saccades and gaze impersistence also occurs. Juvenile HD often manifests itself as an akinetic rigid syndrome (Westphal variant).

Differential Diagnosis

Adult onset chorea has a wide differential. Other genetic conditions that may mimic (HD phenocopies) or appear similar to HD are listed in **Table 1**. The HD phenocopies known as HD-like (HDL) syndromes have become increasingly appreciated.

HDL1, 2, and 4 are AD disorders. HDL1 is due to 168 or 192 base pair in frame insertions in the *PRNP* gene, encoding additional octapeptide repeats. HDL2 occurs mostly in families of African ancestry and is due to a CAG repeat expansion in the *JPH3* gene. Pathological repeat length is 44–57 and it is unstable on maternal transmission. HDL4 is also known as SCA17. Cerebellar ataxia is the most common feature, often occurring with extrapyramidal and pyramidal signs and dementia, but a form indistinguishable from HD occurs. It is due to an expanded CAG repeat within the *TBP* gene. HDL3 is an autosomal recessive disorder and of childhood onset – its features are not reminiscent of HD.

Diagnostic WorkUp

PCR of DNA obtained from peripheral blood identifies the CAG repeat expansion. MRI imaging may show prominent caudate nucleus atrophy and atrophy of the cerebral cortex.

Table 1 Summary of hereditary disorders that may mimic or have features similar to Huntington's disease

Disorder	*Inheritance*	*Gene*	*Average age of onset*	*Clinical features*
HDL1	AD	*PRNP*	20–40	HD phenocopy
HDL2	AD	*JPH3*	25–45	HD phenocopy
HDL3	AR	Unknown		
HDL4/SCA17	AD	*TBP*	25–40	HD phenocopy/ataxia
SCA1	AD	*Ataxin-1*	30–40	Ataxia, extrapyramidal features, spasticity
SCA2	AD	*Ataxin-2*	25–45	Ataxia, extrapyramidal features, ophthalmoparesis, neuropathy, dementia
SCA3	AD	*Ataxin-3*	20–50	Ataxia, extrapyramidal features, ophthalmoplegia, neuropathy
DRPLA	AD	*Atrophin-1*	>40	Ataxia, chorea, myoclonus, dementia
Neuroferritinopathy	AD	*FTL*	40	Parkinsonsim, chorea, dystonia
Neuroacanthocytosis	AR	*VPS13A*	20–30	Dystonia with oromandibular involvement, chorea, neuropathy, self mutilation, red cell acanthocytes
McLeod Syndrome	X linked	*XK*	40–60	Similar to neuroacanthocytosis, seizures, myopathy in addition
Pantothenate kinase associated neurodegeneration	AR	*PANK2*	Childhood	Dystonia, Parkinsonism, chorea, dementia, occasionally acanthocytes
Wilson's disease	AR	*ATP7B*	20–30	Parkinsonism, dystonia, chorea, ataxia, psychiatric features, liver disease, Kayser Fleischer rings

PRNP, prion protein.
JPH3, junctophillin 3.
TBP, TATA binding protein.
FTL, ferritin light polypeptide.
VPS13A, vacuolar protein sorting 13 homolog A (encodes chorein).
XK, X-linked Kx blood group.
PANK2, pantothenate kinase 2.
ATP7B, ATPase CU^{2+} transporting beta polypeptide.

Management

Multidisciplinary management is essential. Psychiatric features may require atypical antipsychotic drugs and antidepressants. Chorea may be controlled with antipsychotic drugs and tetrabenazine can be useful. Weight loss is a common feature requiring expert dietetic advice. Speech therapy is often useful to help speech and swallowing. Predictive testing of family members is a major issue and is best carried out with a geneticist under the auspices of the expert HD clinic.

Prognosis

Generally, life span after diagnosis is 15–20 years but this is influenced by the severity of the disease, which is variable and related to CAG repeat length.

Dentatorubral–Pallidoluysian Atrophy

Definition and History

Dentatorubral–pallidoluysian atrophy (DRPLA) is an AD neurodegenerative disorder caused by an expanded CAG repeat in the *atrophin-1* gene on chromosome 12p. It shares many clinical and pathological features with HD.

Pathogenesis

Macroscopically, there is cerebellar and brainstem hypoplasia with microscopic features of degenerated denatatorubral and pallidoluysian systems. Neuronal loss in the dentate nucleus and pallidum is constant, while the red nucleus is least affected. Toxic gain of function of mutant polyQ atrophin-1 is thought to be pathogenic with ubiquitinated NIIs developing.

Epidemiology

The disease is found most commonly in Japan. The length of the repeat on the normal allele is 7–34 and on the expanded, 58–88. There is clear anticipation particularly with paternal transmission.

Clinical Features and Diagnostic Criteria

The juvenile form usually manifests itself as progressive myoclonus epilepsy (PME) with cognitive decline. In early adulthood (third decade), DRPLA may present in a similar manner to HD with prominent chorea or with prominent ataxia/myoclonus all associated with cognitive decline. Seizures may also develop. In cases developing later in life, a milder cerebellar ataxia may predominate.

Differential Diagnosis

The differential diagnosis is similar to HD (**Table 1**). In juvenile cases with PME, other conditions such as mitochondrial disease (MERRF), Lafora body disease, Unverricht Lundborg disease, sialidosis type 1, neuronal ceroid lipofuscinoses, and GM_2 gangliosidoses may need to be considered.

Diagnostic Workup

PCR of DNA obtained from peripheral blood identifies the CAG repeat expansion. Some cases may be identified in investigating HD or cerebellar ataxia. MRI imaging may show cerebellar and midbrain atrophy and high signal change in cerebral white matter.

Management

Management of the movement disorder and psychiatric manifestations is similar to HD as is the genetic counselling.

Prognosis

The prognosis for juvenile myoclonus epilepsy is poor. As in HD, prognosis is influenced by the severity of disease, which in itself is related to CAG repeat length.

Spinocerebellar Ataxia

Definition and History

There are at least 28 different AD SCAs. SCA1, 2, 3, 6, 7, and 17/HDL4 are polyQ diseases. In SCA8 and 12, a CTG and CAG expansion remains untranslated (**Table 2**).

Pathogenesis

Macroscopically, there is atrophy of cerebellum, brain stem nuclei, basal ganglia, spinal cord long tracts, and cerebral cortex varying with the specific syndrome. The pathogenesis of the polyQ SCAs shares features in common with HD, with a toxic gain of function of mutant proteins thought to be the primary pathogenic mechanism. The pathogenesis in SCA8 and 12 remains unclear.

Epidemiology

The incidence of SCA in general is ~1–5/100 000. SCA3 is the most common, worldwide (20–50% of cases), and is common in Brazil. SCA1 is more common in South Africa.

Clinical Features and Diagnostic Criteria

The clinical classification of these disorders as autosomal dominant cerebellar ataxias (ADCA) remains useful (**Table 3**). A cerebellar syndrome of progressive ataxia and dysarthria is common to all with the average onset in the third decade. The ADCA classification is not exhaustive. For example, a peripheral neuropathy is common in SCA3 and an upper limb tremor common in SCA12. Slow ocular saccades usually occur in SCA2. The polyQ SCAs exhibit anticipation except in SCA6 where the CAG repeat is short and relatively stable.

Differential Diagnosis

The differential diagnosis for cerebellar ataxia is wide. This discussion is limited to genetic causes. It can be difficult to differentiate the SCAs clinically and this often relies on genetic testing. Several SCAs have been identified that are not due to trinucleotide repeat expansions (**Table 4**). Late-onset DRPLA can appear similar to SCA. Often, a family history of SCA is not clear and recessive forms of ataxia may be considered, although these often have systemic features, which are not found in AD SCAs. However, several recessive forms are associated with cerebellar atrophy and have additional clinical

Table 2 Summary of genetic features of the trinucleotide repeat spinocerebellar ataxias

Disorder	*Gene*	*Trinucleotide repeat*	*Normal range*	*Pathological range*
SCA 1	*Ataxin-1*	CAG	6–44	40–82
SCA 2	*Ataxin-2*	CAG	14–31	32–200
SCA 3	*Ataxin-3*	CAG	12–40	61–84
SCA 6	*CACNA1A*	CAG	4–20	20–29
SCA 7	*Ataxin-7*	CAG	4–27	37–306
SCA 8	*Unknown*	CTG	15–91	>74
SCA 12	*PPP2R2B*	CAG	<29	55–78
SCA 17	*TBP*	CAG	25–42	47–63

CACNA1A = α_{1A} subunit of P/Q-type voltage gated calcium channel.
PPP2R2B = protein phosphatase 2 regulatory subunit B.
TBP = TATA binding protein.

Table 3 Harding's classification of the autosomal dominant cerebellar ataxias

ADCA I	*ADCA II*	*ADCA III*
Cerebellar syndrome with involvement of other regions within the CNS, e.g., pyramidal and extrapyramidal signs, supranuclear ophthalmoplegia and dementia	Cerebellar syndrome with pigmentary retinal degeneration	Pure cerebellar syndrome
SCA1, 2, 3, 8, 12, 17	SCA7	SCA6

Only the trinucleotide repeat SCAs are included in the table.

Table 4 Other genetically defined autosomal dominant SCAs

Disorder	*Gene*	*Clinical features*
SCA4	*PLEKHG4*	Ataxia, sensory neuropathy, pyramidal signs
SCA5	*βIII Spectrin*	Pure cerebellar syndrome
SCA10	*Ataxin10* (intronic ATTCT repeat)	Pure cerebellar syndrome with seizures
SCA11	*TTBK2*	Pure cerebellar syndrome
SCA13	*KCNC3*	Ataxia, developmental delay, onset usually in childhood
SCA14	*PRKCG*	Ataxia, myoclonus and tremor
SCA15	*ITPR1*	Pure cerebellar syndrome
SCA27	*FGF14*	Ataxia, tremor, orofacial dyskinesia, psychiatric features

PLEKHG4, pleckstrin homology domain-containing protein, family G, member 4.
TTBK2, tau tubulin kinase 2.
KCNC, A-type potassium channel.
PRKCG, protein kinase Cγ.
ITPR1, inositol 1,4,5-triphosphate receptor type 1.
FGF14, fibroblast growth factor 14.

features, including eye movement disorders and extrapyramidal features that may be reminiscent of the ADCA I disorders (**Table 6**).

Diagnostic Workup

MRI brain imaging typically shows cerebellar atrophy. There may be associated brainstem and cerebral cortex atrophy. PCR of DNA obtained from peripheral blood identifies the repeat expansion.

Management

Physiotherapy to prevent falls and to provide mobility aids should be offered. Speech therapy is also helpful. Spasticity, chorea, and dystonia may be amenable to drug treatment. Genetic counseling is important.

Prognosis

The prognosis is variable (years) and depends on disease severity, which is influenced as in other polyQ diseases by the trinucleotide repeat length.

Fragile X Tremor Ataxia Syndrome

Definition and History

Fragile X syndrome is the most common form of inherited mental retardation. It is due to a > 200 CGG repeat expansion located in the promoter region of *FMR1*, which causes complete or partial silencing of the gene. Fragile X tremor ataxia syndrome (FXTAS) was reported in 2001, affecting carriers of the CGG repeat in the premutation range (55–200).

Pathogenesis

Fragile X syndrome is associated with silencing of the *FMR1* gene on the X chromosome. In FXTAS, overexpression of *FMR1* and/or the presence of the expanded repeat may result in a toxic gain of function of *FMR1* mRNA. Eosinophillic ubiquitinated intranuclear inclusions form in neurons and astrocytes throughout the cerebral cortex, deep cerebellar nuclei, and brain stem. Inclusion number seems directly related to the number of repeats. Deep white matter change within the cerebral hemispheres and cerebellum is increasingly recognized.

Epidemiology

It has been estimated that ~1/800 males and 1/260 females carry the fragile X premutation. Up to 1/3000 males may have a lifetime risk of FXTAS. CGG repeat length appears to be directly related to disease severity and inversely related to the age of death.

Clinical Features and Diagnostic Criteria

Typical features are progressive action tremor and gait ataxia. Parkinsonism, cognitive decline, emotional problems, autonomic dysfunction, and peripheral neuropathy also occur. Cognitive problems mostly affect short-term memory and executive function. The condition typically affects older males with an average age of onset of 60. Women are less severely affected.

Differential Diagnosis

In the elderly population, acquired forms of ataxia with Parkinsonism and autonomic dysfunction may be considered, for example, multiple systems atrophy and paraneoplastic disorders. Other genetic conditions such as SCA can develop later in life. FXTAS may appear similar to

essential tremor and Parkinson's disease. Cognitive decline may predominate and with associated autonomic dysfunction, a diagnosis of dementia with Lewy bodies may be considered.

Diagnostic Workup

PCR of DNA obtained from peripheral blood identifies the CGG repeat expansion. MRI brain imaging typically shows high signal abnormality within the middle cerebellar peduncles and deep cerebral white matter change also occurs.

Management

Beta blockers and primidone may help the tremor. Standard SSRI antidepressants can be used for depression and anxiety. Physiotherapy and speech therapy may be helpful.

Prognosis

Currently, prognostic details are imprecise. However, FXTAS is a progressive disorder and over several years, the patient may become dependent on a walking aid. Swallowing problems can occur late in the disorder.

Friedreich's Ataxia

Definition and History

Nicholaus Friedreich described this autosomal recessive disease in 1863. In 1996, expanded GAA trinucleotide repeats in the first intron of the *FRDA* gene on chromosome 9q were identified.

Pathogenesis

Pathologically, there is degeneration in the spinal cord of the spinocerebellar tracts, the pyramidal tracts, and the dorsal columns as well as neurodegeneration in the cerebellum and medulla.

FRDA encodes frataxin, located on the inner mitochondrial membrane and is involved in the synthesis of mitochondrial iron–sulfur cluster containing proteins. Frataxin expression is downregulated in Friedreich's ataxia (FA) resulting in an increased mitochondrial oxidative stress and cell death. There is a correlation between the severity of some clinical features and the age of onset with the shorter of the two expanded repeats.

GAA repeat-induced *FRDA* repression may occur by the repeat impairing *FRDA* transcription and sequestering transcription factors, including RNA polymerase to the 'sticky' repeat. Recently it has been suggested that the GAA repeat affects the chromatin packaging of *FRDA*, rendering it inaccessible to transcription factors. Changes in histone acetylation and methylation found in association with inaccessible condensed chromatin have been found in association with the GAA repeat in downregulated *FRDA* genes.

Epidemiology

FA is the most common hereditary ataxia with a prevalence of ~1/50 000 and the carrier rate in the range 1/50–1/100. The normal repeat length is less than 33 with most expanded disease-causing alleles having from 67 to 1700 repeats. Most patients have repeats of between 600 and 1200. Approximately 2% of patients are compound heterozygotes for a GAA repeat expansion and a point mutation.

Clinical Features and Diagnostic Criteria

Harding's essential clinical features of FA are autosomal recessive inheritance, onset before the age of 25 (although with the advent of genetic testing onset at later ages has become apparent), progressive limb and gait ataxia, absent deep tendon reflexes in the lower limbs, and electrophysiological evidence of a sensory axonal neuropathy. Within 5 years, there should be dysarthria, areflexia, distal loss of proprioception and vibration sense, extensor plantar reflexes, and pyramidal leg weakness. There is associated cardiomyopathy, scoliosis, pes cavus, optic atrophy, hearing loss, extrapyramidal features, and diabetes in some patients. The Acadian form is milder and without cardiomyopathy. Late onset and FA with retained reflexes also occurs.

Differential Diagnosis

Disorders phenotypically similar to FA may lack (as in FA) or possess significant cerebellar atrophy, which can be a useful differentiating feature. There is a large collection of autosomal recessive cerebellar ataxias and several of the more commonly encountered conditions are summarized in **Tables 5** and **6**. Many of these conditions develop in the teens, similar to FA.

Diagnostic WorkUp

PCR and Southern blotting of DNA obtained from peripheral blood identifies the GAA repeat expansion. Sequencing of the FRDA gene may be required to look for a point mutation if only a single GAA expansion is found. An ECG and echocardiogram should be performed

Table 5 Autosomal recessive disorder with similar phenotype to Friedreich's ataxia, including minimal cerebellar atrophy

Disorder	*Gene*	*Clinical features*
Friedreich's ataxia	*FRDA*	See text
Ataxia with vitamin E deficiency	*TTPA*	Ataxia, peripheral neuropathy, cardiomyopathy, head tremor, retinitis pigmentosa, low serum vitamin E
Abetaliproteinaemia	*MTP*	Ataxia, peripheral neuropathy, lipid malabsorption, hypocholesterolaemia, acanthocytosis, retinitis pigmentosa
Refsum's disease	*PNYH, PEX7*	Cerebellar ataxia, peripheral neuropathy (can be acute), retinitis pigmentosa, anosmia, deafness, skeletal abnormalities, icthyosis, renal failure, cardiomyopathy

TTPA, α-tocopherol transfer protein.
MTP, microsomal triglyceride transfer protein.
PNYH, phytanoyl-CoA hydroxylase.
PEX7, peroxin 7.

due to the hypertrophic cardiomyopathy, present in up to two thirds of patients and blood glucose measured. These should be regularly monitored.

Management

A multidisciplinary approach with physiotherapy, occupational and speech therapy is needed. Mobility aids are required by the majority of patients. Genetic counseling should be offered. Cardiomyopathy and diabetes may require expert advice. Specific therapies used in FA include vitamin E and coenzyme Q10, which may improve cardiac function. Idebanone may improve cardiac function. Several agents have been suggested to increase frataxin expression, including erythropoietin and histone deacetylase inhibitors, but these drugs are not recommended as yet.

Prognosis

The rate of progression of FA is variable with average time from symptom onset to wheelchair dependence being about 10 years. In 1996, the average interval from symptom onset to death was ~36 years. Death is often related to cardiomyopathy or aspiration pneumonia. Improvement in the management of cardiomyopathy may prolong survival times.

Table 6 Autosomal recessive cerebellar ataxias with prominent cerebellar atrophy

Disorder	*Gene*	*Clinical features*
Late onset Tay Sach's disease	*HEXA*	Ataxia, amyotrophy, psychiatric problems, spasticity, seizures
Cerebrotendinous xanthomatosis	*CYP27A1*	Ataxia, pyramidal/extrapyramidal features, peripheral neuropathy, tendon xanthomata, diffuse high signal on MRI brain
POLG disorders (MIRAS)	*POLG*	Ataxia, dorsal column dysfunction, peripheral neuropathy, cognitive features, myoclonus and other involuntary movements, bilateral cerebellar high signal on MRI, common in Finland
Ataxia telangiectasia	*ATM*	Ataxia, oculomotor apraxia, oculocutaneous telangiectasia, extrapyramidal features, immunodeficiency, cancer susceptibility, radiosensitive, elevated serum AFP
Ataxia telangiectasia-like	*MRE11*	Similar to ataxia telangiectasia but later onset, lacks telangiectasia, later onset, slower progression, normal AFP
Ataxia with oculomotor apraxia type 1 (AOA1)	*APTX*	Ataxia, sensorimotor neuropathy, dorsal column involvement, oculomotor apraxia, gaze impersistence, extrapyramidal signs, cognitive impairment, hypoalbuminaemia, hypercholesterolaemia, normal AFP, vermian cerebellar atrophy, onset usually in childhood but can be later
Ataxia with oculomotor apraxia type 2 (AOA2)	*SETX*	Similar to AOA1 but later onset (teens), oculomotor apraxia may be less, normal albumin and cholesterol, elevated AFP, vermian cerebellar atrophy. May appear similar to Friedreich's ataxia

Ataxia telangiectasia and ataxia-telangiectasia like usually have childhood onset with the other conditions often developing in the teens or early 20s.
HEXA, hexosaminidase A.
CYP27, sterol 27 hydroxylase.
POLG, DNA polymerase γ.
ATM, ataxia telangiectasia mutated.
MRE11, meiotic recombination 11.
APTX, aprataxin.
SETX, senetaxin.
MIRAS, Mitochondrial Recessive Ataxia Syndrome.

Summary

The trinucleotide repeat diseases are individually rare but as a group are not uncommonly responsible for disabling movement disorders. One of the major challenges of the future is to develop specific treatments for these diseases.

TWSTRS

E Consky, Consultant Neurologist, Toronto, ON, Canada

Glossary

Anterior sagittal shift – Dystonic deviation of the chin forward rather than downward.

Anterocollis – Dystonic deviation of the chin downward in the sagittal plane toward the chest.

Interrater reliability – The extent to which a rating instrument yields reproducible, accurate, consistent, and stable results when scored by different observers.

Lateral shift – Horizontal displacement of the base of the neck in the absence of tilting of the ear toward the ipsilateral shoulder (unless accompanied by

laterocollis, which usually occurs in the opposite direction).
Laterocollis – Dystonic tilting of the head laterally in the coronal plane, moving the ear toward the ipsilateral shoulder.
Posterior sagittal shift – Backward displacement of the head without upward deviation of the chin.
Retrocollis – Dystonic extension of the head, producing upward excursion of the chin.
Rotational torticollis – Dystonic rotation of the nose and chin around the longitudinal axis toward the shoulder.
Sensory trick (gestes antagonistes) – A pathognomonic feature of CD characterized by the transient correction of head posture with the use of maneuvers such as touching the face, neck, or head with the hand or an object.
Tsui scale – An objective CD rating scale developed by Tsui and colleagues, evaluating the amplitude and duration of sustained movements and head tremor and the presence of shoulder elevation.
Validity – The extent to which a rating instrument accurately measures what it is designed or purports to measure. *Content validity* refers to the extent to which a scale includes all relevant dimensions of the condition being measured and whether it represents these in reasonably weighted proportions. *Construct validity* evaluates whether the rating instrument measures what it intends to measure, and does not measure what it is not intended to measure, predictably distinguishing between groups and producing results consistent with a predetermined theoretical framework. *Convergent validity* refers to the correlation with other measures of the same construct or attribute. In addition, the *responsiveness* of the rating scale to detect clinically significant change is considered an aspect of validity.

TWSTRS

TWSTRS, the Toronto Western Spasmodic Torticollis Rating Scale, developed by Consky and Lang in 1990, is a multidimensional objective and subjective rating scale for cervical dystonia (CD) with subscales for the relevant and distinct clinical dimensions of CD: impairment severity, associated disability and pain (see **Figure 1**). It has been widely accepted and used as an outcome measure in therapeutic intervention studies, including Botulinum toxin (BoNT) therapy, oral pharmacotherapy, and surgical trials for CD. It also has practical applicability in a clinical setting in the ongoing management of individual CD patients. The clinimetric properties of the TWSTRS have been defined in a number of studies that have demonstrated TWSTRS reliability, validity, and responsiveness to change following treatment. A teaching tape for the TWSTRS severity scale and a videotape protocol that contains the elements of a standardized examination for CD have been developed to promote consistent application.

The TWSTRS Severity Scale

The severity scale objectively quantifies the dynamic and varied clinical spectrum of the involuntary movements or abnormal postures of the head and neck seen in CD. The *maximum amplitude of excursion* (A) (sustained or unsustained) is determined on the basis of the standardized examination, the patient being asked to allow the head to deviate fully without resistance or the use of sensory tricks, after activating and distracting maneuvers, walking and sitting, and is determined for all dominant and minor planes of head deviation: rotational torticollis (0–4), laterocollis (0–3), anterocollis or retrocollis (0–3), lateral shift (0–1), and sagittal shift (0–1). The *duration factor* (B) (0–10) for the dominant deviation quantifies the dynamic and variable character of CD, which may change significantly with posture and activity. To account for this variability, the duration factor assesses first the proportion of time for which there is any deviation from a neutral position and second the proportion of time for which the amplitude of the deviation is either predominantly maximal or submaximal. The *efficacy of sensory tricks* (C) (0–2) is a reflection of CD severity. The effectiveness of sensory tricks may vary considerably among patients, may wane over time, and may change following therapeutic intervention. Intermittent or sustained *elevation or anterior displacement of the shoulder* (D) (0–3) is frequently present, commonly ipsilateral to the direction of the turn or tilt. Examination of the *range of active motion* (E) (0–4) in each of the three axes rotational, lateral tilting, and flexion and extension, without the aid of sensory tricks, is also determined. CD severity is also quantified by determining the average *time* (F) (0–4) on two attempts for whcih the patient is able to maintain the head within 10° of a neutral position with active resistance but without the use of sensory tricks. The total TWSTRS Severity Scale score is a summation of items A–F with a maximum score of 35.

The TWSTRS Disability Scale

Disability is task-specific and is not necessarily directly proportional to the clinical severity of the abnormal postures and movements of CD. The direction of head deviation, coexisting dystonic involvement of other sites, pain,

depression, sleep impairment, coping strategies, the availability of support, and the effectiveness of treatment may all significantly influence the level of disability experienced by an individual CD patient. The TWSTRS Disability Scale consists of a broadly based assessment of the performance of daily activities that may be affected by CD. General as well as specific activity categories are assayed, including work performance (employment or domestic work), activities of daily living (hygiene, dressing, feeding), reading, television viewing, driving, and leisure activities outside the home. The extent to which social embarrassment rather than head deviation or pain specifically contributes to disability was initially included as an inverse item but was deleted following initial testing of the scale. The maximum TWSTRS Disability Scale score is 30.

The TWSTRS Pain Scale

Cervical pain is a frequent and prominent feature of CD that often significantly contributes to disability and impairment of quality of life. It is a separate and distinct aspect of CD that may not be directly correlated with

The toronto western spasmodic torticollis rating scale (TWSTRS)

I. TWSTRS Severity Scale

A. Maximal excursion

Rate maximum amplitude of excursion asking patient not to oppose the abnormal movement; examiner may use distracting or aggravating maneuvers. When degree of deviation is between two scores, chose the higher of the two

1. Rotation (turn: right or left)
0 None
1 Slight (<1/4 range) (1–22°)
2 Mild (1/4–1/2 range) (23–45°)
3 Moderate (1/2–3/4 range) (46–67°)
4 Severe (>3/4 range) (68–90°)

2. Laterocollis (tilt: right or left) (exclude shoulder elevation)
0 None
1 Mild (1–15°)
2 Moderate (16–35°)
3 Severe (> 35°)

3. Anterocollis/retrocollis (a or b)
a) Anterocollis
0 None
1 Mild downward deviation of chin
2 Moderate downward deviation (approximates 1/2 possible range)
3 Severe (chin approximates chest)

b) Retrocollis
0 None
1 Mild backward deviation of vertex with upward deviation of chin
2 Moderate backward deviation (approximates '/z possible range)
3 Severe (approximates full range)

4. Lateral shift (right or left)
0 Absent
1 Present

5. Sagittal shift (forward or backward)
0 Absent
1 Present

Figure 1 (Continued)

the severity of motor impairment. The TWSTRS Pain Scale includes an assessment of pain intensity, pain duration, as well as the affective components of pain resulting in disability. A weighted dimensional severity score (0–10) for the patients usual, best, and worst pain, a second-scale item which evaluates the duration of pain typically experienced during the preceding week (0–5), and a third-scale item which assesses the contribution of pain to the disability (0–5) are scored with a maximum TWSTRS Pain Scale score of 20.

The TWSTRS (total) score is the sum of the TWSTRS Severity Scale score (0–35), the TWSTRS Disability Scale score (0–30), and the TWSTRS Pain Scale score (0–20) with a maximum score of 85.

Reliability and validity and comparative testing of TWSTRS

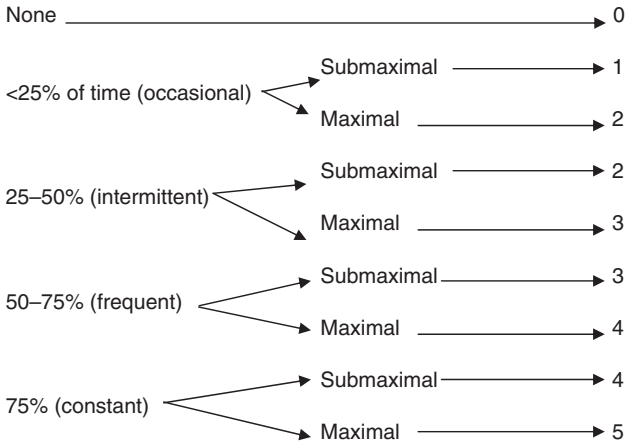
Initial evaluation of TWSTRS by Consky, Lang, and colleagues showed substantial interobserver agreement for each component of the TWSTRS Severity Scale, for the whole Severity Scale, and for the TWSTRS Disability and Pain Scales. The average severity component of the TWSTRS Pain Scale was added subsequently and was not included in the initial testing. High interrater reliability for the change in patients' scores prior to and 6 weeks following BoNT treatment was demonstrated, indicating the responsiveness of the scales for objectively detecting clinical change in severity. Convergent validity of TWSTRS was evidenced by the high correlation of changes in TWSTRS

B. Duration factor

Provide an overall score estimated through the course of the standardized examination after estimating maximal excursion (exclusive of asking patient to allow head to deviate maximally). Weighted × 2 (see schematic representation of scoring duration)

0 None
1 Occasional deviation (<25% of the time), most often submaximal
2 Occasional deviation (<25% of the time), often maximal or intermittent deviation (25–50% of the time), most often submaximal
3 Intermittent deviation (25–50% of the time) often maximal or frequent deviation (50–75% of the time), most often submaximal
4 Frequent deviation (50–75% of the time), often maximal or constant deviation (>75% of the time), most of ten submaximal
5 Constant deviation (>75% of the time), often maximal

Schematic representation*



**The rater determines the proportion of time that the dystonic head posturing is present (left column) and then decides whether the deviations are most often maximal or submaximal, having previously determined the maximal excursion score (A).*

Figure 1 (Continued)

Severity Scale scores from videotape raters with patients' self-reported overall percent improvement. There was also substantial agreement between changes in total TWSTRS Severity Scale scores of videotape raters with changes in patient self-reported TWSTRS Disability and Pain Scale scores following BoNT treatment. The utility of the standardized TWSTRS Videotape Protocol was reflected by the substantial agreement between blinded videotape raters and a direct live examiner.

Further reliability testing of the TWSTRS severity subscale was undertaken by Comella and colleagues in the process of developing a teaching tape for scoring the TWSTRS Severity Scale. There was statistically significant interrater agreement for all individual components as well as for the complete TWSTRS Severity Scale based on the standardized videotape protocol.

Goertelmeyer and colleagues also demonstrated high interrater reliability and high sensitivity to change following BoNT as indicated by the mean change in TWSTRS Severity score, and recently a study by Kaji and colleagues confirmed the high interrater reliability of the TWSTRS Severity Scale

Tarsy compared TWSTRS to the Tsui scale and to a physician-rated subjective global improvement scale in CD patients treated with BoNT. There was a significant correlation between the posttreatment reduction of the Tsui scale and total TWSTRS scores as well as the TWSTRS Severity Scale scores. Both the TWSTRS and the Tsui score reduction rates also correlated with the global improvement scale. However, the TWSTRS Disability and Severity Scale score reduction rates showed a relatively weak correlation. TWSTRS Pain Scale score reduction also showed a weak or no correlation with the TWSTRS Severity scores or the Tsui scale scores, with some patients experiencing a significant reduction in pain scores despite the absence of objective improvement in either the TWSTRS Severity score or the Tsui scale score. The lack of correlation further

C. Effect of sensory tricks

0 Complete relief by one or more tricks
1 Partial or only limited relief by tricks
2 Little or no benefit from tricks

D. Shoulder elevation/anterior displacement

0 Absent
1 Mild (<1/3 possible range), intermittent or constant
2 Moderate (1/3–2/3 possible range) and constant (>75% of the time) or severe (>2/3 possible range) and intermittent
3 Severe and constant

E. Range of motion (without aid of sensory tricks)

If limitation occurs in more than one plane of motion use individual score that is highest

0 Able to move to extreme opposite position
1 Able to move head well past midline but not to extreme opposite position
2 Able to move head barely past midline
3 Able to move head toward but not past midline
4 Barely able to move head beyond abnormal posture

F. Time (*up to 60 s*) for which patient is able to maintain head within 10° of neutral position without the use of sensory 'tricks' (*mean of two attempts*)

0 0 > 60 s
1 46–60 s
2 31–45 s
3 16–30 s
4 <15 s

Total severity score = sum of A–F. Maximum score = 35

Figure 1 (Continued)

emphasizes that the clinical severity, disability, and pain subscales of TWSTRS measure distinct and importantly different attributes of CD.

Lindeboom and colleagues evaluated the extent to which the therapeutic effectiveness of BoNT is captured by various rating instruments. Changes in objective motor impairment evaluated with the Tsui scale correlated poorly with the TWSTRS Pain Scale, TWSTRS Disability Scale, and handicap and quality-of-life (HRQoL) as measured by subscales of the Medical Outcome Study Scale. The decision to continue BoNT treatment in this study correlated with a meaningful improvement to the patient as reflected by changes in TWSTRS Disability and HRQoL scale scores rather than changes in motor severity Tsui scores. These findings further indicate that each TWSTRS subscale assesses different aspects of the disorder and its effect on patients.

Comella and colleagues investigated the internal consistency of TWSTRS, determined the factor structure of TWSTRS, and assessed whether the identified factors form rational domains. High internal consistency was demonstrated for the TWSTRS scale as a whole. Factor structure analysis showed three clinically distinct factors: a motor severity factor, a disability factor, and a pain factor, again indicating that the severity, disability, and pain subscales of TWSTRS form rational domains that assess independent, different features of CD. Items found to contribute least to the factor structure included the effect of sensory tricks and the dichotomous items for anterior and sagittal shift.

Grafe and Goertelmeyer undertook a study to demonstrate the construct validity of the TWSTRS Severity Scale and examine the responsiveness of the factorial scores in a trial comparing different BoNT brands.

II. TWSTRS Disability Scale

1. Work (occupation or housework/home management)

0 No difficulty
1 Normal work expectations with satisfactory performance at usual level of occupation but some interference by torticollis
2 Most activities unlimited, selected activities very difficult and hampered but still possible with satisfactory performance
3 Working at lower than usual occupational level; most activities ham peers, all possible but with less than satisfactory performance in some activities
4 Unable to engage in voluntary or gainful employment; still able to perform some domestic responsibilities satisfactorily
5 Marginal or no ability to perform domestic responsibilities

2. Activities of daily living
(e.g., feeding, dressing, hygiene, includes washing, shaving, makeup, etc.)

0 No difficulty with any activity
1 Activities unlimited but some interference by torticollis
2 Most activities unlimited, selected activities very difficult and hampered but still possible using simple tricks
3 Most activities hampered or laborious but still possible; may use extreme 'tricks'
4 All activities impaired; some impossible or require assistance
5 Dependent on others in most self-care tasks

3. Driving

0 No difficulty (or has never driven a car)
1 Unlimited ability to drive but bothered by torticollis
2 Unlimited ability to drive but requires 'tricks' (including touching or holding face, holding head against head rest) to control torticollis
3 Can drive only short distances
4 Usually cannot drive because of torticollis
5 Unable to drive and cannot ride in a car for long stretches as a passenger because of torticollis

Figure 1 (Continued)

Factorial analysis revealed a clinically meaningful four factor solution. Factor one was primarily loaded by rotation, duration, range of movement, and time in midline; factor two by laterocollis and shoulder elevation/anterior displacement; factor three by lateral shift and sensory tricks; and factor four by retrocollis/anterocollis and sagittal shift. The total TWSTRS Severity Scale score as well as the factorial subscores was sensitive to change due to

4. Reading

0 No difficulty
1 Unlimited ability to read in normal seated position but bothered by torticollis
2 Unlimited ability to read in normal seated position but requires use of 'tricks' to control torticollis
3 Unlimited ability to read but requires extensive measures to control torticollis or is able to read only in nonseated position (e.g., lying down)
4 Limited ability to read because of torticollis despite tricks
5 Unable to read more than a few sentences because of torticollis

5. Television

0 No difficulty
1 Unlimited ability to watch television in normal seated position but bothered by torticollis
2 Unlimited ability to watch television in normal seated position but requires the use of tricks to control torticollis
3 Unlimited ability to watch television but requires extensive measures to control torticollis or is able to view only in nonseated position (e.g., lying down)
4 Limited ability to watch television because of torticollis
5 Unable to watch television for more than a few minutes because of torticollis

6. Activities outside the home

(e.g., shopping, walking about, movies, dining, and other recreational activities)

0 No difficulty
1 Unlimited activities but bothered by torticollis
2 Unlimited activities but requires simple 'tricks' to accomplish
3 Accomplishes activities only when accompanied by others because of torticollis
4 Limited activities outside home; certain activities impossible or given up because of torticollis
5 Rarely if ever engages in activities outside the home

Total disability score = sum of 1–6. Maximum score = 30

Figure 1 (Continued)

the therapeutic intervention with the exception of factor three (lateral shift and sensory tricks). The latter finding is consistent with the study of Comella and colleagues, which found a lack of variability of scale items for shift and sensory tricks. There were no compensation effects between the single items. The study's findings provide further support that the TWSTRS Severity Scale is a valid and responsive tool for assessing change following therapeutic intervention.

Several deficiencies and ambiguities of TWSTRS have been identified by Comella and others, including the absence of a scale component to assess the presence and severity of associated dystonic head tremor, the lack of the specification of midline and the full range of active motion in each of the three planes, and the absence of specification of the duration of relief provided by the use of sensory tricks. Elimination or modification of the dichotomous items for lateral and sagittal shift as well as the item for the effect of sensory tricks has been suggested because of the lack of variability of these items. Further data-driven refinement and testing of TWSTRS are required.

Substantial evidence for TWSTRS reliability and validity as well as its responsiveness to detect a clinically significant change following treatment has steadily accumulated. TWSTRS encompasses the heterogeneity and variability of the clinical features of CD, and the subscales for severity, disability, and pain evaluate distinct aspects of CD. Consistent application of TWSTRS is promoted by the standardized examination contained in the TWSTRS Videotape Protocol as well as the availability of a teaching

III. TWSTRS Pain Scale

1. Rate the severity of neck pain during the last week on a scale of 0–10 where a score of 0 represents no pain and 10 represents the most excruciating pain imaginable

Best 0–10
Worst 0–10
Usual 0–10

Severity = [(2 × usual) + best + worst]/4

Maximum score = 10

2. Rate the duration of neck pain

0 None
1 Present <10%' of the time
2 Present 10%–<25% of the time
3 Present 25%–<50% of the time
4 Present 50%–<75% of the time
5 Present >75% of the time

3. Rate the degree to which pain contributes to disability

0 No limitation or interference from pain
1 Pain is quite bothersome but not a source of disability
2 Pain definitely interferes with some tasks but is not a major contributor to disability
3 Pain accounts for some (less than half) but not all disability
4 Pain is a major source of difficulty with activities; separate from this, head pulling is also a source of some (less than half) disability
5 Pain is the major source of disability; without it most impaired activities could be performed quite satisfactorily despite the head pulling

Total pain scale score = sum of 1–3. Maximum score = 20

TWSTRS score = Severity + disability + pain Maximum score = 85

Figure 1 (Continued)

TWSTRS videotape protocol

1. **Standing-viewed from front, side, and back x 10 s each**

2. **Walking-20 feet back and forth**

   a) Without instructions × 2
   b) With instructions not to resist deviation (i.e., allow head to deviate to maximum)× 2

3. **Sitting-in preferred or most comfortable position**

   a) Without instructions × 30 s
   b) With instructions not to resist deviation × 30 s

4. **Distracting or activating maneuvers: (sitting) (R and L separately) each× 10 s**

   a) Finger tapping
   b) Opening and closing fist
   c) Pronation and supination forearm
   d) Arms outstretched, held under nose, finger to nose × 3
   e) Foot tapping

5. **Time in midline**

   With active resistance to deviation but without aid of sensory tricks or support. Patient asked to maintain head in midline for as long as possible-maximum 60 s× 2 attempts. Patient instructed not to talk.

6. **Effect of 'tricks'**

   Including touching side of face, holding chin, holding back of neck or head, pressing against wall behind head, and other preferred tricks used by patient

7. **Active range of movement (× 2 each time)**

   Rotation, lateral flexion, forward flexion, extension

8. **Writing name, sentence, repetitive words or phrase × 10 s**

9. **Lying supine × 20 s**

Figure 1 The Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS).

tape for the TWSTRS Severity Scale. TWSTRS has gained widespread acceptance and is the outcome measure most commonly used in CD intervention studies.

U

Unified Parkinson's Disease Rating Scale (UPDRS) and The Movement-Disorder Society Sponsored-unified Parkinson's Disease Rating Scale (MDS-UPDRS)

C G Goetz

The UPDRS

The Unified Parkinson's Disease Rating Scale (UPDRS) was originally developed in the 1980s and has become the most widely used clinical rating scale for Parkinson's disease (PD). In almost all instances, for clinical trials assessing new treatments for PD, the UPDRS has been the scale used to determine the treatment-related benefits. The original scale was composed of four parts: part I assesses behavioral problems such as intellectual decline, hallucinations, and depression; part II assesses patients' perceptions of their ability to carry out activities of daily living, including dressing, walking, and eating; part III covers the motor evaluation of disability and includes ratings for tremor, slowness (bradykinesia), stiffness (rigidity), and balance; part IV covers a number of treatment complications including ratings of involuntary movements (dyskinesias), painful cramps (dystonia), and irregular medication responses (motor fluctuations). The goal of the UPDRS was to provide a comprehensive, practical, and easy to administer scale that can be used across all patients regardless of severity, medication treatment, or age. Clinimetric testing was performed on components of the original UPDRS; recommendations were published on enhancing uniform application of the scale, and a teaching video-tape was formulated.

Needs for Changes to Reflect Scientific Advances

Over its 20 years of usage, the UPDRS has been lauded as the best available rating scale for rating PD. Nonetheless, over time, many investigators have commented on some weaknesses of the scale, including a number of unclear questions or answers. Further, many current research trials increasingly focus on very early PD, and the scale was not designed to detect patterns of changes that occur particularly in mildly disabled patients. Finally, with scientific advances, experts now recognize several aspects of PD that are not assessed with the original UPDRS.

In 2001, the Movement Disorder Society (MDS) sponsored a critique of the UPDRS, and the summary document recommended the development of a new version of the UPDRS. According to the published recommendations from this critique, the new version should retain the core four-part structure of the original scale, but resolve identified ambiguities, provide clear instructions, and incorporate the clinically pertinent PD-related problems poorly captured in the original version. The effort resulted in a new scale, termed the MDS-sponsored UPDRS revision (MDS-UPDRS). This version was presented in a full format in June 2008 and has undergone clinimetric testing in its original English version. Official foreign translations and introduction of the scale into clinical trials are anticipated.

How is the New Scale Different?

Patient/Caregiver Involvement

The new scale has direct patient and caregiver involvement, and many questions as a patient-based questionnaire are formulated in standard language. This questionnaire can be filled in the waiting room or after the physician visit. These questions focus on the activities of daily living and several behaviors such as fatigue and anxious mood. The new scale is organized so that all questions have a consistency that is anchored in the concept that a zero means normal or no problems; one slight problems; two mild problems; three moderate problems; and four severe

problems. In all instances, descriptive language is added for each question so that the patient and rater have clear explanations.

New Questions

The MDS-UPDRS contains more questions than the UPDRS (**Table 1**), but because of the questionnaire methodology for many items, the time estimate for the entire scale is estimated to remain ~30 min for the physician.

More Emphasis on Rating Mild Impairment/Disability

The original UPDRS placed considerable emphasis on marked and severe disabilities or impairments. The scientific advances since the original scale's development, along with the growing emphasis on neuroprotection and early therapies, prompted a strong recommendation in the published critique to adapt the scale so that it measured more mild deficits and allowed detection of small changes in early disease. In order to respect the limitation of five rating options for each item, this decision necessarily collapses impairments that separated severe versus marked impairments in favor of allowing a wider range of differentiation among the lower ranges of disability.

Cultural Sensitivity and Official Non-English Translations

The published critique identified cultural biases in the original scale and considered some questions to be restrictive to developed countries. Further, the original scale focused on specific activities and was not tailored to assess the impact of PD on activities (hobbies, personal interests) that are particularly important to an individual subject. The MDS-UPDRS addresses these issues first by focusing on the experiences (e.g., feeding) rather than tasks (e.g., handling utensils). Second, a new question addresses the impact of PD disability on the performance of tasks related to areas of personal interest, without specifying a given activity. This question allows patients to sculpt their response to consider areas of personal importance, remaining bias-free, applying to piano playing, ping-pong, or raising snakes with equal specificity. This question is aimed to relate to different activities for different patients, but allows each subject to choose a key activity of interest for a focused response. Finally, though the first phases of testing use only an English version, official translations in multiple languages will be prepared and tested.

Table 1 MDS-UPDRS

Part I: Nonmotor aspects of experiences of daily living (13 questions)
- Cognitive impairment
- Hallucinations and psychosis
- Depressed mood
- Anxious mood[a]
- Apathy
- Features of dopamine dysregulation syndrome[a]
- Sleep problems
- Daytime sleepiness[a]
- Pain and other sensations
- Urinary problems[a]
- Constipation problems[a]
- Lightheadedness on standing
- Fatigue[a]

Part II: Motor experiences of daily living (13 questions)
- Speech
- Saliva and drooling
- Chewing and swallowing
- Eating tasks
- Dressing
- Hygiene
- Handwriting
- Doing hobbies and other activities[a]
- Turning in bed
- Tremor impact on activities
- Getting in and out of bed
- Walking and balance
- Freezing

Part III: Motor examination (18 questions)
- Speech
- Facial expression
- Rigidity
- Finger tapping
- Hand movements
- Pronation–supination movements of hands
- Toe tapping[a]
- Leg agility
- Arising from chair
- Gait
- Freezing of gait
- Postural stability
- Posture
- Global spontaneity of movement (body bradykinesia)
- Postural tremor of hands
- Kinetic tremor of hands[a]
- Rest tremor amplitude
- Constancy of rest tremor[a]

Part IV: Motor complications (6 questions)
- Dyskinesias: time spent with dyskinesias
- Dyskinesias: functional impact of dyskinesias
- Dykinesia: painful off-state dystonia
- Motor fluctuations: time spent in the off state
- Motor fluctuations: functional impact of fluctuations
- Motor fluctuations: complexity of motor fluctuations

[a]Are domains not previously assessed.
The unmarked items are newly written, but were covered in some capacity in the original UPDRS.

Clinimetric Testing Program

The MDS-UPDRS has been tested in a direct comparison with the original version and found to have a very strong clinimetric profile. This effort involved over 800 patients with Parkinson's disease and had both Caucasian and minority racial/ethnic representation. The factor structure of the new scale favors utilizing each of

the four parts separately rather than collapsing all values into a final 'total' score. For official non-English translations, a centralized clinimetric program exists within the MDS so that each translation effort meets standardized clinimetric criteria. A teaching tape is also part of the training program so that standardized methods of application are utilized.

Unverricht–Lundborg's Disease

A Magaudda, University of Messina, Messina, Italy

Glossary

Action myoclonus – Myoclonic jerks provoked by the intentional movements.
Cystatin B – Its function is to ensure protection of cells against the proteolytic activity of lysosomal peptidases that are released occasionally during normal cell death or activated by proliferating cancer cells.
Progressive myoclonus epilepsies (PME) – Represent a heterogeneous group of often familial, sometimes sporadic, diseases that are characterized by the occurrence of epileptic seizures, prominent myoclonus, and a progressive course.
Sensitive-myoclonus – Myoclonic jerks provoked by light, touching, noise, especially emotion.
Unverricht–Lundborg disease – PME characterized by stimulus-sensitive action myoclonus, clonic–tonic–clonic epileptic seizures, and ataxia.

Introduction

ULD, first described by Unverricht in 1891 and by Lundborg in 1903, is a progressive myoclonus epilepsy (PME) type 1 (EPM1) characterized by myoclonus, epilepsy, and ataxia, without major cognitive decline.

The disease is inherited in an autosomal recessive manner and it is caused by an unstable expansion of a 12-nucleotide (dodecamer) repeat 5-CCC-CGC-CCC-GCG-3t in the promoter region of the cystatin B (CSTB) gene, mapping on CR 21q22.31.

Cystatin B is an inhibitor of cysteine proteases that are thought to be involved in the initiation of apoptosis. With mutation in cystatin B gene and loss of inhibition of cysteine proteases, apoptosis proceeds uncontrolled.

Although ULD occurs worldwide, its prevalence is increased in certain populations, for example, in Italy, southern France, and in the North African countries of Tunisia, Algeria, and Morocco. The age of onset is between 6 and 16 years and the symptom(s) at onset can be either myoclonic jerks and/or generalized tonic–clonic seizures. The most incapacitating symptom is stimulus-sensitive action myoclonus, exacerbated by light, noise, physical exertion, and emotions. Tonic–clonic seizures, often preceded by massive myoclonic jerks, are the most common type of epileptic seizures in ULD patients. EEGs show normal or mildly slow background activity (BA), brief bursts of generalized spike-wave discharges (GSWD) both spontaneous and provoked by intermittent photic stimulation (IPS). Classic treatment includes Valproate usually in combination with

Clonazepam. Levetiracetam and Zonisamide have been recently reported to be efficacious in ULD. Although the disease is progressive, the condition of patients affected by ULD appears less serious than reported in the past. The intensity of myoclonus is mild at the disease onset and worsens only during the first 5 to 10 years of illness, to stabilize thereafter; epilepsy has an active phase in the early 10 years of illness and remits in most patients thereafter.

Pathogenesis

The pathogenesis by which a deficit of CSTB leads to ULD has not yet been elucidated. CSTB knock-out mice display a behavioral phenotype similar to that shown by human patients affected by ULD, and the analysis of the CSTB-deficient brain reveals the presence of apoptosis mainly involving cerebellar granular cells and cerebellar atrophy.

CSTB knock-out mice show an increased susceptibility to seizures and a greater degree of neuronal damage after seizures than WT mice. It has been hypothesized that the lack of CSTB, besides playing an etiological role in triggering neurodegeneration and seizures in ULD, may also worsen brain damage after the disease onset, when seizures and epileptic events recur persistently.

Epidemiology

Although ULD occurs worldwide, its prevalence is increased in certain countries, for example, in Italy, southern France, and North Africa (Tunisia, Algeria, and Morocco), where the exact prevalence figures are not available. The incidence of ULD in Finland is about 1:20 000 births per year. Patients with ULD have been observed also in the Reunion Island, North America, The Netherlands, the Arabian peninsula, the Galilee region of Israel, Cuba, Southern India, and the Congolese Africa.

Clinical Features and Diagnostic Criteria

The age of onset is between 6 and 16 years and the symptom(s) at onset can be either myoclonic jerks and/or generalized tonic–clonic seizures.

Myoclonus

The most incapacitating symptom is stimulus sensitive action myoclonus, exacerbated by light, noise, physical exertion, and emotions. Its severity changes at different times in the same day, being usually more pronounced in the morning upon wakening, and varies from day to day (good day, bad day). Handwriting, drinking, standing up from a sitting position, walking, and speaking are performed with difficulty. Myoclonic jerks are asynchronous, may be focal or multifocal, and are not related to epileptiform discharges on the EEG. They may generalize to a massive myoclonic seizure, which can lead to a fall or a tonic–clonic seizure. Negative myoclonus is often found in association with positive myoclonus. The worsening of myoclonus is observed between the first and the fifth years of illness and thereafter stabilizes.

A great variability of the myoclonus severity exists among patients, even among siblings.

Epilepsy

Tonic–clonic seizures are the most common type of epileptic seizures in ULD patients. They can be preceded by a series of massive myoclonic jerks (clonic–tonic–clonic seizures). Absence, simple motor, or complex focal seizures may be present, but they are not common. Epilepsy has an active phase in the first 10 years of illness and remits in most patients thereafter.

Other Neurological Findings

Ataxia, incoordination, and dysarthria are usually observed some years after the onset of the disease.

It is difficult to assess whether they represent independent cerebellar signs or just the effect of action myoclonus.

Neuropsychological Profile

A progressive cognitive decline of about 10 points of total IQ every 10 years of disease, reported by Koskiniemi et al. in ULD patients of Finnish origin, has been later attributed by the same authors to the use of high-phenytoin regimen in Finnish patients. Indeed, no significant cognitive decline has been observed in patients from Mediterranean areas. In a recent study performed in 20 patients from Italy, France, and North Africa, with a mean duration of disease of 22 years, a mild to moderate cognitive impairment, in particular of memory abilities, was found in 11 patients.

Depression, anxiety, aggressiveness, and mood lability are frequently observed, especially in patients seriously handicapped by severe myoclonus. These symptoms often make the patient interrupt education, cause major problems in interpersonal relations, and sometimes, produce suicide attempts.

Diagnosis

Diagnosis may be difficult at the beginning of the disease, when myoclonus is very mild or even absent and

tonic–clonic seizures are rare and easily controlled by antiepileptic drugs.

Parental consanguinity and the presence of affected siblings may rouse the suspicion for ULD.

Diagnosis is easier 1–2 years after the onset, when action myoclonus becomes evident, stimulus sensitive, and progressively worsens.

Photoparoxysmal responses (PPRs) and the features of GSWD, showing an irregular pattern and very rapid spikes, can lead an expert electroencephalografist to differentiate them from the more regular GSWD observed in the idiopathic generalized epilepsy (**Figure 2**) and suspect the diagnosis of ULD.

MRI is not contributing to the diagnosis, being very often normal, especially in the early stage of the disease.

The diagnosis must be confirmed by genetic test, with the detection of the cystatin B gene mutation.

Workup

EEG

At the disease onset, background activity (BA) is normal or mildly slow (BA at 6–7 Hz).

Superimposed slower activity at 4–5 Hz can be present, resulting in an irregular appearance of BA. BA keeps stable during the course of the disease.

During the initial years of the disease, EEGs show spontaneous brief bursts of GSWD, characterized by very rapid spikes (**Figure 1**). Focal epileptiform abnormalities can be observed over the central and posterior regions of the scalp. Intermittent photic stimulation (IPS) provokes the appearance of GSWD and increases myoclonus, both generalized and focal.

During sleep, a normal representation of physiological sleep patterns and a reduction of GSWD during nREM and REM sleep, along with the presence of fast spikes and polyspikes over the central and the vertex regions during REM sleep, were observed.

Long-term evolution of EEG in ULD is characterized by no relevant deterioration of BA, a gradual reduction of GSWD and PPR, correlating with good seizure outcome, and a progressive disappearance of physiological sleep patterns 10–20 years after the disease onset.

Neuroimaging

MRI, recorded during the early stage of the disease, is usually normal. MRI of the brain and MRS of the pons and dentate, obtained in 10 patients at a later stage of the disease, showed decreased bulk of the basis pontis, medulla, and cerebellar hemispheres. Cerebral atrophy was present in six patients.

The *N*-acetylaspartate/creatine and choline/creatine ratios were reduced in the pons but not in the dentate. Brainstem involvement could play a role in the pathophysiology of ULD.

Differential Diagnosis

In the early stage of the disease, ULD can be misdiagnosed as Juvenile Myoclonic Epilepsy (Janz syndrome) due to

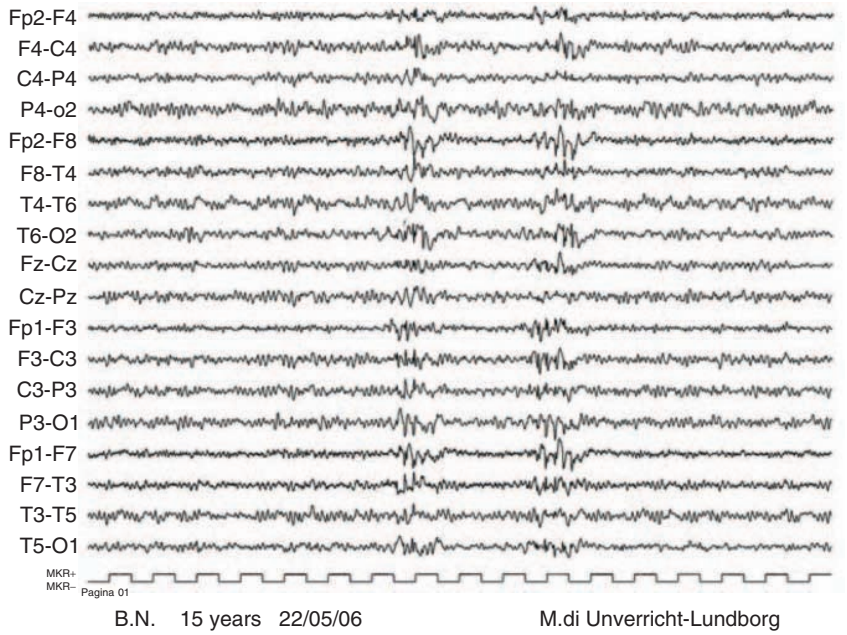

Figure 1 EEG in a 15-year-old ULD patient, showing normal background activity and brief bursts of irregular generalized spike – wave discharges, characterized by very rapid spikes.

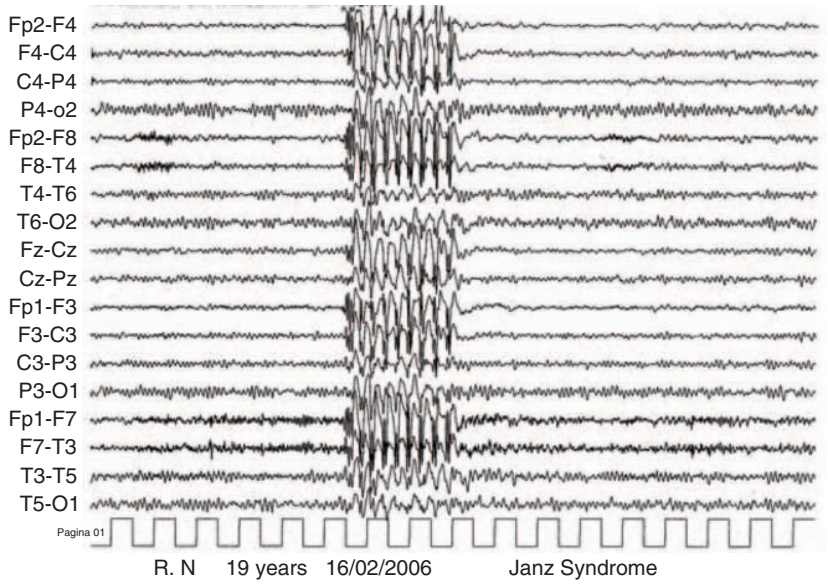

Figure 2 EEG in a 19-year-old patient affected by Janz Sindrome, showing a very regular generalized spike-wave discharges, clearly different from the irregular pattern observed in ULD patient (**Figure 1**).

the association of myoclonic jerks, tonic–clonic seizures, GSWD, and PPRs on the EEG. The progressive worsening of action myoclonus lead to the correct diagnosis of PME.

Other forms of PME, for example, myoclonic epilepsy with ragged red fibers (MERRF), neuronal ceroid lipofuscinosis (NCL), Lafora's disease, dentato-rubral-pallido-luysian atrophy (DRPLA), and sialidoses may be differentiated from ULD, on the basis of the inheritance manner, age of onset, and associated symptoms other than epilepsy and myoclonus (dementia, visual symptoms, dysmorphism). A Palestinian family with ULD phenotype, with a relatively earlier age of onset, with a linkage on chromosome 12, has been described.

Management

Valproate (VPA) is effective both on myoclonus and epileptic seizures. It is usually associated with Clonazepam (CZP), which can be used at high doses, up to 20 mg day^{-1}. High-dose Piracetam (PIR), up to 37 500 mg day^{-1}, has a good antimyoclonic effect, but can provoke chronic diarrhea. Levetiracetam (LEV), a drug chemically related to PIR, has been found useful for both myoclonus and epileptic seizures and should be considered as a first-line option in the treatment of ULD, because it has fewer adverse effects than VPA and is much less expensive than high-dose PIR. Zonisamide (ZNS) has a good antimyoclonic and antiepileptic efficacy. Other drugs used as antimyoclonic agents, including topiramate, baclofen, and chloral hydrate, do not show any satisfactory efficacy in ULD. *N*-Acetylcysteine, an antioxidant, has been reported to slow the course of ULD. Phenytoin, carbamazepine, oxcarbazepine, tiagabine, vigabatrin, gabapentin, and pregabalin should be avoided, since they may aggravate myoclonus.

Prognosis

Although the course of the disease is progressive, the current condition of patients affected by ULD appears less serious than reported in the past. It appears that avoidance of phenytoin and other potentially aggravating drugs, along with an early use of VPA and CZP, has contributed to the improvement of the clinical picture.

In a recent study on the long-term follow-up of ULD patients, has been observed that (1) the intensity of myoclonus is mild at the disease onset and worsens only during the first 5–10 years of illness, to stabilize thereafter (see Video clip, showing a 46-year-old patient affected by ULD with a disease duration of 35 years, who is still able to walk on his own), (2) epilepsy has an active phase in the early 10 years of illness and remits in most patients thereafter; (3) GSWD and PPRs disappear in most patients and BA remains stable. Life expectancy appears to be much longer than in the past, when many individuals died between 8 and 15 years after the onset of disease. Sixty and seventy-year-old patients have been reported.

The phenotype of ULD is very heterogeneous: the severity of myoclonus and epilepsy and the rate of their progression are very different from one patient to another, even within the same family. Phenotypic variability does not correlate with the repeat-size expansion, but no detailed evaluation of phenotype–genotype correlation has been made so far.

V

Variant Creutzfeldt–Jakob Disease

S Notari, X Xiao, M Shimoji, J Yuan, H Bi, I Cali, Q Kong, and W-Q Zou, Case Western Reserve University School of Medicine, Cleveland, OH, USA

Glossary

Ataxia – Inability to coordinate voluntary movements, leading to unsteady movements and staggering gait; most often associated with lesions of the cerebellum.

Bovine spongiform encephalopathy (BSE) – A prion disease of cattle; the bovine prions are transmitted to humans through consumption of contaminated meat products, and lead to variant Creutzfeldt–Jacob Disease (vCJD).

Cellular prion protein (PrP^C) – A normal glycoprotein attached to the cell surface through a glycosylphosphatidylinositol (GPI) anchor most abundant in the brain but also in other organs.

Myoclonus – A sudden twitching of muscles or parts of muscles, without rhythm or pattern.

Psychiatric symptoms – Early symptoms frequently seen in vCJD including depression, anxiety, and withdrawal.

Scrapie prion protein (PrP^{Sc}) – An infectious and pathogenic protein also called prion that derives from PrP^C via a structural transition from α-helix into β-sheet. In sharp contrast to PrP^C, PrP^{Sc} is detergent-insoluble, resistant to protease, prone to aggregation, and infectious.

Variant Creutzfeldt–Jakob disease (vCJD) – A variant form of Creutzfeldt–Jakob disease acquired from the consumption of BSE-contaminated meat. It is characterized by young age at onset; early dominant psychiatric symptoms followed by neurologic deficits (cerebellar ataxia, involuntary movements, dystonia, and myoclonus); abundant florid prion plaques; and PK-resistant PrP^{Sc} in the brain.

Definition and History

Variant Creutzfeldt–Jakob disease (vCJD) belongs to a group of highly heterogeneous and fatal transmissible spongiform encephalopathies, or prion diseases, that affect both animals and humans. Animal prion diseases include scrapie in sheep and goats, bovine spongiform encephalopathy (BSE or mad cow disease) in cattle, as well as chronic wasting disease in deer and elk. In humans, prion diseases can be sporadic, inherited, or acquired by infection, depending on their etiology. They mainly manifest four major phenotypes: CJD, Gerstmann–Sträussler–Scheinker disease, kuru, and fatal familial insomnia. As a group, prion diseases are characterized clinically by disorders of cognition and movement; pathologically by spongiform degeneration, neuronal loss, and astrocytosis; and biochemically by deposition of an infectious proteinaceous pathogen called prion or scrapie prion protein (PrP^{Sc}). In addition to these basic characteristics, vCJD also possesses a unique identity: early dominant psychiatric symptoms followed by late neurologic deficits, young age at death, presence in the brain of florid prion plaques, and an abnormal PrP that is resistant to protease digestion and displays distinctive electrophoretic characteristics (**Figure 1**).

vCJD was first discovered by Will and colleagues in the United Kingdom in 1996. Its discovery, together with the immediate demonstration of the causal link between vCJD and BSE, represent milestones in the history of prion disease. Not only did these findings demonstrate, for the first time, that prion disease could be transmitted from animals to humans, but they also greatly accelerated the establishment of surveillance and control of prion diseases. Following the outbreak of BSE, the surveillance of CJD was heightened in the United Kingdom in 1990 in order to monitor any changes in this condition that might be associated with transmission of BSE to humans. Subsequently,

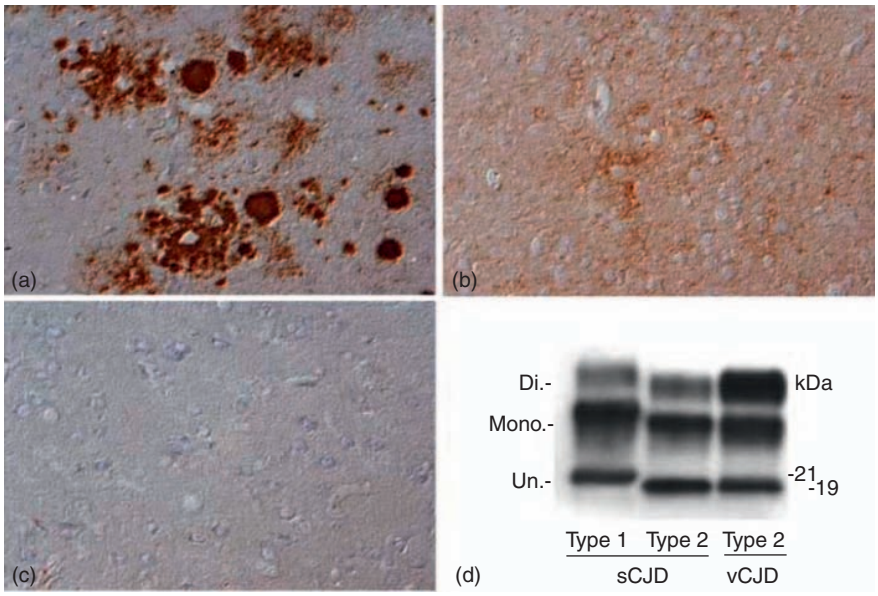

Figure 1 PrP^{Sc} detection by immunohistochemistry and Western Blot analysis. Immunohistochemistry of brains affected by vCJD (a) and sCJD (b), and of a normal brain (c) with anti-PrP antibody 3F4. Amount and pattern of distribution of PrP^{Sc} are different between vCJD, where PrP^{Sc} forms clumps, and sCJD, which shows dot-like formations. No PrP is seen in the normal brain (J. Ironside, National CJD Surveillance Center, Edinburgh, UK, and P. Gambetti, National Prion Disease Pathology Surveillance Center, Cleveland, OH, USA). Probed with 3F4 (d) Homogenates of the frontal cortex from sCJDMM1 (type 1), sCJDMM2 (type 2) and vCJD were treated with proteinase K (PK) prior to Western blotting with 3F4 antibody. The PK-resistant PrP core fragments from sCJD exhibit a dominant middle band corresponding to monoglycosylated PrP and a lower band corresponding to unglycosylated PrP migrating at ~21 kDa (PrP^{Sc} type 1) or at ~19 kDa (PrP^{Sc} type 2). In contrast, the PK-resistant PrP core fragments from all vCJD show a single uniform profile: a dominant upper band corresponding to diglycosylated PrP and a lower band migrating at ~19 kDa. Di.: diglycosylated PrP; Mono.: monoglycosylated PrP; and Un.: unglycosylated PrP.

in 1993, the European Union started a project involving the majority of European countries (extended to all member states in 1998) in which common methodologies and criteria for case definition were adopted. In 1995 and early 1996, through these efforts a number of cases of CJD were identified in the United Kingdom with a unique phenotype distinct from sporadic CJD. By March 1996, ten cases of CJD sharing a very similar phenotype had been collected: the patients were of a young age at death (mean 29 years vs. 66 years in sporadic CJD); and the illness was characterized by long duration (mean 14 months vs. 4.5 months in sporadic CJD) and an unusual and remarkably uniform clinical presentation, distinct from that previously seen in CJD. Subsequent animal inoculation studies confirmed that this novel human prion disease is caused by the same prion strain that causes BSE in cattle.

Pathogenesis

vCJD, along with kuru of New Guinea, and iatrogenic CJD, are the three forms of the disease known to date to be acquired by infection. However, unlike kuru and iatrogenic CJD (caused, respectively, by human-to-human transmission through ritual cannibalism, or medical and surgical procedures), vCJD is caused by transmission from cattle, most likely through an oral route by consumption of prion-contaminated meat products, or possibly through parenteral routes. In addition to the acquired form, the other forms of prion diseases comprise sporadic CJD, the most common form and genetically determined or familial CJD. However, regardless of their distinct etiologies, all prion diseases share a fundamental pathogenetic mechanism: the conversion of the normal or cellular PrP (PrP^{C}) into an isoform, identified as scrapie PrP (PrP^{Sc}). PrP^{Sc} is the only known component of prion that is believed to be pathogenic and infectious but at the same time (and in contrast to viruses and bacteria) is thought to be free of nucleic acids. It is postulated that in acquired prion diseases, including vCJD, prions are acquired by exogenous infection whereas in sporadic and familial CJD prions form spontaneously, either as a result of a random misfolding event or as a result of the presence of PrP destabilizing mutation.

Most of PrP^{C} is full-length, diglycosylated, and attached to the cell surface via a glycosylphosphatidylinisotol (GPI) anchor; but small amounts of PrP^{C} may be N-terminally truncated, monoglycosylated or unglycosylated, anchorless, or cytosolic. PrP^{C} and PrP^{Sc} share their primary structure. The critical difference between these two proteins lies in the conformation, in that PrP^{C} converts into PrP^{Sc} through an α-helix to β-sheet structural transition which results in profound differences in the physicochemical and biological

properties of the two conformers. PrP^{Sc} is rich in β-sheets and is detergent-insoluble, multimeric, resistant to proteinase K (PK) treatment, and infectious. In contrast, PrP^{C} is rich in α-helix, detergent-soluble, monomeric, sensitive to PK, and noninfectious.

Although there is no doubt that the coexistence of PrP^{Sc} and PrP^{C} in the central nervous system (CNS) is a prerequisite for prion diseases, the role of these two PrP conformers in the pathogenesis of prion disease is not completely understood. Two major hypotheses have been proposed to explain how changes in PrP^{C} conformation could cause neurodegeneration: first, functional gain, in which prion pathology is attributable to the acquisition of toxic function; and second, functional loss, in which a PrP^{C} physiologic activity is lost upon conversion to or interaction with PrP^{Sc}.

A Single Uniform Prion Strain

Based on gel mobility and glycoform ratio, PrP^{Sc} detected in sCJD can be divided into two types: PrP^{Sc} type 1 with an unglycosylated PrP migrating at ~21 kDa and a dominant N-terminal protease cleavage site at residue 82; and PrP^{Sc} type 2 with an unglycosylated PrP migrating at ~19 kDa and a cleavage site at residue 97 on the gel (**Figure 1**). Moreover, all PrP^{Sc} species from sCJD exhibit a dominant monoglycosylated PrP. In contrast, PrP^{Sc} from all vCJD examined so far is invariably of a dominant diglycosylated PrP and a 19-kDa unglycosylated PrP with a primary cleavage site at residue 97 (**Figure 1**). The electrophoretic profile of PrP^{Sc} detected in all vCJD cases is virtually identical to that found in BSE, which indeed implies that prion present in vCJD derives from BSE.

Polymorphism at Residue 129 of PrP

It has been believed that polymorphism at residue 129 of PrP (either methionine (M) or valine (V)) is associated with susceptibility to human prion. Although most sporadic CJD occurs in individuals homozygous for 129 MM, it also affects individuals with genotype 129 MV or 129 VV. Remarkably, all clinically affected vCJD cases studied so far have been 129 MM homozygous. However, the identification, in an anonymous screening study, of two positive appendix tissues from subjects with 129 VV genotype, together with the description of an asymptomatic case of vCJD in an 129 MV patient infected by blood transfusion, highlight the possibility that polymorphisms rather than 129 MM could also be susceptible to variant CJD although they might exhibit atypical phenotypes such as a subclinical form.

Involvement of the Lymphoreticular System

The distinctive pathogenesis of vCJD in comparison with other forms of CJD is also reflected in the involvement of the lymphoreticular system. PrP^{Sc} is readily detectable in lymphoreticular tissues in vCJD including gut-associated lymphoid tissue, tonsil, spleen, appendix, and lymph nodes, whereas it is only detected in the spleen of some sporadic CJD using highly sensitive methods. Prion neuroinvasion bears remarkable similarities to neuroinvasion by viral agents.

Oral or Parenteral Transmission Route

Presumably, all clinically infected vCJD cases are contracted orally, through consumption of contaminated meat products derived from BSE cattle. But exactly how the BSE prion spreads from the gastrointestinal system to the CNS remains an unresolved question. It has been hypothesized that the invading prions undergo two phases to reach the CNS: they accumulate and replicate in the lymphoreticular organs (primary phase) and then disseminate to the CNS through the peripheral nerves. Studies in prion-infected animals revealed that the autonomous nervous system, including both vagal and sympathetic nerve fibers, contributes to the spread of orally administered prions. These results are consistent with a finding that PrP^{Sc} is detected in the sympathetic nervous system (stellate and celiac ganglia) in vCJD but not in sCJD. In addition to the oral route, recent identification of three cases of transfusion-associated vCJD prion infection has raised significant concerns that there may be substantial risks of iatrogenic transmission of vCJD prions. Surprisingly, an asymptomatic transfusion-associated vCJD case exhibited MV polymorphism at residue 129 but no neurologic disorders and no prion-related neuropathologic changes. Moreover, PrP^{Sc} was detectable only in the lymphoreticular tissues but not in the brain. It is unclear whether this preclinical stage resulted from the parenteral route transmission or from the 129 MV heterozygous polymorphism.

Epidemiology and Risk Factors

Variant CJD has been reported in many countries particularly in Europe. As of February 2009, 214 cases of vCJD have been identified worldwide, mostly in the United Kingdom (**Table 1**). The patients in Ireland, Canada, and the United States of America had spent significant periods of time in the United Kingdom, which suggests that these patients contracted the disease through dietary exposure to BSE in the United Kingdom. However, the Italian patient and most French patients had not visited the United Kingdom. How were these patients infected by the BSE prion? Brandel and colleagues recently conducted a study in which they demonstrated that the British and French vCJD cases manifested very similar clinical, histopathologic, and molecular features and concluded that the two sets of vCJD patients shared the same

prion strain. These findings highlight two issues. First, they raise the question of the origin of the infectious prion in the French vCJD: whether it originates from British BSE or from indigenous French BSE; and second, whether vCJD worldwide is caused by one prion strain or whether all vCJD cases carry the same British prion strain. It is critical that these two issues be clarified, so that the diffusion of the BSE epidemics through different continents can be understood and arrested.

Table 1 Number of vCJD reported and countries with the disease

Country	*Number of cases*
Unite Kingdom	169
France	23
Spain	5
Republic of Ireland	4

Clinical Features, Diagnostic Work-Up and Tests, and Diagnostic Criteria

It is widely believed that the high heterogeneity of sporadic CJD results mainly from the chameleon-like conformation of prions. Indeed, at least five clinical subtypes of sCJD have been identified based on a combination of PrP^{Sc} types and PrP polymorphism at residue 129. Surprisingly, the clinical manifestations of vCJD linked to a single uniform prion strain (PrP^{Sc} type 2 with the homozygous MM) remain relatively heterogeneous (**Table 2**). According to an analysis of clinical features of the first 100 cases by Will and colleagues, 63% of cases present with psychiatric symptoms alone, 15% with isolated neurologic symptoms and 22% with mixed features. Patients with vCJD usually

Table 2 Differences between variant and sporadic CJD

	Variant CJD	*Typical sporadic CJD (MM1)*
Clinical features[a,b]		
Mean age at death	29 years	65 years
Median duration of illness	14 months	4 months
Neurological signs	*Presentation*: affective or psychotic disorder, persistent pain, sensory symptoms, sometimes gait ataxia or dysarthria	*Presentation*: cognitive impairment, ataxia, mental, and visual signs
	Later stage: ataxia, dementia	*Later stage*: myoclonus, ataxia, and pyramidal signs
General diagnostic test[a]		
Thalamic MRI high signal	Pulvinar 90%	Caudate/putamen 60%
EEG	'Typical' 0%	'Typical' 80%
PrP^{Sc} detection in tonsil biopsy	Positive	Negative
Neuropathological features[b,c]		
Cerebral and cerebellar cortex	Multiple florid plaques in H&E sections, numerous small clusters of plaques in PrP stained sections, amorphous pericellular and perivascular PrP accumulation	Widespread fine spongiform degeneration, astrogliosis, neuronal loss; punctate PrP immunoreactivity; 'brush stroke' pattern in cerebellar molecular layer
Caudate nucleus and putamen	Severe spongiform change, perineuronal and axonal PrP accumulation	Fine spongiform degeneration and astrogliosis; punctate PrP immunoreactivity
Posterior thalamic nuclei and midbrain	Marked astrocytosis and neuronal loss	Fine spongiform degeneration and astrogliosis; punctate PrP immunoreactivity; substantia nigra not affected
Brainstem and spinal cord	Reticular and perineuronal PrP accumulation in gray matter	No spongiform degeneration and PrP immunoreactivity
Molecular features of PrP^{Sc}		
129 Polymorphism	MM	MM
Gel mobility (type)	19 kDa (type 2)	21 kDa (type 1)
N-terminal PK cleavage site	Residue 97	Residue 82

Source EEG, Electroencephalogram.

manifest early psychiatric disorders such as depression, anxiety, and withdrawal. About 6 months later, neurologic disorders emerge, including cognitive impairment, ataxia, and involuntary movements. Chorea, dystonia, and myoclonus are also observable. During the progressive clinical course, dementia and diffuse cortical deficits are predictable. Finally, patients are mute and bed-bound. Death is inevitable after a median of 14 months from the onset of symptoms (range, 6–39 months), largely due to an intercurrent infection such as respiratory infection. It is recommended that the combination of an affective or psychotic disorder with persistent pain, sensory symptoms, gait ataxia, or dysarthria should signal a diagnosis of vCJD, especially in younger patients.

Unlike sCJD, 14–3–3 protein in the cerebrospinal fluid, the electroencephalogram and CT brain scan are less helpful in diagnosing vCJD because these are usually normal. However, an MRI scan may be helpful. For example, specific high signal in the posterior thalamus on T2-weighted images can be detected in over 75% of vCJD cases. Moreover, the sensitivity of an MRI brain scan in vCJD can be improved by fluid-attenuated inversion recovery (FLAIR). The definite diagnosis of vCJD requires neuropathologic examination of brain tissue obtained either at biopsy or autopsy. In 2000, Will and colleagues established the diagnostic criteria, by which accurate antemortem diagnosis can be achieved using a combination of clinical history with special investigations including tonsil biopsy using PrP immunohistochemistry and Western blotting, as well as MRI brain scan.

Differential Diagnosis

For suspect vCJD cases, the main differential diagnosis lies with other human prion diseases, especially sCJD. Sporadic CJD can be readily excluded if detailed clinical data are available and special investigations are included following Will et al. diagnostic criteria. A detailed differential diagnosis between sCJDMM1 (the most common subtype of sCJD) and vCJD, including pathology, is listed in **Table 2**.

Management and Prognosis

Although scrapie in sheep and goats has been recognized for more than 200 years and the first CJD case in humans was identified almost 90 years ago, to date no effective treatment has been found. Many attempts to treat experimental prion diseases in animals have been made over the past 30 years but only a few therapeutic compounds have been tested in patients, and none of them have been found effective in treating human prion diseases.

The following compounds have being studied in clinic. Quinacrine, a widely used antimalarial drug, was found to successfully block formation of PrP^{Sc} in infected mouse neuroblastoma cells. A recent patient-preference trial on all forms of CJD showed acceptable level of tolerance but no effect on the clinical course of CJD. Flupirtine maleate, a centrally acting nonopioid analgesic, has been tested in a randomized double-blind study of subjects with the diagnosis of probable CJD. Treated patients showed significantly slower rate of cognitive deterioration but no significant difference in survival time. Pentosan polysulfate (PPS), a drug for the treatment of interstitial cystitis, has been reported to stabilize and delay the progression of prion disease but there are controversial results in clinical studies. A major problem is that PPS does not cross the blood–brain barrier and it has to be administered intraventricularly. To date, this compound has not been tested in any case-control study. Administration of doxycyclin, a member of the tetracycline group, to sCJD patients under compassionate treatment has been reported to more than double survival rate compared to untreated sCJD subjects. A phase II, multicenter, randomized, double-blind study is ongoing.

Acknowledgments

The authors want to thank Dr. Pierluigi Gambetti for providing Fig. 1 and Dr. James Ironside for providing vCJD samples. Supported by the CJD Foundation, NIH R01 NS062787, NIA AG-14359, CDC UR8/CCU515004, and Charles S. Britton Fund.

W

Weaver Mouse

L C Triarhou, University of Macedonia, Thessaloniki, Greece

Glossary

Basal ganglia – A group of gray matter nuclei inside the brain, subserving movement control, learning, emotions, and cognitive functions.
Cerebellum – A brain structure that subserves balance, movement coordination, and certain cognitive functions. Damage to the cerebellum may lead to ataxia.
Dopamine – An organic molecule used by the brain for the chemical communication (neurotransmission) of neurons.
Hippocampus – A structure in the forebrain that belongs to the limbic system and subserves memory.
Mutation – A change in the genetic material of an organism, induced either spontaneously or experimentally.
Potassium channel – A common type of ion channel found in the membranes of living cells. In neurons, they are crucial for setting the resting potential and for shaping the action potential.

Definition and History

In the era of neurobiological research prior to the advent of targeted knockout and transgenic technology, spontaneous mutations in inbred mouse strains were studied as models of developmental and degenerative neurological conditions. One such mutation is the weaver (*wv*), which occurred in 1961 in a C57BL/6J genetic stock of mice.

Weaver mutants have neuron abnormalities in the cerebellum, mesotelencephalic dopamine (DA) projection system, hippocampus, and pontine nuclei. The cerebellum of the weaver mouse has been investigated in particular regarding neurite extension, neuronal migration, and the remodeling of synaptic circuitry. The loss of DA cells in the weaver mouse midbrain produces a pathophysiological phenocopy of Parkinsonism, useful in tackling issues of the survival and growth of intrastriatal grafts in the chronically denervated striatum.

Cerebellar Pathology

The cerebellum of homozygous weaver mutants is atrophic. Postmitotic granule cell precursors in the external germinal layer fail to migrate inward to the internal granular layer and die massively at the interface of the former and the molecular layer during the first 2 weeks postnatally. Heterozygous weaver mice (*wv*/+) show reduced rates of granule cell migration and an intermediate degree of granule cell loss; in adult animals, arrested granule cells are found at the interface of the molecular and Purkinje cell layer.

Purkinje cells are reduced in number as early as postnatal day 5. Overall reduction in Purkinje cells is 28% in homozygotes and 14% in heterozygotes. The apical dendrites of Purkinje cells in the weaver cerebellum are oriented randomly and display a 'weeping willow' shape of arborization. One observes unattached Purkinje dendritic spines with postsynaptic specialization densities but devoid of a presynaptic input from the parallel fibers; the circuitry remodeling involves formation of heterologous synapses on free spines by axon terminals of mossy fiber rosettes and by climbing fiber varicosities, and formation of attachment plate-like junctions by free postsynaptic sites of apposing Purkinje dendritic spines.

Mesotelencephalic Dopamine System Deficits

The cerebrum of adult weaver homozygotes has 52% lower DA levels than normal. At birth, young weaver neurons undergo degeneration beneath the subependymal plate. The substantia nigra of weaver mice has 40%

fewer DA cells than the wild-type on postnatal day 20 and 70% fewer DA cells at 3 months of age; DA neuron loss is also seen in the ventral tegmental area and retrorubral nucleus. A further wave of DA neuron degeneration is effected during the second year of life, bringing the total DA cell loss to 85% in the substantia nigra by 24 months. In regression fits, DA neuron fallout combines two independent components, an initial exponential decay, superceded by a linear regression, with a threshold at about 100 days. The half-life ($T_{1/2}$) of neurons degenerating during the first (exponential) phase is 58 days; the probability per unit time that a neuron will die is a constant (λ), estimated at 0.012 per day. During the second (linear) phase of degeneration, the probability of a neuron dying becomes a function of time and declines with advancing age, that is, the longer a cell survives, the less likely it is to degenerate.

Heterozygous weaver mice have normal midbrain DA neuron numbers at 3 months of age. However, DA dendrites projecting from the substantia nigra pars compacta into the pars reticulata appear defective in length and density, varicosity diameter, intervaricose segment length, and afferent synaptic connectivity.

Additional Phenotypic Characteristics

In hippocampal area CA3 of adult homozygous weaver mice, one observes pyramidal cell ectopia as well as alterations of hippocampal mossy fiber trajectories, most likely reflecting disturbances in neuronal migration. The weaver mutation also affects neuronal survival in pontine nuclei that project to the cerebellar cortex via pontocerebellar mossy fibers; while neuronal numbers appear normal in the first week of life, they become reduced to one-third of the wild-type values by postnatal day 18.

The phenotype of weaver mutants further includes reduced levels of serum thyroid hormone (hypothyroidism) in association with delays in somatic development and a decreased expression of striatal transforming growth factor alpha (TGFα), possibly stemming from a regulatory defect at the level of the hypothalamic–hypophyseal axis.

Behavioral Signs

Homozygous weaver mutants (*wv*/*wv*) display locomotor, spatial orientation, and memory deficits, including gait instability, poor limb coordination, resting and intention tremor, navigational deficits, reduced activity in the open-field, delayed spontaneous alternation, and a hind-paw clasping reflex when held by the tail. Moreover, weaver mice express learning deficits similar to those found in other DA-deficient organisms.

Heterozygous weaver mice (*wv*/+) do not have locomotor abnormalities, but they intermittently manifest generalized tonic–clonic convulsions that are usually lethal. Such an effect might conceivably pertain to the DA dendrite deficit of the substantia nigra pars reticulata, as that midbrain structure implicated in the pathophysiology of experimental seizures.

It appears that chronic pharmacologic treatment of homozygous weaver mutants with fluoxetine (a serotonin reuptake inhibitor) may alleviate some of the motor defects and prevent neuron loss in the cerebellum and pontine nuclei. Intrastriatal grafting of fetal mesencephalic tissue – containing primordial DA cells – partially counteracts the structural and functional neurological deficits of weaver homozygotes.

Molecular Genetic Defect

The *wv* allele has been mapped to the distal end of mouse chromosome 16 (at a distance of 68.75 cM from the centromere), within a phylogenetically conserved region highly homologous to telomeric human chromosome 21 (gene map locus 21q22.1). The *wv* mutation, which is considered to be incomplete dominant or semidominant, was identified as a missense mutation with a G→A substitution in nucleotide 953 of the G-protein-activated inwardly-rectifying K^+ channel gene *Kcnj6* or *Girk2* (subfamily J, member 6) and an ensuing Gly→Ser replacement at residue 156 of the encoded protein (alternatively called $K_{ir}3.2$).

The amino acid residue substitution in the pore-forming H5 region of $K_{ir}3.2$ disturbs the homomeric channel properties, producing a lethal depolarized state in weaver neurons. In hippocampal slices from weaver mice in particular, the mutation in the pore region of the K^+ channel subunit results in a functional phenotype that resembles $K_{ir}3.2$-deficient mutants, since in disinhibited slices the $GABA_B$ receptor agonist R-baclofen fails to induce K^+ currents or any other conductance change.

Western Blot

S E Counts, Rush University Medical Center, Chicago, IL USA

Glossary

Chemiluminescence – The emission of light through a chemical reaction.
Homogenization – The process by which a complex sample is dispersed into a uniform mixture of components.
Immunoreactivity – The binding of an antibody to a specific target antigen in vitro, as detected by an antibody-specific labeling reaction.
Proteomics – The study of the expression and structural and functional properties of the entire protein complement in an organism, tissue, or cell.
Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) – The process by which proteins extracted from a complex cell or tissue sample are denatured in anionic SDS and separated by molecular weight in a polyacrylamide gel subjected to an electric current.

Introduction

The western blot (or immunoblot) analytical procedure enables the identification and quantitation of individual proteins from a complex mixture (e.g., cell or tissue extract). In general, the technique involves separating proteins under denaturing conditions by gel electrophoresis, transferring or 'blotting' the proteins electrophoretically from the gel to a solid support membrane, probing the membrane with an antibody specific for a target protein, and then visualizing the bound antibody using labeled secondary immunological reagents. Hence, the western blot technique is an essential assay for proteomic analysis of tissues in health and disease or cultured cells under varying conditions. The following are more specific technical considerations for performing western blot analysis.

Preparation of Samples

Protein samples from cultured cells can be extracted either by direct dissolution in a denaturing buffer or by homogenization in a buffer containing protease inhibitors. Sample denaturing buffers contain the powerful anionic detergent sodium dodecyl sulfate (SDS), which linearizes the proteins, and a reducing agent such as 2-mercaptoethanol to break disulfide bonds. Cells and tissue (e.g., frozen postmortem brain samples) collected in homogenization buffers are mechanically disrupted using methods such as sonication and tissue grinding. This process permits fractionation protocols to remove debris, pellet nuclei, and separate functional compartments (e.g., membrane and cytosolic) prior to denaturation. Sample extracts

must be analyzed for protein concentration using one of the several commercially available methods in order to ensure that the total protein amount in each sample under analysis is equivalent.

Electrophoresis of Proteins

Denatured proteins in individual samples are separated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE, **Figure 1**). Polyacrylamide gels are formed from the polymerization of two compounds, acrylamide and the cross-linking agent *N*,*N*-methylenebisacrylamide, in a buffered solution containing 1% SDS. The polymerized gels are essentially three-dimensional networks of long hydrocarbons cross-linked by methylene groups, thus, creating a sieve of pores through which the proteins migrate within an electric field. The sieving properties of this separating gel are determined by the pore size; higher percentages of acrylamide (e.g., 12%) create smaller pore sizes which favor resolution of lower molecular weight proteins, whereas lower percentages of acrylamide (e.g., 8%) provide a better resolving environment for higher molecular weight proteins. The migration speed during SDS-PAGE is based on protein molecular weight since the amount of anionic SDS bound by each denatured protein in a sample is proportional to its size (i.e., larger proteins will move more slowly toward the anode than smaller proteins). After the separating gel is polymerized in a vertical gel casting stand, a second, stacking gel (5% acrylamide) containing sample loading wells is polymerized on top of the separating gel.

SDS-PAGE is typically carried out in a discontinuous buffer system wherein the ionic strength of the buffer used to cast the gel (Tris–HCl) is different from the running buffer (Tris–glycine) which conducts the electric field. Thus, the SDS–protein complexes sieve through the relatively large pores of the stacking gel in a zone of lower conductivity and steeper voltage gradient that concentrates the proteins on the surface of the separating gel, and greatly increases their resolution during separation. Molecular weight standard proteins are loaded concurrent with the sample proteins in a separate lane to track the progress of different size proteins during SDS-PAGE, and to gauge the relative molecular weight of the target proteins. However, it should be mentioned that posttranslational modifications such as glycosylation or phosphorylation will impede the migration of proteins in the gel. If a target protein migrates more slowly than expected based on its primary sequence, then the presence of these modifications can be verified by preincubating the samples with commercially available glycosylase or phosphatase.

Transfer of Proteins to Solid Supports

Once SDS-PAGE is complete, the proteins in the gel can be visualized directly by staining with coomassie blue or silver stain. Alternatively, the proteins can be transferred electrophoretically from the gel onto a sheet (or membrane) composed of nitrocellulose or polyvinylidene difluoride (PVDF). The proteins transferred to the membrane retain the same pattern of separation they had in the gel and will now be accessible to antibody detection (**Figure 1**). Transfer can be done in wet or semi-dry conditions. In wet transfer, the gel and membrane are sandwiched tightly together between filter paper

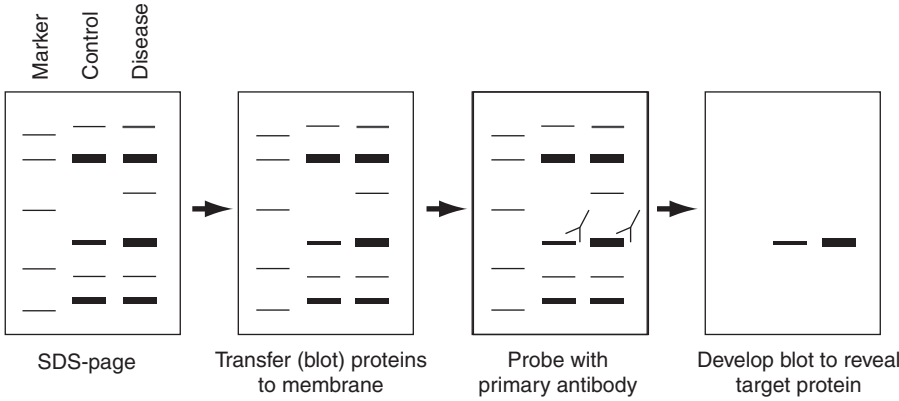

Figure 1 Schematic of western blotting process. In this example, denatured proteins from control and disease tissue are separated by SDS-PAGE. The approximate molecular weight of the proteins in the gel is determined by the protein standards (marker) that run in the left lane. The proteins are transferred electophoretically (or 'blotted') to a PVDF membrane, and probed with a specific primary antibody. The primary antibody is followed with a labeled secondary antibody (not shown), and the label is developed to reveal the target protein. Here, the target protein is revealed to be more abundant in the disease tissue relative to control.

(membrane side toward the anode), and submerged in a transfer cell to which an electrical field is applied. A standard transfer buffer is composed of Tris–glycine without SDS (which can impede blotting of smaller proteins). 20% methanol is added to the buffer for nitrocellulose membranes; PVDF membranes can be prewetted with methanol, and then used with standard transfer buffer. The success of the protein transfer can be assessed by staining the membranes with Ponceau S, which is compatible with immunological methods of detection.

Binding of the Primary Antibody to the Target Protein

Significant background may be introduced through the nonspecific binding of proteins in the immunological reagents. To reduce this background and increase sensitivity, the membranes should first be 'blocked' in a solution containing irrelevant proteins such as 1–5% nonfat dry milk or bovine serum albumin. A nonionic detergent (e.g., 0.01% Tween 20) can also be included to reduce nonspecific binding without disrupting specific binding of antibody to target. Once effectively blocked, the membranes can then be incubated with the primary antibody (**Figure 1**). Virtually, all western blotting techniques involve a two-step incubation process wherein incubation with an unlabeled primary antibody specific for the target protein is followed by a species-specific labeled secondary antibody directed against the primary immunoglobulin (e.g., goat antirabbit IgG for rabbit primary antiserum). The antibodies are typically diluted in the blocking buffer at empirically determined concentrations. In addition, proteins A and G, which bind immunoglobulin heavy chains, can also be used as secondary reagents. These secondary reagents can be radiolabeled (e.g., with ^{125}I) or, more commonly, conjugated to biotin, fluorescein, or to an enzyme such as horseradish peroxidase (HRP). A major advantage of the two-step procedure is that a single secondary reagent can be used to detect a wide variety of primary antibodies. Moreover, more than one molecule of secondary reagent can usually bind one primary antibody molecule, thus achieving signal amplification.

Visualization of the Bound Primary Antibody

Visualization of immunoreactive bands on the membrane requires development of the conjugated label on the secondary reagent (**Figure 1**). For instance, HRP labeled secondary antibodies are visualized using chemiluminescence by incubating the membrane with commercially available solutions containing the HRP substrate luminol. The membrane is then exposed to X-ray film or a digital imager.

Quantitative Assessment of the Target Protein

The optical density of immunoreactive bands is considered a proxy to target protein concentration in the sample. Several programs, including the publicly accessible NIH Image programs (http://rsb.info.nih.gov/nih-image/) and digital image analysis software, are available which allow bands of interest to be selected and quantified based on the signal intensity. However, a few caveats should be considered to ensure that measurements are quantitative. First, the specificity of the antibody should be rigorously characterized to mitigate concerns over cross-reactivity with nontarget proteins. For instance, structurally similar proteins can migrate to the same position on the gel (**Figure 2(a)**); hence, control experiments should be performed to show that the primary antibody does not erroneously bind nonspecific proteins and alter the quantitative data. In addition, the membranes should be probed with the secondary reagent alone to ensure the immunoreactive band is specific for the primary antibody. Second, although the advent of digital imaging has broadened the linear dynamic range of signal detection compared to traditional X-ray film, a standard curve showing antigen signal intensity in a range of samples with varying total protein should be generated to ensure that immunoreactive signals in the sample amount loaded will fall along a linear range of detection (**Figure 2(b)**). Finally, the membranes should also be probed with a primary antibody to a 'housekeeping' protein (e.g., β-tubulin or glyceraldehyde-3-phosphate dehydrogenase) that is not expected to change under the experimental conditions examined (**Figure 2(c)**). Immunoreactivity of this housekeeping protein serves as an internal control for even sample loading. Hence, the immunoreactivity of the target antigen is normalized to the immunoreactivity of the housekeeping protein in each sample for quantitative analysis. Care should be taken in selecting the loading control, and the ideal antigen may need to be determined empirically. For example, western blotting and densitometry of housekeeping protein levels can be performed in samples from different experimental or diagnostic groups, and equivalent total protein loading for each sample can be assessed by staining of the same gels or membranes.

Beyond Western Blotting

Western blots are commonly incorporated with other techniques to allow for more detailed proteomic studies.

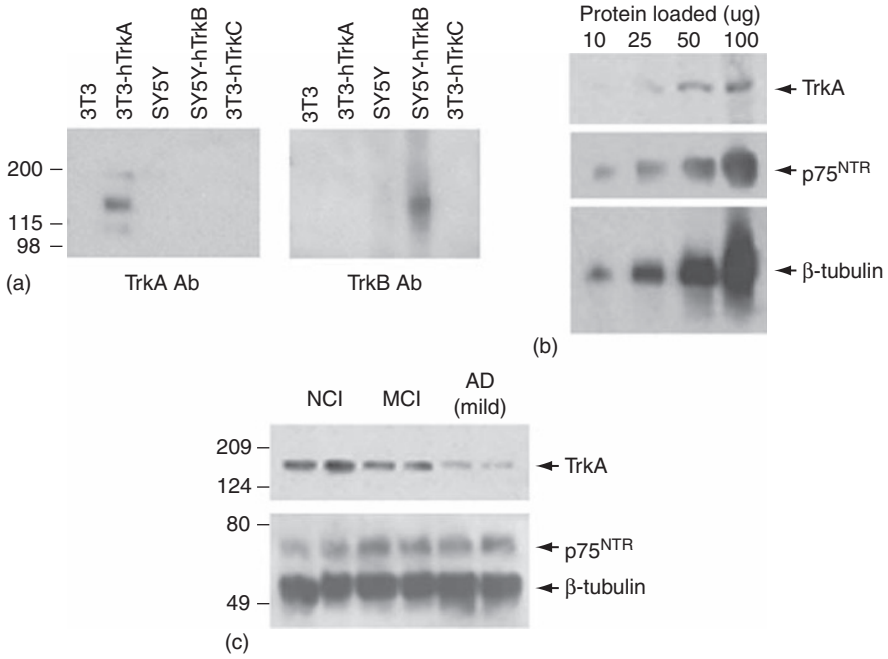

Figure 2 Representative western blotting data and quality control considerations for quantitative analysis. (a) Western blot showing that a primary antibody is specific for its target. Denatured protein samples (25 μg) of naïve NIH-3T3 mouse fibroblast cells, NIH-3T3 cells transfected with human trkA (3T3-hTrkA) or trkC (3T3-hTrkC) receptor tyrosine kinase cDNA, naïve SH-SY5Y human neuroblastoma cells (SY5Y), and SH-SY5Y cells transfected with human trkB cDNA (SY5Y-hTrkB) were separated by SDS-PAGE, blotted to a PVDF membrane, and probed with rabbit TrkA antiserum or rabbit TrkB antiserum. The TrkA antiserum detected hTrkA, but not the structurally similar hTrkB or hTrkC proteins. The anti-TrkB antiserum confirmed the presence of hTrkB in the SY5Y-hTrkB sample. (b) Western blot shows increasing antigen immunoreactivity for TrkA, the $p75^{NTR}$ neurotrophin receptor, and β-tubulin with incremental amounts of denatured protein sample (10–100 μg) extracted from the temporal cortex of an aged, cognitively intact individual. Densitometry (not shown) demonstrated that immunoreactive signals from 50 μg loaded protein fell within a linear range of detection. (c) Western blot shows TrkA, $p75^{NTR}$, and β-tubulin immunoreactivity in denatured protein samples (50 μg) from the temporal cortex of people who died with no cognitive impairment (NCI), mild cognitive impairment (MCI), and mild Alzheimer's disease (AD). Densitometry (not shown) was performed by normalizing TrkA or $p75^{NTR}$ immunoreactive signals to β-tubulin signals on the same blots. TrkA levels were reduced ~50% in the temporal cortex of mild AD subjects, whereas $p75^{NTR}$ levels were not changed across the diagnostic groups. Adapted from Counts SE, et al. (2004) Reduction of cortical TrkA but not p75(NTR) protein in early-stage Alzheimer's disease. *Annals of Neurology* 56: 520–531, with permission from John Wiley & Sons Inc.

For instance, to analyze protein–protein interactions, target protein complexes can be isolated by immunoprecipitation or chromatography followed by western blotting to probe for potential binding partners. Likewise, western blotting can be used to verify proteins of interest in exploratory proteomic techniques such as two-dimensional gel electrophoresis. Thus, the western blot procedure is an essential tool for protein analysis of complex systems, and the identification of potential mechanisms underlying aberrant tissue function or disease.

Westphal Variant

M A Nance, University of Minnesota, Minneapolis, MN, USA

Glossary

Athetosis – A worm-like, twisting or writhing movement of the limbs or trunk.
Bradykinesia – Slowness of movement. Often accompanied by hypokinesia or paucity of movement.
Chorea – 'Dance-like' involuntary movements that can affect the limbs, trunk, diaphragm, tongue, facial muscles, and any other muscles that are ordinarily under voluntary control.
Dopaminergic agent – A drug that increases dopamine content, function, or action in the brain. Includes levodopa, which is converted into dopamine in the brain, dopamine agonists, such as pramipexole and ropinirole, monoamine oxidase inhibitors such as selegiline and rasagiline, which prevent the breakdown of dopamine released into the presynaptic space, and amantadine, the exact mechanism of action of which is not fully understood.
Dystonia – An increase in muscle tone accompanied by stiff or awkward posturing of the affected body part, typically in an extreme end of the range of motion.
Hyperkinesia – Excessive amounts of movement. Depending on the part of the limb affected, hyperkinetic movements may appear fidgety (for instance, in the fingers of trunk), athetotic, choreiform, of ballistis (for instance, involuntary movements of the shoulder girdle may result in ballistic, flinging movements of the entire arm).
Opisthotonus – Hyperextension and rigidity of the back and neck.

Definition and History

'Westphal variant' is an eponym of moderate historical interest, but of unclear definition and uncertain clinical or biological relevance. The term was coined in recognition of the lengthy description by Professor Westphal in 1883 of an 18-year old with progressive posture and gait changes, his term for which was translated into English as 'pseudosclerosis,' to emphasize its distinction from other progressive sclerosing conditions (such as multiple sclerosis). It was recognized only later that Westphal's patient in fact had Huntington's disease, and the term 'Westphal variant' came to be used to describe people with Huntington's disease whose initial clinical presentation was heavily laden with rigidity and hypokinesia. Additional reports accrued over the next 80 years of dystonic, hypokinetic Huntington's disease patients, whose presentation contrasted strikingly with the typical choreiform, hyperkinetic movements that defined this disease (which at that time was known as Huntington's chorea). These case reports were summarized in great detail in a lengthy and influential work by Professor Georges Bruyn in 1968.

Bruyn used the term 'Westphal variant' to describe a broad range of Huntington's disease-related features. In addition to a 'primary' Westphal presentation, he recognized that adults with Huntington's disease often 'develop the Westphal variant in the ultimate stage' of their disease. He made a number of other observations about the Westphal variant:

1. it may present with rigidity alone or in combination with dystonic chorea.
2. rigidity may later give way to chorea.
3. there can be a dissociation between the akinesia or bradykinesia, and the rigidity. He was quite emphatic but confusing on this point, perhaps meaning that akinesia can be seen in patients who do not have the Westphal variant, but that it is the combination of akinesia with rigidity that is critical to the definition of the Westphal variant.
4. a fine (postural) tremor often accompanies the other symptoms.
5. an abnormal 'putaminal' posture is common (adduction of the arm with flexion of the elbow, wrist, and fingers, and hyperextension of the lower extremities, similar to a 'decorticate' posture).
6. other clinical features that often accompanied akinesia and rigidity in the Westphal variant included dystonia, athetosis, torticollis, opisthotonus, pyramidal involvement, abnormal vertical pursuit eye movements, and inability to perform facial commands such as frowning, raising eyebrows, protruding the tongue, and whistling. Dementia and dysarthria were universal, and patients often developed complete immobility, mutism, cachexia, and decubitus ulcers.

This represents, historically, the broadest use of the term 'Westphal variant.' The term is usually used in a more restricted fashion today.

Epidemiology

The majority of people presenting with this variant are children or young adults. Noting this, Kremer went so far as to say that 'a patient with a Westphal variant and a disease onset after age 50 should be considered exceptional, warranting publication.' The published incidence of this variant among adults with Huntington's disease is 6–12%.

Bruyn made the interesting observation, based on his thorough review, that the vast majority of Westphal variant cases reported in the literature were female. This thought, otherwise forgotten – and still unexplained – was echoed three decades later by Louis and his colleagues at Columbia University, who found that 13 of their 15 dystonic Huntington's disease patients were female.

Confusion About the Definition

The concept of the Westphal variant has been confounded by the distinct tendency for patients with juvenile-onset Huntington's disease to present with rigidity and akinesia rather than chorea. Bruyn would use the term 'Westphal variant' to describe anyone, child or adult, presenting with (or later developing) rigidity, hypokinesia/akinesia, and lack of chorea, as the predominant motor phenotype. Some later writers use the term specifically to refer to (rigid) juvenile-onset Huntington's disease, while others use the term to refer only to adults presenting with rigidity and hypokinesia. Still some use the term essentially as a synonym for rigid-akinetic Huntington's disease whenever it occurs in any patient.

Two other issues complicate today's interpretation of the clinical literature on the Westphal variant. Firstly, twenty-first century readers of the twentieth century literature maintain some skepticism about the accuracy of the diagnosis of reported cases prior to the advent of genetic testing. And secondly, the use of neuroleptic and other dopamine-depleting and dopamine-blocking agents, popularized in the later half of the twentieth century, could easily render a choreic Huntington's disease patient rigid and bradykinetic, creating a 'secondary Westphal variant.'

It remains unclear today whether the term Westphal variant should be used to describe the entire syndrome complex (including nonmotor features) in patients presenting with early rigidity-akinesia or just the motor syndrome, whether it should refer solely to children, solely to adults, or both, and whether it should refer to a patient's initial (untreated) presentation it can also encompass the later development of rigidity and akinesia in late-stage patients or patients whose rigidity and akinesia are entirely or partially caused by medications.

Pathological Correlates

Lending some biological credence to the concept of a rigid form of Huntington's disease are two pathological studies hinting at a neuropathological correlate to the clinical syndrome. While in hyperkinetic Huntington's disease, striatal neuronal loss is most prominent in the projections to the globus pallidus externa, two groups have shown an association between rigidity as a primary clinical feature and prominent loss of striatal projections to the substantia nigra and globus pallidus interna. It should be a testable hypothesis, in the modern brain imaging era, that early and prominent loss of pallidal (interna) projections is more common in children and young adults (and perhaps in females) and that the timing and severity of this loss is what determines whether a person clinically presents with (or develops) the Westphal variant.

Clinical Relevance

In the end, it is debatable whether the term 'Westphal variant' is a useful one. The concept of a rigid-akinetic form of Huntington's disease is certainly important in the diagnosis, treatment, and understanding of the disease. Clinicians unattuned to the possibility of Huntington's disease in a patient lacking chorea who has evident rigidity, dystonia, or bradykinesia can fail to make the correct diagnosis, with consequences for both the patient and the family. Although there is no rationale for the use of dopaminergic agents in patients with chorea, there are case reports documenting the benefits of dopaminergic agents such as levodopa and amantadine in Huntington's disease patients with rigidity, dystonia, and hypokinesia. And indeed, a better understanding of influences of age, gender, and disease duration on the development of this clinical phenomenon might help us to understand the genetic, environmental, biological, developmental, and neuropathological underpinnings of Huntington's disease.

Unfortunately, the eponym 'Westphal variant' has no firm definition, is used in a contradictory fashion by different experts in the field, and as an eponym, conveys no information directly to the listeners or readers. It may be preferable to abandon the use of this term and instead refer to the 'rigid-akinetic presentation' of Huntington's disease, which, in summary, (1) is common as an initial presentation in juvenile Huntington's disease, (2) occurs in 6–12% of adults with Huntington's disease, but almost exclusively in young adults, (3) appears to be more common in females, (4) may correlate with loss of neuronal projections to the globus pallidus interna, and (5) commonly develops as the disease progresses in patients of all ages.

Whipple's Disease

S S Kapur, University of IL at Chicago, Chicago, IL, USA

Glossary

Bruxism – Grinding of the teeth or clenching of the jaw which may be involuntary (may be considered a form of focal dystonia).

Cell-mediated immunity – Recognition of antigen by T cells and secretion by T cells of lymphokines that enhance the ability of macrophages to remove the antigen. Independent of antibody production.

Humoral immunity – Antibody production by B cells for the purpose of neutralizing foreign antigen.

Myorhythmia A hyperkinetic involuntary movement disorder characterized by a tremor of irregular frequency (from 1 to 4 Hz).

Myoclonus – Quick lighting-like involuntary twitch or spasm of a muscle or group of muscles. The pattern of the movements is usually not rhythmic.

Periodic acid-Schiff (PAS) – A histological staining technique used to identify carbohydrates in tissues.

Polymerase chain reaction (PCR) – A technique used in molecular genetics to analyze short segments of DNA or RNA by amplifying it in a test tube so it can be studied in greater detail.

Definition and History

Whipple's disease is a rare disease that predominantly affects the gastrointestinal (GI) tract, the mesentery, the heart, the joints, and the central nervous system (CNS), but can affect almost any tissue of the body. The illness is caused from infection by the bacillus *Tropheryma whipplei.* Dr. George H. Whipple first described a disease he called lipodystrophia intestinalis in 1907. His patient had infiltration of the intestinal mucosa and lymph nodes with foamy cells as well as inflammatory changes in the aorta, the pleura, and the pericardium. Curiously, it was later discovered that Whipple's patient was not the first documented case of the disease. A.D. Morgan, when reorganizing GI sections at Westminster Hospital in London, discovered a specimen of intestine that was incorrectly labeled as stomach. When he applied the periodic acid-Schiff (PAS) stain to it, it was strongly positive. This specimen was from a patient evaluated in 1895, making it the first documented case of Whipple's disease, though it was not correctly diagnosed at the time. In 1948, Black-Shaffer et al. in the *American Journal of Pathology* described the histopathological criteria for the diagnosis of lipodystrophy intestinalis and recommended it be named 'Whipple's disease.'

CNS symptoms of Whipple's disease were only thought to be present in patients who had not been

appropriately treated. It was Knox et al. in 1976 who first described late CNS complications ('dementia, myoclonus, ataxia, and supranuclear ophthalmoplegia') in patients who were treated and had shown initial response to antibacterial therapies.

The organism initially described by Whipple was thought to perhaps be a spirochete, because he was able to demonstrate rod-shaped organisms that 'closely resembled the tubercle bacillus.' It was not until the early 1960s that the bacillus was demonstrated using electron microscopy and was confirmed to be of bacterial origin. The bacterium was found by most to be Gram positive and Acid-Fast Bacillus (AFB) negative. Its bacterial genome was sequenced in 1991 and was classified into the Actinomycetes class at that time. The name *Tropheryma whipelii* was given, but this was changed in 2001 to the current form to accurately represent the true spelling of Dr. Whipple's name.

Pathogenesis/Pathophysiology

The pathogenesis of *Tropheryma whipplei* is as yet still very poorly understood. The DNA of the bacillus has been found in sewage plant waste and in human feces, so it is speculated that the organism could be transmitted through a fecal–oral route similar to that of *Giardia lamblia*. The DNA of *T. whipplei* has been found in the saliva and the feces of a small percentage of healthy subjects. It has also been speculated, therefore, that people who do get Whipple's disease are genetically predisposed to it. *T. whipplei* tends to invade the small intestine from the lamina propria layer rather than from the lumen. When it is found intracellularly it does not seem to cause any direct cell injury, nor does it cause an intense immune response. Rather, it causes an influx of macrophages, and to a much lesser degree, neutrophils and eosinophils. It seems that the bacillus induces a cell-mediated immune response rather than a humoral immune response. The majority opinion is that T cells are diminished in their ability to activate macrophages in affected patients. The macrophages still maintain their ability to phagocytosize, but their ability to completely degrade all bacterial antigens is impaired. Of note, granulomas can also be found in Whipple's disease patients. They have been reported in one-tenth of patients, which has caused some of them to be misdiagnosed as having sarcoidosis.

Epidemiology/Risk Factors

The typical patient who has contracted Whipple's disease is male (87% of patients), Caucasian (over 95%), and is 40–60-year old (60%). Overall, though, it is a very rare disease as >1000 cases have been reported so far. Patients who have been farmers or who are in farm-related trades account for <1/3 of reported cases. There have also been cases of multiple first-degree relatives acquiring the disease as well as multiple people from the same village or town who had the disease. From these latter points, it may be deduced that the disease may be acquired from the environment, that either the disease is transmissible from human to human (though direct transmission is highly unlikely), or that there is genetic predisposition to fall sick from it. Accordingly, about 26% of cases of the disease have been found to be HLA-B27 positive further suggesting a genetic tendency for Whipple's.

Clinical Features and Diagnostic Criteria

The classic clinical features of Whipple's disease are weight loss, diarrhea, and arthralgias though about 15% of cases can present with other symptoms. Other manifestations may also include culture negative endocarditis (rare) or Whipple's with isolated infection of somewhere along the neuroaxis. The Whipple bacillus can infect almost any organ or tissue of the body. The organs that seem to be least affected are the kidneys, the thyroid, and the testes.

Neurologically, the most common symptoms encountered are cognitive changes, ophthalmoplegia, and myoclonus. The cognitive changes usually present as an encephalopathy that can advance to a progressive dementia. Ophthalmoplegia with this disease is of the external type; vertical supranuclear gaze palsy may occur. Myoclonus tends to affect the head, trunk, and upper extremities, though it can occur anywhere. It has been proposed that these three symptoms be a diagnostic triad for CNS Whipple's disease. Other neurologic symptoms may include seizures, nystagmus, hypothalamic signs (insomnia, hypersomnia, polydipsia), cerebellar ataxia, cranial nerve dysfunction, and hemiparesis. Movement disorders associated with this disease include myoclonus (cerebral, brainstem, and spinal localizations), palatal tremor, parkinsonism, other types of tremor, dystonia (in the form of bruxism), and oculomasticatory myorhythmia. Oculomasticatory myorhythmia and the associated oculofacialskeletal myorhythmia are seen in about 15% of cases and are considered pathognomonic signs of CNS Whipple's disease. Whipple's disease not only can present with any of these isolated symptoms, but also these symptoms can be seen with more classic Whipple's symptoms (see above). The last form of neurologic symptomotology is relapse from classic disease after successful treatment. This form may occur many years after successful treatment, and it usually involves a progressive dementia that is quite refractory to medical treatment. Other symptoms of CNS relapse may include ataxia, hypothalamic signs, ophthalmoplegia, seizures, and hemiparesis, and psychosis.

E.D. Louis et al. have proposed diagnostic criteria for CNS Whipple's disease in their 1996 paper (see **Table 1**) based on a literature review of 84 cases.

Table 1 Guidelines for diagnostic screening, biopsy, and treatment of CNS Whipple's disease (WD)

Definite CNS WD
Must have any one of the following three criteria:
1. Oculomasticatory myorhythmia or oculofacialskeletal myorhythmia
2. Positive tissue biopsy
3. Positive polymerase chain reaction (PCR) analysis
If histological or PCR analysis is not performed on CNS tissue, then the patient must also demonstrate neurological signs. If histological or PCR analysis is performed on CNS tissue, then the patient need not demonstrate neurological signs (i.e., asymptomatic CNS infection)
Possible CNS WD
Must have any one of four systemic symptoms, not of another known etiology:
1. Fever of unknown etiology
2. Gastrointestinal symptoms (steatorrhea, chronic diarrhea, abdominal distension, or pain)
3. Chronic migratory arthralgias or polyarthralgias
4. Unexplained lymphadenopathy, night sweats, or malaise
Also must have any one of four neurological signs, not of another known etiology:
1. Supranuclear vertical gaze palsy
2. Rhythmic myoclonus
3. Dementia with psychiatric symptoms
4. Hypothalamic manifestations

Source: Louis ED, Lynch T, Kaufmann P, Fahn S, and Odel J (1996) Diagnostic guidelines in central nervous system Whipple's disease. *Annals of Neurology* 40(4): 561–568.

Differential Diagnosis

Because it can affect almost every organ system, Whipple's disease is a mimicker of many diseases. In the classic presentation, it can be confused with any disease that causes malabsorption. As other symptoms become apparent, the disease has historically been misdiagnosed as other multisystem diseases such as sarcoidosis, collagen vascular diseases, syphilis, and lymphoma. Because of the wide variety of presentations of CNS Whipple's, the diagnosis should be entertained in suspected cases of any progressive dementia (e.g., Alzheimer's disease and Creutzfeld–Jacob disease), HIV infection, Lyme disease, CNS lymphoma, neurosarcoidosis, Lupus cerbebritis, and vitamin B12 associated neurologic disease.

Diagnostic Work-up/Tests

After the diagnosis of Whipple's disease has been considered based on clinical criteria (see **Table 1**), there are a number of blood, radiological, and pathological studies that can be done to help confirm the diagnosis. In lab studies, some expected findings would be leukocytosis, steatorrhea, anemia, and elevation of acute-phase reactants. For CNS disease, MRI has been shown to be superior to CT for detecting smaller lesions. Expected MRI lesions may show T1 hypointensity and T2 hyperintensity. The lesions typically do not have any mass effect and may enhance after administration of gadolinium. The most common sites of involvement on MRI imaging are the medial temporal lobes, the hypothalamus, and the pons. Atrophy may also be present.

Widely considered one of the most sensitive techniques, biopsy of the small bowel via endoscopic techniques can be done to reveal PAS positive macrophages. Electron microscopy can also be done in conjunction to reveal the characteristic tri-laminar appearance of the organism's cell wall or sickle-shaped inclusions inside of macrophages (remnants of the cell walls). PAS staining can also be done on other tissues, but it can be less specific of a test.

A more recently utilized procedure of testing is polymerase chain reaction (PCR) techniques. If a patient is suspected of having more localized symptoms of Whipple's disease, a PCR assay can be done on most tissues. Multiple reviews suggest that a diagnosis of certain Whipple's disease can be made if a tissue is both PAS and PCR positive while positivity of either one or the other implies a possible diagnosis.

Management

Management of this disease involves introduction of antibiotics as soon as the diagnosis is suspected or confirmed. Because of the high rate of CNS involvement, the antibiotic should have the ability to penetrate the CNS by crossing the blood–brain barrier. Some such medications are trimethoprim-sulfamethoxazole (TMP/SMX) and ceftriaxone. Some other medications that have been used include penicillin, chloramphenicol, tetracyclines, doxycycline, ampicillin, some fluoroquinolones, and streptomycin. There does not seem to be a universal consensus for treatment, and no clinical trials exist for treatment because of the rarity of the disease. Some recommended antibiotic courses include IV penicillin G and streptomycin for 10–14 days followed by TMP/SMX by mouth for 1 year; doxycycline and hyroxychloroquine for 1 year with possible addition of SMX if CNS symptoms are present; and Penicillin G for 2 weeks followed by TMP/SMX by mouth for 1 year. Previously treatment courses were prescribed for as little as 3–6 months, but now that there is more experience in the outcomes of relapses, treatment for a year or more is the norm. When treating CNS disease or CNS relapse, monitoring of CSF PCR may help to dictate how long the treatment should last. Some recommend at least 2 years of additional treatment following CNS relapse.

Corticosteroids should not be used for treatment of this disease unless it is for symptomatic treatment of the acute phase of the illness. One study has cited that use of intravenous immunoglobulin (IVIg) in conjunction with antibiotic therapy in a patient who was diagnosed after

3 years of disease progression. The IVIg was started after the patient failed to show clinical response after being treated with antibiotics for 2 weeks. The patient subsequently showed some improvement. Use of interferon γ has also been used specifically for the CNS relapse form of the disease.

Prognosis

Untreated Whipple's disease invariably leads to death. With proper treatment, though, the disease can be brought into remission. Treatment with antibacterial agents treats any and all of the symptoms listed above. The exception is that if the disease is left untreated for some time, CNS symptoms such as dementia arise and may be more refractory to treatment. The earlier the patient is treated in the course of the disease, the higher the likelihood of treatment success.

Wilson, Samuel Alexander Kinnier

T U Hoogenraad, Former Staff Member, University Department of Neurology, University Medical Center, Utrecht, The Netherlands

Glossary

Clinical method of neurology – The rational process by which a neurologist makes a diagnosis, which is the sequence from symptoms to syndrome to disease. In the diagnostic process, laboratory data are subordinated to the clinical aspects of the disease.
Extrapyramidal motor system – Motor structures in the basal ganglia: caudate nucleus; lenticular nucleus with its two subdivisions, the putamen and globus pallidus; thalamus; subthalamic nucleus; substantia nigra.
Extrapyramidal syndromes – Clinical syndromes characterized by reduction of movement (akinesis, rigidity, or dystonia) or excess of movement (hyperkinesis, ataxia, or athetosis) due to disease of the extrapyramidal motor system.
Movement disorders – A group of diseases and syndromes affecting the ability to produce and control movement. Disorders causing abnormal movements and postures due to disease of the extrapyramidal motor systems include, among many others: Wilson's disease, Parkinson's disease, Huntington's disease, inherited ataxias, and Tourette syndrome.
Orphan diseases – Rare diseases, prevalence less than 150 per 1 000 000. Wilson's disease has been the first orphan disease for which an orphan drug, penicillamine, has been developed.

Biographical Data

Samuel Alexander Kinnier Wilson (1878–1937) studied medicine in Edinburgh. He obtained his Bachelor of Medicine degree in 1902 and started to work in 1904 in the National Hospital, Queen's Square, London, where he became a registrar in neurology and trained to become a pathologist. While working at the National Hospital, Wilson became interested in a patient whose mysterious disorder prompted him to perform a thorough clinical and pathological study. His thesis (University of Edinburgh, 1911) was

entitled '*Progressive Lenticular Degeneration; A Familial Nervous Disease Associated with Cirrhosis of the Liver.*' Wilson was appointed as the professor of neurology at King's College Hospital – the first chair of this discipline in England. He died of cancer in 1937, at the age of 59.

Thesis (1911)

In his thesis, Wilson described four patients whom he had observed personally and eight similar cases he had found in the literature. Wilson performed the autopsy and neuropathological studies on three of his patients. Wilson's paper introduced the term 'extrapyramidal' into neurology and focused attention upon the importance of the basal ganglia. Wilson gave an exceptionally thorough and well-written description of the clinical characteristics of progressive lenticular degeneration, and much of what he reported is still valid today (**Figure 1**). To illustrate this, a summary of one of the case histories is given.

Patient ST

A 26-year old woman was under observation in the National Hospital, London. She was the youngest of nine children. The family history was uneventful. Except for dysmenorrhea, the patient had been in perfect health up to the age of 21, when she suffered a self-limiting attack of jaundice with duration of ~5 weeks (**Figure 2**). Since then, she has complained of edema in her legs. At the age of 25, she experienced that her right hand trembled when she attempted to write, and that her speech had become slurred. In the course of the next year, her condition worsened noticeably. The tremor spread to the left arm. A stiffness of the musculature was noted and abnormal posturing of the head, trunk, and limbs developed. Her mouth was often open; her face wore a constant smile, and saliva occasionally escaped from her mouth. Her relatives said that her emotional condition had changed; she had become restless, was easily provoked to laughter, and had become unnaturally cheerful. Her mental acuity and memory had apparently been left unchanged.

It was obvious to Wilson that the nervous disease of this patient did not correspond to any familiar type. Although the disease bore some resemblances to disseminated sclerosis and paralysis agitans, it was quite distinct from either. Wilson was struck by the fact that the clinical condition of this patient was quite similar to that of another patient with a mysterious neurological disease, in whom, autopsy revealed unexpected cirrhosis of the liver. The patient died suddenly after an acute attack of hematemesis at the age of 29 years.

Wilson himself performed the autopsy, 25 h after death. The liver had a striking appearance. It was cirrhotic and its surface was covered with irregular rounded nodules. Histological examination of the brain showed that bilateral and symmetrical destruction of the lenticular nucleus had occurred (**Figure 3**).

Wilson concluded his thesis with the hypothesis that the abnormalities in the brain might be caused by a toxin generated within the cirrhotic liver.

Figure 1 Samuel Alexander Kinnier Wilson (1878–1937), the British neurologist who described, in 1911, an extrapyramidal movement disorder associated with progressive lenticular degeneration and cirrhosis of the liver (hepato-lenticular degeneration, 'Wilson's disease'). Reproduced from Hoogenraad TU (2001) Kinnier Wilson SA (1878–1937) *Journal of Neurology* 248: 71–72, with permission from Jim Kinnier Wilson.

The First Extrapyramidal Motor Syndrome: Rigidity, Distorted Posture, and Tremor

In 1911, Wilson introduced the term extrapyramidal motor syndrome, which he delineated on clinical grounds. In the movement disorder, he described that the most striking abnormality in the nervous system was cavitation

Figure 2 Pictures from Wilson's PhD thesis. Patient S.T. (left) before the onset of symptoms; (right) at the age of 28 years, 4 years after the onset of neurological symptoms, she had a spastic smile and severe generalized dystonia. Reproduced from Wilson (1912), with permission from Oxford University Press.

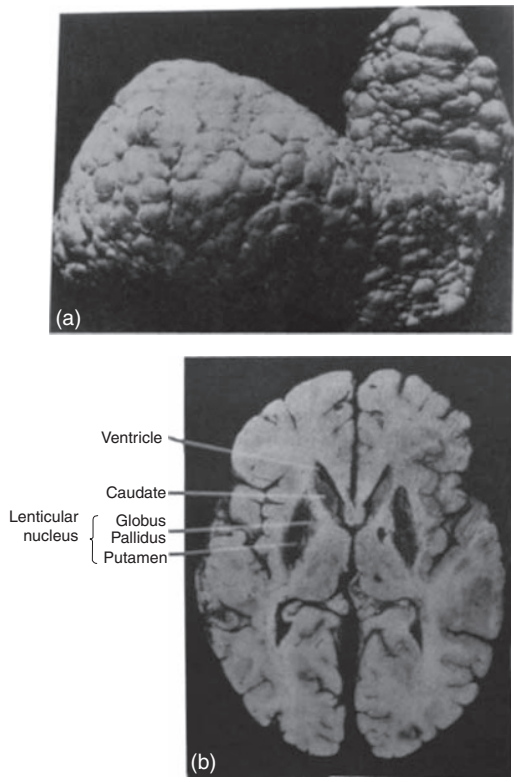

Figure 3 Patient S.T. (a) Cirrhotic liver; (b) bilateral and symmetrical cavitation of the lenticular nucleus. Reproduced from Wilson (1912), with permission from Oxford University Press.

of the putamen of the nucleus lentiformis. Wilson attributed the characteristic symptoms of rigidity, distorted posture, and tremor to the lenticular lesion and in this way, these three symptoms formed the first extrapyramidal motor syndrome. We now know that in Wilson's disease, the neurodegenerative changes are widespread and not at all localized to the nucleus lentiformis. Nevertheless, the striking demonstration by Wilson of lenticular cavitation in patients with rigidity, distorted posture, and tremor is a milestone in the history of movement disorders.

Wilson's Disease and the 'Clinical Method of Neurology'

In the preface of their textbook '*Principles of Neurology*,' Adams and Victor remarked that although neurology is regarded by many as one of the most difficult and exacting specialities of medicine, many of the difficulties could be overcome by adhering to the basic principles of '*The Clinical Method of Neurology*.' Subsequently, they refer to the rational mental process by which a neurologist makes an accurate diagnosis, by following the diagnostic sequence from symptoms to syndrome to disease. In this mental process, laboratory data are subordinated to the clinical aspects of the disease. Wilson has been a protagonist of this clinical method of neurology. As clinician, Wilson took little interest in laboratory work and most of his numerous papers concerned clinical neurology.

A major purpose of the clinical method of neurology is to accomplish an accurate diagnosis and to determine the proper treatment of the patient. By creating the concept of the extrapyramidal system and the extrapyramidal syndrome, Wilson made a major contribution to the syndrome diagnosis, an important step in the clinical method of neurology.

A major aim of the clinical neurologist is not to overlook a disease for which there is an effective treatment. For copper toxicosis in Wilson's disease, effective and safe treatment is available since the introduction of antidotal zinc therapy. Therefore, in accordance with the principles of neurology and in order not to overlook the treatable hereditary copper toxicosis, Wilson's disease should be included in the differential diagnosis of all patients with unexplained movement disorders, especially in syndromes dominated by dystonia, parkinsonism, or ataxia.

Wilson's Disease

T U Hoogenraad, Former Staff Member, University Department of Neurology, University Medical Center, Utrecht, The Netherlands

Glossary

Antidote – A substance which can counteract a form of poisoning; zinc is an antidote for copper poisoning.
Chelating agent – Metal binding agent used to remove metals from the body.
Clinical method of neurology – The evidence based approach to neurologic medicine.
Deductive method – The method of offering general causal explanations for a phenomenon and then testing them deductively against their predictions. The method aims at identifying errors.
Evidence-based medicine – The conscientious use of current best evidence in making decisions about the care of individual patients.
Free copper – The small portion of plasma copper that is not bound to ceruloplasmin.
Inductive method – Induction-based experiments seek verification of the theory.This method does not detect errors and may lead to entrapment in fallacies.
Penicillamine fallacy – The tragic, induction-based misconception that treatment of copper toxicosis can best be started with the chelating agent penicillamine.
Seductive method – The method of choosing a therapy simply on the basis of recommendations of authorities, experts, pharmaceutical representatives, or advertisements.
Zinc therapy – The use of zinc supplements to treat copper poisoning. It is based on the current best evidence available. Zinc therapy offers maximum benefits with minimal risks.

Definition and History

Wilson's disease is a rare autosomal recessive hereditary disease caused by a defect in the cellular copper transport that leads to failure of copper excretion into the bile and to a failure of incorporation of copper into the ceruloplasmin. Poisoning by unbound 'free' copper results and manifests itself with neurological symptoms and liver disease.

The approach to the patient with neurological Wilson's disease should be in accordance with the clinical method of neurology, that is, with the basic principles of clinical medicine.

Milestones in the history of Wilson's disease (**Figure 1**; **Table 1**): In 1911, Wilson gave a conscientious description of the clinical characteristics of hepatolenticular degeneration. It was the first study in which a link was made between a movement disorder and degenerative lesions in the basal ganglia. In 1912, Alzheimer described abnormal glia cells and normal ganglion cells in the grey matter of a patient with hepatolenticular degeneration (**Figure 2**). In 1912, Fleischer described that the brown–greenish corneal ring, first described by Kayser, is a highly specific characteristic of hepatolenticular degeneration (**Figure 3**). In 1948, Cumings discovered that the urinary copper excretion is increased in patients with Wilson's disease, and suggested that copper accumulation could be the cause of Wilson's disease. In 1956, the biochemist Walshe published in *The Lancet* an article on a new oral therapy after he had discovered that treatment of Wilson's disease patients with penicillamine stimulated excretion of copper via the urine. It became a methodological milestone: a shift in approach from the clinical method of neurology to an inductive biochemical method. In 1961, the neurologist Gerrit Schouwink (**Figure 4**) published, in Dutch, his doctoral thesis on the influence of zinc supplementation in Wilson's disease. He described that the copper balance became negative when zinc sulfate was administered.

In 1978, we published, a letter to the editor of *The Lancet* entitled: 'Oral zinc in Wilson's disease.' This letter to *The Lancet* would generate widespread interest in the possibilities of zinc therapy. In 1996, publication of monograph: Wilson's disease, in the *Series Major Problems in Neurology*. Development of hypothesis that Wilson's disease can be seen as juvenile free copper toxicosis (**Figure 5**). In 2008, disclosure of hypothesis that age-related (type-II) free copper toxicosis may play a role in the pathogenesis of age-related cortical neurodegenerative Alzheimer's disease (**Figure 5**).

Pathogenesis/Pathophysiology

Wilson's disease is an autosomal recessive disorder. The responsible gene on chromosome 13 encodes a transmembrane protein ATPase (ATP7B), which functions as a copper-dependent P-type ATPase. The protein has a synthetic role for incorporation of copper into ceruloplasmin, and an excretory role for excretion of copper into the bile. In Wilson's disease, defective ATP7B function results

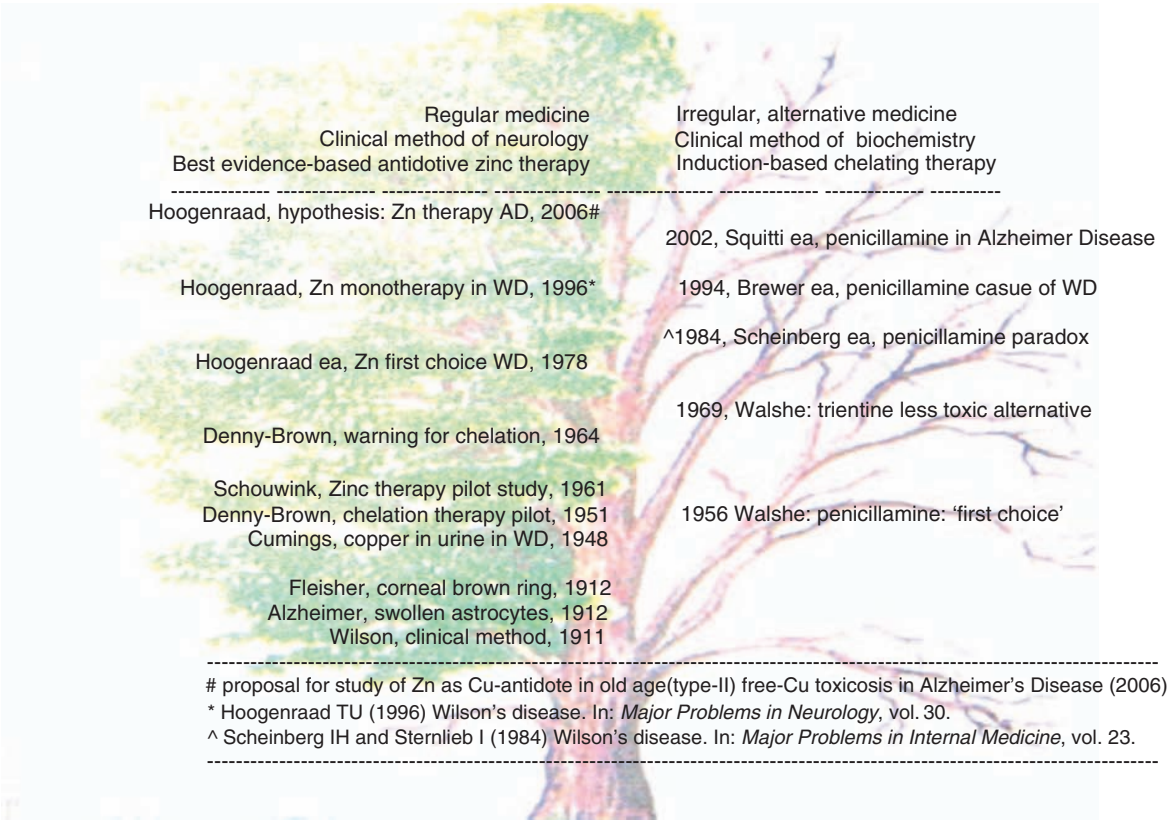

Figure 1 Symbolic tree of historic milestones of WD. Left: healthy, but rare, branches of regular medicine. Right: unhealthy, withered, but popular, ways of irregular, alternative treatments with chelating agents.

Table 1 Milestones in the history of Wilson's disease

1. Description of clinical characteristics of a juvenile movement disorder (Wilson, 1911)
2. Discovery of copper poisoning (Cumings, 1948)
3. Discovery of decoppering treatment: two oppositional strategies
   - Penicillamine therapy; chelation strategy (Walshe, 1956)
   - Zinc sulfate therapy; antidotal strategy (Schouwink, 1961)
4. Methodological shifts
   - 1956: from the clinical method of neurology to the inductive biochemical method
   - 1996: paradigm shift from copper accumulation to free copper poisoning

in increased serum level of free copper. This leads to free copper poisoning which causes the hepatic and neurological features of Wilson's disease.

The primary pathogenetic mechanism is the inherited defect in cellular copper transport that leads to failure of copper excretion into the bile and to a failure of incorporation of copper into ceruloplasmin. Increased levels of nonceruloplasmin bound copper induce metallothionein, a metal binding and detoxificating protein. Hepatic copper levels rise as increasing amounts of 'free' copper are bound to metallothionein in the hepatocytes. Increase of free plasma copper, and not copper accumulation, is the central feature of Wilson's disease. Poisoning by free copper manifests itself with neurological symptoms and liver disease.

Epidemiology/Risk Factors

The prevalence of Wilson's disease is about 1 in 30 000 with a carrier frequency of about 1 in 90.

Clinical Features and Diagnostic Criteria

Clinical symptoms of Wilson's disease usually develop between 3 and 40 years of age, but may begin even at an advanced age. Approximately 40% of patients present with hepatic disease, and another 40% present with nervous system disease.

Neurologic Wilson's Disease

There are three movement disorder syndromes in Wilson's disease: (1) dystonic, (2) ataxic, and (3) parkinsonian syndrome. These syndromes seldom occur in isolation.

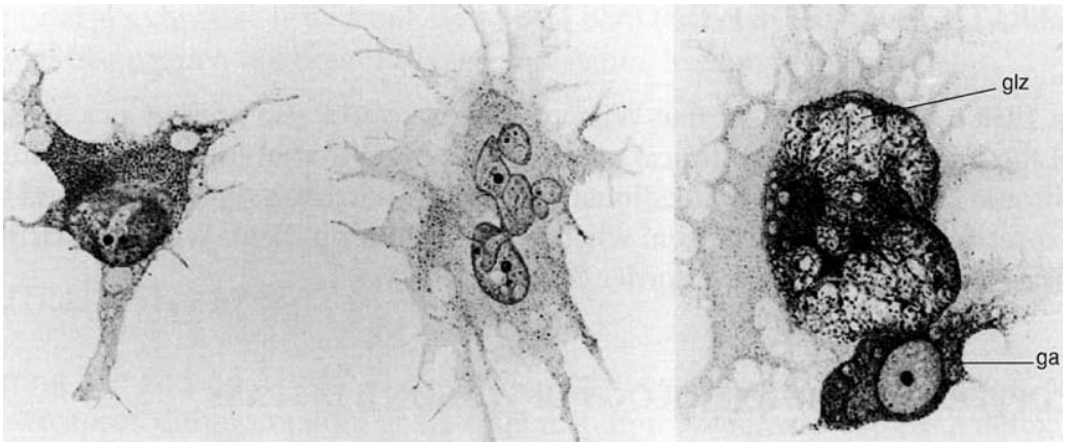

Figure 2 Pictures from Alzheimer's study on the neuropathology of pseudosclerotic hepatolenticular degeneration. *Left* – Alzheimer type-I cell: astrocyte with swollen nucleus and many granules. *Middle* – Alzheimer type-II cell: abnormal astrocyte with vesicular nucleus. *Right* – normal ganglion cell (ga) next to abnormal swollen glia cell (glz).

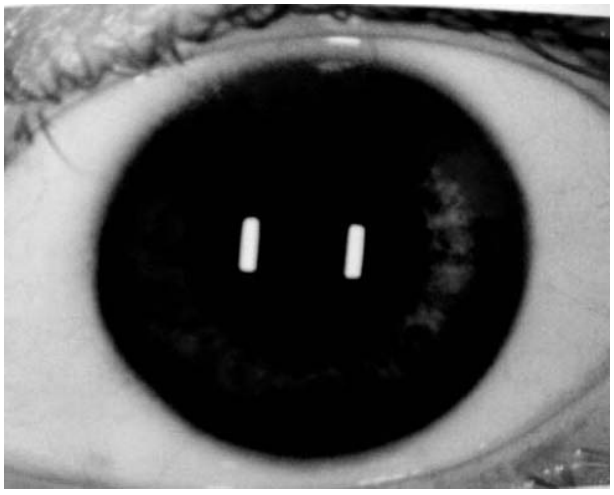

Figure 3 Circumferential brown-golden Kayser–Fleischer ring in the cornea of a 25-year old woman with Wilson's disease. The presence of the Kayser–Fleischer ring indicates that free copper has been released into the circulation. The deposits of copper in the ring are protein-bound and harmless.

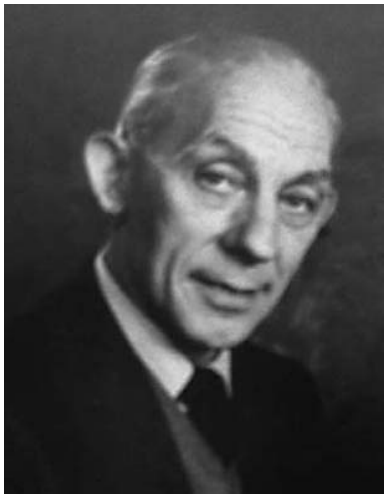

Figure 4 Gerrit Schouwink (1926–1999).
The Dutch neurologist Gerrit Schouwink who postulated in 1961 the hypothesis of zinc therapy in Wilson's disease.

Dystonia and choreoathetosis

Dystonia may be focal or generalized. Focal dystonia can appear in almost any part of the body. In severe cases generalized dystonia develops. Limbs become stiffer and over extension of the legs can lead to a clumsy gait. The fixed smile (risus sardonicus) seen in Wilson's disease represents a lower facial dystonia. Involuntary tic-like movements, like those seen in Tourette's syndrome, may be the first signs of Wilson's disease. Choreoathetosis is frequently seen in Wilson's disease. It is a major clinical problem.

Ataxic tremor

Various types of ataxic tremor may occur in one patient, especially postural and action tremor. Denny-Brown used the term flapping tremor when describing the postural tremor of the outstretched arms of Wilson's disease patients. The term wing-beating tremor is sometimes used for the proximal postural tremor enhanced by lifting the arms, flexing at the elbow, and holding the hands in pronation at chest level. The classical form of cerebellar tremor when the limb is in motion is also common. This type of tremor is present during voluntary movements such as drinking or writing.

Parkinsonian syndrome

Rigidity with lead-pipe stiffness, bradykinesia with slowness of movements, parkinsonian gait, and micrographia resemble the signs of the hypokinetic-rigid syndrome of Parkinson's disease. A typical rest tremor is frequently seen in the parkinsonian type of Wilson's disease.

Figure 5 Bronze sculpture symbolizing the hypothetic Wilsonian/Alzheimerian free copper toxicosis connection. The fish riding musselman (T.U.H) guides, with help of the small (Wilsonian) pilot fish on his fishing rod, the big (Alzheimerian) fish away from the dangerous, irregular, penicillamine pathway towards the regular, best evidence based, zinc route. The sculpture was modelled by T.U.H in 2006 and presented at conference on Alzheimer Disease at the Department of Neurology, Fatebenefratelli Hospital Rome as an illustration to the paper entitled: Free-copper disease: a new way of looking at Alzheimer's disease (June 19, 2006).

Another common symptom of Wilson's disease is dysarthria, related to involvement of the extrapyramidal system, the cerebellar nuclei, and the upper motor neurons. A mixed dysarthria with ataxic, hypokinetic, and dysphonic features is typical. Some patients may have anarthria with complete loss of speech.

Psychiatric symptoms are very common in Wilson's disease, and include irritability, depression, cognitive impairment, hallucinations, and delusions.

Hepatic Wilson's Disease

Liver disease may present as tiredness, increased bleeding tendency, or confusion (due to hepatic encephalopathy), and portal hypertension. The latter condition leads to esophageal varices, splenomegaly, and ascites. Chronic active hepatitis has caused cirrhosis in the liver of most patients by the time they develop symptoms. A small proportion, that is, ~5% of all patients is diagnosed only when they develop fulminant acute liver failure, often in the context of hemolytic anemia.

The Kayser–Fleischer ring is a golden brown or greenish pigmentation at the margin of the cornea near the limbus. It can often be detected with the naked eye, but slit-lamp examination may be required.

Early diagnosis is the keystone of the successful management of the patients with Wilson's disease. Most patients are children, adolescents, or young adults. Patients presenting with neurological manifestations often report symptoms suggestive of hepatic disease.

Table 2 Two laboratory tests needed to calculate free plasma copper for monitoring Wilson's disease

1. Total plasma copper (normal value: ± 1.00 mg l^{-1} or 16 μmol l^{-1})
2. Ceruloplasmin (normal value: >200 mg l^{-1})
Ceruloplasmin contains 0.3% copper.
Normal value of free copper: <0.10 mg l^{-1}
Example: (untreated Wilson's disease with free copper poisoning)
1. Total plasma copper: 0.60 mg l^{-1}. (decreased)
2. Ceruloplasmin: 100 mg l^{-1} (=0.30 mg l^{-1} copper bound to ceruloplasmin)
Calculated free copper = 0.60 mg l^{-1} minus 0.30 mg l^{-1} = 0.30 mg l^{-1} (increased)

Determination of free copper level is important for monitoring the effect of treatment (**Table 2**).

Differential Diagnosis

Wilson's disease should be included in the differential diagnosis of patients with unexplained syndromes dominated by dystonia, Parkinsonism, or ataxia. The diagnosis is easy to establish in individuals with neurological symptoms, Kayser–Fleischer rings, and low ceruloplasmin concentration.

Diagnostic Tests

There are several diagnostic laboratory tests:

1. Ceruloplasmin concentration decreased (<200 mg l^{-1});
2. Slit-lamp examination for Kayser–Fleischer rings;
3. Free plasma copper level (>0.10 mg l^{-1} or 1.6 μmol l^{-1});
4. Urine copper (>0.10 mg l^{-1} or 1.6 μmol l^{-1});
5. Liver copper concentration (>250 μg g^{-1} dry tissue);
6. Absence of incorporation of radio copper into ceruloplasmin;
7. DNA analysis.

Management

The approach to the treatment of a patient with neurologic Wilson's disease should be directed on the basis of its evidence.

The treatment of Wilson's disease has undergone a marked change over the years.

Old Treatment Aim: Stimulation Urine Copper Excretion

Initially, the focus of treatment was ridding the body of copper by increasing its excretion through the urine using chelation therapy.

Penicillamine

The aim of penicillamine chelation is to increase the copper excretion and remove copper from deposits in the tissues. Chelation promotes 'cupriuresis', the excretion of copper from the body via the urine. Walshe advised to start treatment with 1.5–2.0 g day^{-1}, but when used, the dose is more likely to be 125 mg day^{-1}. Penicillamine chelation is associated with Iatrogenic worsening of neurologic manifestations in a minority of patients during the first weeks of therapy. Even in those who tolerated the adverse effects, clinical improvement is slow, the first signs of improvement occurring after ~6 months. The side effects of penicillamine may be serious, and include systemic lupus erythematosus, nephrotic syndrome, myasthenia gravis, and elastosis perforans serpiginosa.

Penicillamine therapy is monitored by urinary copper levels. Scheinberg and Sternlieb advised to maintain urinary free copper at the normal value of 0.10 mg l^{-1}.

Penicillamine Fallacy

Evidence-based medicine disputes its efficacy and safety, and indeed much of the theory behind chelation therapy. The fatal flaw of the chelation strategy is that it is based on the method of induction. By abdicating, in 1956, to the copper chelation strategy, the approach to the patient with Wilson's disease changed from the scientific clinical method of neurology to an unscientific, inductive, alternative method of clinical biochemistry. In 1964, Denny-Brown warned against copper chelation using penicillamine and in 1969, Walshe introduced the concept of using trientene, a copper chelating agent believed to be less toxic than penicillamine. In 1994, Brewer warned against iatrogenic copper poisoning, the induction of copper poisoning by chelating agents.

New Treatment Aim: Normal Free Copper Level

Zinc therapy aims at the normalization of increased levels of free plasma copper, providing effective therapy with few side effects and low costs. The mechanism of action is based on the antagonism between copper and zinc. Zinc antagonizes the absorption of copper in the gut and promotes the excretion of copper via the stools. Zinc supplements stimulate the synthesis of the copper binding protein metallothionein in the mucosal cells in the gut and in the hepatocytes. Zinc supplements tend to normalize the plasma free copper level and the urine copper level.

Zinc Sulphate

Three daily doses of 200 mg zinc sulfate provide 135 mg of elemental zinc, and the dose is given in the form of tablets, capsules, or liquid before meals. The recommended dose is lower for children and adolescents. For children of age 6 and younger, 110 mg zinc sulfate is given twice daily (50 mg elemental zinc daily). Between age 7 and 16 years, 110 mg zinc sulfate is given three times daily (75 mg elemental zinc daily). The first effects of treatment can be expected within the first weeks or months of treatment. In general, the results are excellent or good. Zinc sulfate is an effective, well-tolerated, and inexpensive therapy for Wilson's disease. It is an excellent choice for both neurologic and hepatic Wilson's disease. Normalization of plasma free copper concentrations is a good intermediate goal of decoppering treatment. During effective therapy, urinary excretion of copper will also normalize to values below 0.10 mg Cu per liter.

Changing from Penicillamine to Zinc

Czlonkowska et al. compared treatment with penicillamine to treatment with zinc in 67 newly diagnosed Wilson's disease patients. The two treatments were equally efficacious, but penicillamine was less well tolerated. About 44% of penicillamine-treated *versus* 12% of zinc-treated patients discontinued treatment due to side effects. In 2002, Squitti et al. published on a clinical trial of penicillamine for free copper poisoning in Alzheimer's disease. The trial was discontinued due to severe, even fatal toxicity (**Figure 5**). Evidence-based medicine now suggests that copper chelation is hazardous, and favors a strategy aimed at normalization of free plasma and urine copper. The risks of treatment should be as low as possible.

Physicians treating penicillamine-treated Wilson's disease patients should inform them that penicillamine may be effective in the majority of patients, but that zinc therapy is the prefered mode of treatment of copper poisoning in Wilson's disease and that penicillamine should be withdrawn and that zinc therapy should be started.

Prognosis

Over the last 50 years, most patients with Wilson's disease have been treated with chelating agents. In these years, the prognosis has changed from a uniformly fatal disease to a treatable disease. However, the success of chelation treatment of copper toxicosis is counterbalanced by serious adverse effects. Up to now, only a few patients have profited from the therapeutic improvements realized by zinc sulfate monotherapy. The prognosis of treatment will profit intensively if the patients treated with penicillamine are changed over to zinc sulfate.

Acknowledgments

This article is dedicated to the clinical neurologist Gerrit Schouwink, and to Cassandra, patron of modellers. This work on rational treatment of copper poisoning could not

have been fruitfully accomplished without the very special stimulating help of Prof. J.van Gijn, former series editor of the series: Major problems in Neurology and former Head of the Department of Neurology of the UMC Utrecht.

Writer's Cramp

B Illowsky Karp, National Institutes of Health, Bethesda, MD, USA

Glossary

Writer's cramp – A form of focal hand dystonia activated by writing.
Musician's cramp – A form of focal dystonia activated by and specific to playing a musical instrument.
Repetitive stress injury – Damage to an area of the body, such as the hand, due to overuse. The predominant symptom of repetitive stress injury (RSI) is pain.
Complex regional pain syndrome (CRPS) – A syndrome consisting of pain, autonomic dysfunction, and skin changes in a traumatized body area.

Introduction

Focal hand dystonia (FHD) refers to dystonia, usually idiopathic and of adult onset, that affects the hand, fingers, and arm. FHD can interfere with the ability to perform activities of daily living, hobbies, and occupations. FHD is often named according to the affected activity, such as 'writer's cramp (WC),' or 'musician's cramp.' WC is the most common form of FHD.

Clinical Features

The onset of WC is usually insidious. Most patients recall a feeling of fatigue or aching when using the affected hand and arm with the need to take frequent breaks or rests. Eventually, there is involuntary posturing of the hand, cramping of muscles, and loss of motor control, leading to difficulty in controlling a pen and writing. The loss of fine motor control is particularly disabling to those with other types of FHD, such as musicians who rely on fast, fine, and accurate hand and finger movements.

Dystonic posturing in WC can involve flexors, extensors, or both of individual or multiple fingers, the wrist, and the

more proximal arm, as well as pronators, supinators, abductors, and adductors. Muscle tightness and cramping are uncomfortable, but rarely cause severe pain. Reflexes and sensation are normal, although careful testing may uncover subtle sensory integration deficits. Some patients have a decreased arm swing or a slightly increased resting tone in the affected arm but no other parkinsonism signs. Postural tremor accompanies WC in a little less than half of the patients. Primary writing tremor, in which tremor rather than dystonic posturing is elicited during writing, may be a variant of WC. Up to 50% of those with WC have 'mirror dystonia' in which the affected hand assumes a dystonic posture while writing with the nonaffected, nondominant hand.

FHD tends to develop in those who perform small, repetitive hand and finger movements. The particular pattern of flexion and extension can be characteristic of the type of activity usually performed. For example, writing requires flexion of the wrist and fingers and thus flexor muscles are more commonly involved in WC than extensors. Pianists and violinists with musician's cramp both tend to have dystonic flexion of the fourth and fifth fingers. However, in pianists, the right hand, which faces more technical demands in playing than the left hand, is more commonly affected. In violinists, the technical burden is on the left hand, which is thus more likely to become dystonic than the right bowing hand.

An interesting aspect of WC, present in about half of patients, is 'task specificity.' In such cases, the dystonia is only elicited by writing. Other actions, including those performed using the same hand and similar muscles or movements, are spared so that patients are able to type, draw, and put on makeup normally. Task specificity is also a feature of other forms of FHD. Some musicians with FHD can play other, even similar, instruments without difficulty. While task specificity is common and characteristic of FHD, in many patients, dystonia is elicited by almost any use of the hand or even imagined use of the hand. When severe, patients have dystonic posturing at rest. WC rarely generalizes, but can spread to more proximal muscles or to involve the other hand.

Differential Diagnosis

The differential diagnosis of WC includes repetitive stress injury (RSI) and mononeuropathy of the median or ulnar nerve. Similar to WC, RSI commonly affects a hand used in a repetitive fashion. Unlike dystonia, the most prominent symptom of RSI is pain, which may initially be present only during the use of the hand but can progress to produce pain even at rest. RSI is due to injury and inflammation and responds to rest and antiinflammatory medication.

Median and ulnar neuropathies can often be identified by sensory loss or weakness in the appropriate distribution, which are not present in WC. Although uncommon, some patients with ulnar neuropathy have involuntary flexion of the fourth and fifth fingers in the absence of other sensorimotor disturbances. In those cases, identification of ulnar nerve entrapment may require near nerve recording. In some cases, ulnar nerve release leads to resolution of dystonic posturing.

About 10–30% of patients with complex regional pain syndrome (CRPS), especially type 2 CRPS, have dystonia. The dystonia may appear before other CRPS symptoms and often differs from idiopathic FHD by the presence of fixed postures, pain, and persistence during sleep.

Epidemiology

WC most often begins in the fourth decade, somewhat earlier than blepharospasm or cervical dystonia. Epidemiologic studies report a prevalence of 7–69 per million population for writer's cramp and 0.2–0.5% for musician's cramp. Although most other focal dystonias are more common in women, FHD, especially musician's cramp, affects men more commonly than women. There appears to be a genetic component to FHD. Up to 20% of those with WC and 9% of those with musician's cramp have a family member with some form of dystonia. However, the genes and mutations identified to date in association with generalized and a few other focal dystonias are not common in those with FHD.

Pathophysiology

The diagnosis of WC is made clinically, based on the characteristics of the movement disorder and the absence of other neurological signs. There are no imaging or laboratory tests that are useful in making the diagnosis, although they may help to exclude an underlying cause of a secondary dystonia. The diagnosis of WC may be supported by EMG demonstration of a difficulty in initiating movement, prolonged and uncoordinated cocontraction of agonist/antagonist muscle pairs, and activation of muscles not typically used for a particular task.

While not specific to dystonia, physiologic studies have revealed a loss of inhibition at multiple cortical and subcortical levels involved in motor control and in sensorimotor integration. There is a loss of reciprocal inhibition at spinal and cortical levels. Transcranial magnetic stimulation studies have identified deficient intracortical and 'surround' inhibition, which serves to prevent movement of nearby muscles not needed during the performance of a particular task.

Increasing attention is being focused on identifying and understanding sensory abnormalities in dystonia and the role the sensory system may play in the pathophysiology of this movement disorder. Defects in temporal and spatial sensory discrimination as well as distortion of cortical sensory maps have been identified in patients with WC, both in the dystonic and in the nondystonic hand.

Many people who develop WC report writing excessively. However, the role of overuse in the development of such focal dystonia is uncertain. Similarly, while musicians and others with occupations who rely on overpracticed, repetitive movements seem prone to FHD, most of those in such occupations do not develop dystonia. In addition, FHD and WC often arise in those with no more than average use of their hands. It has been proposed, therefore, that the development of FHD requires both a genetic predisposition and a trigger, such as overuse.

Treatment

Most people who develop symptoms of FHD first try adapting or altering the way they perform the acts that elicit the dystonia. For example, those with WC often try different pens or pen grips; musicians try to refinger passages, change hand position, or modify their instruments. When these measures are unsuccessful, some musicians practice longer or harder, while others try to rest and practice less. Neither approach is usually helpful. Those with WC often limit writing as much as possible and many resort to writing with the nondominant hand. Unfortunately, about 25% of those who successfully switch go on to develop dystonia in the nondominant hand.

Many nonpharmacological approaches have been applied to the treatment of FHD, including physical therapy, occupational therapy, chiropractic treatment, and acupuncture, but none has been shown to be particularly effective. In some patients, splinting to restrain the use of the dystonic limb for various periods of time can improve dystonia briefly after the splint is removed. However, in other patients, especially those with CRPS, dystonia can first appear following splinting or immobilization. Sensory retraining therapy focuses on trying to improve motor function by remediating the deficient sensory discrimination associated with dystonia. Sensory retraining procedures studied to date include having sighted patients learn to read Braille with the affected hand or stimulating dystonic fingers individually with or without additional motor training. Such approaches have led to improvement in WC in small clinical trials. However, it is not yet known whether long-term benefit can be achieved or whether maintenance of any benefit attained will require sustained practice or therapy.

Brain stimulation techniques such as repetitive transcranial stimulation of motor cortex or transcranial direct current stimulation are presently being explored for possible therapeutic application to WC. Stereotactic neurosurgery, including pallidotomy, thalamotomy, and deep brain stimulation, has rarely been performed in patients with WC but appears to be effective in carefully selected patients.

Oral medications used for generalized dystonia or other focal dystonias include anticholinergics, benzodiazepines, muscle relaxants, dopamine agonists, dopamine antagonists, and dopamine depletors. These medications can be tried in those with FHD. However, they are rarely more than minimally successful and often have unacceptable side effects.

The current first line treatment for WC is chemodenervation with botulinum toxin. For botulinum toxin treatment to be successful, the selection of muscles to be injected and the dose of toxin must be carefully tailored to the individual. Proper selection of muscles relies on patient report and physician observation of muscle tightness and dystonic postures. Patients should be watched at rest and with actions that elicit the dystonia. The delineation of involved muscles can be complicated by the presence of compensatory movements. For WC, it may be necessary to inject small muscles, such as hand intrinsics or individual fascicles of finger flexor or extensor muscles. Every effort should be made to adjust the dose and concentration of the toxin in a way that limits toxin spread to adjacent unaffected muscles. A series of injection sessions is usually required to determine the best combination of muscles and doses for an individual patient.

The most limiting side effect of botulinum toxin when used for WC is weakness of injected or nearby muscles, which may be unavoidable. Weakness is usually most intense during the first few weeks after injection and then diminishes. Once dose and muscle selection have been optimized, about 60% of patients have at least 25% improvement in WC with botulinum toxin. Benefit lasts ~3 months, and with repeat injection, can be sustained for years without loss of benefit or tolerance to the dose.

Yale Global Tic Severity Scale (YGTSS)

T K Murphy, E A Storch, and D K Bodzin, University of South Florida, St. Petersburg, FL, USA

Glossary

Global severity score – This score is derived by summing the total motor tic score, total phonic tic score, and overall impairment rating (range = 0–100).

Overall impairment rating – Score rated on a 50-point scale anchored by 0 (no impairment) and 50 (severe impairment) to assess impairment experienced in interpersonal, academic, and occupational realms.

The Yale Global Tic Severity Scale (YGTSS) – A semistructured rating that is administered by a trained clinician to assess the presence, severity, and interference associated with motor and phonic tics.

Total Tic Severity Score – This score is derived by adding the total motor tic (range 0–25) and total phonic tic (range 0–25) scores and is often the score (0–50) used in treatment studies to rate tic severity.

The Yale Global Tic Severity Scale (YGTSS) was developed by Leckman and colleagues (1989) to assess the presence, severity, and interference associated with motor and phonic tics. Prior to its development, a range of methods for assessing tic severity was used, most notably the Tourette Syndrome Severity Scale (TSSS), the Tourette Syndrome Global Scale (TSGS), and structured protocols for assessing tic frequency. While informative, concerns about their use as a primary outcome measure existed such as differing ranges and item weights on the TSSS, an incomplete assessment of both tic severity and functional impairment, the practicality and efficiency of several of the methods, and finally, limited psychometric support of certain approaches (e.g., tic counts).

Given the multiple drawbacks inherent in such existing measures, Leckman and colleagues set out to create an improved scale to measure tic severity. Currently considered as the gold standard of tic assessment for adult and pediatric populations, the YGTSS incorporates a semistructured instrument that is administered by a trained clinician to assess symptomology over the previous week. The presence of motor and phonic tics is rated based on child and parent(s) reports as well as behavioral observations made by the clinician. Thereafter, the severity of motor and phonic tics is rated across five separate dimensions each: number, frequency, intensity, complexity, and interference. An item assessing the distress and impairment experienced in interpersonal, academic, and occupational realms is also rated at the end of the interview.

Overall, five index scores are obtained from the YGTSS: Total Motor Tic Score, Total Phonic Tic Score, Total Tic Score, Overall Impairment Rating, and Global Severity Score. The Total Motor Tic Score is derived by adding the five items pertaining to motor tics (range = 0–25); the Total Phonic Tic Score is derived by adding the five items pertaining to phonic tics (range = 0–25); the Total Tic Severity Score is derived by adding the Total Motor Tic and Total Phonic Tic Scores and is often the score used in treatment studies; and the Overall Impairment Rating is done on a 50-point scale anchored between 0 (no impairment) and 50 (severe impairment). A Global Severity Score is derived by summing the Total Motor Tic Score, Total Phonic Tic Score, and Overall Impairment Rating (range = 0–100). This measure is less often used in treatment studies due to the influence on the impairment rating by comorbid conditions.

Psychometric Properties

Overall, psychometric studies on the YGTSS are quite positive. In the original psychometric study by Leckman et al., involving 105 adults and children with a tic disorder, reliability, and validity of the YGTSS were examined. Generally strong interrater agreement was found in a subsample of participants (intraclass correlation coefficients (ICC) for index scores ranging from 0.62 to 0.85): a finding that was further supported by Walkup et al. The YGTSS ratings

showed a strong convergent validity vis-a-vis robust correlations with corresponding TSGS scores (*r*s ranging from 0.86 to 0.90), strong correlations with clinician impairment-ratings (*r*s ranging from 0.65 to 0.82), and moderate to strong relations with the TSSS (*r*s ranging from 0.54 to 0.76). Support for discriminant validity was demonstrated by weak to moderate relations with clinician impairment-ratings of other forms of psychopathology.

Recently, Storch et al. investigated the reliability and validity of the YGTSS in a study of 28 children and adolescents (between 6 and 17 years of age) with TS. Internal consistency was high with Cronbach's α of 0.92 at the first and second administrations (separated by 6 weeks) for the Total Motor Tic Score, $\alpha = 0.93$ and $\alpha = 0.93$ for the Total Phonic Tic Score, and $\alpha = 0.93$ and $\alpha = 0.94$ for the Total Tic Score. The Total Motor Tic Score was moderately correlated with the Total Phonic Tic Score and YGTSS Overall Impairment Rating, signifying that these measures are distinct, but the associated aspects of TS. The Total Phonic Tic Score and YGTSS Overall Impairment Rating were strongly correlated for both assessments, suggesting that phonic tics may result in a greater impairment than motor tics. Stability over a period of 48 days ranged from good to excellent for the Total Motor Tic Score (ICC = 0.77), Total Phonic Tic Score (ICC = 0.90), Total Tic Score (ICC = 0.88), Overall Impairment Rating (ICC = 0.88), and the Global Severity Score (ICC = 0.89). Convergent validity was supported with strong correlations among the YGTSS scores and parent-reports of tics. Divergent validity was supported, as the YGTSS showed weak correlations with measures of obsessive-compulsive, aggression, inattention/hyperactivity, depressive, and anxious symptoms.

Storch et al. conducted a factor analytic study of the YGTSS in 76 youth with TS to confirm the optimal factor structure of the measure. Overall, the factor structure found by Leckman et al. was supported with the resultant factors showing good reliability and validity with measures of diverging and converging constructs. For example, parent-rated tics were moderately correlated with the YGTSS Motor Tic Scale ($r = 0.47$) and strongly correlated with the YGTSS Phonic Tic Scale ($r = 0.72$). Similarly, in terms of divergent validity, the YGTSS Phonic Tic Scale was directly, albeit weakly, correlated with ADHD symptoms and overall psychopathology.

Several translations of the YGTSS and studies of their psychometric properties have been published, including versions in Spanish and Polish. Garcia-Lopez et al. investigated the psychometric properties of the Spanish version of the YGTSS. Principal component factor analysis confirmed that the scale consists of two factors: Motor Tic factor and Phonic Tic factor. The internal consistency was high across factors, with Cronbach's α of 0.997 and 0.996, respectively. Interrater reliability was high for Motor Tic, Phonic Tic, and Overall Impairment ratings (ICC $\geq$ 0.95). Finally, scores showed good treatment sensitivity over 15 days of pharmacological intervention. Stefanoff and Wolanczvk examined the psychometric properties of a Polish version of the YGTSS. Factor analysis again supported the two-factor model with Motor Tic and Phonic Tic factors. Internal consistency for the Global Severity Score was adequate ($\alpha = 0.73$).

In addition to these studies, which have directly examined the psychometric properties of the YGTSS, there have been a number of studies that support its treatment sensitivity to psychiatric medications. Similarly, treatment sensitivity has been shown in trials of habit reversal training. Across trials, score reductions on the YGTSS correspond well with change ratings on the Clinical Global Improvement scale.

Conclusions

Clearly, the YGTSS has many positive qualities that result in its widespread use, including an intuitive scoring structure, comprehensiveness of item content, and strong psychometric properties. However, at times, the YGTSS Severity Score may provide a misrepresentation of symptom severity when a person has primarily motor or phonic tics. For example, if a person presents with only phonic tics, the maximum YGTSS rating could be 25. Yet, the associated impairment and symptom severity may be greater than a person receiving respective scores of 12 and 13 on the Motor and Phonic Tic scales, despite the fact that both the Total Tic Scores are equal. This rating disparity may hold particular import, given that many clinical trials utilize a cutoff score as a part of the inclusion criteria or to assess treatment response. In the instance where the presentation involves primarily one form of tics, either primarily motor or phonic tics, the person may be excluded from clinical trials with clinically impairing symptoms. Many experts believe that the separation between phonic and motor tics is artificial and the scale may benefit from an integrated scoring rather than the two subscales.

In addition, there are several areas that warrant further empirical attention. First, it is unclear whether there is differential item treatment sensitivity,that is, do certain items respond more or less rapidly to particular interventions? Second, should certain items receive higher weighting such as intensity or interference? Each item on the scale is cumulative so that an individual with a very loud and frequent simple phonic tic may score 13 for severity (1 = number, 0 = complexity, 4 = frequency, 4 = intensity, 4 = interference), whereas someone with complex motor tics that are infrequent or less intense may also score 13, but the impact is different (3 = number, 4 = complexity, 2 = frequency, 2 = intensity, 2 = interference). The Impairment score reflects overall coping and functioning that may be worsened by coexisting depression, OCD,

or ADHD. Finally, the YGTSS can be lengthy to complete and requires a trained clinician. Thus, there may be benefit to developing a parent-rated measure that parallels the YGTSS in item content for a more rapid assessment of symptoms.
