Preface

The twenty-first century continues to provide new advances in health care through the efforts of the many professionals working in scientific research and development. In particular the field of orthotics and prosthetics continues to make profound advancement through the dedication of scientists and clinicians at the U.S. Department of Veterans Affairs Office of Research and Development and in medical centers and private industry across the globe. The use of technology such as computer-aided design (CAD) and computer-aided engineering systems has been developed to support advances in product development that reduce the need for physical prototypes, as well as costs and fabrication time. The clinical application of assistive devices, such as those available in the field of orthotics and prosthetics, offer relief from physical impairments and reduce the activity limitations and participation restrictions presented by disease and disability to individuals of varied ages and backgrounds, including the men and women who courageously serve in the different branches of the United States Armed Forces.

Advancements in the use of "smart" technology in the rehabilitation of persons using orthotic and prosthetic devices challenges health professionals such as physicians, physical therapists, occupational therapists, orthotists, prosthetists, nurses, and social workers to aspire for continuous quality improvement in service delivery models of care. Health care professionals seek to provide quality care using evidence-based best practice recommendations and clinical guidelines available in their respective fields. The need for integrated knowledge and collaborative collegial relationships among health professionals is critical for optimal delivery of health care to consumers across the life span. The 4th edition of *Orthotics and Prosthetics in Rehabilitation* provides clinicians, educators, and students of physical therapy, occupational therapy, prosthetics, and orthotics an updated textbook on common health conditions and available interventions for persons with physical impairments and disabilities that require the use of assistive devices such as an orthosis or prosthesis.

The challenges facing health professionals who are dedicated to providing effective and efficient evidence-based rehabilitative care to individuals with conditions affecting their ability to engage in essential daily activities and participate in meaningful roles are many. These challenges include (1) the ever more rapidly advancing technology that tests our ability to remain up to date about available prosthetic and orthotic options, (2) expectations for productivity in practice reflected in the very real time constraints of daily patient care, and (3) the need to be good stewards of the health care dollar while at the same time providing the best orthosis or prosthesis and associated rehabilitation care so that the individual can meet his or her personal goals when using the device. Clearly, optimum care for these individuals and their family requires the combined expertise of health professionals from many different disciplines. The complexity of the health care delivery system, the varied options and alternatives for health care, and information available through the internet can present challenges to health professionals and consumers alike. To address this complexity, the 4th edition of *Orthotics and Prosthetics in Rehabilitation* incorporates information from the perspectives of different members of the rehabilitation team.

The goal of the 4th edition of *Orthotics and Prosthetics in Rehabilitation* is to present best available evidence for entry-level physical therapy, occupational therapy, and orthotic/prosthetic students and to provide a positive model of clinical decision making in the context of multidisciplinary and interdisciplinary care. We also intend the text to be a comprehensive and accessible reference for practicing clinicians; a resource for their person-centered examination, evaluation, intervention planning, and outcome assessment. Our contributors are professionals from the fields of orthotics and prosthetics, physical and occupational therapy, biomechanics, engineering, and medicine (including surgery). We present this text as an example of the value of collaborative and interdisciplinary patient care. Each contributor has carefully researched the developments in technology, examination, and intervention for the revised or new chapter presented in this edition. We have incorporated concepts and language of the World Health Organization's International Classification of Functioning, Disability, and Health (ICF) to enhance communication across disciplines. We have included case examples, posing sequential relevant questions to provoke discussion of alternatives as a model of effective clinical decision making. We have opted not to "answer" the questions posed, on the grounds that the general principles we present in the text must be adapted appropriately to meet individual needs, daring readers to work through the problem-solving process and debate the pros and cons of the various options with their peers. We seek to provide opportunity to "practice" the process of evidence-based clinical decision making, rather than present an absolute prescription or plan of care. We hope that this approach will provide a workable model, prompting the reader to appraise critically evidence from a variety of sources, integrate this material with the clinical expertise of self and others, and include the individual and family's values and goals when making clinical decisions.

As in previous editions, we have chosen purposefully to continue using "person-first" language to reflect the humanity and value of the individuals we care for. Person-first language utilizes phrases such as "person with stroke" or "person with amputation" rather than stating "stroke patient" or "amputee patient". The use of person-first language is the standard approach in addressing individuals with disabilities. We hope that this example assists students and clinicians using the text to embrace person-centered care.

The text begins with a set of chapters that provides foundation and context for the care of persons who might benefit, in terms of function and of quality of life, from prescription of an orthosis or prosthesis. Although chapters on exercise prescription for older adults, motor learning and

motor control, and evidence-based practice may not initially seem to "fit" with the remaining chapters, they are written with the intent to apply these concepts to the rehabilitation of individuals using an orthosis or prosthesis, and we trust that those who read them will recognize their relevance. The chapters on assessment of the ability to walk, the methods of fabrication and fitting, and on footwear choices have obvious relevance.

The second part of the text takes us into the world of orthotic design and application, starting with orthoses for foot and lower limb, spine, and hand. We challenge our readers to think not only about selecting the most appropriate orthosis for persons with musculoskeletal or neuromuscular system problems, but also to design a rehabilitation intervention based on principles of motor learning that will facilitate the person's use of the orthoses and ability to participate in activities most meaningful to the individual. We then consider wheelchairs and seating as an orthosis-of-sorts, designed to enhance mobility for persons when functional walking is not a viable option.

The third part of the text focuses on the care of persons with amputation, beginning with consideration of why amputations are performed, care of those at risk of amputation (with prevention as a focus), how amputations are done, and postoperative/preprosthetic care. The following chapters provide an overview of prosthetic options and alignment issues for those with partial foot, transtibial, transfemoral, transhumeral, and bilateral amputations. We then consider initial prosthetic rehabilitation, including chapters on advanced skills for community function and athletics following amputation. The chapter on children with limb deficiency prompts us to incorporate our understanding of motor, cognitive, and emotional development, as well as family dynamics, into prosthetic rehabilitation. We include chapters on prosthetic options and rehabilitation for persons with upper extremity amputation meant to provide exposure to this more specialized aspect of prosthetic and rehabilitative care.

With this 4th edition of *Orthotics and Prosthetics in Rehabilitation*, we hope that our work will enhance collaboration, mutual respect, and communication, as well as broaden the knowledge base of health professionals involved in orthotic or prosthetic rehabilitation. It is our belief that collaborative and interdisciplinary care not only enriches clinical practice and teaching, but also insures the best possible outcomes for individuals for which we provide rehabilitative care.

Michelle M. Lusardi, PT, DPT, PhD

Acknowledgments

To my family, for their endless support. To Dr. Michelle Lusardi, PT, DPT, PhD, FAPTA, for believing in me. To our colleagues, for their commitment to this project. And to my Executive Dean, Dr. Ann Barr-Gillespie, PT, DPT, PhD, for her guidance.

K.K.C.

To Mitchell B. Horowitz

In thanksgiving for our wonderful married life together and in memory of my beloved brother William Jorge. "The way to love anything is to realize that it may be lost."– G.K. Chesterton

M.J.

To my beloved wife, Shao-Jen Cheng

You have been my source of inspiration and interest for all of my scholarly work.

S.Y.

To all who have served as my mentors, I as truly grateful and blessed to have followed in your footsteps.

To all of the former students who have come through my classroom, what a privilege to have been part of your journey.

To my beloved husband, Lawrence, and my wonderful son, Tigre, you have been the wing beneath my wings…

M.M.L

1 Orthotics and Prosthetics in Rehabilitation: Multidisciplinary Approach☆

MILAGROS JORGE

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Describe the role of the orthotist, prosthetist, physical therapist, and other professionals in the rehabilitation of persons with movement dysfunction.
2. Discuss the history and development of physical rehabilitation professions associated with the practice of orthotics and prosthetics in health care.
3. Identify contemporary critical factors that continue to influence the need for the use of orthotics and prosthetics in rehabilitation.
4. Apply the use of disablement frameworks in physical rehabilitation.
5. Discuss the role of health professionals in multidisciplinary and interdisciplinary rehabilitation teams.
6. Determine key attributes and attitudes that health professionals should possess to be successful members of interdisciplinary rehabilitation teams.

The author extends appreciation to Caroline Nielson, whose work in prior editions provided the foundation for this chapter.

Health professionals work in health care settings to meet the physical rehabilitation needs of diverse patient populations. The current health care environment strives to be patient-centered and advocates the use of best-practice models that maximize patient outcomes and contain costs. The use of evidence-based treatment approaches, clinical practice guidelines, and standardized outcome measures provides a foundation for evaluating and determining efficacy in health care across disciplines and health conditions. The World Health Organization (WHO) International Classification of Functioning, Disability and Health (ICF)[1] provides a disablement framework that enables health professionals to maximize patient/client participation and function while minimizing disability. The current complex environment of health care and evolving patterns of health care delivery require a focus on multidisciplinary and interdisciplinary approaches to the total care of the patient.

For a health care team to function effectively, each member of the health care team must develop a positive attitude toward multidisciplinary and interdisciplinary collaboration. The collaborating health professional must understand the functional roles of each health care discipline within the team and must respect and value each discipline's input in the decision-making process of the health care team. Rehabilitation, particularly when related to orthotics and prosthetics, requires an interdisciplinary approach and lends itself well to collaboration among the various health professionals involved in the management of providing physical rehabilitation. Persons with orthopedic and neurologic impairments caused by a variety of health conditions require a wide range of expert knowledge and technical skills. The physician, prosthetist, orthotist, physical therapist, occupational therapist, nurse, and social worker are important participants in the rehabilitation team who will provide the knowledge and skills necessary for effective patient management. Understanding the roles and professional responsibilities of each of these disciplines maximizes the ability of the rehabilitation team members to function effectively to provide comprehensive care for the patient.

According to disability data from the American Community Survey 2017,[2] 12.6% of noninstitutionalized populations, male or female, of all ages and races regardless of ethnicity, reported having a disability. Nearly 24% (23.6%) of noninstitutionalized civilian veterans aged 21 to 64 years report having a Veterans Administration (VA) service–connected disability. In the 2015 US Congressional Research Service report, "A Guide to U.S. Military Casualty Statistics,"[3] the US military engagements that have continuously persisted for the past 15 years in Iraq, Afghanistan, and other countries have resulted in traumatic brain injury (TBI), amputation, and physical disabilities with life-long impairments.[4] The continued rise in persons with obesity has increased the number of people with diabetes. The Centers for Disease Control and Prevention 2017 Diabetes Surveillance System Report indicates 30.3 million Americans have diabetes[5]—1 out of every 10 persons; 84 million Americans (1 out of every 3 persons) have prediabetes (Box 1.1). Persons with diabetes are at risk for dysvascular

☆The author extends appreciation to Caroline C. Nielsen, whose work in prior editions provided the foundation for this chapter.

Box 1.1 Fast Facts on Diabetes

30.3 million Americans have diabetes (1 out of every 10 persons)
Diagnosed: 23.1 million people
Undiagnosed: 7.2 million people
84 million Americans have prediabetes (1 out of every 3 persons)

Source: https://www.cdc.gov/diabetes/pdfs/data/statistics/national-diabetes-statistics-report.pdf.

disease, such as peripheral arterial disease (PAD),[6] which often results in musculoskeletal and neuromuscular impairments to the lower extremities. Ischemic disease can cause peripheral neuropathy, loss of sensation, poor skin care and wound formation, trophic ulceration, osteomyelitis, and gangrene, which can result in the need for limb amputation.

Persons coping with illness, injury, disease, impairments, and disability often require rehabilitation inclusive of special orthotic and prosthetic devices to help with mobility, stability, pain relief, and skin and joint protection. Appropriate prescription, fabrication, instruction, and application of the orthotic and prosthetic devices help persons to engage in activities of daily living as independently as possible. Orthotists and prosthetists are health care professionals who custom-fabricate and fit orthoses and prostheses. Along with other health care professionals, including nurses, physical therapists, and occupational therapists, orthotists and prosthestists are integral members of the multidisciplinary and interdisciplinary rehabilitation teams responsible for returning patients to productive and meaningful lives. The WHO ICF[7] is a common framework to understand and describe functioning and disability. To make the ICF more applicable for everyday use, the WHO and ICF research branch created a process for developing core sets of data to be considered when addressing persons with disabilities. ICF categories, or ICF Core Sets,[8] facilitate the description of functioning by providing lists of essential categories that are relevant for specific health conditions and health care contexts. The use of the WHO ICF disablement framework enables health professionals to evaluate and support individuals with impairments that maximize function and minimize disability. The WHO ICF disablement framework has broadened considerably the original pathology model framework in which disability was a function of a particular disease or group of diseases.[9] In developing the ICF Core Sets, the WHO engages professionals from across health care disciplines to endorse a more inclusive model that uses expertise within the many sectors in rehabilitative care. A multidisciplinary approach to patient care in rehabilitation is the current standard when addressing the needs of persons with physical impairments, limitations, and disabilities. The 2016 American Heart Association (AHA)/American College of Cardiology (ACC) clinical guideline supports an interdisciplinary approach to the management of persons with PAD.[10] The AHA/ACC clinical guideline identifies a team of professionals representing different disciplines to assist in the evaluation and management of the patient with PAD. This chapter discusses the developmental history of the art and science of orthotics, prosthetics, and physical therapy as professions dedicated to rehabilitating persons with injury, impairment, and disability.

Orthotists and Prosthetists

Orthotists provide care to persons with neuromuscular and musculoskeletal impairments that contribute to functional limitation and disability by designing, fabricating, and fitting orthoses or custom-made braces. The orthotist is responsible for evaluating the patient's functional and cosmetic needs, designing the orthosis, selecting appropriate components, and fabricating, fitting, and aligning the orthosis. The orthotist educates the patient and the care providers on appropriate use of the orthosis, care of the orthosis, and how to assess continued appropriateness of the orthosis (Figs. 1.1 and 1.2).

Prosthetists provide care to patients with partial or total absence of limbs by designing, fabricating, and fitting prostheses or artificial limbs. The prosthetist creates the design to fit the individual's particular functional and cosmetic needs; selects the appropriate materials and components; makes all necessary casts, measurements, and modifications (including static and dynamic alignment); evaluates the fit and function of the prosthesis on the patient; and teaches the patient how to care for the prosthesis (Figs. 1.3 and 1.4).

According to the US Department of Labor, Bureau of Labor Statistics, in 2016, there were 7500 certified orthotists and prosthetists practicing in the United States.[11] Individuals who enter the fields of orthotics and prosthetics must complete advanced education (beyond an undergraduate degree) and a residency program before becoming eligible for certification. Registered assistants and technicians in orthotics or prosthetics assist the certified practitioner with patient care and fabrication of orthotic and prosthetic devices.

Fig. 1.1 Orthotist is evaluating the proper fit of a spinal orthosis to determine whether it meets the prescriptive goals and can be worn comfortably during functional activities or whether modifications need to be made.

Fig. 1.2 Child is wearing a spinal orthosis during a physical therapy session. Orthotist is observing the child as she is engaged in therapeutic play, to assess the child's level of support and comfort while wearing the orthosis.

Fig. 1.3 Prosthetist is assisting child in donning prosthetic limb. Prosthetist will check the prosthesis for alignment, fit, and comfort.

History

The emergence of orthotics and prosthetics as health care professions has followed a course similar to the profession of physical therapy. Development of all three professions is closely related to three significant events in world history: World War I, World War II, and the onset and spread of polio in the 1950s. Unfortunately, it has taken war and disease to provide the major impetus for research and development in these key areas of rehabilitation.

Although the profession of physical therapy has its roots in the early history of medicine, World War I was a major impetus to its development. During the war, female "physical educators" volunteered in physicians' offices and Army hospitals to instruct patients in corrective exercises. After the war ended, a group of these "reconstruction aides" joined together to form the American Women's Physical Therapy Association. In 1922, the association changed its name to the American Physiotherapy Association and opened membership to men and aligned itself closely with the medical profession. In the late 1940s the Association had once again changed its name to the American Physical Therapy Association (APTA), as it remains at present.[12]

Fig. 1.4 Prosthetist using computer-aided design in fabricating a lower-extremity prosthesis.

Until World War II, the practice of prosthetics depended on the skills of individual craftsmen. The roots of prosthetics can be traced to early blacksmiths, armor makers, other skilled artisans, and even the individuals with amputations, who fashioned makeshift replacement limbs from materials at hand. During the Civil War, more than 30,000 amputations were performed on Union soldiers injured in battle; at least as many occurred among injured Confederate troops. At that time, most prostheses consisted of carved or milled wooden sockets and feet. Many were procured by mail order from companies in New York or other manufacturing centers at a cost of $75 to $100 each.[13] Before World War II, prosthetic practice required much hands-on work and craftsman's skill. D.A. McKeever, a prosthetist who practiced in the 1930s, described the process: "You went to [the person with an amputation's] house, took measurements and then carved a block of wood, covered it with rawhide and glue, and sanded it." During his training, McKeever spent 3 years in a shop carving wood: "You pulled out the inside, shaped the outside, and sanded it with a sandbelt."[14]

The development of the profession of orthotics mirrors the field of prosthetics. Early "bracemakers" were also artisans such as blacksmiths, armor makers, and patients who used many of the same materials as the prosthetist: metal, leather, and wood. By the 18th and 19th centuries, splints and braces were also mass produced and sold through catalogs. These bracemakers were also frequently known as "bonesetters" until surgery replaced manipulation and bracing in the practice of orthopedics. "Bracemaker" then became a profession with a particular role distinct from that of the physician.[15]

World War II and the period following were times of significant growth for the professions of physical therapy, prosthetics, and orthotics. During the war, many more physical therapists were needed to treat the wounded and rehabilitate those who were left with functional impairments and disabilities. The Army became the major resource for physical therapy training programs, and the number of physical therapists serving in the armed services increased more than sixfold.[16] The number of soldiers who required braces or artificial limbs during and after the war increased the demand for prosthetists and orthotists as well.

After World War II, a coordinated program for persons with amputations was developed. In 1945, a conference of surgeons, prosthetists, and scientists organized by the National Academy of Sciences revealed that little scientific effort had been devoted to the development of artificial limbs. A "crash" research program was initiated, funded by the U.S. Department of Veterans Affairs Office of Scientific Research and Development and continued by the VA. A direct result of this effort was the development of the patellar tendon–bearing prosthesis for individuals with transtibial (below-knee) amputation and the quadrilateral socket design for those with transfemoral (above-knee) amputation. This program also included educating prosthetists, physicians, and physical therapists in the skills of fitting and training of patients with these new prosthetic designs.[16]

The needs of soldiers injured in the military conflicts in Korea and Vietnam ensured continuing research, further refinements, and development of new materials. The development of myoelectrically controlled upper extremity prostheses and the advent of modular endoskeletal lower extremity prostheses occurred in the post–Vietnam conflict era. The US Department of Defense reports data on the casualties from military engagements in Iraq and Afghanistan, including Operation Freedom's Sentinel; Operation Inherent Resolve; Operation New Dawn; Operation Iraqi Freedom; and Operation Enduring Freedom. Based on the 2015 Congressional Research Service report on the military casualties of war, 327,299 service men and women sustained TBI and 1645 sustained major limb amputations.[17]

The use of orthotics and prosthetics to support individuals with TBI and amputation is critical when seeking to reduce impairments and enhance functional abilities. The Veterans Health Administration Research Development is committed to exploring the use of new technology such as robotics, tissue engineering, and nanotechnology to design and build lighter, more functional orthoses and prostheses.[18]

The current term *orthotics* emerged in the late 1940s and was officially adopted by American orthotists and prosthetists when the American Orthotic and Prosthetic Association was formed to replace its professional predecessor, the Artificial Limb Manufacturers' Association. *Orthosis* is a more inclusive term than *brace* and reflects the development of devices and materials for dynamic control in addition to stabilization of the body. In 1948 the American Board for Certification in Orthotics and Prosthetics[19] was formed to establish and promote high professional standards.

Although the polio epidemic of the 1950s played a role in the further development of the physical therapy profession, this epidemic had the greatest effect on the development of orthotics. By 1970, many new techniques and materials, some adapted from industrial techniques, were being used to assist patients in coping with the effects of polio and other neuromuscular disorders. The scope of practice in the field of orthotics is extensive, including working with children with muscular dystrophy, cerebral palsy, and spina bifida; patients of all ages recovering from severe burns or fractures; adolescents with scoliosis; athletes recovering from surgery or injury; and older adults with diabetes, cerebrovascular accident, severe arthritis, and other disabling conditions.

Like physical therapists, orthotists and prosthetists practice in a variety of settings. The most common setting is the private office, where the professional offers services to a patient on referral from the patient's physician. Many large institutions, such as hospitals, rehabilitation centers, and research institutes, have departments of orthotics and prosthetics with on-site staff to provide services to patients. The prosthetist or orthotist may also be a supplier or fabrication manager in a central production laboratory. In addition, orthotists and prosthetists serve as full-time faculty in orthotic and prosthetic professional education programs. Orthotists and prosthetists also serve as residency directors and clinical educators in a variety of facilities for the yearlong residency program required before the certification examination.

Prosthetic and Orthotic Professional Roles and Responsibilities

With rapid advances in technology and health care, the roles of the prosthetist and orthotist have expanded from a technologic focus to a more inclusive focus on being a member of the rehabilitation team. Patient examination, evaluation, education, and treatment are currently significant responsibilities of practitioners. Most technical tasks are completed by technicians who work in the office, in the laboratory, or at an increasing number of central fabrication facilities. The advent and availability of modifiable prefabrication systems have reduced the amount of time that the practitioner spends crafting new prostheses and orthoses.

Current educational requirements reflect these changes in orthotic and prosthetic practice. Entry into professional training programs requires completion of a bachelor's degree from an accredited college or university, with a strong emphasis on prerequisite courses in the sciences. Professional education in orthotics or prosthetics requires an additional academic year for each discipline. Along with the necessary technical courses, students study research methodology, kinesiology and biomechanics, musculoskeletal and neuromuscular pathology, communication and education, and current health care issues. Orthotics and prosthetics programs are most often based within academic health centers or in colleges or universities with hospital affiliations. On completion of the educational and experiential requirements, the student is eligible to take the certification examinations. To address the rehabilitation needs of individuals who will benefit from the art and science of the fields of prosthetics and orthotics, physical therapists,

orthotists, prosthetists, and other members of the health care team must have discreet knowledge and skills in the management of persons with a variety of health conditions across the life span. Working as a rehabilitation team, physicians, nurses, prosthetists, orthotists, physical therapists, occupational therapists, social workers, patients, and family members seek to alleviate disease, injury, impairments, and disability by maximizing function.

Disablement Frameworks

Historically, disability was described using a theoretical medical model of disease and pathology. Over time, various conceptual frameworks have been developed to organize information about the process and effects of disability.[20] Disablement frameworks in the past have been used to understand the relationship of disease and pathology to human function and disability.[20-23] The need to understand the impact that acute injury or illness and chronic health conditions have on the functioning of specific body systems, human performance in general, and on the typical activities of daily living from both the individual and a societal perspective has been central to the development of the disablement models. The biomedical model of pathology and dysfunction provided the conceptual framework for understanding human function, disability, and handicap as a consequence of pathological and disease processes.

The Nagi model was among the first to challenge the appropriateness of the traditional biomedical model of disability.[21] Nagi developed a model that looked at the individual in relationship to the pathologic condition, functional limitations, and the role that the environment and society or the social environment played. The four major elements of Nagi's theoretical formulation included active pathology (interference with normal processes at the level of the cell), impairment (anatomic, physiologic, mental, or emotional abnormalities or loss at the level of body systems), functional limitation (limitation in performance at the level of the individual), and disability. Nagi defined disability as "an expression of physical or mental limitation in a social context."[21] The Nagi model was the first theoretical construct on disability that considered the interaction between the individual and the environment from a sociologic perspective rather than a purely biomedical perspective. Despite the innovation of the Nagi model in the 1960s, the biomedical model of disability persisted.

In 1980, the WHO developed the International Classification of Impairments, Disabilities, and Handicaps (ICIDH) to provide a standardized means of classifying the consequences of disease and injury for the collection of data and the development of social policy.[24] This document provided a framework for organizing information about the consequences of disease. However, it focused solely on the effects of pathologic processes on the individual's activity level. Disability was viewed as a result of an impairment and considered a lack of ability to perform an activity in the normal manner. In 1993, the WHO began a revision of ICIDH disablement framework that gave rise to the concept that a person's handicap was less related to the health condition that created a disadvantage for completing the necessary life roles but rather to the level of participation that the person with the health condition was able to engage in within the environment. The concept of being handicapped was changed to be seen as a consequence of the level of participation for the person and the interaction within an environment.

The Institute of Medicine enlarged Nagi's original concept in 1991 to include the individual's social and physical environment (Fig. 1.5). This revised model describes the environment as "including the natural environment, the built environment, the culture, the economic system, the political system, and psychological factors." In this model, disability is not viewed as a pathologic condition residing in a person but instead is a function of the interaction of the person with the environment.[25]

In 2001 the ICIDH was revised to ICIDH-2 and renamed "International Classification of Functioning, Disability and Health" and is commonly referred to as ICF.[26] The ICF disablement framework includes individual function at the level of body/body part, whole person, and whole person within a social context. The model helps in the description of changes in body function and structure, what people with particular health conditions can do in standard environments (their level of capacity), and what they actually do in their usual environments (their level of performance). One of the major innovations of the ICF model is the presence of an environmental factor classification that considers the role of environmental barriers and facilitators in the performance of tasks of daily living. Disability becomes an umbrella term for impairments, activity limitations, and participation restrictions. The ICF model emphasizes health and functioning rather than disability. The ICF model provides a radical departure from emphasizing a person's disability to focusing on the level of health and facilitating an individual's participation to whatever extent is possible within that level of health. In the ICF, disability and functioning are viewed as outcomes of interactions between health conditions (diseases, disorders, and injuries) and contextual factors (Fig. 1.6).

As is stated on the ICF website,[27] "To make the ICF more applicable for everyday use, WHO and the ICF Research Branch created a process for developing core sets of ICF categories, or "ICF Core Sets."[28] ICF Core Sets facilitate the description of functioning, for example, in clinical practice by providing lists of essential categories that are relevant for specific health conditions and health care contexts. These ICF categories were selected from the entire ICF following a scientific process based on preparatory studies and the involvement of a multidisciplinary group of experts.

The evolution of disablement frameworks from the biomedical models to the newer, contemporary models that include the biopsychosocial domains provides theoretical constructs that guide the rehabilitation professional in clinical practice. The development of the ICF Core Sets derived from input members of the rehabilitation team is essential for clinical decision-making that addresses pathologic conditions or disease processes, impairments, functional limitations, and disabilities. Interrelationships among all four of these elements are the focus of the rehabilitation team. The physical therapist, orthotist, prosthetist, and other team members work together to create the most effective outcome for the patient by identifying and addressing pathologic processes, functional limitations, impairments, and disability. The ICF Core Sets and ICF Documentation System[29] allow for data collection that can be useful in research leading to

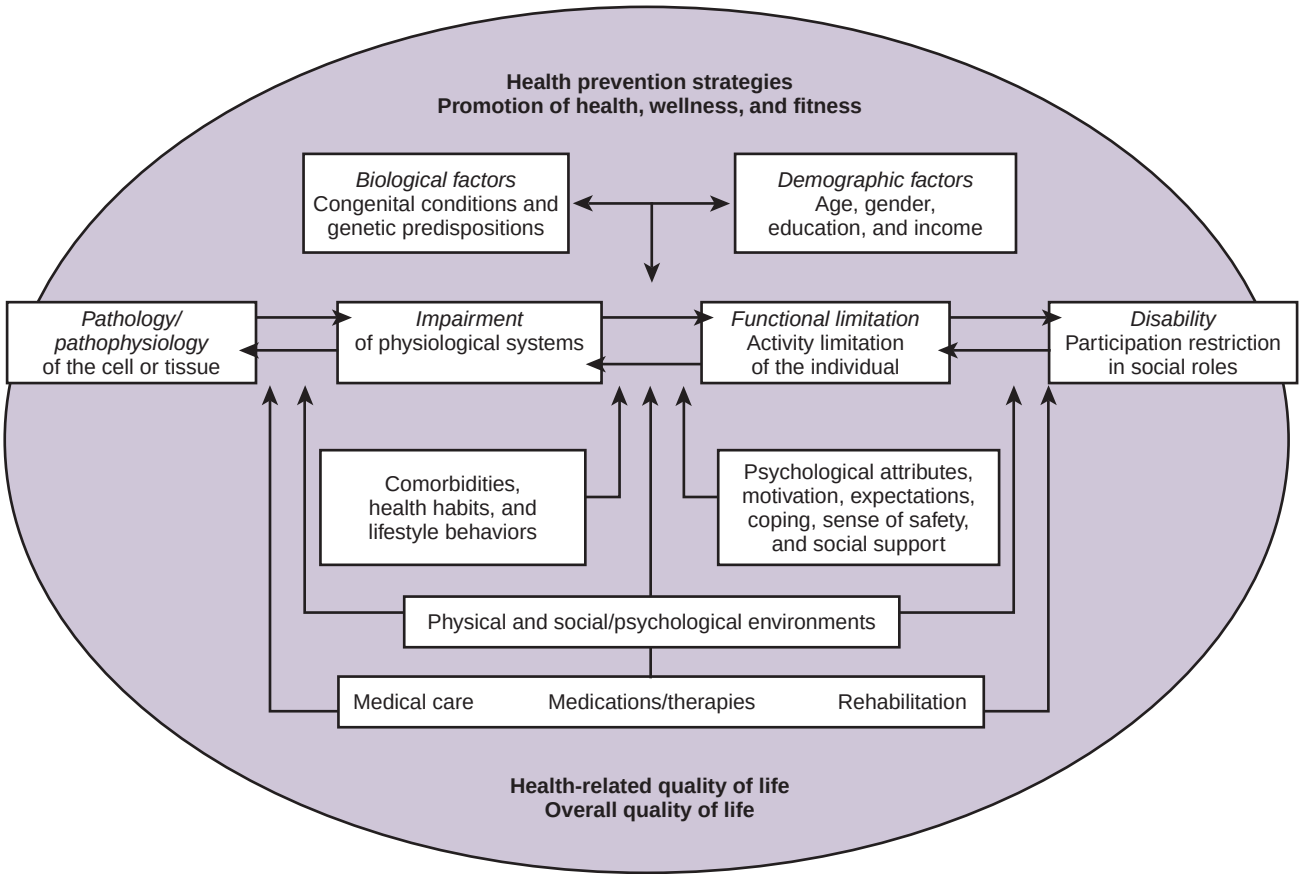

Fig. 1.5 The revised Institute of Medicine/Nagi model of the disablement process considers the impact of pathologic conditions and impairment, as well as intraindividual and extraindividual factors, that may influence functional limitation and disability affecting health-related and overall quality of life. (Modified from Guccione AA. Arthritis and the process of disablement. *Phys Ther.* 1994;74[5]:410, the Nagi Model.)

improved patient interventions, assessment of patient outcomes, and development of health and social policies.

Characteristics of Rehabilitation Health Care Teams

The complexity of the health care arena and the level of care required by individuals in rehabilitation care settings require the collaboration of many health care practitioners with varied professional skills who can form multidisciplinary, interdisciplinary, and transdisciplinary teams as needed.[30-32] The multidisciplinary rehabilitation team is composed of the different health professionals such as the physician, nurse, physical therapist, occupational therapist, prosthetist, orthotist, and social worker. Each professional operates with an area of specialization and expertise. The members of the multidisciplinary team work parallel to one another, and the medical record is the collecting source for the information gleaned and shared. Interdisciplinary teams also include the representatives of a variety of health disciplines, but there is interdependence among the professionals. In the interdisciplinary team process, there is structure and organization that promotes program planning to support patient-centered care through effective communication and effective clinical management. Clinical practice guidelines that seek to promote best practices for

Table 1.1 AHA/ACC Clinical Guidelines for Management of Patients With Lower-Extremity Peripheral Artery Disease

- Nurses
- Orthopedic surgeons and podiatrists
- Endocrinologists
- Internal medicine specialists
- Infectious disease specialists
- Radiology and vascular imaging specialists
- Physical medicine and rehabilitation clinicians
- Orthotics and prosthetics specialists
- Social workers or exercise physiologists
- Physical and occupational therapists
- Nutritionists/dieticians

Recommendations for interdisciplinary care team members include: Vascular medical and surgical specialists (i.e., vascular medicine, vascular surgery, interventional radiology, interventional cardiology).

From Gerhard-Herman MD, et al. 2016 AHA/ACC Lower Extremity PAD Guideline. 2016 AHA/ACC Guideline on the Management of Patients With Lower Extremity Peripheral Artery Disease. A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Journal of the American College of Cardiology*. 2017;69(11):1465-1508.

specific health conditions often include information on the interdisciplinary team.[33] Table 1.1 provides an example of the suggested composition of an interdisciplinary team for the management of patients with PAD. The interdisciplinary team members work to establish goals for the team that drive the rehabilitation process for the patient. Interdisciplinary teams traditionally follow a patient-centered approach to goal setting. Establishing the patient as the focus of the work for the team, the interdisciplinary team members collaborate to execute the goals and meet the desired outcomes. Most team processes in rehabilitation centers strive for an interdisciplinary team approach that promotes patient-centered care. Each discipline works within its scope of practice to optimize care through coordinated efforts.

Transdisciplinary teams are comprised of the same professional members identified in the multidisciplinary and interdisciplinary teams; however, the team members in the transdisciplinary model function differently in that they share clinical responsibilities and overlap in duties and responsibilities. In the transdisciplinary model of team building, the professional roles and responsibilities are so familiar to the team members that there is an interchange of tasks and functions.[34] Transdisciplinary teams engage in release of professional roles typical to the discipline in an effort to have the patient receive the interventions needed within a context that is supportive of the learning and the practice. The transdisciplinary model is operational in the management of infants and toddlers who receive early intervention rehabilitation services and have an Individualized Family Service Plan (IFSP).[35]

Two major issues emerging in health care that affect health care professionals include (1) the need for health care professionals with advanced education and training in specialty and subspecialty areas and (2) the need for collaboration among health practitioners to ensure efficiency of patient management that results in best practice and improves patient outcomes. The information explosion in health care, particularly in rehabilitation, has led to increasing specialization and subspecialization in many fields. The multidisciplinary, interdisciplinary, or transdisciplinary health care team concept has evolved, in part, because no single individual or discipline can have all the necessary expertise and specialty knowledge required for high-quality care, especially the care of patients with complex disorders. Rehabilitation health care teams provide patient care management approaches that capitalize on clinical expertise by engaging members from diverse medical and rehabilitation professions working together, collaborating, and communicating closely to optimize patient care.[36]

Collaboration is defined as a joint communication and decision-making process with the goal of meeting the health care needs of a particular patient or patient population. Each participant on the rehabilitation team brings a particular expertise, and leadership is determined by the particular rehabilitation situation being addressed. The rehabilitation team has the opportunity to meet and engage in "asking the answerable questions" that are critical in current clinical practice when engaging in an evidence-based model of practice. According to Strauss and colleagues,[37] evidence-based practice is the integration of the best research evidence, clinical expertise, and patient values. Evidence-based practice and clinical decision-making enhance the role of the rehabilitation team professionals as they share their clinical insights supported by historical and current evidence. Rehabilitation teams that are diverse in professional representation can bring a wide perspective of expertise on particular rehabilitation issues. With this perspective, clinical decision-making becomes a more inclusive process.

The role of the health care professional on a rehabilitation team begins during professional education. Rehabilitation sciences health professionals must work at understanding, evaluating, and analyzing the many facets of health care that require specialized professionals who will work to meet the goals and objectives of the specialty and of health care delivery on the whole. The formation of a rehabilitation team provides a cohort of professionals who individually and collectively strive for effective and efficient management of patients. The team process allows for a deeper understanding of and appreciation for the contributions of the other rehabilitation disciplines in the assessment and treatment of the patient and management of patient problems.

In addition to discipline-specific skills and knowledge, health professionals must be aware of the interrelationships among health care workers. One of the major barriers to effective team functioning is a lack of understanding or misconception of the roles of different disciplines in the care of the whole patient.[38] A clear understanding of the totality of the health care delivery system and the role of each professional within the system increase the potential effectiveness of the health care team. A group of informed, dedicated health professionals working together to set appropriate goals and initiate patient care to meet these goals uses a model that exceeds the sum of its individual components.

Almost all current rehabilitation health care is provided in a team setting using a patient-centered approach. This integrated approach facilitates appreciation of the patient as a person with individual strengths and needs rather than as a dehumanized diagnosis or problem. The diverse perspectives and knowledge that are brought to the rehabilitation process by the members of the interdisciplinary team provide insight into all aspects of the patient's concerns

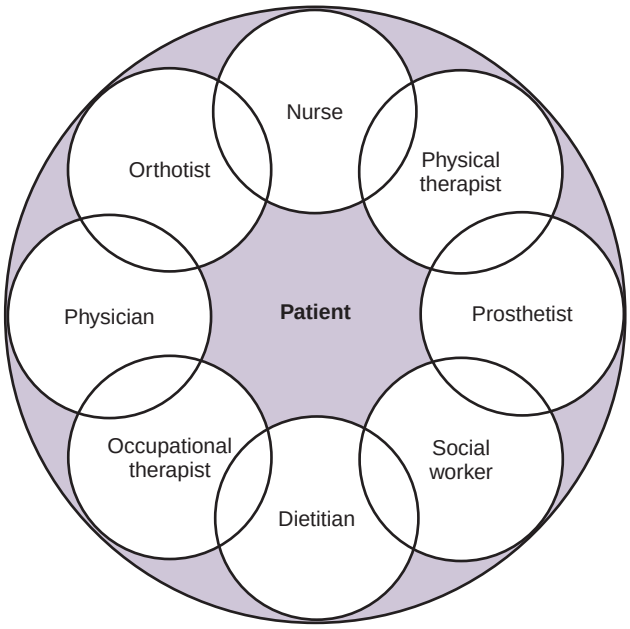

Fig. 1.7 Patient-centered rehabilitation teams. Key components of the successful health care team are a clear understanding of the role, responsibilities, and unique skills and knowledge of each member of the rehabilitation team, combined with open and effective communication.

(Fig. 1.7). Conceptually, all members of the health care team contribute equally to patient care. The contribution of each is important and valuable; otherwise, quality of patient care and efficacy of intervention would be diminished. Although one member of the team may take an organization or management role, decision-making occurs by consensus building and critical discussion. Professionals with different skills function together with mutual support, sharing the responsibility of patient care.

Effective team-based health care assumes that groups of health care providers representing multiple disciplines can work together to develop and implement a comprehensive, integrated treatment plan for each patient.

Much of our understanding of team function is drawn from organization and management research literature, the theories of which provide insight and information on how interdisciplinary teams operate and the factors that facilitate or inhibit their effectiveness. A number of factors are important influences on health professionals' perception of team membership that can be positive or negative to the team process.

VALUES AND BEHAVIORS

Some of the factors that tend to limit the effectiveness of a work group are large group size, poor decision-making practices, lack of fit between group members' skills and task demands, and poor leadership.[39-41] Other factors that influence team dynamics are classified as formal (tangible or visible) and informal (submerged). Formal factors include the policies and objectives of the group or its parent organization, the systems of communication available to the group, and the job descriptions of its members. Informal factors, which are often less obvious but equally influential on group process, include working relationships among team members; power networks within and external to the group; and the values, beliefs, and goals of individuals within the group. Team-building initiatives are often focused on the formal, or visible, areas, but informal communication, values, and norms play key roles in the functioning of the health care team.

A variety of characteristics and considerations also enhance the effectiveness of the interdisciplinary health care team. In addition to having strong professional backgrounds and appropriate skills, team members must appreciate the diversity within the group, taking into account age and status differences and the dynamics of individual professional subgroups.[42] The size of the team is also important: the most capable and effective teams tend to have no more than 12 members. Team members who know each other and are aware of and value each other's skills and interests are often better able to set and achieve goals. Clearly defined goals and objectives about the group's purpose and primary task, combined with a shared understanding of each member's roles and skills, increase the likelihood of effective communication.

Values and behaviors that facilitate the collaborative team care model include the following:

- Trust among members that develops over time as members become more familiar with each other
- Knowledge or expertise necessary for the development of trust
- Shared responsibility for joint decision-making regarding patient outcomes
- Mutual respect for all members of the team
- Two-way communication that facilitates sharing of patient information and knowledge
- Cooperation and coordination to promote the use of skills of all team members
- Optimism that the team is indeed the most effective means of delivering quality care

In the early stages of development, it is essential that the team spend time developing goals, tasks, roles, leadership, decision-making processes, and communication methods. In other words, the team needs to know where it is going, what it wants to do, who is going to do it, and how it will get done. One of the most important characteristics of an effective health care team is the ability to accommodate personal and professional differences among members and to use these differences as a source of strength. The well-functioning team often becomes a means of support, growth, and increased effectiveness and professional satisfaction for the physical therapist and other health professionals who wish to maximize their strengths as individuals while participating in professional responsibilities.

REHABILITATION TEAMS

The interdisciplinary health care team has become essential in the rehabilitation of patients whose body function and level of participation in the tasks of daily living could be enhanced by assistive technology such as an orthosis or prosthesis. The complexity of the rehabilitation process and the multidimensional needs of patients frequently

require the expertise of many different professional disciplines. The rehabilitation team is often shaped by the typical needs and characteristics of the patient population that it is designed to serve. The individuals most often represented on the rehabilitation team include one or more physicians with specialties in rehabilitation medicine, orthopedics, vascular surgery or neurology; nurses; prosthetists and/or orthotists; physical therapists; occupational therapists; dietitians; social workers; and vocational rehabilitation counselors, as well as patients and caregivers (see Fig. 1.7). Each member of the interdisciplinary team has an important role to play in the rehabilitation of the patient. Patient education is often one of the primary concerns of the team. Imparting information regarding the health condition, etiology, treatment, progression, management, and prognosis helps patients to become active partners in the rehabilitation process rather than passive recipients of care. Patient education addresses prevention and treatment strategies; patients and their families are able to identify their needs and concerns and communicate them to the team members. Each member of the team has the responsibility for contributing to patient education so that patients have the information needed for an effective partnership and positive outcome of rehabilitation efforts.

Research studies across a wide variety of medical conditions and health disciplines contain evidence that patients who feel prepared and informed are most likely to invest in and comply with recommended interventions and often have the most positive health outcome. Ideally, patient education about amputation and prosthetics begins in advance of, or at least immediately after, the amputation surgery.[43]

The Department of Veterans Affairs has instituted a system of care for US veterans with limb amputations, using outcome measures. The Amputation System of Care (ASoC) was introduced in 2008 with a goal of providing "lifelong care for service members with combat-related amputations from military conflicts in Iraq and Afghanistan and for veterans with amputations from diseases such as diabetes and peripheral vascular disease." The ASoC provides coordinated care that enables persons with amputation to receive the prosthetic technology and rehabilitation management that will maximize function and independence.[44]

Coordinated patient-centered care by an interdisciplinary rehabilitation team is just as essential for effective rehabilitation of children as it is for adults. For children with myelomeningocele or cerebral palsy, the broad knowledge base available through team interaction provides a stronger foundation for tailoring interventions to the ever-changing developmental needs of the child and family. Initially, the optimal delivery of care for children is best provided in a comprehensive health care setting in which the various specialists can provide a truly collaborative approach. Orthopedic surgeons, neurologists, orthotists, prosthetists, physical therapists, occupational therapists, nurses, dietitians, social workers, psychologists, and special education professionals may all be involved in setting goals and formulating and carrying out plans for intervention and outcomes assessment.

The concept of a multidisciplinary pediatric clinic team was formulated as World War II came to an end.[45] This structure has evolved further over the years and is particularly effective for the more complex orthotic and prosthetic challenges. A "mini-team" consisting of the patient's physician, a physical therapist, and a prosthetist or orthotist can usually be assembled, even in a small town with few facilities. Regardless of its size, an effective team views the child and family from a holistic perspective, with the input from each specialty being of equal value. Under these circumstances, the setting of treatment priorities, such as whether prosthetic fitting or training in single-handed tasks is most appropriate at a child's current age or developmental level, is made on the basis of the particular needs of the individual. Children with orthotic and prosthetic needs are followed in the community and within the school setting. As appropriate, a child may receive rehabilitation or habilitation services under the Individuals with Disabilities Education Act (IDEA).[46] The rehabilitation/educational team is a diverse group of health care professionals, educators, family, and caregivers, each with essential skills necessary to address the needs of the child that encourage maximum participation in tasks of daily living. Each member of the team works in a collaborative manner with the family and caregivers and with the child's teachers and other health professionals to ensure that the goals of the IFSP or the Individualized Education Plan (IEP) are addressed and met. Clear and frequent communication is essential for the team to function effectively and to achieve the desired outcomes for the child.

Case Example 1.1 **Interdisciplinary Teams**

P.G. is a 23-year-old man admitted to a level 3 trauma center 2 weeks ago after sustaining severe crush injuries to both lower extremities and a closed-head injury in an accident involving a motorcycle and a sport utility vehicle. Initially unconscious with a Glasgow Coma Scale score of 8, P.G. was placed on life support in the emergency department. Radiographs revealed a severely comminuted fracture of the distal right femur and displaced fractures of the left tibia and fibula at midshaft. Examination revealed partial-thickness "road burn" abrasions on the left anterior thorax and thigh; these were thoroughly cleaned and covered with semipermeable dressings. A computed tomography scan of his cranium and brain revealed a subdural hematoma over the left Sylvian fissure and moderate contusion of the anterior pole and undersides of the frontal lobes. Arteriography indicated rupture of the right femoral artery 4 inches above the knee. Given the extent of the crush injuries, the trauma team determined P.G. was not a candidate for reconstructive surgery to salvage his right limb.

P.G. was taken to the operating room, where a standard-length transfemoral amputation was performed on the right lower extremity. Simultaneously, orthopedic surgeons performed an open-reduction internal fixation with an intramedullary rod in the tibia and used surgical plates and screws to repair the fibula. Neurosurgeons drained the subdural hematoma through a burr hole in his skull. P.G. was started on high-dose broad-spectrum antibiotics in the operating room. He was transferred to the surgical intensive care unit for postoperative care.

P.G. was weaned from the ventilator and is now functioning at a Rancho Los Amigos Scale level of 7. He is able to follow one- and two-step commands but becomes easily confused and

Case Example 1.1 **Interdisciplinary Teams (Continued)**

angry in complex environments and when fatigued. His postoperative pain is currently being managed with Tylenol #3 as needed. His right lower extremity has been managed with soft dressings and elastic bandages; his residual limb is moderately bulbous, with resolving ecchymosis from the accident and surgery. Moderate serosanguineous drainage continues from the medial one third of the suture line. Although most of the skin abrasions show signs of regranulation, one area on his left thigh is red and hot, with yellowish drainage. When transferred (maximum assist of two) into a bedside recliner, P.G. tolerates 30 minutes in a 45- to 60-degree reclined position. He becomes lightheaded and has significant pain when sitting upright with his left lower extremity dependent. He has been referred to physical therapy for evaluation of rehabilitation potential and initiation of mobility activities.

Before his accident, P.G. was a graduate student in physics at a nearby university. He lived in a third-floor walk-up apartment with his fiancé and his golden retriever. Besides his motorcycle, his interests and hobbies included long-distance running and mountain climbing. His mother and father have traveled to be with him during the acute hospital stay.

QUESTIONS TO CONSIDER

- Who are the clinical specialists and health professionals needed to address the medical needs of the patient?
- What are the priorities, specific roles, and responsibilities for each potential member of the team? What team structure do you envision?
- How are the roles and responsibilities similar or different across the team?
- What external influences will affect team formation and functioning in a busy level 3 trauma center?
- What factors might facilitate team development?
- What factors might challenge the effectiveness of the team?
- As P.G. recovers from his injuries, how might the roles and responsibilities of the various team members change or evolve?
- When and how would you apply the International Classification of Functioning (ICF) disablement model for P.G.?
- Is there an ICF Core Set that applies to this clinical situation?
- Are there recommended clinical practice guidelines that apply to the management of this patient?

Case Example 1.2 **Interdisciplinary Teams**

E.L. is a 73-year-old woman with a 10-year history of type 2 diabetes mellitus. She is insulin dependent. Two weeks before her most recent hospitalization, she and her husband (who is in the early stages of Alzheimer disease) moved from their home of 50 years to an assisted-living complex in a neighboring town. Although the furniture is set up and functional, they have not had the chance to fully unpack and make the apartment their own.

Over the past 3 years, E.L. has been monitored by her team of physicians for progressive polyneuropathy of diabetes and for moderate peripheral vascular disease. She had a transmetatarsal amputation of her right forefoot 8 months ago because of nonhealing recurrent neuropathic ulcer. Despite wearing custom-molded shoes and accommodative orthoses, another ulcer of her first metatarsal head developed on the left foot 2 months ago. This new ulcer did not heal with conservative care and progressed to osteomyelitis 2 weeks ago. When vascular studies suggested inadequate circulation to heal the ulcer, she received arterial revascularization intervention, but the ischemia persisted and E.L. underwent an elective transtibial amputation of her left lower extremity. Despite a short bout of postoperative delirium thought to be related to pain management with morphine, E.L. (5 days postoperatively) was adamant about returning to her new assisted-living apartment, using a wheelchair for mobility, and receiving home care until her residual limb is healed and ready for prosthetic fitting.

Currently she is able to ambulate two lengths of 15-foot-long parallel bars before needing to rest and has begun gait training with a "hop-to" gait pattern with a standard walker. She is able to transfer from sitting on a firm seating surface with armrests to standing with standby guarding and verbal cueing and needs minimal assistance from low and soft seats without armrests. She believes that she and her husband will be able to manage at home because her bathroom has grab bars on the toilet, and a tub seat and handheld shower head are available from the "loaner closet" at her assisted-living facility.

At discharge, the suture line had one small area of continued moderate drainage, requiring frequent dressing changes. She is unable to move her residual limb into a position for effective visual self-inspection of the healing surgical wound without significant discomfort. Her husband, although attentive, becomes confused with the routine of wound care. E.L.'s postoperative limb volume and edema are being managed with a total contact cast, which she is able to don and doff independently. She had one late evening fall, when she awoke from a sound sleep having to go to the bathroom and was surprised when her left limb "wasn't really there" to stand on when she tried to get out of bed.

Since her amputation, E.L.'s insulin dosages have had to be adjusted frequently because of unpredictable changes in her serum glucose levels. She has lost 20 pounds (half of which can be attributed to her amputation) since admission.

QUESTIONS TO CONSIDER

- Who are the health care professionals likely to be involved in her care?
- Which team approach is most desirable for patient-centered care: multidisciplinary, interdisciplinary, or transdisciplinary? Why?
- What are the major challenges facing the team of care providers involved in the postoperative, preprosthetic care of E.L and her husband? How are these similar to or different from challenges and issues the trauma center team considered before her amputation?
- What strategies are currently in place or must be developed to ensure that E.L.'s care at home is comprehensive and coordinated?
- How will the roles and responsibilities of the team members evolve and change as she recovers from her surgery and is ready to begin prosthetic use?
- When and how would you apply the International Classification of Functioning (ICF) disablement model for E.L.?
- Is there an ICF Core Set that applies to this clinical situation?
- Are there recommended clinical practice guidelines that apply to the management of this patient?

Case Example 1.3 **Interdisciplinary Teams**

M.S. is a 12-year-old girl with myelomeningocele (spina bifida) who uses a wheelchair for mobility. In the past year, she has developed significant thoracolumbar scoliosis believed to be associated with a growth spurt. Concerned about the rate of increase in her S-shaped thoracolumbar curve, her parents sought the advice of an orthopedic surgeon who has been involved as a consultant in her care since birth. The surgeon recommends surgical stabilization of M.S.'s spine with Harrington rods and bony fusion to (1) prevent further progression of the curve and rib hump so that secondary impairment of the respiratory system will be minimized as she grows and (2) provide more efficient upright sitting posture for wheelchair propulsion in the years ahead.

M.S. currently attends classes in her neighborhood middle school where she receives related health services including physical therapy. Until 2 years ago, she ambulated for exercise by using a reciprocal gait orthosis during gym periods at school, but with recent spurts in growth the use of a manual wheelchair is more efficient for mobility (to keep up with her classmates). She is also followed up on a regular basis by a neurologist who monitors the operation of her ventriculoperitoneal shunt (commonly used in the management of hydrocephalus associated with myelomeningocele).

In addition to their concerns about the risk of the surgical procedure, M.S.'s parents are quite concerned about how the anticipated 4-month postoperative immobilization in a thoracolumbosacral orthosis will affect her capacity for self-care and independent wheelchair mobility. They are also concerned about how the surgery and postoperative period will potentially interrupt the effective bowel and bladder management routine for which M.S. has just begun to assume responsibility. As witnesses to their daughter's deconditioning and loss of stamina over the past 6 months, they are concerned that she might not be "physically ready" for the surgery and postoperative rehabilitation. They are also asking questions about whether this spinal surgery will ultimately improve the prognosis of a successful return to ambulation with her reciprocal gait orthosis.

QUESTIONS TO CONSIDER

- Who are the members of the rehabilitation team?
- What is the structure of the team that will best address the needs of the patient?
- What are the priorities, roles, and responsibilities of the health professionals involved in the care of this child and her family?
- How is the composition of M.S.'s rehabilitation team similar to or different from that of P.G.'s and E.L.'s teams?
- How will the health and education professionals support M.S. and her family through the postoperative recovery process?
- When and how would you apply the International Classification of Functioning disablement model to M.S.?

Summary

Patient-centered care, whether in tertiary care medical centers, in-patient rehabilitation facilities, skilled nursing facilities, or ambulatory community settings, currently relies on interdisciplinary rehabilitation teams that function to address the patient goals and maximize patient outcomes. The use of rehabilitation teams has evolved in part because no one person or discipline has the expertise in all the areas of specialty knowledge required for the established standards of care. The success of the rehabilitation team process requires health professionals to work together in a collaborative and cooperative manner. The rehabilitation team professional must demonstrate attitudes and attributes that foster collaboration, including:

1. Openness and receptivity to the ideas of others
2. An understanding of, value of, and respect for the roles and expertise of other professionals on the team
3. Value interdependence and acceptance of a common commitment to comprehensive patient-centered care
4. Willingness to share ideas openly and take responsibility

This chapter introduces the topic of orthotics and prosthetics in rehabilitation and advocates for a multidisciplinary and interdisciplinary approach to patient-centered care. There is a burgeoning demand for the use of orthotics and prosthetics, based on several varying health concerns for the population, including limb loss associated with US service men and women military duties; traumatic injuries sustained by US service men and women involved in military conflicts; and on the projected rise in the number of persons with chronic health conditions such as obesity, type 2 diabetes, and vascular disease. The overarching goal is to rehabilitate persons to the highest level of functional independence which is possible for the individual. The WHO ICF is the current disablement framework endorsed by 191 countries. Rehabilitation professionals including orthotists, prosthetists, and physical and occupational therapists will apply the ICF disablement model to maximize strategies for patient participation in the tasks of daily living through enhancement of environmental factors such as providing appropriate, cost-effective assistive technology including orthoses and prostheses. A rehabilitation model of patient-centered care that uses a multidisciplinary or interdisciplinary team approach to enhance communication, address goals and objectives, apply best practice, and improve patient outcomes is the current standard of care for persons in rehabilitation settings. Collaboration, mutual respect, and an understanding of the roles and responsibilities of colleagues engender productive teamwork and improved outcomes for the rehabilitation patient.

2 Aging and Activity Tolerance

ETHAN A. HOOD, KEVIN K. CHUI, and MICHELLE M. LUSARDI

IMPLICATIONS FOR ORTHOTIC AND PROSTHETIC REHABILITATION

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Describe the role of the cardiopulmonary and cardiovascular systems as "effectors" for goal-driven functional motor activity.
2. Define the key components of the cardiopulmonary and cardiovascular systems as they relate to energy expenditure during functional activity.
3. Describe the functional consequences of age-related change in cardiopulmonary and cardiovascular structures, especially with respect to exercise and activity tolerance.
4. Apply principles of cardiopulmonary/cardiovascular conditioning to rehabilitation interventions for older and/or deconditioned individuals who will be using a prosthesis or an orthosis.
5. Weigh the benefits and limitations with respect to energy cost and facilitation of daily function in selecting an appropriate orthosis or prosthesis for an older or deconditioned individual.
6. Appreciate technologic advances in prosthetics and orthotics and their role in activity tolerance.

Many individuals who rely on orthotic or prosthetic devices to walk or to accomplish functional tasks have impairments of the musculoskeletal or neuromuscular systems that limit the efficiency of their movement and increase the energy cost of their daily and leisure activities. The separate and interactive effects of aging, inactivity, and cardiac or pulmonary disease can also compromise the capacity for muscular "work," tolerance of activity, and ability to function.

Consider this example: a 79-year-old woman with insulin-controlled type 2 diabetes has been referred for physical therapy evaluation after transfemoral amputation following a failed femoral-popliteal bypass. She has been on bed rest for several weeks because of her multiple surgeries. The physical effort required in undergoing rehabilitation and prosthetic training may initially feel overwhelming to this woman. In her deconditioned state, preprosthetic ambulation with a walker is likely to increase her heart rate (HR) close to the upper limits of a safe target HR for aerobic training. What, then, is her prognosis for functional use of a prosthesis? What are the most important issues to address in her plan of care? What intensity of intervention is most appropriate given her deconditioned state? In what setting and for how long will care be provided? These questions have no simple answers.

The physical therapist, orthotist, and prosthetist must recognize factors that can be successfully modified to enhance performance and activity tolerance when decisions about prescription and intervention strategies are being made. Aerobic fitness should be a key component of the rehabilitation program for those who will be using a prosthesis or orthosis for the first time. It is vitally important that rehabilitation professionals recognize and respond to the warning signs of significant cardiopulmonary or cardiovascular dysfunction during treatment and training sessions.

Although the anatomic and physiologic changes in the aging cardiopulmonary system are important to our discussion, our focus is on the contribution of cellular and tissue-level changes to the performance of the cardiopulmonary and cardiovascular systems and, consequently, on the individual's ability to function. This view provides a conceptual framework for answering four essential questions:

- Is this individual capable of physical work?
- If so, what is the energy cost of doing this work?
- Is it possible for this individual to become more efficient or more able to do physical work?
- What impact does the use of an orthosis or prosthesis have on energy use and cost during functional activities for this person?

Oxygen Transport System

The foundation for the functional view of the cardiopulmonary system is the equation for the oxygen transport system (Fig. 2.1). Aerobic capacity (VO_{2max}) is the body's ability to deliver and use oxygen (maximum rate of oxygen consumption) to support the energy needs of demanding physical activity. VO_{2max} is influenced by three factors: the efficiency of ventilation and oxygenation in the lungs, how much oxygen-rich blood can be delivered from the heart (cardiac output, or CO) to active peripheral tissues, and how well oxygen is extracted from the blood to support muscle contraction and other peripheral tissues during activity (arteriovenous oxygen difference, or AVO_{2diff}).[1–4] Aerobic capacity can be represented by the following formula:

$$VO_{2\,max} = CO \times AVO_{2\,max}$$

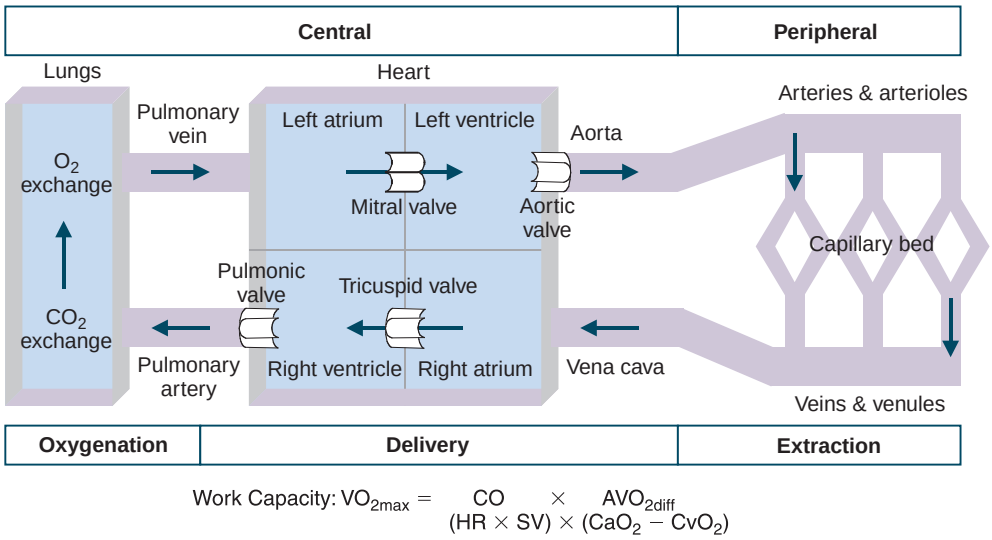

Fig. 2.1 Functional anatomy and physiology of the cardiorespiratory system. After blood has been oxygenated in the lungs, the left side of the heart contracts to deliver the blood, through the aorta and its branches, to active tissues in the periphery. Oxygen must be effectively extracted from blood by peripheral tissues to support their activity. Deoxygenated blood, high in carbon dioxide, returns through the vena cava to the right side of the heart, which pumps it to the lungs for reoxygenation. Aerobic capacity (VO_{2max}) is the product of how well oxygen is delivered to cardiac output (CO) and extracted by arterial-venous oxygen difference (AVO_{2diff}) active tissues. *HR,* Heart rate; *SV,* stroke volume.

The energy cost of doing work is based on the amount of oxygen consumed for the activity, regardless of whether the activity is supported by aerobic (with oxygen) or anaerobic (without oxygen) metabolic mechanisms for producing energy. VO_{2max} provides an indication of the maximum amount of work that can be supported.[1–4]

CO is the product of two elements. The first is the HR, the number of times that the heart contracts (or beats) per minute. The second is stroke volume (SV), the amount of blood pumped from the left ventricle with each beat (measured in milliliters or liters). CO is expressed by the following formula (measured in milliliters or liters per minute):

$$CO = HR \times SV$$

As a product of HR and SV, CO is influenced by four factors: (1) the amount of blood returned from the periphery through the vena cava, (2) the ability of the heart to match its rate of contraction to physiologic demand, (3) the efficiency or forcefulness of the heart's contraction, and (4) the ability of the aorta to deliver blood to peripheral vessels. The delivery of oxygen to the body tissues to be used to produce energy for work is, ultimately, a function of the central components of the cardiopulmonary system.[1–4]

The second determinant of aerobic capacity, the AVO_{2diff}, reflects the extraction of oxygen from the capillary by the surrounding tissues. The AVO_{2diff} is determined by subtracting the oxygen concentration on the venous (postextraction) side of the capillary bed (CvO_2) from that of the arteriole (preextraction) side of the capillary bed (CaO_2), according to the formula:

$$AVO_{2\,max} = CaO_2 - CvO_2$$

The smaller vessels and capillaries of the cardiovascular system are involved in the process of extraction of oxygen from the blood by the active tissues. Extraction of oxygen from the blood to be used to produce energy for the work of the active tissues is a function of the peripheral components of the cardiopulmonary system.[1–4]

During exercise or a physically demanding activity, CO must increase to meet the need for additional oxygen in the more active peripheral tissues. This increased CO is the result of a more rapid HR and a greater SV: As the return of blood to the heart increases, the heart contracts more forcefully and a larger volume of blood is pumped into the aorta by the left ventricle. Chemical and hormonal changes that accompany exercise enhance the peripheral shunting of blood to the active muscles, and oxygen depletion in muscle assists transfer of oxygen from the capillary blood to the tissue at work.[1,4,5]

The efficiency of central components, primarily of CO, accounts for as much as 75% of VO_{2max}. Peripheral oxygen extraction (AVO_{2diff}) contributes the remaining 25% to the process of making oxygen available to support tissue work.[6] In healthy adults under most conditions, more oxygen is delivered to active tissues (muscle mass) than is necessary.[4,6] During exercise in healthy adults, CO may increase five times, allowing for oxygen to be available to working muscles.[1] For those who are significantly deconditioned or who have cardiopulmonary or cardiovascular disease, the ability to deliver oxygen efficiently to the periphery as physical activity increases may be compromised. With normal aging, there are age-related physiologic changes in the heart itself that limit maximum attainable HR. Because of these changes, it is important to assess whether and to what degree SV can be increased effectively if rehabilitation interventions are to be successful.

The Aging Heart

The ability to plan an appropriate intervention to address cardiovascular endurance and conditioning in older adults who may need to use a prosthesis or orthosis is founded on

an understanding of "typical" age-related changes in cardiovascular structure and physiology as well as on the functional consequences of these changes.

CARDIOVASCULAR STRUCTURE

Age-related structural changes in the cardiovascular system occur in five areas: myocardium, cardiac valves, coronary arteries, conduction system, and coronary vasculature (i.e., arteries) (Table 2.1).[7–10] Despite these cellular and tissue-level changes, a healthy older heart can typically meet energy demands of usual daily activity. Cardiovascular disease, quite prevalent in later life, and a habitually sedentary lifestyle coupled with unhealthy lifestyle choices can, however, significantly compromise activity tolerance.[11,12]

Myocardium

In advanced age, cells of the myocardium show microscopic signs of degeneration, including increases in myocardial fat content (i.e., storage of triglyceride droplets within cardiomyocytes); however, the relationship between the quantity of fat and disease severity remains unclear.[13] Unlike aging skeletal muscle cells, there is minimal atrophy of cardiac smooth muscle cells. More typically, there is hypertrophy of the left ventricular myocardium, increasing the diameter of the left atrium.[12,14–16] These changes have been attributed to cardiac tissue responses to an increased systolic blood pressure (SBP) and to reduced compliance of the left ventricle; they are associated with an increase in the weight and size of the heart.[15–19]

Valves

The four valves of the aged heart often become fibrous and thickened at their margins as well as somewhat calcified.[20] Calcification of the aorta at the base of the cusps of the aortic valve (aortic stenosis) is clinically associated with the slowed exit of blood from the left ventricle into the aorta.[21] Such aortic stenosis contributes to a functional reduction in CO. A baroreflex-mediated increase in SBP attempts to compensate for this reduced CO.[22,23] Over time, the larger residual of blood in the left ventricle after each beat (increased end systolic volume, or ESV) begins to weaken the left ventricular muscle.[24] This muscle must work harder to pump the blood out of the ventricle into a more resistant peripheral vascular system.[25,26]

Calcification of the annulus of the mitral valve can restrict blood flow from the left atrium into the left ventricle during diastole. As a result, end-diastolic volume (EDV) of blood in the left ventricle is decreased because the left atrium does not completely empty. Over time, this residual blood in the left atrium elongates the muscle of the atrial walls and increases the diameter of the atrium of the heart.[25–27]

Coronary Arteries

Age-related changes of the coronary arteries are similar to those in any aged arterial vessel: an increase in the thickness of the vessel walls and tortuosity of the vessel's path.[28] These changes tend to occur earlier in the left coronary artery than in the right.[29] When coupled with atherosclerosis, these changes may compromise the muscular contraction and pumping efficiency and effectiveness of the left ventricle during exercise or any activity of high physiologic demand.[3,4,30]

Conduction System

Age-related changes in the conduction system of the heart can have a substantial impact on cardiac function. The typical 75-year-old person has less than 10% of the original number of pacemaker cells of the sinoatrial node.[31,32] Fibrous tissue builds within the internodal tracts as well as within the atrioventricular node, including the bundle of His and its main bundle branches.[31,32] As a consequence, the ability of the heart to coordinate the actions of all four of its chambers may be compromised.[31] Arrhythmias are pathologic conditions that become more common in later life; they are managed pharmacologically or with implantation of a pacemaker/defibrillator.[33] Rehabilitation professionals must be aware of the impact of medications or pacemaker settings on an individual's ability to physiologically respond to exercise and to adapt to the intervention accordingly, whether it be a conditioning program or early mobility after a medical/surgical event.[34]

Arterial Vascular Tree

Age-related changes in the arterial vascular tree, demonstrated most notably by the thoracic aorta and eventually

Table 2.1 Age-Related Changes in the Cardiovascular System

Structure	Change	Functional Consequences
Heart	Deposition of lipids, lipofuscin, and amyloid within cardiac smooth muscle	Less excitability
	Increased connective tissue and fibrosity	Diminished cardiac output
	Hypertrophy of left ventricle	Diminished venous return
	Increased diameter of atria	Susceptibility to dysrhythmia
	Stiffening and calcification of valves	Reduction in maximal attainable heart rate
	Fewer pacemaker cells in sinoatrial and atrioventricular nodes	Less efficient dilation of cardiac arteries during activity
	Fewer conduction fibers in bundle of His and branches	Less efficient left ventricular filling in early diastole, leading to reduced stroke volume
	Less sensitivity to extrinsic (autonomic) innervation	Increased afterload, leading to weakening of heart muscle
	Slower rate of tension development during contraction	
Blood vessels	Altered ratio of smooth muscle to connective tissue and elastin in vessel walls	Less efficient delivery of oxygenated blood to muscle and organs
	Decreased baroreceptor responsiveness	Diminished cardiac output
	Susceptibility to plaque formation within vessel	Less efficient venous return
	Rigidity and calcification of large arteries, especially the aorta	Susceptibility to venous thrombosis
	Dilation and increased tortuosity of veins	Susceptibility to orthostatic hypotension

the more distal vessels, can disrupt the smooth or streamlined flow (i.e., laminar flow) of blood from the heart toward the periphery.[33,35,36] Altered alignment of endothelial cells of the intima creates rough or turbulence flow (i.e., nonlaminar flow), which increases the likelihood of deposition of collagen and lipid.[37] Fragmentation of elastic fibers in the intima and media of larger arterioles and arteries further compromises the functionally important "rebound" characteristic of arterial vessels.[38] Rebound normally assists directional blood flow through the system, preventing the backward reflection of fluid pressure waves of blood. This loss of elasticity increases vulnerability of the aorta, which, distended and stiffened, cannot effectively resist the tensile force of left ventricular ejection. Not surprisingly, the incidence of abdominal aortic aneurysms rises sharply among older adults, and stiffness (distensibility) of the ascending aorta is associated with the severity of coronary artery disease.[39,40]

CARDIOVASCULAR PHYSIOLOGY

Although the physiologic changes in the cardiovascular system are few, their impact on the performance of the older adult can be substantial. The nondiseased aging heart continues to be an effective pump, maintaining its ability to develop enough myocardial contraction to support daily activity. The response of cardiac muscle to calcium (Ca^{2+}) is preserved and its force-generating capacity maintained.[41] Two aspects of myocardial contractility do, however, change with aging: the rate of tension development in the myocardium slows, and the duration of contraction and relaxation becomes prolonged.[42,43]

Sensitivity to β-Adrenergic Stimulation

One of the most marked age-related changes in cardiovascular function is the reduced sensitivity of the heart to sympathetic stimulation, specifically to the stimulation of β-adrenergic receptors.[43,44] Age-related reduction in β-adrenergic sensitivity includes a decreased response to norepinephrine and epinephrine released from sympathetic nerve endings in the heart as well as a decreased sensitivity to any of these catecholamines circulating in the blood.[44,45] Normally, norepinephrine and epinephrine are potent stimulators of ventricular contraction.

An important functional consequence of the change in receptor sensitivity is less efficient cardioacceleratory response, which leads to a lower HR at submaximal and maximal levels of exercise or activity.[46] The time for HR rise to the peak rate is prolonged, so more time is necessary to reach the appropriate HR level for physically demanding activities. A further consequence of this reduced β-adrenergic sensitivity is less than optimal vasodilation of the coronary arteries with increasing activity.[44,47] In peripheral arterial vessels, β-adrenergic receptors do not appear to play a primary role in mediating vasodilation in the working muscles.[48]

Baroreceptor Reflex

Age-related change in the cardiovascular baroreceptor reflex also contributes to prolongation of cardiovascular response time in the face of an increase in activity (physiologic demand).[43] The baroreceptors in the proximal aorta appear to become less sensitive to changes in blood volume (pressure) within the vessel. Normally any drop in proximal aortic pressure triggers the hypothalamus to begin a sequence of events that leads to increased sympathetic stimulation of the heart. Decreased baroreceptor responsiveness may increase an older individual's susceptibility to orthostatic (postural) and postprandial (after eating) hypotension or may compromise his or her tolerance of the physiologic stress of a Valsalva maneuver associated with breath holding during strenuous activity.[49–51] Clinically this is evidenced by lightheadedness when rising from a lying or sitting position, especially after a meal, or if one tends to hold one's breath during effortful activity.

The effects of age-related physiologic changes on the cardiovascular system can often be managed satisfactorily by routinely using simple lower extremity warmup exercises before position changes. Several repetitions of ankle and knee exercises before standing up, especially after a prolonged time sitting (including for meals) or lying down (after a night's rest), help maximize blood return to the heart (preload), assisting cardiovascular function for the impending demand. In addition, taking a bit more time in initiating activities and progressing their difficulty may help the slowed cardiovascular response time reach an effective level of performance. Scheduling physical therapy or physical activity at a distance from mealtimes might also be beneficial for patients who are particularly vulnerable to postprandial hypotension. Fortunately many of the aging effects on the cardiovascular system can be minimized or reversed with exercise training.[1]

FUNCTIONAL CONSEQUENCES OF CARDIOVASCULAR AGING

What are the functional consequences of cardiovascular aging for older adults participating in exercise or rehabilitation activities? This question can best be answered by focusing on what happens to the CO (Fig. 2.2). The age-related structural and physiologic changes in the cardiovascular system give rise to two loading conditions that influence CO: cardiac filling (preload) and vascular impedance (afterload).[4,22]

Preload

Cardiac filling/preload determines the volume of blood in the left ventricle at the end of diastole. The most effective ventricular filling occurs when pressure is low within the heart and relaxation of the muscular walls of the ventricle is maximal.[1,2,6] Mitral valve calcification, decreased compliance of

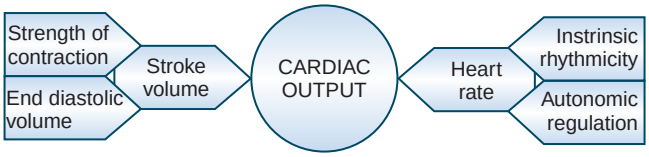

Fig. 2.2 Factors affecting cardiac output are influenced by the aging process. If strength of contraction decreases and end-diastolic volume increases, stroke volume is reduced. Coupled with alterations in heart rate response to increasing workload, activities that were submaximal in intensity at a younger age may become more physiologically demanding in later life.

the left ventricle, and the prolonged relaxation of myocardial contraction can contribute to less effective filling of the left ventricle in early diastole.[52] Doppler studies of the flow of blood into the left ventricle in aging adults demonstrate decreased rates of early filling, an increased rate of late atrial filling, and an overall decrease in the peak filling rate.[6,24,52] When compared with healthy 45- to 50-year-old adults, the early diastolic filling of a healthy 65- to 80-year-old is 50% less.[6,24,53] This reduced volume of blood in the ventricle at the end of diastole does not effectively stretch the ventricular muscle of the heart, thus compromising the Frank-Starling mechanism and the myocontractility of the left ventricle.[54] The functional outcome of decreased early diastolic filling and the reduced EDV is a proportional decrease in SV, one of the determinants of CO and, consequently, work capacity (VO_{2max}).[6,23,43]

Afterload

High vascular impedance and increased afterload disrupt the flow of blood as it leaves the heart and moves toward the peripheral vasculature. Increased afterload is partly a function of age-related stiffness of the proximal aorta, an increase in systemic vascular resistance (elevation of SBP, hypertension), or a combination of both.[43,55] Ventricular contraction that forces blood flow into a resistant peripheral vascular system produces pressure waves in the blood. These pressure waves reflect back toward the heart, unrestricted by the stiffened walls of the proximal aorta. The reflected pressure waves, aortic stiffness, and increased systemic vascular resistance collectively contribute to an increased afterload in the aging heart.[42,55] Increased afterload is thought to be a major factor in the age-associated decrease in maximum SV, hypertrophy of the left ventricle, and prolongation of myocardial relaxation (e.g., slowed relaxation in the presence of a persisting load on the heart).[7,8,10]

An unfortunate long-term consequence of increased afterload is weakening of the heart muscle itself, particularly of the left ventricle. Restricted blood flow out of the heart results in a large residual volume (RV) of blood in the heart at the end of systole, when ventricular contraction is complete. Large ESVs gradually increase the resting length of ventricular cardiac muscle, effectively weakening the force of contraction.[3,7,8,10,24,56]

Left Ventricular Ejection Fraction

Left ventricular ejection fraction (LVEF) is the proportion of blood pumped out of the heart with each contraction of the left ventricle, which is expressed by the following equation:

$$\text{LVEF} = (\text{EDV} - \text{ESV}) + \text{EDV}$$

At rest, the LVEF does not appear to be reduced in older adults. Under conditions of maximal exercise, however, the rise in LVEF is much less than that in younger adults.[23,57,58] This reduced rise in the LVEF with maximal exercise clearly illustrates the impact that functional cardiovascular age-related changes in preload and afterload have on performance.

A substantial reduction in EDV, an expansion of ESV, or a more modest change in both components may account for the decreased LVEF of the exercising older adult:

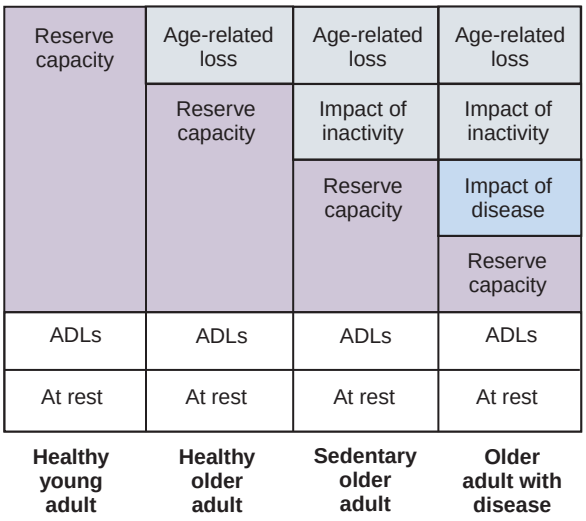

Fig. 2.3 Comparison of the effects of aging, inactivity, and cardiopulmonary disease on functional reserve capacity, expressed as cardiac output (CO in L/min). At rest, the heart delivers between 4 and 6 L/min of blood to peripheral tissues. This may double during many activities of daily living (ADLs). In a healthy young person, the CO may increase to as much as 24 L/min to meet the metabolic demands of sustained exercise. This reserve capacity decreases to approximately 18 L/min in healthy, fit adults after the age of 60 years. A sedentary lifestyle decreases functional reserve capacity further. Superimposed cardiopulmonary disease further limits the ability to do physical work, in some cases approaching or exceeding cardiopulmonary reserve capacity. *ADLs,* Activities of daily living. (Modified from Irwin SC, Zadai CC. Cardiopulmonary rehabilitation of the geriatric patient. In Lewis CB, ed. *Aging: the health care challenge*. Philadelphia: F.A. Davis; 1990:190.)

$$\downarrow \text{EDV} = \downarrow \text{LVEF}$$
$$\uparrow \text{ESV} = \downarrow \text{LVEF}$$

When going from resting to maximal exercise conditions, the amount of blood pumped with each beat for young healthy adults increases by 20% to 30% from a resting LVEF of 55% to an exercise LVEF of 80%. For a healthy older adult, in contrast, LVEF typically increases less than 5% from rest to maximal exercise.[57,59] The LVEF may actually decrease in adults who are 60 years of age and older.[57,60] As LVEF and CO decrease with aging, so does the ability to work over prolonged periods (functional cardiopulmonary reserve capacity) because the volume of blood delivered to active tissue decreases (Fig. 2.3). Functional reserve capacity is further compromised by the long-term effects of inactivity and by cardiopulmonary pathology.[23,30,61,62] The contribution of habitual exercise to achieving effective maximum exercise LVEF is not well understood, but the decline may not be as substantial for highly fit older adults.[23]

Pulmonary Function in Later Life

Several important age-related structural changes of the lungs and of the musculoskeletal system have a significant impact on pulmonary function.[63] These include change in the tissues and structures making up the lungs and airways, alteration in lung volume, reduced efficiency of gas exchange, and a mechanically less efficient ventilatory pump related to changes in alignment and posture

Table 2.2 Summary of Age-Related Changes in the Cardiopulmonary System and Functional Consequences

Anatomic Changes	Physiologic Changes	Consequences	Change in Lung Function Tests
Rearrangement and fragmentation of elastin fibers Stiffened cartilage in compliant articulation of ribs and vertebrae Increasing stiffness and compression of annulus fibrosus in intervertebral disks Reduction of strength and endurance of respiratory musculature	Less elastic recoil for expiration Greater compliance of lung Decreased vital capacity, forced More rigid thoracic cage Decreased volume of maximum voluntary ventilation and maximum sustained ventilatory capacity Greater mismatch between ventilation and perfusion within lung	Greater airspace within alveoli, less surface area for O_2/CO_2 exchange thoracic cage Increased work of breathing Less force during inspiration Less efficient cough Diminished exercise tolerance Reduced resting PaO_2	Increased functional residual capacity and residual volume tissue Shorter, less vital capacity, and forced expiratory volume in 1 s (FEV_1) Decreased maximum inspiratory pressure, maximum expiratory pressure, and maximum voluntary ventilation

(Table 2.2).[64,65] Although a healthy adult at midlife uses only 10% of the respiratory system's capacity at rest, aging of the pulmonary system, especially when accompanied by chronic illness or acute disease, negatively affects the ability of the lungs to respond to increasing demands of physical activity (Fig. 2.4).[66] Age-related changes in the pulmonary and musculoskeletal systems also contribute to an increase in the physiologic work of breathing.

CHANGES WITHIN THE LUNG AND AIRWAY

The production of elastin, which is the major protein component of the structure of the lungs, decreases markedly in late life. The elastic fibers of the lung become fragmented, and, functionally, the passive elastic recoil or rebound important for expiration becomes much less efficient. The elastic fibers that maintain the structure of the walls of the alveoli also decrease in number. This loss of elastin means loss of alveoli and consequently a less surface area for the exchange of oxygen as well as an increase in RV associated with more "dead space" within the lung, where air exchange cannot occur.[64–66] There may be as much as a 15% decrease in the total number of alveoli per unit of lung volume by the age of 70 years.[67]

With aging, there is also an increase in diameter of major bronchi and large bronchioles as well as a decreased diameter of smaller bronchioles, often leading to a slight increase in resistance to airflow during respiration.[67] This contributes to greater physical work of breathing as age advances.

Starting at midlife and continuing into later life, there tends to be a growing mismatch between lung area ventilated with each breath and lung area perfused by pulmonary arterioles and capillaries, which is attributed to alteration in alveolar surface, vascular structures, and posture.[68] This mismatch compromises the efficiency of diffusion of oxygen across the alveoli into the capillary bed (i.e., decreasing arterial oxygen tension) within the lung becomes less efficient from midlife into later life.[64,68] However, fit elderly can produce levels of maximum oxygen consumption that match those of untrained middle-aged men. This suggests that pulmonary rehabilitation can play a large role in improving exercise tolerance in the elderly.[65,69–71]

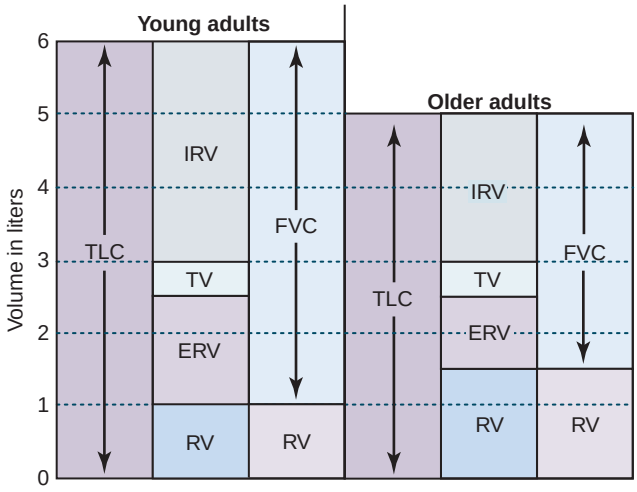

Fig. 2.4 Changes in the distribution of air within the lungs (volume) have an impact on an older adult's efficiency of physical work. Loss of alveoli and increasing stiffness of the rib cage result in a 30% to 50% increase in residual volume *(RV)* and a 40% to 50% decrease in forced vital capacity *(FVC)*. FVC includes three components: inspiratory reserve volume *(IRV)* and expiratory reserve volume *(ERV)* tend to decrease with aging, whereas resting tidal volume *(TV)*, the amount of air in a normal resting breath, tends to be stable over time. Total lung capacity *(TLC)* and inspiratory capacity (IRV + TV) also tend to decrease. Over time, the physiologic consequences of these changes make the older adult more vulnerable to dyspnea (shortness of breath) during exercise and physically demanding activity.

CHANGES IN THE MUSCULOSKELETAL SYSTEM

The decreasing elastic recoil and alveolar surface area for oxygen exchange may be further compounded by increased stiffness (loss of flexibility); "barreling" of the thoracic rib cage, which houses the lungs; and a decrease in height as intervertebral disks narrow and stiffen.[72] Much of this stiffness is attributed to changes in the articulation between ribs and vertebrae as well as decreased elasticity of intercostal muscle and soft tissue.[73] Although the stiffened rib cage may be as much a consequence of a sedentary lifestyle as of advancing age, lack of flexibility compromises inspiration and also decreases the elastic recoil of expiration.[65,74] In addition, the forward head and slight kyphosis that tend to develop with aging alter the position of both ribs and diaphragm, thus decreasing the mechanical efficiency of inspiration.[66,72,74] The net effect of a stiffer thoracic cage is an increase in the work of taking a breath, since muscles of respiration must work harder during inspiration to counteract the stiffness.[66]

The striated muscles of respiration are composed of a combination of type I (slow twitch and fatigue resistant, for endurance) and type II (fast twitch, for power) fibers and are susceptible to the same age-related changes in strength and endurance that have been observed in muscles of the extremities.[75] Normally type I muscle fibers are active during quiet breathing, whereas recruitment of type II fibers is triggered by increasing physiologic demand as activity increases. Age-related decrements in the strength and efficiency of the diaphragm, intercostals, abdominal muscles, and other accessory muscles of respiration affect the effectiveness and work of breathing.[66,76] Altered posture and higher RV within the lung also contribute to an increased work of breathing; when the diaphragm rests in less than optimal position and configuration for contraction, accessory muscles become active sooner as physiologic demand increases. Oxygen consumption in respiratory muscles, as in all striated muscle, decreases linearly with age, making older muscle more vulnerable to the effects of fatigue in situations of high physical demand, especially in the presence of lung disease or injury.[64]

CONTROL OF VENTILATION

The rate of breathing (breaths per minute) is matched to physiologic demand by input from peripheral mechanoreceptors in the chest wall, lungs, and thoracic joints, as well as centers in the brain stem of the central nervous system (CNS) and peripheral aortic and carotid bodies that are sensitive to concentration of CO_2, O_2, and hydrogen ions (pH) in the blood.[77] With aging, stiffness of the thorax tends to reduce the efficiency of mechanoreceptors, and the CNS and peripheral nervous system (PNS) centers that monitor CO_2, O_2, and pH to detect hypoxia during activity slowly begin to decline.[65]

Gradual loss of descending motor neurons within the CNS also occurs, with less efficient activation of neurons innervating muscles of respiration via the phrenic nerve to the diaphragm for inspiration and of spinal nerves to intercostals for expiration.[68] These three factors combine to compromise the individual's ability to quickly and accurately respond to increasing physiologic demand and increase the likelihood of dyspnea during activity.

FUNCTIONAL CONSEQUENCES OF PULMONARY AGING

With less recoil for expiration and reduced flexibility for inspiration, the ability to work is compromised in two ways (see Fig. 2.4). First, vital capacity (VC), the maximum amount of air that can be voluntarily moved in and out of the lungs with a breath, is decreased by 25% to 40%. Second, RV, the air remaining in the lungs after a forced expiration, is increased by 25% to 40%.[64] This combination of reduced movement of air with each breath and increased air remaining in the lung between breaths leads to higher lung-air carbon dioxide content and, eventually, lower oxygen saturation of the blood after air exchange. The increase in RV also affects the muscles of inspiration: the dome of the diaphragm flattens and the accessory respiratory muscles are elongated. As a result of these length changes, the respiratory muscles work in a mechanically disadvantageous range of the length-tension curve, and the energy cost of the muscular work of breathing rises.[66]

Functionally, the amount of air inhaled per minute (minute ventilation) is a product of the frequency of breathing and the tidal volume (volume of air moving into and out of the lungs with each usual breath). In healthy individuals, the increased ventilatory needs of low-intensity activities are usually met by an increased depth of breathing (i.e., increased tidal volume).[78] Frequency of breathing increases when increased depth alone cannot meet the demands of activity, typically when tidal volume reaches 50% to 60% of the VC.[78] For the older adult with reduced VC who is involved in physical activity, tidal volume can quickly exceed this level so that the frequency of breathing increases much earlier than would be demonstrated by a young adult at the same intensity of exercise.[79] Because the energy cost of breathing rises sharply with the greater respiratory muscle work associated with an increased respiratory rate, an important consequence of increased frequency of breathing is fatigue.[80] This early reliance on an increased frequency of breathing combined with a large RV and its higher CO_2 concentration in lung air results in a physiologic cycle that further drives the need to breathe more frequently. Overworked respiratory muscles are forced to rely on anaerobic metabolism to supply their energy need, resulting in a buildup of lactic acid. Because lactic acid lowers the pH of the tissues (acidosis), it is also a potent physiologic stimulus for increased frequency of breathing.[80–82] The older person can be easily forced into a condition of rapid, shallow breathing (shortness of breath) to meet the ventilatory requirements of seemingly moderate-intensity exercise.

Implications for Intervention

Rehabilitation professionals must consider two questions about the implications of age-related changes in the cardiovascular and cardiopulmonary systems on an older person's ability to do physical work. First, what precautions should be observed to avoid cardiopulmonary and cardiovascular complications? Second, what can be done to optimize cardiopulmonary and cardiovascular function for maximal physical performance?

PRECAUTIONS

Because of the combined effects of the age-related changes in the cardiovascular and cardiopulmonary systems, the high incidence of cardiac and pulmonary pathologies in later life, and the deconditioning impact of bed rest and inactivity, older patients who require orthotic or prosthetic intervention may be vulnerable if exercise or activity is too physiologically demanding. The clinician must also consider whether the intervention is occurring after a recent major surgery, which may compound these age-related changes. High-complexity patients with a prolonged hospitalization that have undergone multiple procedures may demonstrate compromised airway protective responses to clear the airway and may be susceptible to diaphragmatic fatigue, which complicates mechanical ventilation weaning and overall recovery from surgery.[83,84] Although most

older adults can tolerate exercise and respond to it positively, exercise is not appropriate in a number of circumstances (Table 2.3).

Estimating Workload: Heart Rate and Rate Pressure Product

One of the readily measurable consequences of the reduced response of the heart to sympathetic stimulation in later life is a reduction in the maximal attainable HR.[42,77,85] This reduction in maximal HR also signals that an older person's HR reserve, the difference between the rate for any given level of activity and the maximal attainable HR, is limited as well. For older patients involved in rehabilitation programs, the difference between resting and maximal HR is narrowed. One method of estimating maximal (max) attainable HR is the following[6]:

$$\text{Max HR} = 220 - \text{Age}$$

For healthy individuals, the recommended target HR for aerobic conditioning exercise is between 60% and 80% of maximal attainable HR. For many older adults, especially those who are habitually inactive, resting HR may be close to the recommended range for exercise exertion.[86] Consider an 80-year-old individual with a resting HR of 72 beats per minute. His maximal attainable HR is approximately 140 beats per minute (220–80 years). A target HR for an aerobic training level of exertion of 60% of maximal HR would be 84 beats per minute. His resting HR is within 12 beats of the HR for aerobic training. Functionally this means that an activity as routine as rising from a chair or walking a short distance on a level surface may represent physical work of a level of exertion equated with moderate- to high-intensity exercise. Because of the reduction in maximal attainable HR with age, older adults may be working close to their VO_{2max} range even in usual activities of daily living (ADLs).[86,87]

Because HR essentially signals the work of the heart, with each beat representing ventricular contraction, increased HR relates closely to increased heart work and increased oxygen consumption by the myocardium.[85] Given that afterload on the heart increases with age, the overall work of the heart for each beat is likely greater as well.[23,41–43] A more representative way to estimate the work of the heart during activity for older adults is the rate pressure product (RPP),[88–90] using HR and SBP as follows:

$$\text{RPP} = \text{HR} \times \text{SBP}$$

The linear relationship between VO_{2max} and HR for younger adults actually levels off for older adults.[91] Because of

Table 2.3 Signs and Symptoms of Exercise Intolerance

Category	Cautionary Signs/Symptoms	Contraindications to Exercise
Heart rate	<40 bpm at rest >130 bpm at rest Little HR increase with activity Excessive HR increase with activity Frequent arrhythmia	Prolonged at maximum activity
ECG	Any recent ECG abnormalities	Prolonged arrhythmia or tachycardia Exercise-induced ECG abnormalities Second or third-degree heart block
BP	Resting SBP >165 mm Hg Resting DBP >110 mm Hg Lack of SBP response to activity Excessive BP response to activity	Resting SBP >210 mm Hg Resting DBP >110 mm Hg Drop in SBP >10 mm Hg in low level exercise Drop in DBP during exercise
Angina	Low threshold for angina	Resting or unstable angina New jaw, shoulder, or left arm pain
Respiratory rate	Dyspnea >35 breaths/min	Dyspnea >45 breaths/min
Blood gas values	O_2 saturation <90%	O_2 saturation <86%
Other symptoms	Mild to moderate claudication Onset of pallor Facial expression of distress Lightheadedness or mild dizziness Postactivity fatigue >1 h Slow recovery from activity	Severe, persistent claudication (8/10 pain scale) Cyanosis, severe pallor, or cold sweat Facial expression of severe distress Moderate to severe dizziness, syncope Nausea, vomiting Increasing mental confusion, onset of ataxia, incoordination
Additional considerations	Fever >100°F Aortic stenosis Recent mental confusion Abnormal electrolytes (potassium) Known left main coronary artery disease Idiopathic hypertrophic subaortic stenosis Compensated heart failure	Any acute illness Digoxin toxicity Overt congestive heart failure Untreated second- or third-degree heart block Acute pericarditis <4–6 weeks after myocardial infarction <2 days after pulmonary embolism Acute thrombophlebitis Acute hypoglycemia

BP, Blood pressure; *bpm*, beats per minute; *DBP*, diastolic blood pressure; *ECG*, electrocardiogram; *HR*, heart rate; *SBP*, systolic blood pressure.
Modified from Hillegass E, ed. *Essentials of cardiopulmonary physical therapy*. 4th ed. St. Louis: Elsevier Saunders; 2017:574, 582.

this, HR alone cannot accurately reflect the physiologic work that the older patient experiences; the RPP provides a clearer impression of relative work.[90] For older individuals with HR reserve limited by age, adjusting activity to keep the rise in HR within the lower end of the HR reserve is wise, especially for those with known coronary artery compromise.

Blood Pressure as a Warning Sign

An older person's blood pressure (BP) must also be considered. Hypertension, particularly increased SBP, is common in older adults. SBP also provides a relative indication of the level of afterload on the heart.[43,92,93] Resting BP can be used to indicate whether an older person can safely tolerate increased physiologic work. Persons with resting BPs of more than 180/95 mm Hg may have difficulty with increased activity. A conservative estimate of the safe range of exercise suggests that exercise should be stopped if and when BP exceeds 220/110 mm Hg, although some consider 220 mm Hg too conservative a limit for older adults.[85] SBP should rise with increasing activity or exercise.[94]

The older adult with limited HR reserve must increase SV to achieve the required CO.[23,42,57] SBP rises as SV increases and blood volume in the peripheral vasculature rises.[43] If SBP fails to rise or actually decreases during activity, this is a significant concern.[85] The drop or lack of change in SBP indicates that the heart is an ineffective pump, unable to contract and force a reasonable volume of blood out of the left ventricle. Continuing exercise or activity in the presence of a dropping SBP returns more blood to a heart that is incapable of pumping it back out to the body. Elevated diastolic blood pressure (DBP) suggests that the left ventricle is maintaining a higher pressure during the filling period.[42,43,77] Early diastolic filling during preload will be compromised,[43,53] and the heart will be unable to capitalize on the Frank-Starling mechanism to enhance the force of ventricular contraction.[23,57]

Respiratory Warning Signs

Dyspnea, or shortness of breath, is an important warning sign as well. Age-related changes in the pulmonary system increase the work of breathing, and breathing becomes less efficient as work increases.[80] Because an older person is prone to shortness of breath, recovering from shortness of breath during exercise may be difficult. Breathing more deeply requires a disproportionately greater amount of respiratory muscle work, which further increases the cost of ventilation.[81,82] The use of supplemental oxygen by nasal cannula for the postoperative or medically ill older adult who is beginning rehabilitation may be quite beneficial.

Oxygen supplementation may prevent or minimize shortness of breath, enabling an older person to tolerate increased activity better and to participate in rehabilitation more fully. During this oxygen-assisted time, any conditioning exercise to improve muscular performance (especially if combined with nutritional support) delivers blood to the working tissues and improves tissue oxygenation, ultimately aiding pulmonary function. Improved muscular conditioning and cardiovascular function may prevent or delay the onset of lactic acidemia and the resultant increased desire to breathe that would trigger shortness of breath.[80,95]

OPTIMIZING CARDIOPULMONARY PERFORMANCE

For most older adults, conditioning or training is an effective way to improve function, although some may need a longer training period than younger adults to accomplish their desired level of physical performance.[96–100] Physical conditioning in situations of acute and chronic illness enables the older person to do more work and better accomplish desired tasks or activities.

Older adults, including those who are quite debilitated, experience improvement in physical performance as a result of conditioning exercises (Fig. 2.5).[98] For some, significant gains are made as work capacity increases from an initial state below the threshold necessary for function, such that an older person appears to make greater gains than a younger individual in similar circumstances.[101,102] In many cases the cardiopulmonary system efficiency gained through conditioning means the difference between independence and dependence; functional recovery and minimal improvement; life without extraordinary means and life support; and, for some older individuals, life and death.

The physiologic mechanisms for achieving the conditioned responses of older adults may vary slightly from those of younger individuals. With increasing activity or exercise in the submaximal range, older adults demonstrate greater increases in SV and less rise in HR than do young adults.[23,43,53,57,85] This increase in SV is accomplished with an increased EDV, usually without change in the ESV.[23,43,53] Increasing the EDV enhances the force of

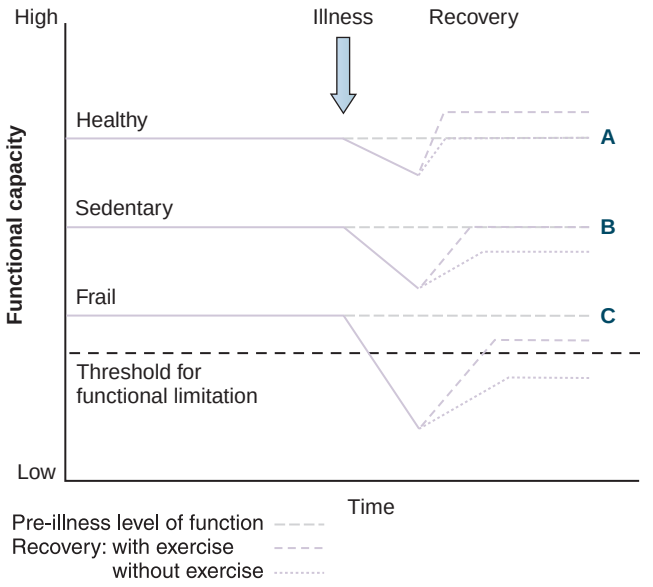

Fig. 2.5 Comparison of the impact of illness or prolonged inactivity or both on functional status and of exercise on recovery of premorbid functional levels of healthy, sedentary, and frail older adults. Each individual's functional reserve is represented by the distance between the threshold for functional limitation and the adult's functional capacity. *(A)* Healthy older adults have the most functional reserve and may recover preillness functional capacity without conditioning exercise; however, they often show improvement above baseline with exercise. *(B)* Sedentary older adults may not resume preillness functional capacity without the benefit of conditioning exercise. *(C)*, Frail older adults have the least functional reserve, often falling below threshold for function when illness occurs and tending to remain below this threshold without conditioning exercise. However, even frail older adults can regain functional status with conditioning exercise.

ventricular contraction by the Frank-Starling mechanism, which, in turn, increases CO despite the age-related impairment of the cardioacceleratory responses, which limits the rise in HR.[23,42,43,53,57] An increased preload, which improves CO, is the usual outcome of training at any age because improved conditioning of the peripheral musculature prevents distal pooling of blood and increased resting tension of the muscles assists blood return.[85]

Preparation for Activity and Exercise

Simple lower extremity exercise as a warmup before any functional activity or training session enhances the preload of the heart. Any gentle, repetitive, active lower extremity motions (e.g., ankle "pumps" in dorsiflexion/plantarflexion, knee flexion/extension, or cycling movements of the legs) before transfer or ambulation activities, before upper trunk and upper extremity activities or as part of the warmup portion of an aerobic or strength training exercise, effectively improves the EDV. This increased EDV compensates in part for age-related preload problems, which might otherwise compromise work capacity.

Additionally, the muscular work of preliminary lower extremity exercise initiates the electrolyte and hormonal changes that promote the metabolic changes and vasodilation in peripheral tissues necessary to support aerobic metabolism for meeting energy demands of the task.[85,98] Peripheral oxygen exchange improves as much as 16% with regular exercise training.[23] The peripheral vasodilation associated with exercise helps to check the rise in afterload on the heart and also minimizes the development of lactic acidemia and the resulting drive to breathe more rapidly.[103]

As submaximal levels of exercise increase toward maximal exercise, SV continues to increase, maintaining CO.[23,53,57] When cardiopulmonary disease is present in addition to aging, however, this continued increase in SV is likely to be blunted.[42,85] Under these circumstances, the reduced sensitivity of the heart to sympathetic stimulation limits the force of contraction of the ventricle so that the ejection fraction decreases and the ESV rises slightly.[43]

MONITORING THE CARDIORESPIRATORY RESPONSE TO EXERCISE

Consistent monitoring of the cardiopulmonary response is an essential component of rehabilitation interventions aimed at optimizing the endurance or fitness of older frail or deconditioned individuals.[86,104] The positive effects of training occur only when the older person is appropriately challenged by the exercise or activity. According to the principle of overload, functional improvements occur only when the body is asked to do more than the customary workload for that individual.[6] For an individual who has been on prolonged bed rest and is quite deconditioned, simple lower extremity exercises while sitting upright may be as challenging as training for a marathon in a healthy young adult. The level of physiologic exertion is relative to the individual's customary work. Providing the physiologic overload necessary to produce improvements in performance while avoiding a decline in performance because of exercise-induced fatigue or exhaustion requires that the therapist monitor the individual's level of exertion.

Heart Rate and Blood Pressure

Maximum oxygen consumption (VO_{2max}) is the most accurate and sensitive measure of the individual workload, but the special equipment and technology necessary to determine VO_{2max} are not typically available in routine clinical practice.[85,86] Although the linear relationship between HR and VO_{2max} plateaus so that HR becomes an inaccurate reflection of the workload for older adults, HR does partially indicate the work of the heart.[85,91] For a rapid clinical impression of the physiologic burden of an activity or exercise, HR is helpful as long as the clinician recognizes its limitations when the measure is being used with elders. Preexercise or activity BP provides some indication of likely afterload against which the heart will be working.[43,85,94] Continuing to monitor BP during the activity helps the clinician recognize if the exercising cardiovascular system can meet the requirements of an increasing workload.[85] Calculation of the RPP (HR × BP) may be a more accurate estimate of cardiac workload for older adults.[89,90,94]

Perceived Exertion

Ratings of perceived exertion are also effective indicators of the level of physiologic exertion experienced by patients who are exercising or involved in a strenuous physical activity (Table 2.4).[85,105,106]

These scales ask individuals to assess subjectively how much effort they are expending during an exercise session or activity, with higher ratings indicating greater effort. Similar scales have been developed to assess breathlessness, fatigue, and discomfort or pain during exercise (Table 2.5). In the clinical use of these ratings of perceived exertion, many older persons using ratings of perceived exertion tend to overestimate their true physiologic stress as indicated by their HR during exercise sessions.[85,105] Clinicians who appropriately recommend exercise for older adults relying on perceived exertion to limit the activity safely may find this phenomenon comforting.

Table 2.4 Borg Scales: Ratings of Perceived Exertion

LINEAR SCALE		RATIO SCALE	
Value	**Description**	**Value**	**Description**
6	No exertion	0	No effort at all
7–8	Extremely light effort	1	Very little (very weak) effort
9–10	Very light effort	2	Light (weak) effort
11–12	Light effort	3	Moderate effort
13–14	Somewhat hard effort	4	Somewhat strong effort
15–16	Heavy or hard	5–6	Strong effort
17–18	Very hard effort	7–8	Very strong effort
19	Extremely hard effort	9	Extremely strong effort
20	Maximum exertion	10	Maximal exertion

Modified from Borg G, Ottoson D. *The perception of exertion in physical work.* London: Macmillan; 1986.

Table 2.5 Ratio Scales of Perceived Breathlessness, Fatigue, or Discomfort During Exercise

Value	Breathlessness/ Dyspnea	Fatigue	Discomfort or Pain
0	No breathlessness at all	No fatigue at all	No pain or discomfort
1	Very light breathlessness	Very light fatigue	Very little (weak) pain
2	Light breathlessness	Light fatigue	Little (weak) discomfort
3	Moderate breathlessness	Moderate fatigue	Moderate discomfort
4	Somewhat hard to breathe	Somewhat hard	Somewhat strong discomfort
5-6	Heavy breathing	Heavy work/fatigue	Strong discomfort or pain
7-8	Very heavy breathing	Very heavy fatigue	Very heavy discomfort
9	Very, very breathless	Very, very fatigued	Very, very hard discomfort
10	Maximum breathlessness	Maximally fatigued	Maximal discomfort or pain

Exercise Testing Protocols

Standard exercise testing protocols are appropriate for assessment of the status of conditioning of the cardiovascular system and exercise tolerance of older adults.[86,107] The "gold standard" treadmill test, a cycle ergometer, or a step test can be used to assess the cardiovascular performance of the older person unless the specific clinical setting or associated musculoskeletal dysfunction (e.g., balance problems, arthritic joints, or lower extremity muscle weakness) precludes this type of testing.[86] Alternatives for individuals who can walk distances include the One-Mile Walk Test and the Six-Minute Walk Test.[108–110] A brief step test performed while sitting in a chair has been developed for individuals who cannot otherwise be safely tested on a treadmill, with an ergometer, or by distance walked.[85,111]

Careful monitoring of HR and BP before the sitting step test—at predetermined points during testing, at the completion of a brief bout of exercise, and a short while into recovery from the exercise bout—provides a comprehensive picture of the cardiovascular function of any given older patient. This information often proves important in clinical decision making and program planning. Similarly, careful monitoring of HR and BP before, during, and after a bout of exercise during rehabilitation allows the clinician to compare the pattern of responses with the expected pattern for conditioned adults.[112] Normal exercise-induced cardiovascular responses include a slow rate of rise of HR, a rise in SBP, and minimal (if any) rise in DBP during the exercise bout. For the conditioned older adult, HR and SBP should return toward preexercise values during the immediate postexercise recovery period on the order of 50% of the changes during exercise. The pattern of change in the RPP for the exercise bout and recovery period may be an even more descriptive measure of the cardiovascular response.

Expecting individuals who are significantly deconditioned, can barely tolerate sitting for 30 minutes, are short of breath after 10 repetitions of simple lower extremity exercises while sitting, or are fatigued after 5 minutes of a sitting step test to be fully able to participate in gait and balance training is unreasonable. How can older individuals who are working at 90% or more of their maximum target HR be truly concerned with much more than delivering oxygen to the working tissues? Deconditioned individuals who are working at a high intensity in simple, well-known tasks have seriously restricted energy reserves; they are likely to have difficulty with focus and attention, processing, and the therapist's directions and supporting muscle activity—all necessary components for motor learning in performing a new skill such as gait training with a prosthetic device. Under these circumstances emphasis must first be placed on improving cardiovascular conditioning so as to improve energy reserves; then subsequent functional training with an orthosis or prosthesis will have a greater likelihood of a successful outcome.

PHYSICAL PERFORMANCE TRAINING

The same principles of training that are used with young adult athletes can be adapted and applied to frail or deconditioned older adults who are recovering from amputation in prosthetic rehabilitation or to a neuromuscular or musculoskeletal event that necessitates use of an orthosis. The primary goals of conditioning for frail individuals are (1) to develop enough aerobic capacity to do work and (2) to ensure efficient muscle function to produce work.[85,86,113] These concepts can guide any single rehabilitation session, as well as the progression of the rehabilitation program, over time. An understanding of exercise for improving fitness and of the few physiologic age-related changes in cardiopulmonary function provide a foundation for exercise prescription, which then is individualized on the basis of current exercise tolerance of a specific older patient. This strategy can likely optimize the performance and recovery of older adults in rehabilitation.

An effective strategy to improve cardiopulmonary response to exercise and activity for older patients who are deconditioned by bed rest, acute illness, or sedentary lifestyle begins with a warmup of continuous alternating movements using large muscle groups, particularly of the lower extremities. The goal of such activity is facilitation of the preload and SV; any increase in SV realized through this training regimen helps an older patient maximize cardiovascular function despite age-associated limitations in HR, cardioacceleratory responses, and baroreceptor sensitivity.

For healthy young adults, the recommended regimen for aerobic conditioning and endurance training involves at least three sessions per week of 30 to 60 minutes' duration in activities that use large muscles (running, cycling, swimming, brisk walking) and keep HR in a target range between 60% and 80% of the individual's maximal attainable HR.[114,115] This may be unreasonable for an older adult

who is recovering from an acute illness, habitually sedentary, or coping with age- or pathology-related impairments of cardiac or pulmonary function. Evidence suggests that, for older adults who are deconditioned, slower but significant improvement in functional capacity can occur at exercise intensities as low as 40% of maximal HR.[97,116–118] Although high-frequency, high-intensity exercise can maximize increase in work capacity (VO_{2max}), high-intensity exercise performed less frequently and low-intensity exercise performed more frequently can also yield positive endurance training effects.[118,119] Evidence is also growing that improvement in oxygen extraction and muscle function occurs when older adults are involved in regular endurance training.[119]

In addition to aerobic conditioning, the rehabilitation program might include exercises that focus on flexibility. One goal of stretching and flexibility exercise for older adults is to preserve or restore any limited joint mobility that would otherwise compromise essential functions.[120] As flexibility of the trunk and thorax improves, a more effective alignment of the diaphragm and improved elastic recoil of the chest wall will have a positive impact on VC and inspiratory reserve volume and minimize RV, reducing the work of breathing and improving ventilation. The availability of essential range-of-motion exercises is especially important for energy-efficient gait with lower limb orthoses or prostheses. Contracture of the hip, knee, or ankle has an impact on the alignment of orthotic and prosthetic components and often leads to greater sway and smaller stride length during gait, significantly increasing the energy cost or workload of walking.

Muscle strengthening can begin as soon as the aerobic conditioning appears adequate to oxygenate the peripheral muscular tissue sufficiently. Assessment of the adequacy of peripheral oxygenation might include monitoring the coloring of the distal extremities before and during exercise and noting whether cramping or claudication occurs during exercise. One of the most sensitive indicators of appropriate intensity and duration of exercise is whether the activity can be increased without a marked rise in respiratory rate or onset of shortness of breath; a potent stimulus for frequency of breathing is the pH of the exercising tissues with decreases as lactic acid builds up during anaerobic exercise.

Two factors should be considered when strengthening exercises are included in a rehabilitation program.[104] First, is there adequate muscle strength for consistent and safe performance of the motor tasks needed for functional independence (including the use of assistive devices)? Second, is the muscle mass large enough to support a VO_{2max} that allows ADLs to represent a light to modest work intensity level? For many older people who have lost muscle mass (whether as a result of disuse and sedentary lifestyle or because of recent health problems that limit activity), the development of more muscle mass increases lean body mass and improves the basal metabolic rate, thus improving overall health, fitness, and functional status.[121,122] Healthy but sedentary elderly subjected to high-load (80% of one rep max until muscular failure) resistance exercise to improve strength has been found to be safe when compared with low load (30% of one rep max until muscular failure) resistance exercise.[123]

Energy Cost of Walking

The human body is designed to be energy efficient during upright bipedal gait. Muscles of the trunk and extremities are activated by the CNS in a precise rhythmic cycle to move the body forward while maintaining dynamic stability, adapting stride length and walking speed to the constraints and demands of the task, the force of gravity, and the characteristics of the environment in which walking is occurring.[124,125] The advancing foot is lifted just enough to clear the surface in swing, and muscle activity at the stance-side hip and lower torso keeps the pelvis fairly level and the trunk erect, thus minimizing vertical displacement of the body's center of mass.[126] Normal arthrokinematic and osteokinematic relationships between body segments ensure a narrow base of support in quiet stance and relaxed walking, and reciprocal arm swing counterbalances the dynamic pendular motion of the lower extremities, ensuring that the center of mass progresses forward with minimal mediolateral sway.[126–129] Much of the energy cost of walking is related to the muscular work performed to keep the center of mass moving forward with a minimum of vertical and mediolateral displacement.[130]

SELF-SELECTED WALKING SPEED

Since self-selected walking speed emerges from the interaction of the cardiovascular, pulmonary, musculoskeletal, and neurologic systems, it reflects the overall health and functional status of an individual.[131–134] Walking speed is recognized as a vital sign that not only captures current function but also can be used to predict the risk of functional decline, adverse health events and morbidity, length of stay and discharge location after hospitalization, and mortality.[132,135–152]

A recent study found that increases in the energetic costs of walking predicted the decline in self-selected walking speed in adults 65 years of age and older.[153] Although self-selected walking speed tends to decrease with aging, multiple studies have demonstrated that even into the ninth and tenth decades of life, healthy older adults are able to walk at speeds at or greater than 1 m/s (Table 2.6).[132,154–156] Values for typical walking speed are also becoming available for community living older adults with impaired mobility and physical frailty.[133,150,157–160] There is also evidence that the ability to increase walking speed is an indicator of functional reserve.[154,158,161]

Walking speed can be quickly and reliably measured using a stopwatch and either a 20- or 6-m walkway (Fig. 2.6). The individual is instructed to walk over the entire distance of the walkway but is timed only while walking the middle two thirds (10 or 4 m, respectively) of the distance so that steady-state speed is more likely and the impacts of acceleration (at the start) and deceleration (at the end) are minimized. Reliability is strong at either distance for persons with amputation, stroke, and spinal cord injury as well as for those with chronic disease, physical frailty, and other neurologic pathologies.[162–165] Minimal detectable differences (MDDs) have been consistently reported as between 0.08 m/s and 0.1 m/s for community-living persons, those with cognitive impairment, and those with hip fractures.[154,166,167] The minimal clinically important difference for walking

speed following stroke is reported to be 0.16 m/s to 0.175 m/s.[168,169] Walking speed has been successfully used to evaluate the outcome of interventions for persons with cognitive impairments as well as those with hip fractures.[154,166,167]

Any musculoskeletal or neuromuscular pathologic condition that interferes with the alignment of body segments, the carefully controlled sequential activation of muscles, or the effectiveness of muscle contraction increases the energy cost of walking.[133] As vertical displacement and mediolateral sway increase and gait deviations occur, muscles must work harder to keep the center of mass moving forward despite extraneous displacing moments. As muscle work increases, the cardiopulmonary system responds to this physiologic demand with increased HR, SV, and respiratory rate. Any orthosis or prosthesis that adds mass to or alters movement of the lower extremity potentially increases the work of walking. However, in individuals with amputation or neuromuscular dysfunction, walking with an appropriate prosthesis or orthosis may actually require less energy than walking without it.[130,170,171]

MEASURING ENERGY COSTS OF WALKING

Measurement of physiologic energy expenditure by direct calorimetry is not realistic in all but the most sophisticated research laboratory settings. Instead, several indirect indicators have been found to be valid and reliable estimates of the energy cost and the efficiency of gait in research and clinical applications. These include calculation of oxygen consumption (VO_{2max}) and oxygen cost while walking, monitoring blood lactate levels, calculating the physiologic cost index (PCI) of walking, and monitoring heart and respiratory rates during activity.

Oxygen Rate and Oxygen Cost

The most precise indirect measurements of energy and gait efficiency use special equipment (e.g., a portable spirometer or a Douglas bag) to monitor ventilatory volumes and to measure how much oxygen is taken in and how much carbon dioxide is exhaled during physical activity. This type of testing is usually done while the subject or patient walks, runs on a treadmill or track, or cycles on a stationary bicycle. The rate of oxygen consumption (O_2 rate), measured as volume of oxygen consumed per unit of body weight in 1 minute (mL/kg/min), provides an index of intensity of physical work at any given time.[128,172] VO_{2max} is the highest rate of oxygen uptake possible and is determined by progressing the exercise test to the point of voluntary exhaustion, when the age-adjusted maximum attainable HR is approached or reached.[173,174]

If oxygen consumption during gait is low, an individual is likely to be able to walk long distances. If it is high, however,

the distance of functional gait is likely to be limited. The oxygen cost of walking is determined by dividing the rate of oxygen consumption by the speed of walking. Oxygen cost is a precise indicator of efficiency of gait, or the amount of energy expended to walk over a standard distance (mL/kg/m).[128] Most of what researchers currently understand about energy expenditure when a prosthesis or orthosis is being used is based on studies that have measured oxygen rate and the oxygen cost of walking.

Serum Lactate

The energy efficiency of walking is also assessed by evaluating serum carbon dioxide and lactate levels as indicators of anaerobic energy production. The energy (adenosine triphosphate [ATP]) required for muscle contraction during gait can be derived from a combination of aerobic oxidative and anaerobic glycolytic pathways.[175] The aerobic oxidative pathway, which depends on oxygen delivery to active muscle cells, is the most efficient source of energy, producing almost 19 times as much ATP as the anaerobic pathway. In healthy, fit individuals, this aerobic pathway is more than able to meet energy requirements of relaxed walking. If energy demands of an exercise or activity are met by aerobic oxidation, the activity can be sustained for long periods with relatively low levels of fatigue. As activity becomes strenuous (i.e., as walking speed or surface incline increases) and the need for energy begins to exceed the availability of oxygen for aerobic oxidation, additional energy is accessed through anaerobic metabolism.[176] This transition to anaerobic metabolism is reported to begin at work levels of 55% of VO_{2max} in healthy, untrained individuals but may begin at 80% of VO_{2max} in highly trained athletes.[177]

When the ability to deliver oxygen is compromised by the physical deconditioning of a sedentary lifestyle or by cardiac, pulmonary, or musculoskeletal pathology, anaerobic glycolysis becomes a primary source of energy at lower levels of work.[178] Whenever the anaerobic pathway is the major source of energy, blood levels of lactate and carbon dioxide rise, lowering blood pH and increasing the respiratory exchange ratio (CO_2 production/O_2 consumption).[179] Under these conditions, the ability to sustain activity is limited, with an earlier onset of fatigue as workload increases. Serum lactate levels are most often used in studies of assisted ambulation using hybrid orthotic/functional electrical stimulation (FES) systems for those with spinal cord injury.

Heart Rate and Physiologic Cost Index

High correlations between HR and oxygen consumption during gait have been reported for children and for healthy young adults at a variety of walking speeds.[180,181] Although this suggests that HR monitoring may be a reliable substitute for oxygen consumption, it should be used with caution in older adults because of the age-related changes in cardiopulmonary function discussed earlier in this chapter. This is especially true for older adults with heart disease who are being managed with medications that further blunt HR response.[182,183] The RPP or the PCI may be a more appropriate indicator of the energy cost of walking in these circumstances. The PCI is calculated as follows[184]:

$$\text{PCI} = (\text{HR walking} - \text{HR resting})/\text{Walking speed}$$

Measured in beats per meter, the PCI reflects the effort of walking; low values suggest energy-efficient gait. The PCI was originally used to assess gait restrictions in adults with rheumatoid arthritis or a similar inflammatory joint disease.[184] For children between 3 and 12 years of age, the mean PCI at self-selected or preferred walking speed has been reported to be between 0.38 and 0.40 beats per meter.[185] Typical PCI values for adolescents and young adults at usual walking speeds ranged from 0.3 to 0.4 beats per meter.[186] In a study of healthy adults older than age 65 years, the mean PCI value when walking on a flat 10-m track was 0.43 (SD = 0.13) beats per meter; when calculated while walking on a treadmill, mean PCI increased to 0.60 (SD = 0.26) beats per meter.[187]

The PCI has been used to assess the effect of different assistive devices on the effort of walking,[187,188] evaluate the short- and long-term impact on neuromuscular stimulation on the ability to walk and run in older adults and in children with hemiplegia, assess outcomes of orthopedic surgery in children with cerebral palsy, and evaluate the efficacy of reciprocal gait orthosis (RGO)/FES systems for individuals with spinal cord injury.[189–197] High correlation among the PCI, percent maximum HR, and oxygen rate ($r = 0.91$, $P > .005$) in able-bodied children and children with transtibial amputation supports its validity as an indicator of energy cost for children.[198] A similar study of energy cost of walking in young adults using a microprocessor-controlled transfemoral prosthesis suggests that PCI is comparable with oxygen uptake as an indicator of the energy cost of walking.[199] The PCI has also been used to compare energy cost of walking in different types of transfemoral prosthetic sockets and to assess efficacy of a stance control knee orthosis.[200,201]

Studies of variability in PCI values on repeated measures have raised questions about its accuracy and sensitivity to change in energy cost of gait as compared with monitoring oxygen consumption and oxygen cost.[202–204] Although the relationship between PCI and the gold standards of oxygen consumption and oxygen cost may not be strong enough for researchers, it remains an important tool for clinicians who lack the resources necessary to directly monitor oxygen consumption and cost yet want to estimate the energy cost of walking and assess the impact of orthotic or prosthetic rehabilitation over time.

ENERGY EXPENDITURE AT SELF-SELECTED WALKING SPEEDS

The energy requirements of walking vary with age and walking speed.[204–210] Oxygen consumption is highest in childhood and decreases to approximately 12 mL/kg/min in healthy adults and elders.[205] When oxygen consumption during walking is expressed as a percent of VO_{2max}, a slightly different picture emerges. For a healthy, untrained young adult, oxygen consumption at a comfortable walking speed may be 32% of VO_{2max}, whereas for an older adult walking at a similar speed, oxygen consumption may be as much as 48% of VO_{2max}.[126,211] For functional gait, if walking is to cover long distances or is to be sustained over prolonged periods of time, oxygen consumption must be less than 50% of that individual's VO_{2max} so that aerobic oxidation will be used as the primary source of energy.[6]

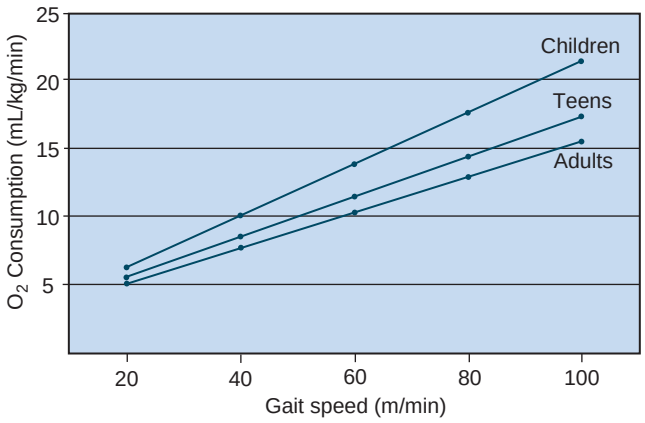

Fig. 2.7 Relationship between walking speed and oxygen consumption (O_2 rate). The differences in O_2 rate between children and adults (20 to 80 years) are attributed in part to differences in body composition. (From gait-velocity regression formulas reported by Waters RL. Energy expenditure. In Perry J, Burnfield JM, eds. *Gait analysis: normal and pathological function*. Thorofare, NJ: Slack; 2010:483–518.)

At comfortable walking speeds, older adults are working nearer the threshold for transition to anaerobic metabolism than are younger adults. If some form of gait dysfunction is superimposed, increasing the energy cost of gait, the work of walking will transition to anaerobic glycolysis unless a cardiovascular conditioning program is included in the rehabilitation program.[212–216]

For individuals without neuromuscular or musculoskeletal impairment, the relationship between the energy cost of walking and walking speed is nearly linear (Fig. 2.7).[215] Gait is most efficient, as indicated by oxygen cost (O_2 rate/velocity), at an individual's self-selected or customary walking speed; energy requirements increase whenever walking speed is much slower or much faster.[215–218] The customary walking speed of most individuals with neuromuscular or musculoskeletal impairments is often much slower, a strategy that minimizes the rate of energy used during walking. As a result of slower speed, however, it takes longer to cover any given distance. Any impairment that reduces walking speed leads to increased oxygen cost, even if oxygen consumption remains close to normal.[219–224]

The weight and design of the prosthesis or orthosis are also determinants of energy cost of gait. The impact of added mass on the energy cost of gait depends on where the load is placed: Extra weight loaded on the trunk (e.g., a heavy backpack) changes oxygen rate during walking less than would a smaller load placed around the ankle.[225] Adding weight to the prosthesis center of mass increases the energy cost of gait by 7%, whereas adding the same weight to the ankle increases the energy cost by 12%.[226] Despite theories that increasing prosthesis weight may improve gait symmetry, they may have not taken into account the increase in energy cost for the patient. This highlights the importance of minimizing weight of lower extremity orthoses and prostheses to keep the energy cost of walking within an individual's aerobic capacity.[226,227]

WORK OF WALKING WITH AN ORTHOSIS

When the energy cost of walking with an orthosis is being discussed, it is important to remember that, for those with significant neuromuscular or musculoskeletal impairment, the energy cost of walking without the orthosis is typically higher than that of walking with an appropriate orthosis.[228–232] One of the determinants of energy cost when walking with a cast or an orthosis is the degree of immobility that the orthosis imposes on the ankle, knee, and hip and the associated change in walking speed.[233] For individuals with restriction of knee motion because of a cast or orthosis, the energy cost of gait can be reduced by placing a shoe lift on the contralateral limb to improve swing limb clearance.[234]

Recent advances in materials and computer technology have significantly increased material options and ankle/foot orthosis (AFO) design types. The use of carbon fiber's energy return characteristics may improve walking speed and gait kinematics in patients after stroke, and the use of traditional thermoplastic material and an articulated joint may provide similar improvements when compared with a solid joint.[235–238] Newer technology including computer-controlled active ankle/foot orthoses (AAFOs) may normalize ankle gait kinematics.[239,240] Despite the differences in design, all AFOs will reduce energy expenditure with walking. The true key for the clinician is to determine which type of AFO design is optimal for their patient based on the patient's individual deficits.[241]

The movement dysfunction associated with stroke and other neuromuscular impairments tends to reduce walking speed, with the degree of slowing determined by the severity of neuromuscular impairment.[134,231,242] As abnormal movement patterns and impaired postural responses compromise the cyclic and dynamic flow of walking, the higher levels of muscle activity that are required to remain upright and to move forward increase the energy cost of gait.[243] Reduction of walking speed is a functional strategy to keep energy expenditure within physiologic limits in addition to maintain postural stability. Oxygen rate (consumption) of persons with stroke who walk at a reduced walking speed is close to that of older adults who walk at their customary walking speed; however, oxygen cost is significantly higher.[130,220,230] When stroke survivors are able to improve their gait symmetry and walking speed, their overall oxygen consumption is reduced dramatically.[243] Orthosis use on the affected lower extremity may be one of the easiest methods to help facilitate improved gait quality and functional walking distance.

For individuals with spinal cord injury, regardless of age, the potential for functional ambulation appears to be determined by four conditions: the ability to use a reciprocal gait pattern, the adequacy of trunk stability, at least fair hip flexor strength bilaterally, and fair quadriceps strength of at least one limb.[243,244] This corresponds to an ambulatory motor index (AMI) score of 18 of 30 possible points, or 60% of "good" lower extremity strength.[207] In this instance, gait may be possible with bilateral AFOs or an AFO and knee/ankle/foot orthosis combination. Those with spinal cord injury at mid- to low-thoracic levels with AMI scores of less than 60% often require bilateral knee/ankle/foot orthoses with Lofstrand or axillary crutches in a swing-through gait pattern to ambulate. Waters[130] reports a near linear positive relationship between AMI scores and gait velocity as well as a somewhat curvilinear inverse relationship between AMI score and oxygen rate (percent above normal) and oxygen cost. For persons with spinal cord injury who

FNS, Functional neuromuscular stimulation; *MET,* metabolic equivalent of the task; *RGO,* reciprocal gait orthosis; *SCI,* spinal cord injury.

have the potential for functional ambulation, continued cardiovascular conditioning after discharge from rehabilitation improves the efficiency of walking as reflected in lower oxygen cost and improvement in walking speed.[244–246]

The development of RGOs and "parawalkers," at times augmented by functional neuromuscular stimulation (FNS), has also made modified ambulation possible for those with injury at mid and upper thoracic levels.[247–255] The high energy cost of the intense upper extremity work using crutches to propel the body forward during swing and maintain upright position in stance, however, restricts functional ambulation as a primary means of mobility.

The clinician must consider the potential energy requirement of using a functional orthosis such as an RGO, FNS, and exoskeleton with gait for a patient with a spinal cord injury (SPI) (Table 2.7).[256–260] An able-bodied individual ambulating at a normal walking speed of 1.3 m/s will use 3.4 times the average amount of oxygen at rest, or 3.4 metabolic equivalents (METs).[256] One MET is equal to 3.5 mL O_2/min/kg—essentially the amount of oxygen consumed while sitting at rest. When tasked with gait using a functional orthosis, patients with SCI demonstrate significantly higher energy requirements to complete the task. It is important to note that the energy expenditures listed in Table 2.7 were mostly performed at nonfunctional walking speeds. Despite the abundance of technology, there have been no significant findings of improved patient functional outcomes with using FNS, RGO, body weight–supported treadmill training (BWSTT), and FES versus conventional treatment with SCI patients.[261]

WORK OF WALKING WITH A PROSTHESIS

The characteristics of gait and the energy cost of walking with a prosthesis are related to the etiology and the level of amputation.[262–264] The walking speed, stride length, and cadence of persons with lower extremity amputation who walk with a prosthesis are typically lower than those of individuals without impairment regardless of the cause of amputation,[265] although individuals with a traumatic etiology tend to walk faster than those with a dysvascular etiology.[264,266,267] Additionally, biomechanical and energy efficiency of prosthetic gait decreases as amputation level increases. Therefore preservation of the anatomic knee joint appears to be especially important.[264,265,268]

A classic study by Waters and colleagues[267] (Table 2.8) demonstrated that, for young adults with traumatic transtibial amputation, walking speed, oxygen rate, and oxygen cost were quite close to the normal values reported by Perry.[126] Recent studies by Esposito and colleagues[269] support the initial findings of Waters and colleagues[267] demonstrating similar metabolic demands for the same velocity of walking between young adults with traumatic transtibial amputation and controls.[269] For those with traumatic transfemoral or dysvascular amputation, diminishing walking speeds kept oxygen consumption close to that of normal adult gait; however, oxygen cost increased well beyond the normal value of 0.15 mg/kg/m.[233] Although walking speeds reported 20 years later by Torburn and colleagues[266] are much higher (most likely from biomechanical advances in prosthetic components in the time between the studies), the difference in performance between traumatic and dysvascular groups was consistent. Other studies report oxygen costs of prosthetic gait at between 16% and 28% above normal for individuals with transtibial amputation and between 60% and 110% above normal for individuals with transfemoral amputation.[270–275] For hip disarticulation due to pathology, the oxygen cost of prosthetic gait can be more than 60% above normal, even at a significantly lower walking speed.[276] Although the relationship between walking speed and oxygen rate (consumption) in prosthetic gait is linear, just as it is in unimpaired gait, the slope is significantly steeper.[277] The clinical implication of this relationship is that the rate of energy consumption and of cardiac work at any walking speed is higher for those with amputation and that the threshold for transition from aerobic to anaerobic metabolism is reached at lower walking speeds.[278]

Several explanations are possible for the differences in prosthetic gait performance after traumatic versus dysvascular amputation. Because those with dysvascular amputation are typically older than those with traumatic amputation, differences in performance may be the result of age-related changes and concurrent cardiovascular disease in the dysvascular group.[270,279,280] For many older patients with dysvascular amputation, the energy source for walking with a prosthesis may be anaerobic rather than the more efficient aerobic metabolic pathways.[266] A larger cardiac and respiratory functional reserve capacity in younger persons with traumatic transtibial amputation may permit them to meet the increased metabolic demands of prosthetic use because proximal muscle groups work for longer periods at higher intensities to compensate for the loss of those at the ankle.[266,277,281]

Importantly, for most individuals with unilateral transtibial and transfemoral amputation regardless of age or etiology of amputation, the energy cost of walking with a prosthesis is less than that expended when walking without it, using crutches or a walker.[267,282] For most persons with a new transtibial amputation, the ability to ambulate before amputation is the best predictor of tolerance of the increased energy cost of walking with a prosthesis after surgery.[279] For some older individuals with transfemoral amputation and concurrent cardiovascular or respiratory disease and for those with bilateral amputation at transfemoral/transtibial or bilateral transfemoral levels, wheelchair mobility may be preferred.[283–286]

Technologic Advances Impacting Energy Demands

Since the 1990s, significant efforts have been made to reduce the energy cost of prosthetic gait by developing dynamic-response (energy-storing) prosthetic feet and cadence-responsive and microprocessor-controlled prosthetic knee units.[287–301] The flexible keels of most energy storage and return prosthetic feet are designed to mimic those of normal ankle mobility, such that mechanical energy stored by compression during stance is released to enhance push-off in the terminal stance.[302] However, the impact of different prosthetic foot designs on the energy cost is limited. The 1M10 Adjust demonstrated significant improvement in the energy cost of walking and perceived exertion for hypomobile adults with transtibial amputation (TTA).[303] Other studies on adults with TTA found that the FlexFoot functioned more like an anatomic ankle than did four other dynamic response feet and the SACH foot, but little difference in stride, velocity, or energy cost was noted.[266,281,293] However, the materials and designs of most dynamic-response feet may enable transtibial prosthetic users to jump, run, and use a step-over step pattern in stair climbing; these activities are difficult or impossible with a traditional SACH foot.[267,268,270–274,277,293] Additionally, many individuals with transtibial amputation wear their prosthesis for longer periods during the day and report less fatigue in prolonged walking when using a prosthesis with a dynamic-response foot.[279] Additional research is needed focusing on standardized methods to objectively assess function while measuring subjective performance.

Recent research into dynamic ankle and foot system for transtibial amputees provides promise of improved performance of ADLs and even sports. Microprocessor ankle systems like the Proprio have demonstrated both objective and subjective improvements with slope ascent and descent.[304] However, with the varied designs of transtibial prostheses, the research has been mixed in determining whether active push-off reduces walking energy expenditure.[304–308] Some of the variables within the research has been the lack of subjects, weight of the prosthesis, gait analysis on a treadmill versus open ground, and the length of time of gait analysis, which may lead to fatigue becoming another factor. Much focus with these transtibial prostheses has been to replace the 80% of the mechanical work to complete the gait cycle performed by the gastrocsoleus complex.[309,310] However, researchers are realizing that there are more factors besides energy return at toe-off to improve energy expenditure with gait.[311] New designs are taking into account the entire gait cycle to reduce overall energy expenditure while improving gait kinematics.

A patient with a transfemoral prosthesis faces even greater energy requirements for gait and overall stability. Promising research looking at microprocessor-controlled active knee joints has demonstrated a significant reduction in energy expenditure when climbing stairs, even allowing subjects to perform a step-through gait.[312] Further research on the functional application of this latest generation of "smart" joints will definitely improve the overall functional capability of patients with transfemoral prostheses in the future.

Additional technologic advances will likely change how orthotics and prosthetics are designed and manufactured. Breakthroughs in computer modeling and 3D printing are allowing devices to be designed exactly for the wearer and "built" via a 3D printer in precise detail.[313] This holds

promise for patients with unique or less common amputations (such as a Syme or Pirogoff amputation) to have devices designed specifically for their needs and thereby maximizing walking efficiency and reducing energy expenditure.[314]

Summary

An understanding of normal cardiopulmonary function and how it changes in aging as a result of sedentary lifestyle or pathologic conditions provides a necessary foundation for rehabilitation professionals working with patients who require an orthosis or prosthesis to walk. This chapter reviews the anatomy and physiology of the cardiopulmonary system with attention to age-related changes, energy expenditure, and principles of aerobic conditioning for older adults.

Optimal performance of the cardiopulmonary system is influenced by three interrelated factors. First, the patient must have sufficient flexibility and mobility of the trunk for efficient and uncompromised ventilation. Second, adequate mobility of the extremities and excursion of the joints must be present for efficient performance of functional tasks. Third, the individual must have enough muscle mass, strength, and endurance to support the performance of the activity and function of the heart. Immediate and ongoing interventions that functionally enhance preload by returning blood to the older heart and avoidance of conditions (e.g., isometric muscle contraction and Valsalva maneuvers) that unnecessarily increase afterload can result in marked improvement in physical performance of the older person. With these conditions and compensation for the beta-adrenergic receptor–reduced sensitivity with a prolonged period of warmup exercises, an older person can be capable of a physical performance that is quite similar to that of younger counterparts and essential for the process of recovery of function as the optimal outcome of rehabilitation.

The energy cost and efficiency of gait are affected by aging, deconditioning from a sedentary lifestyle, and neuromuscular and musculoskeletal impairments that alter motor control or the biomechanics of walking. Although an orthosis that restricts joint motion increases the energy cost in unimpaired individuals, the same orthosis leads to more efficient gait in those with neuromuscular impairment. Determinants of efficiency of prosthetic gait include the level and cause of the amputation. Reduction of walking speed when using an orthosis or prosthesis helps maintain oxygen consumption at close to normal levels; however, this tends to compromise overall efficiency of gait, as indicated by oxygen cost. Attention to the principles of cardiovascular conditioning—including monitoring the response to exercise so that patients are challenged appropriately—optimizes the outcomes of rehabilitation programs. Further research needs to be performed to assess the efficacy of newer materials and "smart" joints in regard to gait kinematics and energy expenditure for both orthotics and prosthetics.

3 Motor Control, Motor Learning, and Neural Plasticity in Orthotic and Prosthetic Rehabilitation

DONNA M. BOWERS, ANDREA OBERLANDER, KEVIN K. CHUI, KIMBERLY LEIGH MALIN, and MICHELLE M. LUSARDI

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Discuss the strengths, limitations, and implementation for practice of current models of motor control.
2. Compare and contrast the tenets of current motor learning theories.
3. Discuss the role of physical therapy interventions based on knowledge of motor control and motor learning in augmenting neural plasticity after brain injury.
4. Apply principles of practice conditions in the design of therapeutic interventions for individuals using orthoses or prostheses.
5. Appropriately use augmented feedback in therapeutic situations with individuals using orthoses or prostheses.
6. Describe the role of mental practice and imagery on skill acquisition for individuals using orthoses or prostheses.

Why Think About Motor Control, Motor Learning, or Neuroplastcity?

Physical therapists and colleagues in rehabilitation help individuals with movement dysfunction improve or adapt their ways of moving so that they are safe, efficient, and satisfied with their level of function in the activities they consider important for their quality of life.[1] Many different impairments in body structure, including physiologic structures and multiple systems, might lead to ineffective movement, atypical patterns of movement, or lack of movement. These movement problems interfere with an individual's performance of relevant activities and self-selected participation endeavors.[2,3]

Several underlying principles influence current thinking about how people move.[4] The first is that *movement is goal directed*. Individuals move in order to accomplish a task or activity that they want to do during self-care or other activities of daily living (ADLs), as part of their work role, or during leisure activities.[5] The second is that there are *many different ways to accomplish any task*: the central nervous system (CNS) organizes muscles and bodies using available physiologic resources in the context of the environment to accomplish any given task; there is no single "best" way of moving.[6–8] The third is that *each person develops preferential ways of moving:* although there are many possible movement strategies available, people tend to move in ways that are most efficient for their own individual physical characteristics.[9] Preferential movement patterns, however, are not always optimal. Repetitive motion injuries, for example, may be the result of preferential movement patterns that are not biomechanically effective, stressing tissues until inflammation or permanent deformation occurs.[10] The fourth is that people move when they have self-efficacy regarding their movment. Self-efficacy stems from competence with movement (capability) plus confidence in performing such movement.[11] Finally, evidence suggests that appropriate interventions *drive neural plasticity* and enhance recovery following insult to the CNS.

When there are impairments of musculoskeletal, neuromuscular, or cardiopulmonary systems, the resources that an individual can bring to movement may be altered, limited, or constrained.[12] Because movement is goal directed, an individual with impairments will find a way to accomplish movement goals that "work," often using a less effective or abnormal movement strategy. These altered strategies are recognized clinically as movement dysfunction.[13] The use of ineffective or abnormal movement patterns can, over time, lead to inflammation, tissue remodeling, or even deformity.[14] For example, in an individual recovering from stroke who is walking, an "abnormal" extensor synergy of the lower extremity may provide stance-phase stability, but it will impair swing limb advancement, leading to a compensatory circumduction or vaulting step.[15] Abnormal tone may contribute to habitual plantarflexion and eventually an equinus deformity.[16] Someone with a painful knee or back will alter the way in

which he or she uses those joints as well as the limbs or trunk when walking and moving between sitting and standing.[17–21] Over time, the individual may develop secondary musculoskeletal problems at distal or proximal joints or become physically deconditioned, compounding his or her movement dysfunction.[22,23] An individual with pain, shortness of breath, or a sense of fatigue (whether from disease or deconditioning) may choose to be less active to "conserve" energy and, as a result, become even more deconditioned, develop soft tissue tightness that impairs flexibility, and lose muscle mass, thus limiting functional strength.[24–28] Individuals who are concerned about pain, falling, or injury may also limit their physical activity and have similar decrements in physiologic capacity and resources.[29–31] Physical and occupational therapists use various types of therapeutic exercise (e.g., strengthening, endurance programs, flexibility, balance activities) as well as functional training (often with assistive devices or ambulatory aids, orthoses, and prostheses) to minimize movement dysfunction and remediate or accommodate the underlying impairments.[32] To be effective in these interventions, rehabilitation professionals must understand the principles of exercise and the effect that exercise has on the human body.[33–35] They must know both the purpose of an orthosis, prosthesis, or assistive device and how the design of the device will enhance or constrain movement and function.[36,37] If the goal of rehabilitation professionals is to help those with movement dysfunction learn more effective ways to accomplish what is important to them, they must also be aware of the process of learning, both on a cognitive and a motor level, and integrate this understanding into the interventions they plan and implement.[38]

This chapter provides an overview of recent thought on motor control using a dynamic systems perspective. The chapter also reviews the tenets of motor learning and considers practice, augmented feedback, and mental imagery as tools to assist development of new or adapted movement skills. The chapter also considers how physical therapy intervention, founded on knowledge of motor control and motor learning, can augment neural plasticity and recovery after brain injury. The case examples at the end of the chapter are designed to help readers integrate a growing understanding of the principles of motor control and motor learning into the planning of interventions for movement dysfunction.

Theories of Motor Control

Human movement has traditionally been examined from two distinct fields of study: a neurophysiologic control approach and a motor behavioral approach.[4,39–42] The traditional neurophysiologic approach explained movement within a hierarchic system of control on the basis of the development of neural mechanisms within the central and peripheral nervous systems and the interaction of sensory and motor systems. The motor behavioral approach examined movement performance from the perspectives largely from the field of psychology. Only in the past few decades have the two fields of study interfaced to bring about newer theories regarding human movement that more fully explain human movement and performance.[4,42–44] Recently there has been an increasing emphasis on the use of therapeutic intervention as a means of driving neural plasticity as a mechanism of recovery following brain injury.[11,45–48]

The motor behavioral approach and neurophysiologic control approach are further interfaced in the study of functional movement disorder (FMD). Contemporary literature highlights an emerging understanding of the neurobiology of FMD and the importance of developing behavioral models to address abnormal motor control patterns that are atypical of known organic disease processes.[49,50] It is thought that abnormalities in attention, personal agency, and beliefs and expectations about symptoms contribute to the manifestation of abnormal movement based on emotional triggers from prior traumatic events.[50,51] Findings suggest that targeted motor reprogramming using a coordinated interdisciplinary approach is a promising intervention for resolution of this disorder.[49,52] Especially important is interdisciplinary collaboration between neurology, rehabilitation services, and psychiatry. Recent research in psychology emphasizes the likelihood of missing relevant stressors in the absence of a thorough psychiatric evaluation,[53] and although the presence of stressful life events may not be a factor with all patients, it can be an important target of interdisciplinary treatment when it is present.[54] This developing body of research using integrated models from the fields of psychology and physiology advances our understanding of motor control and motor learning. The importance of these findings is highlighted in consideration of complex presentations, including traumatic events, which often accompany traumatic brain injury, spinal cord injury, and limb amputations.

DYNAMIC SYSTEMS PERSPECTIVES

Rehabilitation professionals think about the human body as a complex biologic system with many interacting elements and subsystems (Fig. 3.1). These components have an infinite number of ways to work together in accomplishing a goal-directed motor act.[55–57] Because the human body is a dynamic, adaptive, and inherently complex set of subsystems, motor behaviors and ways of moving become more efficient with practice and experience: motor control systems can consistently generate simple and well-organized movement from a complex array of movement possibilities.[58,59] The dynamic systems perspective of motor control is founded on an understanding of the behaviors that physical systems of various types have in common: the ability to change over time, the ability to be adaptive yet have preference for habitual tendencies, and the context of interaction with the environment in which movement occurs.[44,60–62] In the human movement system, there is great "motor abundance"; each person has a wide variety of ways to accomplish an intended movement goal (i.e., solve a functional movement problem) in whatever environmental conditions or circumstances that function occurs.[63,64]

According to Bernstein's model of motor control, individuals have the capacity "to make a choice within a multitude of accessible trajectories … of a most appropriate trajectory."[65] Dynamic systems theory suggests that there are both opportunities and challenges presented by interaction of the environment and the individual's will to move.[65]

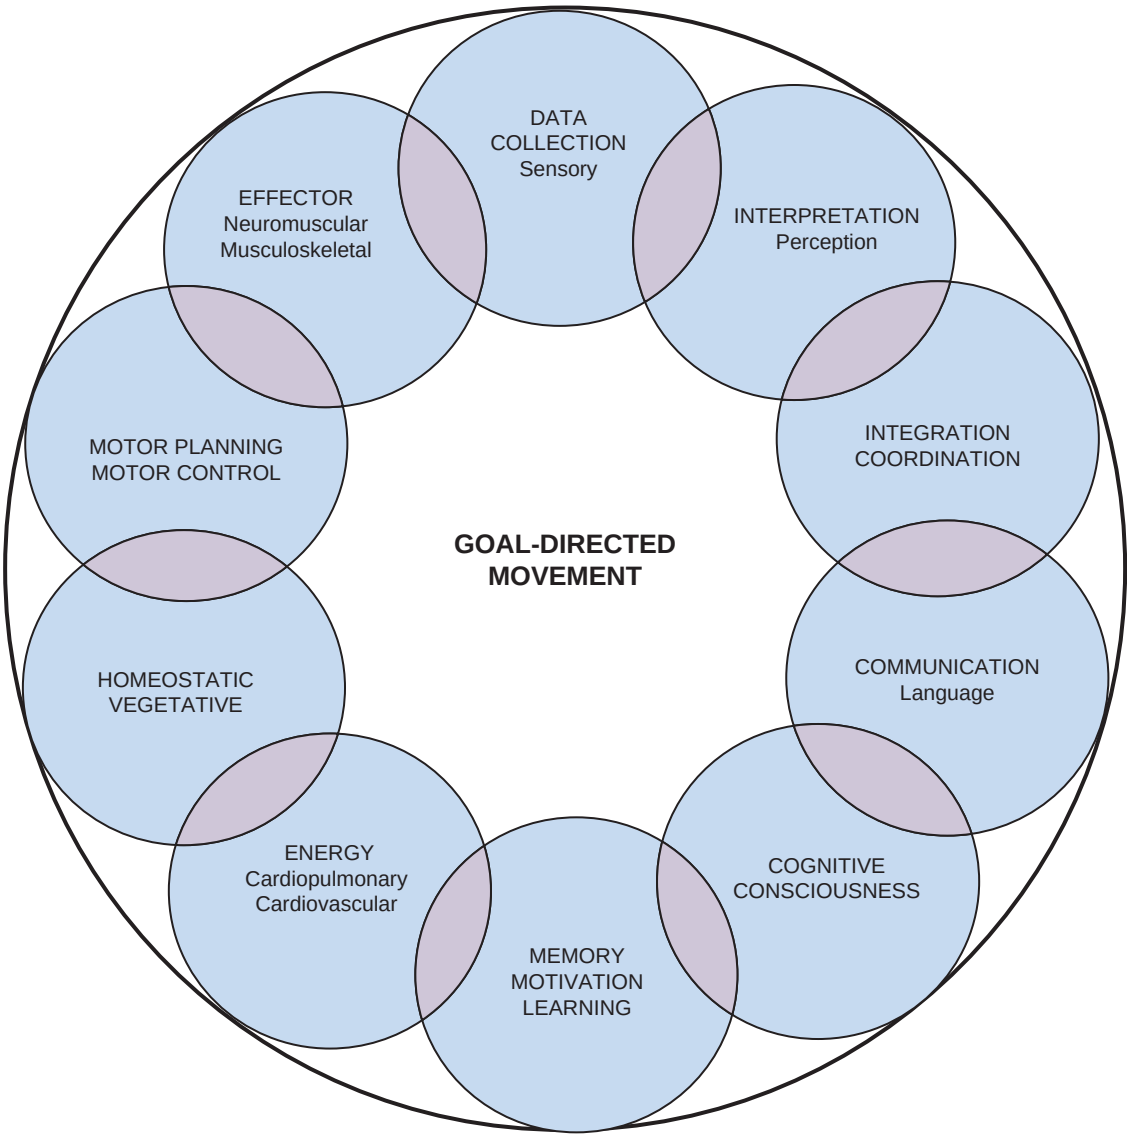

Fig. 3.1 The interactive physiologic systems of the body contribute to an individual's ability to carry out goal-directed (functional) movement. Sensory and perceptual systems contribute by monitoring the environment as well as the position and condition of the body during movement. Interpretive and integrative systems for perception work together with coordination, cognitive, memory, motivational, and planning systems to determine how a goal-directed task might be best implemented, corrected, or adapted for success (action). Homeostatic, vegetative, and energy systems anticipate physiologic demand and insure that oxygen and glucose supplies are sufficient to meet task demands. The neuromuscular system fine tunes postural control, tone, and recruitment so that the musculoskeletal system can be used effectively to accomplish the movement goal. Continuous communication and interaction among physiologic systems occur before, during, and in response to movement so that both feed-forward and feedback can instantaneously influence task performance.

Unlike systems that are purely physical, the human biologic system is a smart, special-purpose machine able to instantaneously and efficiently work to meet many parallel and serial functional demands.[66–68] In addition, biologic systems such as the human body are self-organizing[67,69]; the mutually dependent and complex processes within the body's subsystems allow this wonderfully dynamic structure to enact efficient functional movement patterns. Even though it is an inherently multidimensional biologic system, the human body prefers to be in a state of relative equilibrium.[70,71] This is likely to be the underlying reason why the gait cycle at self-selected (comfortable) walking speed tends to center around one cycle per second and why most individuals transition from walk to run, as gait speed increases, at nearly the same velocity.[72] The human body, as a smart and dynamic biologic system, is also intentional; there is a purposeful, goal-directed, and task-oriented nature in most motor behaviors.[73] The dynamic systems model defines an intention as a purposeful or desired act that influences (attracts) the human system to organize motor behavior toward the desired outcome in the context of the environment in which the movement is occurring.[74] The organism and the environment are interdependent; each is defined with respect to the other.[66,73,74] Although the characteristics of the physical environment are the focus on many studies of goal-directed movement, the social-emotional environment can also influence the emergence of goal-directed movement.[75] The combination of resources

available to the organism-environment interaction, in conjunction with the individual's intention, shapes (constrains) how task-oriented motor behavior is organized.

Motor control has been defined by Shumway-Cook and Woollacott[40] as "the ability to regulate or direct the mechanisms essential to movement." The interactive systems that provide resources that an individual uses to initiate and regulate goal-directed movement include the neurologic, musculoskeletal, sensory/perceptual, cardiorespiratory, and cardiopulmonary systems as well as the cognitive, learning, and memory systems. Human movement, or motor control, is a product of the interaction of the individual (with all of his or her subsystems), the characteristics of the environment, and the nature of the specific task or goal that the individual is involved in (Fig. 3.2). Movement, then, is goal directed and purposeful; it makes use of the innate and learned resources available to the individual and is subject to the influences of the environment in which it is performed. By considering each of these essential contributors to functional movement, rehabilitation professionals can assess potential sources of movement dysfunction, explore alternative movement strategies, and adapt or alter the task or environment to improve movement outcomes.[76,77]

Resources of the Individual

The first component to consider in this model of motor control is the individual, with his or her ability to think and reason, to sense and perceive, and to actively respond or initiate movement (Fig. 3.3). An individual's cognitive resources include the abilities to critically think and integrate concepts, organize and delay gratification, assign emotional meaning/significance to an activity or circumstance, solve problems, access and use memory, manage attention and focus (especially when engaged in concurrent tasks), and learn.[78–80] An individual's perceptual resources are the products of the ability to receive and process many different types of sensory information (i.e., data) and to integrate and interpret these data at both subcortical and cortical levels of information processing.[81–85] An individual's resources for action include the ability to plan motor function and refine motion at cortical and subcortical levels; control error through systems of the cerebellum, pyramidal, and extrapyramidal motor systems; and the neuromuscular, musculoskeletal, and cardiopulmonary/cardiovascular contributors to "effector" systems.[86–101] Perception influences motor action (feedforward movement), and action further leads to the monitoring of the movement (feedback refinement).

To illustrate how individual resources influence movement, consider two individuals who are walking to their cars after a major-league baseball game. Their pathway moves across a gravel-surfaced parking area with a slightly sloped and slightly unstable support surface. One person has the "stocking-glove" sensory and motor impairment typical of diabetic polyneuropathy. The other has consumed a few too many beers in cheering his team to victory, making his thinking and motor behavior less efficient than normal. Both are likely to exhibit less efficient postural responses and unsteady gait patterns as they return to their vehicles, but for very different reasons. The quality of the sensory data that the individual with diabetic neuropathy can collect may not be sufficient for accurate perception of environmental conditions, and, complicated by distal weakness, her patterns of movement may not meet the challenges presented by the sloped and slightly movable ground surface. The individual who is tipsy has normal data collection ability; however, the temporary impairment in cognitive function (judgment and perception) and less efficient "error control" associated with alcohol consumption lead to motor behaviors that are not matched to environmental demands. Both baseball fans may stumble, walk with a wide base of support, or reach for the support of solid objects as they make their way toward their cars, but the underlying individual contributors to this motor outcome are quite different.

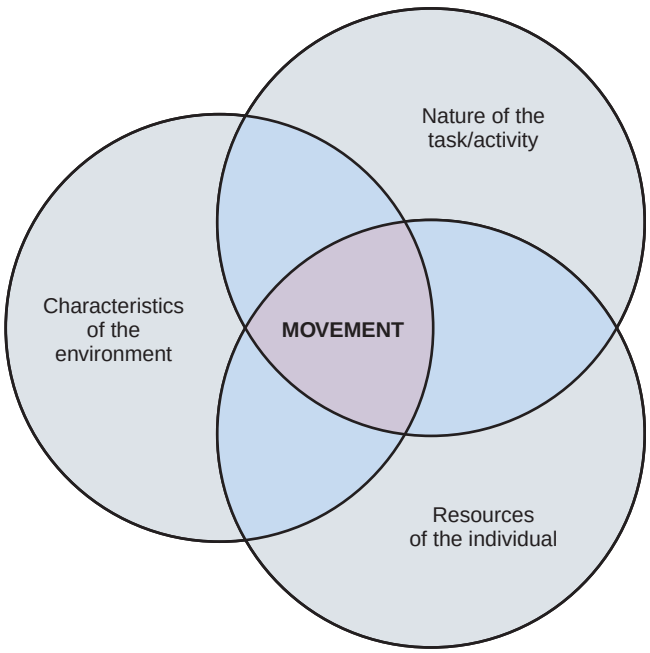

Fig. 3.2 A contemporary model of motor control: movement emerges from the interaction of the individual, the environment, and the task being attempted. Therapists must consider how the characteristics, resources, and constraints of each influence the ability to move and how each might be manipulated during intervention to enhance motor learning and effectiveness of movement.

Nature of the Task

The task is the second essential component to the overall outcome or motor behavior performed. A functional task may require an individual to organize goal-directed movement to address one or more of the following motor control goals (Fig. 3.4):

- Maintaining or adjusting antigravity posture (static, anticipatory, or reactionary postural control)[102–104]
- Transitioning from one stable position to another (quasimobility; e.g., moving from sitting to standing)[105–107]
- Moving a limb or the whole body through space (e.g., reaching, lifting, carrying, walking, stair climbing, walking on inclines, avoiding obstacles, hopping, running)[108–110]
- Using or manipulating tools appropriate to the task (e.g., assistive devices, objects needed for ADLs)[111,112]

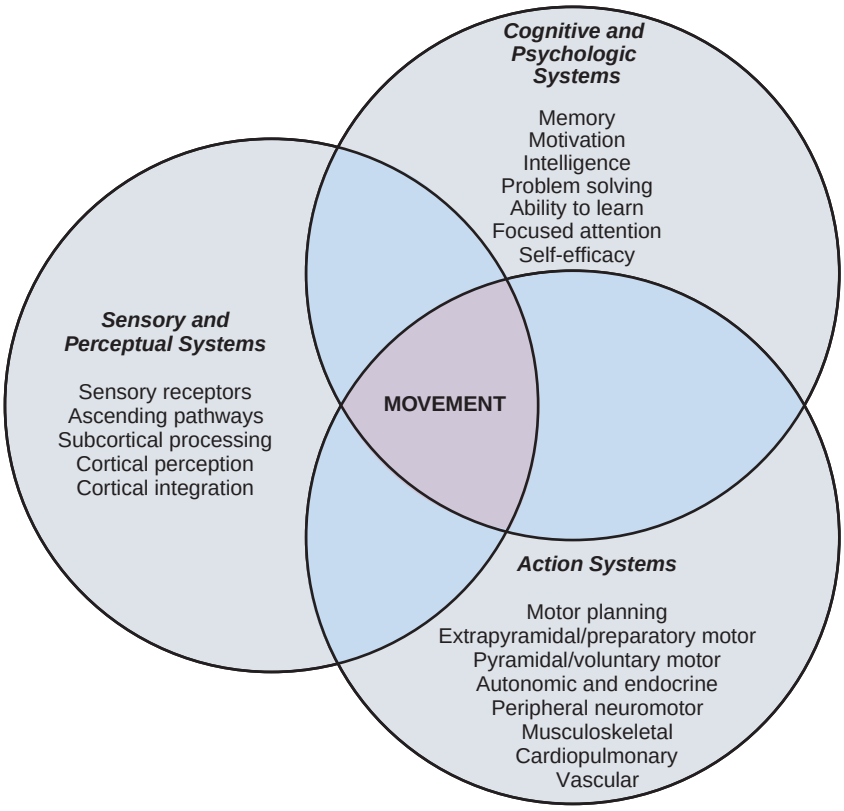

Fig. 3.3 The individual resources that contribute to movement include those in the sensory/perceptual systems, the cognitive systems, and the action systems. For persons recovering from central nervous system insult, the therapist must understand whether dysfunction in any of these systems has occurred and consider how intervention might enhance neural plasticity and recovery of function in each of these areas.

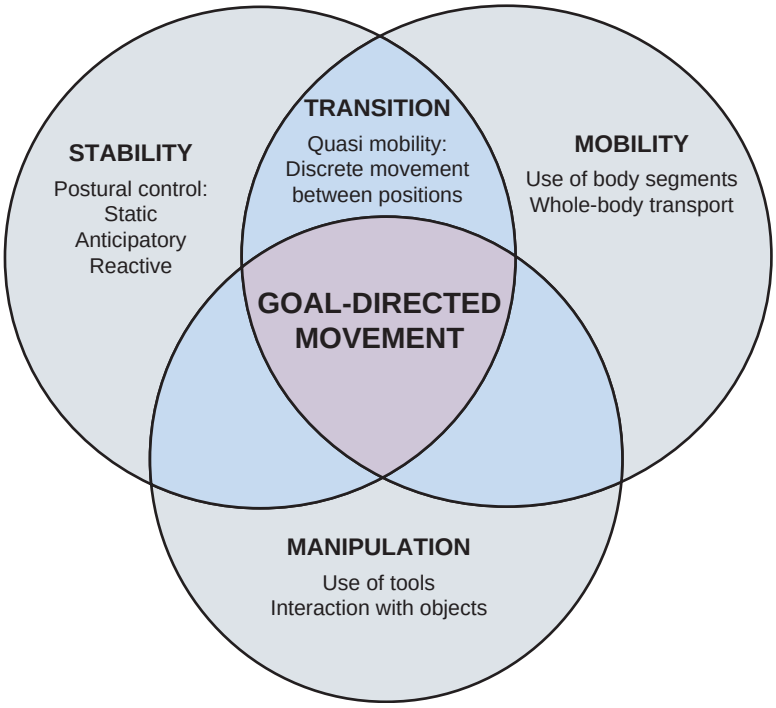

Fig. 3.4 The components or nature of the task being attempted also influence the movement that emerges. The task can include or combine goals of stability, transitions, mobility, and manipulation of tools or objects.

Any task can be described along a number of different dimensions or continua: it can have a *discrete* beginning and end point (e.g., transferring from bed to chair) or be *continuous* (e.g., walking or running over large distances). Tasks can involve *stability* or require *mobility*, occur at *various speeds*, require different levels of *accuracy* or *precision*, and demand different levels of *attention* or *focus* (Box 3.1). Repetitive and overlearned tasks performed in predictable (closed or fixed) environments are often executed on a nearly automatic level, requiring little attention; this allows the individual to focus attentional resources on other priorities.[113] Tasks occurring in a changing (dynamic or open)

Box 3.1 Descriptors of Movements Based on the Attributes/Nature of a Task

- Discrete: The beginning or end point of movement, or both, as determined by the task itself (e.g., stepping onto a curb, donning a prosthesis, catching a ball).
- Serial: An ordered sequence of discrete movements, defined by the task itself (e.g., climbing a flight of stairs).
- Continuous: The beginning and end points of the task are determined and controlled by the individual (e.g., riding a bicycle, deciding when to start or stop).
- Stability: The primary task goal is to maintain position of body segments (often against gravity or in response to perturbation) or to keep the body's center of mass within the available base of support during functional activity (e.g., to provide a secure base in sitting or standing for subsequent skilled use of extremities).
- Transitional (quasimobility): The primary task goal is to move the body from a starting position of stability to a different ending position of stability (e.g., moving from sitting to standing, rolling from supine to prone, getting up from the floor).
- Mobility: The primary task goal is to move a body part, or the entire body, through physical space (e.g., rolling over in bed, walking or running, reaching for an object on a shelf or on the floor).
- Manipulation continuum: The degree to which a task requires the individual to use (manipulate) or interact with one or more external objects in order to complete the activity successfully (e.g., fastening buttons or handling clothes during dressing, donning/doffing a prosthesis or orthosis, opening doors during mobility, locking the brakes on a wheelchair).
- Automaticity: The degree to which the task is well understood and can be carried out automatically or requires attention because of high task demand (level of preciseness, consequence of error) or the changing nature of the task or environmental conditions (e.g., threading a sewing needle, walking down an icy sloping walkway, catching a thrown object).
- Variability in performance: The degree to which an individual is able to adapt the performance of a learned task in response to differences in environmental conditions or changes in task constraints; the flexibility to apply what has been learned to similar or novel situations.

environment must be flexible or adaptable to be successful and require a higher degree of attention during performance.[114,115] Finally, the complexity of the task and the attentional requirements for effective task performance must be considered.[116]

One way to understand the nature of a task (either broken into components or as a whole) is to examine or classify the task using Gentile's Taxonomy of Movement Tasks (Fig. 3.5).[41] The first component considered in the taxonomy is the movement task's outcome goals: does the task

		BODY STABILITY		TRANSITION (Quasi-mobility)		BODY TRANSPORT	
		No object manipulation	Object manipulation	No object manipulation	Object manipulation	No object manipulation	Object manipulation
CLOSED ENVIRONMENT	No variability	Stand in prosthesis unsupported in the parallel bars in a quiet PT gym	Stand in prosthesis unsupported while putting on jacket in a quiet PT gym	Practice the sit-to-stand transition from a single chair with armrests in a quiet PT gym	Practice the sit to stand transition from the same chair while managing axillary crutches	Walk the length of the parallel bars at comfortable speed, turn around, repeat	Walk forward with crutches using a 2-point gait pattern in an empty hallway
	Trial variability	Stand in prosthesis in parallel bars with diagonal weight shifts on command	Stand in prosthesis in parallel bars catching ball from different directions and speeds	Transfer to and from wheelchair, toilet, and shower seat, moving to left and right in random order	Transfer between seating surfaces of different heights while holding a full glass of water in a quiet PT gym	Practice stepping in different directions and distances in the parallel bars	Walk up to a closed door, opening it, and walking through while using a cane
OPEN ENVIRONMENT	No variability	Remain standing upright as people walk by at regular intervals from similar directions	Retrieve an object repeatedly from the same spot on the floor in a corner of a busy PT gym	Practice moving from standing to sitting using arms in a pre-positioned chair in the cafeteria of the rehabilitation hospital	Move from standing to sitting and vice versa from a rocking chair while managing crutches	Practice ascending and descending a set of training stairs in the corner of a busy PT gym	Approach and ascend a full flight of stairs in a quiet hallway, using bilateral canes
	Trial variability	Remain upright while standing in line in a busy public area	Retrieve various randomly dropped objects throughout an active PT gym	Rise repeatedly from a seat in the movie theater so that other people (of various height and weight) can move past into the row	Scoot sideways while sitting, managing the blankets on a soft mattress so that grandchildren can climb into bed to hear a story	Ascend and descend stairs using the railing in a busy public space	Walk from car to supermarket door, pushing the grocery cart across the busy parking lot

Fig. 3.5 Examples of therapeutic activities for an individual learning to use bilateral transtibial prosthesis based on a modified version of Gentile's Taxonomy of Movement Tasks. *PT*, Physical therapy;

primarily focus on stability of the body, on transition between stable positions, or on transport (movement) of the body through space? As an example of a body stability task, consider the ability of an individual learning to use a transfemoral prosthesis to control hip and pelvic position while in single-limb stance on the prosthetic side, while slowly lifting the "intact" limb to place it on a stool or step placed in front of him or her. A transitional (quasimobile) task for this person might be practicing moving between sitting and standing position from various seating surfaces or heights.[4] A body mobility task for the same individual might be to learn to use a cadence-responsive prosthetic knee unit by altering gait speed, changing direction, or navigating through a crowded public space.

The next consideration is whether the task involves use of, or interaction with, a tool or object (i.e., is object manipulation part of the task?). In working with persons with spinal cord injuries to develop postural control in sitting, for example, therapists often use catching and throwing activities with balloons and balls of various weights, thrown at different speeds and in varying directions, to provide opportunity to master this body stability skill.[117–119] Managing assistive devices (e.g., cane, crutches) during transfers or operating orthotic knee locks or prosthetic knee units during transfers are examples of object manipulation during transitional motor tasks. Learning to use an ambulatory assistive device (e.g., crutch walking in a four-point reciprocal pattern; managing crutches when ascending or descending stairs) is a prime example of a body mobility task that requires object manipulation.[120,121]

Characteristics of the Environment

The final component of the Shumway-Cook and Woollacott model of motor control is the setting, environmental context, or conditions in which the goal-directed movement takes place (Fig. 3.6). The physical therapist must examine

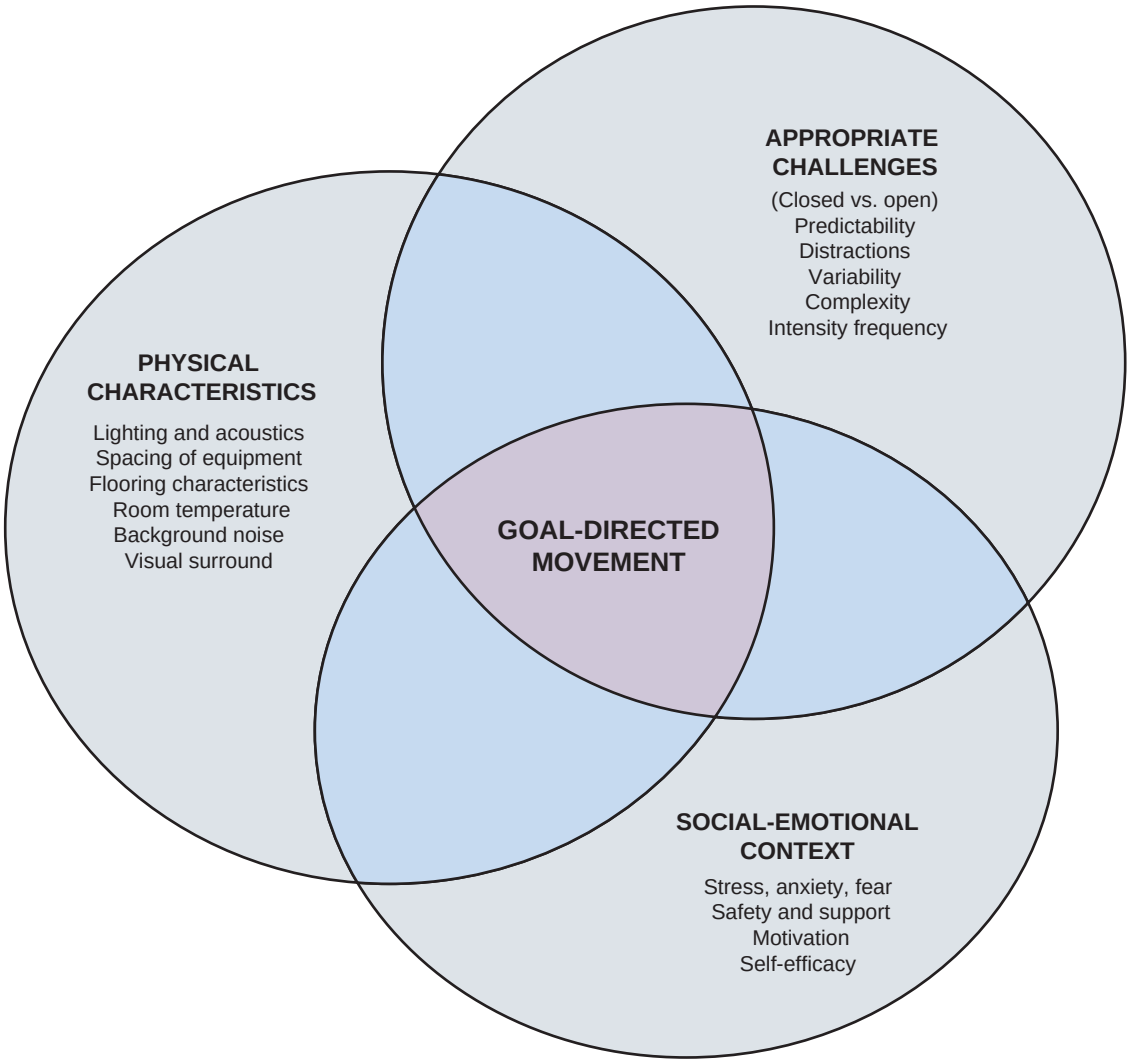

Fig. 3.6 In considering the influence of the environment on motor performance, the therapist must understand the challenges that it presents, the social-emotional context that might influence the individual's ability to move, and the physical characteristics of the movement space that affect the individual's safety and ability to move. Therapists often manipulate the social-emotional context by providing physical support and encouragement to create a situation where it is safe for the individual to attempt difficult movements and to risk failure (error) as part of the motor learning process. (From Shumway-Cook A, Woollacott MH, eds. *Motor control: translating research into clinical practice*. 4th ed. Philadelphia: Wolters Kluwer Lippincott Williams & Wilkins; 2012:84.)

(and, during intervention, purposefully manipulate) the environmental context in which functional movement occurs. Is the physical environment comfortable to be in while taking part in exercise and other rehabilitation interventions? Is it visually interesting and stimulating but not too distracting or challenging? Is the motor task occurring in an environment that is predictable (i.e., in a closed environment), or is there a degree of variability and possibility of change external to the individual (i.e., an open environment) that will require the individual to monitor and respond more carefully while performing the task?[122–124] Therapists must also consider the social-emotional context of the environment that is rooted in the interpersonal interaction: will the individual feel supported and encouraged as he takes risks and makes errors as part of the development of skill in salient activities? Or does the emotional environment contribute to anxiety about receiving negative criticism or a fear of failure?[125,126]

For the therapeutic application of environmental variables, therapists can consider both macroenvironmental influences (e.g., actual physical conditions that influence task demand, the therapeutic setting, or the involvement of family members) and microenvironmental influences (e.g., the level of visual and auditory "noise" present in the therapy room or variations in surfaces over which a client may be sitting or walking). Mastery of a motor task within a single, simple environment does not directly translate into safe performance of the same task under more complex and demanding environmental conditions. Navigating up and down a set of training steps in the physical therapy gym does not mean that the individual with stroke or paraplegic-level spinal cord injury will be functional and safe on a wet, leaf-covered, uneven brick staircase (with no railings) when entering or leaving his best friend's house or favorite neighborhood hangout.[127,128]

When they are working with persons with acquired brain injury functioning at the Rancho Los Amigos cognitive continuum of 4 (confused and agitated), 5 (confused inappropriate), or 6 (confused appropriate), therapists must provide a structured and predictable environment for functional and rehabilitative activities so that the demands of the environment do not exceed the individual's ability to monitor and respond to the challenges that the environment presents.[129–131] A complex environment can be overwhelming to the individual recovering from brain injury; the structured environment provides opportunity to complete key tasks with minimal frustration and behavioral complications. However, the complexity of the environment must be gradually increased as the individual prepares for discharge. Being able to cross the street safely at a crosswalk with real traffic is a more complex task than managing curbs and walking over a distance in the rehabilitation gym.

Gentile's taxonomy provides an organizational strategy for intervention planning by rehabilitation professions working with individuals with musculoskeletal or neuromuscular impairments and limitations in performing functional activities. The primary goal of a man who has had a recent stroke may be to climb stairs so that he can return to his home, where the bedroom and bathroom are upstairs. In the early stages of rehabilitation, it may be necessary to first concentrate on static postural control and controlled weight shifting in sitting and standing on a firm support surface (body stability, no object manipulation, predictable environment). As the quality and control of these motor tasks become more consistent, intervention expands to include ambulation in the parallel bars (body mobility, no object manipulation, unvarying environment), then with an assistive device in a quiet hallway (body mobility, object manipulation, predictable environment), and finally in a busy rehabilitation gym in which the individual must anticipate and react to others in the environment (body mobility, object manipulation, changing environment). As postural control becomes more efficient on level surfaces, task demand is increased by increasing speed or attempting more challenging surfaces such as stairs, inclines, and stepping over obstacles; this may initially occur in a relatively predictable environment but must eventually occur in an "open" situation in which the individual must dynamically react to or navigate around other persons and objects.

SKILL ACQUISITION MODELS

Movement has also been examined from the behavioral perspective, with a focus on quality of motor performance and acquisition of relatively permanent skilled behavior. Researchers with this perspective are interested in the influence of cognitive information processing and cognitive psychology on motor behavior. They concentrate on the acquisition of skills, the learning processes associated with skills, the relatively permanent changes in skills (retention), and the refinement process of skills across applications. Early on, studies of skill acquisition focused on orientation to the task; as the field developed and expanded, focus shifted toward understanding the process of skill development. This led to formulation of the concepts of motor memory and schema. Adams's theory of feedback-based learning was a catalyst for later research, which gave rise to Schmidt's schema theory for motor learning.

Current motor learning theory has become a blend of the various bodies of study presented in this section, integrating neurophysiologic, dynamic systems/ecologic, and behavioral models. This shared interest gave rise to the study of motor learning, which is concerned with the adaptation and application of movement strategies to altered or novel functional, behavioral, and environmental contexts.

Theories of Motor Learning

Although models of motor control focus on how the biologic system organizes and adapts movement as it occurs, models of motor learning consider how the individual comes to understand and consistently perform a particular behavioral task. The outcome of effective motor learning is mastery of skilled behaviors so that the individual can function appropriately in his or her physical and social environment. Most models of motor learning are founded on four distinct notions about learning:

1. Motor learning is a dynamic process that leads to acquisition of ability for skilled actions.
2. In order for motor learning to occur, there must be an opportunity to practice and build experience. Making

errors is a necessary part of the learning process; as learning occurs, motor memories are established.
3. Motor learning itself cannot be observed directly; it is inferred by observing changes in motor behavior that become consistent over time.
4. Learning produces sustainable, relatively permanent changes in the capacity for skilled behavior by building motor memory; as a result, what has been learned can be applied or adapted when altered task or environmental constraints occur.

To effectively master a novel motor task or remaster a previously learned motor task with altered motor function from disease or injury, the individual must have the following[11,60,132]:

- Focused attention to develop sensory and perceptual strategies for collecting information relevant to the task and the environment in which it is occurring
- Active problem solving to understand key features of the task, the performance environment, and any tools required to complete the task successfully
- Motor ability to activate the components of the motor control system (anticipatory, guiding, corrective, and reactive) necessary for skillful performance of the task
- Self-efficacy to apply (transfer) knowledge of the task, environment, and tools to perform skilled movement in situations that are different from the one in which learning took place.

Rehabilitation professionals must be careful to distinguish between the concepts of motor learning and motor performance. *Motor performance* is the observable action or behavior that can be measured (rated) qualitatively or quantitatively by an observer.[42] It is a temporary execution of a motor task at a specific point in time when being measured.[11] As health care professionals who focus on function, therapists are quite skilled at examining motor performance and determining whether an individual is moving effectively and efficiently or is coping with some form of movement dysfunction. Physical therapists use both subjective ratings (e.g., ratings of perceived exertion; using the terms "poor, fair, good, normal/excellent" to describe static postural control, dynamic balance ability, or endurance) and objective performance-based scales and measures (e.g., self-selected and fast walking speeds, Timed Up and Go times, Functional Reach distances, Dynamic Gait Index scores, 6-minute walk test distance, Gross Motor Functional Measure scores, among many others).[133–139]

In contrast, *motor learning* refers to the process that leads to relatively permanent changes in the quality, consistency, and efficiency of motor performance of a given individual. This process is not easily measured except by considering consistency or how other dimensions of performance of the task change over time. Comparisons of baseline performance to postintervention performance indicate changes in quality of performance. Although motor performance tends to transiently improve after a single practice session, we cannot be confident that learning has occurred until performance becomes consistent after multiple sessions over a period of time.[140,141] Improvement in motor performance to a level of consistency implies that effective motor learning has occurred; motor learning has occurred when the task is sustainable, long-lasting, and adaptable to situational demand.[11]

EVOLUTION OF MODELS OF MOTOR LEARNING

Initial models of motor learning were published in the early 1970s, the most prominent being Adams's closed-loop theory and Schmidt's schema theory.[142,143] Both models assume that, as a result of the motor learning process, the brain develops *generalized motor programs:* rules for timing and sequencing of muscle activity for key tasks.[140] The closed-loop theory proposes that sensory information generated from movements occurring during performance of functional tasks provides *feedback* necessary to build the memory and perceptual traces that guide and refine subsequent performance of the task.[142] In contrast, schema theory suggests that an open-loop process occurs in which a general set of rules for a particular movement is developed (motor recall and sensory recognition schema) over time. Such schemas allow the individual to continuously compare actual outcomes of movement with anticipated (feedforward)/predicted outcomes via error detection and correction mechanisms.[143,144] According to schema models, variability of practice must occur to establish and strengthen the movement schema over time.[144,146]

In the 1990s, Newell proposed an alternative ecologic model of motor learning (resonant with Bernstein's dynamic systems model of motor control), which suggests that individuals use a problem-solving approach to discover the optimal strategy to produce the task (performance) given both environmental and task influences.[147,148] By exploring the *perceptual motor work space* during practice, individuals begin to recognize salient sensory/perceptual cues as they explore movement options that might lead to successful task completion. In viewing a demonstration, perceptual information helps the learner better understand the nature of the task and task-related movements that need to be mastered. Perception during (knowledge of performance [KP]) and perception after (knowledge of results [KR]) task-related movement provides intrinsic feedback that assists the problem-solving process in the development of optimal strategies for the task at hand. Therapists can provide augmented information (explicit cues and extrinsic feedback) to facilitate an individual's search for optimal strategies. In this way, the perception (salient cues about the task and the environment) and action (adaptive motor performance of the task.) are linked so that task-relevant connection is established.[149]

Recent evidence (2014) suggests the need for active participation and task relevancy to the learning process. Winstein and colleagues[11] described the necessity of both psychologic elements and motor capabilities for motor learning to occur. A person must possess sufficient voluntary neuromotor capability and relevant motivation to acquire the motor skill. Both of these elements lead to active participation in the acquisition of the skill (motor learning process). Motivation is a complex behavior that involves feelings of self-efficacy (competency plus confidence), social relatedness, and autonomy. This motivation is influenced by a person's sense of involvement, which includes control, choice, and collaboration in the selection of the task activity. This will be further explained in the section on feedback.

TEMPORAL CONSIDERATIONS

Motor learning has also been explained through a temporal perspective in which learning occurs in stages over time. Various three- and two-stage models have been proposed to describe the process of acquisition of a skill and of adaptability or generalization/transfer of the skill (Table 3.1).

Three-stage models generally describe the earliest stage as the discovery stage, in which an understanding of the nature of a task is developed through trial and error, sometimes with guidance.[62,136,145–153] In this initial stage of motor learning, the need for attention is high, and there is significant trial and error–related variability in task performance early on with an eventual understanding or selection of the best plan for the task for that individual. The variability of task performance at this stage is unwanted and undesirable. Once a plan has been settled on, the second stage of motor learning focuses on refinement of the performance; variability and error during performance decreases while efficiency of performance increases, but attention is still required and distraction is often problematic, interfering with performance.[149] In the third and final stage of motor learning, the individual can generalize or adapt the learned skill to changing environmental demands; performance variability is now desired, such that the task can be performed effectively in different ways to meet changing environmental demands.

Building on the work of Lereijken and colleagues, Shumway-Cook and Woollacott describe a system-oriented three-stage model, integrating principles of dynamic systems motor control, human development, and the ecologic model of motor learning.[140,153] Early in motor learning, individuals constrain (freeze) the degrees of freedom among limb segments (joints) involved in the task as a means of reducing task difficulty; this freezing co-contraction around joints results in

Table 3.1 Comparison of Concepts in the Major Models of Motor Learning

Models	Descriptive Stages/Movement Characteristics
THREE-STAGE MODELS	
Fitts and Posner[151]	COGNITIVE
Early skill acquisition through trial and error; high undesirable variability to find most effective strategy for task	ASSOCIATIVE
Refinement of skill; performance less variable and more efficient	AUTONOMOUS
Low attention necessary for task; transfer or adapting skill to other environments; performance of skill during multiple task demands; desired variability	
Vereijken, Whiting, and Beek[62]	NOVICE
Discovery of task constraints; restriction of degrees of freedom to simplify task	ADVANCED
Release of some degrees of freedom to coordinate movement; adaptation of tasks to environmental demands	EXPERT
All degrees of freedom released; exploitation of mechanical forces to complement environmental forces	
Larin[153]	
(Refers to children)	DISCOVERY
Verbal-cognitive stage; physical and verbal guidance necessary	INTERMEDIATE
Motor stage; independent performance, greater consistency	AUTONOMOUS
Skilled performance; economy of effort; task adaptable to environment	
Shumway-Cook, Woollacott Systems Model[140]	STAGE 1
Co-contraction to constrain degrees of freedom to reduce the number of body segments or joints to be controlled during movement, undesired variability	STAGE 2
Gradual release of degrees of freedom of limb segments results in gradual increase in control and flexibility of the body during movement	STAGE 3
Mastery of the skilled movement with automaticity and desired variability during performance, allowing adaptation and transfer of skill in response to changing conditions/demands	
TWO-STAGE MODELS	
Gentile[41]	EXPLICIT LEARNING
Attainment of action-goal; conscious mapping of the movement's structure; rapid stabilization of performance	IMPLICIT LEARNING
Dynamics of force generation; active and passive force components finely tuned unconsciously; gradual change in performance	
Manoel and Connolly[155]	ACQUISITION
Formulation of the action plan; understanding task and how to accomplish it; stabilization of action	ADAPTATION
Task and environment interaction; task is fluid with range of options to cope with new situations; breakdown of stable task and reorganization for new action plans	

relatively accurate movement, although the movement typically has a high energy cost.[154] As learning occurs, there is a tendency to "unfreeze" joints sequentially such that movement becomes more fluid and energy-efficient. With mastery, the individual employs freedom of movement to fluidly perform the task and can adapt to changing characteristics of the environment.[155]

Two-stage models of motor learning focus on (1) acquisition of the skill and (2) adaptation or application of the skilled motor behavior.[156] The initial phase consolidates the first two components of the three-stage models: Acquisition and refinement of performance occur within the same stage. Undesired variability of performance occurs through internal demands within the individual's attempts to find and select a preferred action/strategy before refinement. In the second stage, performance has desired variability due to external demands of the environment: The person must adapt the task accordingly; this is quite similar to the final component of each of the three-stage models.[157]

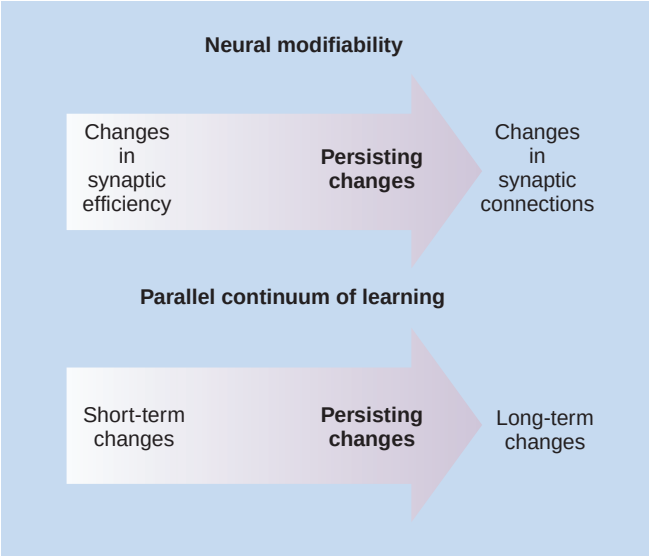

Fig. 3.7 The gradual shift from short-term (acquisition) to long-term (retention) learning and memory is reflected in a move along the continuum of neural modifiability. Short-term changes, associated with an increased synaptic efficiency, persist and gradually give way to structural changes, the underpinnings of long-term learning.

IMPLICIT AND EXPLICIT ASPECTS OF MOTOR LEARNING

To understand the process of motor learning, it is important to consider the principles underlying all learning processes: how new information is translated into memory to become useful. One can think about learning as the process of acquiring new information and new skills; memory then is the product or outcome of the learning process.[158] Learning is one of the major drivers of plasticity within the CNS, stimulating formation of new synapses as well as refinement of existing neural connections throughout the brain.[159,160] This plasticity is evident as information is moved from our short-term (working) memory into initial long-term memory stores, which become better established and more resistant to disruption with practice and experience (Fig. 3.7).[161]

Learning theorists describe two major categories of learning: implicit (nondeclarative) and explicit (declarative) learning (Fig. 3.8).[162] Both categories lead to functional and physiologic changes in synapses of involved areas of the spinal cord, brain stem, and forebrain.[163] One aspect of motor learning falls into the category of implicit procedural learning: it requires trial and error (discovery) in a relevant and functional context.[163] Focused attention is an important requirement during this discovery stage.[11] Consistently improved task performance over time and situation provide evidence of effective procedural learning. Neural structures thought to be necessary for implicit procedural learning include cortex of the frontal and parietal lobes, nuclei of the basal ganglia, and cerebellar cortex and nuclei.[163–166] Recent work has also identified that the hippocampus is involved in perceptual components of procedural learning.[167] Explicit (declarative) learning is founded on attention and conscious thought and can be described or demonstrated by the learner.[168] Neural structures involved with explicit learning include the prefrontal cortex, cingulate gyrus (limbic system), head of the caudate

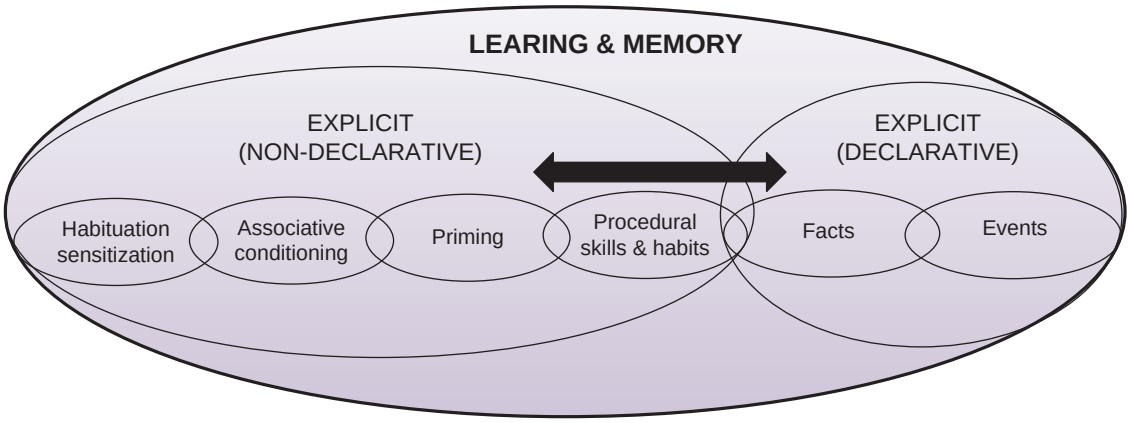

Fig. 3.8 Learning is the process of acquiring information or skill while memory is the product of the learning process. Traditionally, the learning process has been described as having two separate domains: explicit (or declarative) learning, which is primarily involved in acquisition of knowledge about facts and events, and implicit or nondeclarative learning. Much of motor learning falls into the category of procedural implicit learning, or the mastery of skills and habits. Recent research evidence using functional magnetic resonance imaging suggests that there are interactions between explicit and implicit processes *(arrow)* regardless of whether the focus is on fact or movement.

Box 3.2 Summary of the Dimensions or Characteristics of Practice

- Contextual interference: The work of keeping many options available in working memory over time when involved in discovering solutions to movement problems during the acquisition of skill in motor learning.
- Blocked: A single motor behavior (task) is repeated multiple times in unchanging environmental conditions. Performance improves within the practice session, but less than optimal retention across sessions.
- Random (variable): Practice of the targeted motor task is interspersed or embedded within trials of different motor behaviors. Although performance in a single practice session is less consistent, there is better retention of skills across practice sessions and environmental conditions.
- Serial: A series of separate (related or unrelated) tasks is performed in the same sequence for multiple trials.
- Massed: Time for active practice exceeds rest time between trials.
- Distributed: Time for active practice is less than rest time between trials.
- Part task training: Each component of a motor behavior is practiced separately; this assists accuracy or efficiency of performance of the single-task component.
- Whole task training: The entire motor behavior is practiced as a single task. Enhances the individual's ability to solve problems and adapt task performance across practice sessions and differing environmental conditions.

nucleus, medial temporal lobes, and hippocampus.[169] The hippocampus plays a key role in motor learning because it contains a cognitive-spatial map of the typical areas in which humans function.[174] Early motor learning is strengthened, as evidenced by changes in output of the primary motor cortex, when explicit learning of sequences is associated with implicit learning.[170–172]

Once sequential aspects of the task are well understood, the need to pay close attention during motor performance diminishes, and the skill becomes less effortful as it transitions toward automaticity.[173] As automaticity increases, the ability to attend to simultaneous tasks also increases.[174,175] There is growing evidence that the transition from early motor learning of complex, sequentially organized tasks to automaticity requires more time and practice as a person ages.[176–179] Encouragement and feedback that focus on building perceptions of capability (self-efficacy) with respect to better performance than that of peers appears to enhance motor learning in both young and older adults.[180,181] Recently the critical addition of support for the psychologic needs of the learner has been shown to be an important element of the motor learning process. A person's sustained behavioral commitment to learning the skill leads to competence, which leads to self-efficacy and ultimately to retention.[11]

ROLE OF AEROBIC EXERCISE IN MOTOR LEARNING

Recent evidence suggests that aerobic exercise and possibly resistance training play key roles in the motor learning of individuals who have had a stroke. Aerobic exercise leads to upregulation of the protein called "brain-derived neurotrophic factor (BDNF)," which is involved in neuroprotection, neurogenesis, and neuroplasticity.[44] It has been suggested that BDNF is felt to influence the CNS by improving its capability for motor learning. Two different effects on the CNS and motor learning were described in relation to aerobic exercise: (1) Exercise that happens immediately prior to motor task practice assists with improved detection and encoding of information relevant to the motor task and (2) exercise that happens immediately following motor task practice strengthens the motor memory process.[46]

Key motor learning concepts that are employed by physical therapists working with individuals new to prosthetic or orthotic use include *practice* conditions and schedule; appropriate level of *challenge*; the role of *motivation* and *self-efficacy*; the role of *variability, contextual interference,* and *feedback* on skill acquisition; development of *automaticity* of performance; as well as *retention* and *transfer* of the newly learned motor skill (Box 3.2).[136,140] Each is discussed in the following section.

The Importance of Practice

Common to all models of motor learning is the concept of practice. Motor learning cannot occur unless the individual has an opportunity to gain experience through repeated attempts (both successful and unsuccessful) at accomplishing the desired movement task.[182] Much of the research literature in the area of motor learning is devoted to the exploration of practice and the optimal conditions or configurations in which it occurs. Conditions of practice can be classified or designed in several different ways. The type of practice used can influence the efficacy of motor learning that occurs as well as its carryover or generalizability to similar tasks or environmental conditions.

APPROPRIATE LEVEL OF CHALLENGE

Therapists have long understood that finding the optimal level of challenge for a patient is crucial to rehabilitation. Such challenge includes choosing the correct intensity of practice (labor) that will keep a patient engaged and motivated and the correct frequency of repetitions to drive neuroplastic changes in the CNS. Appropriate intensity of challenge allows a patient to work hard during the task without compromising the patient's physical or psychologic health status. A task that is too easy will not drive the physiologic conditioning that leads to neurocognitive changes for motor learning. Conversely, a task that is too difficult can lead to risk of potential harm or injury. A high frequency of repetitions in practice is necessary for neuroplasticity.[183] Research suggests that the neuroplasticity necessary for motor learning requires a range of several hundred to thousands of repetitions. Yet therapeutic sessions often fall well short of that mark. With the intent of bridging this practice gap, telehealth modalities are currently under investigation for stroke rehabilitation. Gaming, avatars, wearable sensors, and remote monitoring and feedback are being studied with an eye on increasing

intervention intensity and patient compliance for improved functional outcomes. This line of research is relatively new, however, and there is currently no strong evidence as to the effectiveness of telehealth for stroke rehabilitation in terms of functional outcomes or cost.[184,185] To choose an appropriate and optimal level of challenge for a patient, a therapist must consider several factors including but not limited to the patient's physiologic conditioning, motor capabilities to meet the challenge, constraints on both patient and therapist time imposed by the health care setting, and evidence-based findings regarding frequency and intensity.

MOTIVATION AND SELF-EFFICACY

Relevancy and meaningfulness of a task are critical for motor learning. Choice of a task for practice must include consideration of the person's desire to change. A task that is not meaningful can lead to disengagement and lack of motivation on the part of the person performing the task. Effective practice occurs only when tasks are meaningful to the patient and the challenge of the task is optimal for learning.[11] Sustained practice leads to increased capability for performing the task; increased capability leads to confidence in performing the task; and the combination of capability (skill) and confidence leads to self-efficacy in acquisition of a new skill. Self-efficacy with a skill is necessary to sustain the use of that skill long enough for a person to get to the late stages of motor learning in which the skill can be adapted as needed for function.

VARIABILITY

In a complex and variable world, there are innumerable ways to respond to challenges that are encountered. Over the life span, typically developing individuals explore many movement options to accomplish salient task goals, developing a set of action plans that demonstrate both automaticity in performance and adaptability to variations in task or environmental constraints (i.e., the mastery of bipedal locomotion, over different surfaces, at various speeds, in closed versus open environments).[186,187] Discovery learning and the feedback/feedforward provided by error during repeated practice across conditions with differing constraints allow the individual to develop an understanding (perception) of the common elements of the task wherever and whenever it is performed.[182,188,189] This perception provides the flexibility to select from a range of task-specific options and to adapt movement in response to variations encountered in daily life; variability in skilled movement is an adaptive resource responsive to variation in environmental demands.[190]

The movement patterns of individuals with neurologic or neuromuscular dysfunction, however, often demonstrate hyper- or hypovariability.[187,191] Too much or too little variability is problematic: perception of the nature of the task and of interaction between task and environment may be limited or altered, and acquisition of skill may be challenged by the constraints associated with altered muscle performance and motor control.[192–194] Functionally, this contributes to a reduced ability to adapt (vary) performance in response to changing environmental conditions. The rigidity characteristic of Parkinson disease, for example, creates "super stability" of the trunk and extremities, which interferes with mobility (locomotion) and postural control when task conditions change (i.e., the need to increase speed, walk through doorways, or to walk on inclines).[192,195] In persons with stroke, impaired ability to move the involved upper extremity has been found to be accompanied by difficulty recognizing action of the corresponding limb when observing others or a computer model.[196] In persons with right hemispheric stroke, impairments of attention and perception challenge the ability to develop the set of task-specific movement options necessary for adaptive function in response to variations in environment and context.[197,198] Although implicit motor learning can be successful after a stroke, movement during acquisition stages is often slower and more variable in both blocked and random practice conditions.[199] Variability in movement is also altered in children with hypertonic and dyskinetic cerebral palsy and in those with developmental coordination disorder.[190,193,200]

In rehabilitation, therapists set up opportunities for discovery motor learning for their patients; these opportunities are designed to enhance the likelihood of discovering, from among all possible movement options, the set of movements most likely to result in successful task performance.[186,187] This is accomplished by manipulating the environmental and task constraints in relevant and meaningful ways to actively engage the individual in iterations of the task with the goal of promoting both perceptual understanding and a usable set of action options for completing the task.[186,201,202]

PRACTICE CONDITIONS: BLOCKED, RANDOM, OR SERIAL?

One way to describe practice is by whether it occurs in a blocked or random sequence. *Blocked practice* (also known as constant practice) is characterized by separate but subsequent repeated trials of the same task.[140,182] For blocked practice, the task is repeated under consistent environmental conditions. Modified blocked practice involves repeating the motor task three or more times in one condition before altering conditions or context in which practice of the same task is repeated. During blocked practice, the individual concentrates on performance of a single task; this focus reduces overall demand on working memory. As a result, quality of performance tends to improve substantially over successive bouts of blocked practice. In healthy adults, acquisition of skill appears to be effective (performance becomes more accurate over a single practice session) with blocked practice; however, retention of the skill over time and transfer of the skill to differing conditions is not as strong.[203] Blocked practice appears to have a positive impact on retention of skill for children younger than 10 years of age; this is thought to be a function of the emergence of information processing ability in late childhood and early adolescence.[204,205]

For the individual with transfemoral amputation working on stance control on the prosthetic limb, a blocked practice session might include stepping up onto a stool with the intact limb for 10 trials (repetitions) while standing in the parallel bars. The level of difficulty of the activity could be advanced by setting up an additional practice session, asking the individual to perform a similar task while supporting

himself or herself with a straight cane to a practice curb or to step outside the parallel bars. Theoretically, practice in the parallel bars would provide a model to use when performing a similar activity outside the parallel bars.

Random practice (also described as variable practice) is characterized as practicing a set of tasks in which order and perhaps difficulty of tasks varies across bouts of practice.[141,182] Because of the variation encountered during random practice, there is less improvement of performance in a given practice session (compared with blocked practice); however, there is greater retention of what has been learned over time. Theoretically, random practice creates *contextual interference* (the work of keeping many options available in working memory over time) that actually enhances learning and mastery over time despite poorer immediate performance.[182,203] Although this may be counterintuitive, the efficacy of contextual interference on mastery of complex movement tasks is well supported.[206–210] One of the proposed mechanisms for enhanced retention in random practice is increased attentional demand, which results in better use of perceptual understanding to prepare for movement.[208,210] The degree of similarity of tasks (distraction) undertaken during a practice session can also be a source of contextual interference; greater attention is required to discriminate between tasks with similar but distinct characteristics.[209] The improvement of retention occurs even when the context or characteristics of the task are somewhat altered; thus random variable practice may enhance the transfer of learning.[182]

To practice the primary task of stance-phase stability using a random practice order, the individual with a transfemoral prosthesis would be involved in an ongoing session of gait training. As this person walked the length of the parallel bars (or across the gym), he or she might be asked to step up onto a stool or over an obstacle at a different point in the walk and to change direction or speed on randomly delivered commands. The walk itself might be repeated 10 times (practice trials), with a step up onto or over the stool and changing speed and direction at a different point in each of the 10 trials of walking. These trials of stepping up or over and altering speed and direction do not occur sequentially but instead are interspersed throughout the entire ambulation event.

A third practice condition called *serial practice* can be thought of as a blending of the blocked and random practice order. Serial practice is a collection of different tasks performed sequentially, from a designated starting point to a defined ending point, always occurring in the same order and repeated as a whole set of movement tasks.[140,182]

In a serial practice session for an individual learning to use a transfemoral prosthesis, the therapist may instruct him or her to repeat a specific sequence of movements such as the following:

1. Rise from a seated position and take three steps toward an obstacle in your pathway.
2. Step over the stool (obstacle) with your intact (right) foot, bringing your prosthetic limb around the object in a small arc.
3. Complete three more gait cycles and turn around to the right.
4. Walk back toward the obstacle, stepping over it with the prosthesis first on the return.
5. Continue walking back to the chair, turn, and sit down.
6. Rise to standing once again and repeat the entire sequence until you have done it a total of × number of times.

The original task of stepping onto the stool with the right foot has been embedded into a series of different (but somewhat related) tasks performed in the same order over multiple trials.

Another way to classify practice is by the relative period of time spent in active practice versus rest time between practice sessions. In conditions of *massed practice*, there is more time spent over a practice trial than there is rest time between trials. Massed practice often increases intensity level. Fatigue may be a factor in decreases in performance over repeated practice sessions if rest periods are insufficient. In conditions of *distributed practice,* the amount of practice time is less than or equal to the amount of rest time between trials.[140,182] Given evidence of better retention and transfer of skills with longer rest periods between practice trials (i.e., distributed practice), rest appears to be more than a period of physical recovery; it may also enhance consolidation of perceptual schemas and action rules associated with the skill that has been practiced into memory.[211] What is not yet understood is how much practice time and how much rest is optimal for tasks of different complexity or learners with various resources or impairments.

PART- VERSUS WHOLE-TASK TRAINING

Many functional tasks have sequential, recognizable subcomponents. The task of rising from a chair, for example, may require moving forward toward the edge of the seat, changing foot position, leaning forward to shift body weight from the ischial tuberosities toward the feet, lifting off the seat, accelerating quickly upward into standing, and then establishing postural control in the upright position.[212] The task of walking can be divided into stages including weight acceptance in early stance, stability during single-limb stance, preparation for swing at the end of stance, and initiation through completion of limb advancement during swing phase.[213] When the physical therapists are working with individuals who have neurologic, neuromuscular, or musculoskeletal related movement dysfunction, they often use task analysis to determine what subcomponents of the task are problematic. The therapist might opt to practice the problematic components of the task to build skill before attempting the entire task *(part-to-whole training)* or to practice the entire task repeatedly *(whole-task training)*. In partial task training, the task is divided into separate parts, and each part is explained or modeled as a distinct component of the whole, whereas in whole-task training the entire task is explained verbally or modeled (demonstrated) in its entirety from beginning to end. The decision to structure training as part versus whole is influenced by the level of difficulty of the task, the degree to which the individual has already mastered some of the task's components, the individual's ability to attend to the task, his or her level of motivation and frustration, and safety considerations as the task is attempted. Tasks that are serial in nature lend themselves in part-to-whole training; spending time practicing complex or difficult task components (ending the session by putting all of the components together to perform

the whole task) often leads to better retention and transfer than the same amount of time spent practicing the entire task.[182,213,214] Tasks that are continuous, such as carrying a tray while walking through a cafeteria, are not as easily separated into components because of the degree of coordination and interplay necessary among task components. When coordination, timing, and interaction must be learned, whole-task training appears to be more efficacious.[182,214,215]

RELATIONSHIPS: PRACTICE, RETENTION, AND TRANSFER

The effectiveness of the various practice conditions on motor learning has been the subject of many studies in psychology, movement science, and rehabilitation. As the evidence that these studies present to us is considered (to determine their clinical relevance and possible application), it is important to note the specific outcome of practice that is being investigated. Are the researchers focused on change in quality of performance during practice trials (i.e., skill acquisition within a session) or in carryover of understanding of the task from one practice session to another (i.e., postpractice performance or retention over time)? This distinction is particularly important for rehabilitation professionals to keep in mind.

How, then, do rehabilitation professionals determine whether the interventions they have implemented have resulted in effective motor learning and skill development? Rather than focusing on improvement in a single session, we look instead at the development of *automaticity* and the ability to adapt performance across sessions and circumstances. Although performance over repeated trials within a practice session is often observed, this is not a reliable indicator that motor learning has occurred. Consistency in motor behavior (as the product of the learning process) across sessions and over time suggests that there has been *retention* (consolidation), or a relatively permanent change in motor behavior. The ability to *transfer* what has been learned and apply the set of movement options across situations appears to be related to the opportunity to practice under a variety of environment conditions and constraints.

Scientists who study motor learning hypothesize that individuals who develop flexible learning strategies through random practice and whole-task training are better able to transfer learned skills to novel situations. This is critical for the individuals we care for, who will ultimately need to perform skills beyond the rehabilitation practice environment (rehabilitation settings) as they return to the real-world environment of their homes and community. This concept links back to self-efficacy for performing the skill when necessary in the typical routine of daily function.[11] Keeping this in mind, rehabilitation professionals need to carefully consider and choose the practice conditions that will lead to the best possible functional outcomes for individuals for whom they care.

Intrinsic and Extrinsic Feedback

A second key concept in motor learning paradigms centers on the provision of feedback during practice trials (Box 3.3).[216] As movement occurs, it generates *intrinsic (inherent) feedback* that the CNS (especially the cerebellum as a system interested in coordination and error control) compares with the sensation that it "anticipates"

Box 3.3 Definitions for Feedback in Motor Learning

Basic Definitions

- Intrinsic (inherent): Sensations generated by movement of the body itself, monitored by sensory receptors (exteroception, proprioception, vestibular, visual, auditory), and transmitted to the brain stem and brain via sensory pathways.
- Extrinsic (augmented): Information provided about the movement task by sources external to the individual who is moving. Extrinsic feedback can be provided by another individual (e.g., the therapist or coach), or by an external device (e.g., biofeedback, other types of signals) that would not necessarily be present during usual performance of the task. It can be provided before, during, or after movement.

Dimensions of Extrinsic Feedback

- Knowledge of performance (KP): Information about the quality of the movement, provided during or following performance.
- Knowledge of results (KR): Information about the outcome (success) of the movement or task, provided after it has been completed.

Variations of Extrinsic Feedback

- "Feedforward": Prompts or clues provided prior to movement to assist the learner's active engagement in problem solving or preparation for the motor task.
- Concurrent: KP information about the movement provided as it occurs.
- Terminal: KP or KR information provided after the movement task has been completed. This can be provided either as soon as the movement is finished (immediate) or after a period of time (delayed).
- Distinct: KP or KR information about one specific practice trial.
- Accumulated (summary): KP or KR information that reflects multiple attempts to perform the task or movement.

Channels Used for Extrinsic Feedback

- Verbal: Questions or statements made by the therapist or coach about the movement.
- Nonverbal: Gestures and facial expressions made by the therapist or coach; touch or guidance used to direct or redirect attention or movement; lights, whistles, or other sounds used to guide or influence the learning during or following the movement.

Timing for Extrinsic Feedback

- Consistent (100%): KR or KP distinct information provided after every practice trial.
- Reduced (50%, 33%, 25%): KR or KP distinct or summary information provided after every other, every third, or every fourth practice trial.
- For poor trials: Providing feedback for trials with large errors during practice.
- For good trials: Providing feedback for trials with relatively small or few errors during a practice trial.

(feedforward) will or should result from the movement. *Extrinsic (augmented) feedback* refers to information about the movement performance that is provided by an external source before, during, or after the movement. If rehabilitation professionals understand the "what, when, why, and how" of extrinsic feedback (and combine them with appropriately structured practice), they will be much more effective in facilitating motor learning as well as the individual's ability to solve problems or adapt a motor skill. Rehabilitation professionals must determine what type of information is most appropriate (KP or KR) for the individual they are working with as well as how and when the feedback would best be provided (feedback mode and schedule).

To initiate a therapy session, the therapist may ask an individual how he or she might approach a functional motor problem and what they expect will happen when they are performing a task: for example, "We're going to practice moving from the bed to the chair. How can you prepare to do this? What is the first thing you need to do? Are you ready to do it?" This provides extrinsic augmented *feedforward* information aimed at engaging the person in the exploration of probable solutions for the initial steps of the transfer task. If the therapist asks the person to assess what he or she felt or experienced during the performance, they are providing *concurrent* extrinsic feedback. If the therapist asks or comments on performance after the task is completed, he or she is providing *terminal* extrinsic feedback. Therapists provide extrinsic feedback, sometimes without careful thought, in each intervention encounter when they say "Good job!" or "Did that work out the way you expected?" or "What might you do differently next time you try this?" In providing extrinsic information, the therapist calls the person's attention to and enhances the use of intrinsically generated feedback (or sometimes the substitution of an alternative source of information in the presence of sensory impairment).

KNOWLEDGE OF PERFORMANCE AND KNOWLEDGE OF RESULTS

Extrinsic information can provide the individual who is learning a new motor strategy or skill with either KR, information about the outcome of the movement (i.e., whether it was successful), or KP, information about the quality or execution of the movement (accuracy of the performance).[216] Much of the research on feedback in motor learning has focused on KR (outcome); however, in rehabilitation, we often use KP (quality; e.g., "Do you think that you were leaning far enough forward as you began to stand up?") to help individuals recognize and respond to movement errors.

Evidence in the literature suggests that, although KR does not necessarily lead to better performance during practice conditions, this type of augmented feedback information contributes to better task performance during retention tests.[141,216] The individual learning a new skill may benefit most by considering whether he or she has accomplished a movement goal (KR), especially in the early and middle stages of motor learning, rather than how accurately or efficiently the goal was attained (KP). This correlates with supporting the psychologic needs of the patient through celebration of the patient's progress and attention to the patient's success (KR).[11] Early on, details about quality of performance may interfere with the individual's developing understanding of the nature of the task and ability to sort through possible strategies that might be used. In later stages of motor learning, when focus shifts to refinement or improved precision of performance, KP is a more appropriate and powerful form of feedback information as long as the task is consistently accomplished.[217] It appears that augmented and intrinsic KP feedback lead to better quality and consistency of performance during practice but perhaps to less accurate performance in retention tests.[173,216] Although KP may not enhance retention as much as hoped, it has been found to be both effective and necessary in the acquisition of complex motor tasks as compared with mastery of simple motor tasks.[217,218] Use of KR to support a patient's self-efficacy may lead to more frequent use of the skill in multiple settings, enhancing activity and participation levels of functioning.

How and When Should Feedback Be Used?

Another thread within the motor learning research literature explores the efficacy of different frequencies and timing in the provision of augmented information. Providing too much anticipatory prompting before initiation of the task or excessive feedback as the task proceeds and is completed can actually be detrimental to the learning process. Frequent KR-focused feedback, provided on almost each trial of the task, often contributes to dependence on external guidance and ultimately degrades performance on retention tests. Summarized KR-focused feedback given at infrequent intervals (after multiple trials) appears to improve performance during practice as well as on retention testing.[219–221] Delaying the timing of KR appears to have a positive effect on performance during practice and on retention tests. Providing feedback after trials that are relatively successful appears to enhance motor learning more than when trials are full of error.[222–224] Researchers have noted that KR, like random practice and whole training methods, better prepares individuals for adapting motor performance to changing environmental demands, resulting in better performance on retention tests. These findings are consistent across individuals with no neurologic impairment; adults with stroke, head injury, and Parkinson disease; children with cerebral palsy and developmental delay; and persons with mild cognitive impairment and early dementia.[225–230] There is gathering evidence that allowing individuals to pace or control feedback frequency also has a beneficial impact on the retention (effectiveness) of what has been learned.[231–233]

What Modality for Feedback Is Appropriate?

Extrinsic feedback (augmented information) can be provided in a number of ways, using the visual system (e.g., demonstration and modeling, targets and other visual cues); the auditory system (e.g., informational verbal prompts or questions, use of tone of voice); and the somatosensory-tactile systems (e.g., manual contacts, tapping/sweeping motions, compression of limb segments to cue stability response, traction/elongation of limb segments to cue mobility, appropriate resistance to guide movement).

Early in the motor learning process, therapists judiciously use all three modalities, keeping in mind that early stages of motor learning are periods of experimentation and trial/error as the individual becomes familiar with the nature of the task and develops strategies that lead to accomplishment of the task. Although it is tempting to explicitly direct and "tell" someone with movement dysfunction how to move more efficiently, prompting by using questions often can more effectively engage the individual in an active learning process. Active engagement in the problem-solving aspect of the activity is a key motivator.[11] It appears that certain tasks are more responsive to particular modalities of feedback than others.[234,235] In persons with stroke, for example, visual feedback about weight distribution is useful for balance activities and auditory feedback about force production positively affects learning the sit-to-stand transition; the efficacy of verbal and kinesthetic feedback is not as well understood.[236,237]

Music and rhythm are frequently used in rehabilitation of gait for persons with Parkinson disease. Recent research suggests that the rhythmic variation fundamental to Argentine tango is an especially useful mode of extrinsic feedback for persons with Parkinson disease, requiring on-the-spot responses to variable stimuli. Outcomes have been positive for balance, functional mobility, and Parkinson-specific motor symptoms using Argentine tango as an intervention.[238–240] Recent research investigates rhythmic cueing further in the form of self-generated rhythm through singing aloud while walking. Results show decreased gait variability for people with Parkinson disease who sing aloud while walking.[241]

Simple tasks appear to be learned more easily following demonstration or physical practice with or without KP-focused feedback. The learning of more cognitively and motorically complex tasks, on the other hand, benefited from a combination of demonstration and practice with KP feedback.[237] Many previous studies suggest that an *external focus* of attention (success or quality of the movement) has a more beneficial effect on motor learning than an internal (kinesthetic) focus of attention during practice.[242–245] However, recent work suggests that focused attention is another key motivator and factor to increase motor learning.[11] Perhaps *prompting* a patient to pay close attention to internal kinesthetic cues is a good method to combine proven elements of previous and newer studies.

As individuals move into the later stages of motor learning, therapists must be aware of the need to wean the amount and frequency of augmented information as the individual moves toward becoming adept at the task. In the final stages of motor learning, augmented information becomes less and less essential or effective as mastery of the motor task is achieved.

Using Normative Feedback

There is increasing evidence that providing information that is normative (social-comparative, social relatedness) has a positive impact on motor learning.[11,242] Providing feedback that suggests that the individual is doing as well or better than others in similar situations, when paired with KR information about outcomes of the individual's actual practice, appears to improve trial-to-trial performance as well as retention.[246,247] Making a statement at the start of a therapy session focused on a difficult motor task indicating that persons facing similar challenges typically do well and are able to master the task with practice enhances the individual's expectations of their own ability (self-efficacy) and reduces anxiety associated with risk of failure; this enhances motor learning as well.[248]

Mental Practice and Imagery

Another resource available to assist the process of motor learning is the incorporation of mental practice and imagery into therapeutic interventions. Mental practice is defined as the imagined execution of a task-related movement without actual movement or muscle activation.[249] Mental practice of a motor task is thought to activate the same areas and networks of the CNS that actual movement does, especially if the task has been previously practiced.[249,250] Growing evidence in both the human performance and rehabilitation literature indicates that mental practice and the use of imagery enhance learning effects of physical practice and improve motor performance and retention.[251–253] Mental practice and motor imagery that focus on ease and quality of movement have been found to be particularly helpful in acquisition of motor skills in persons recovering from acute and chronic stroke.[253–255]

Imagery and mental practice appear to have a more powerful influence on improving performance during skill acquisition; their impact on retention of skills is not as well understood. This has implications for application to practice in therapeutic settings. Given high-volume patient caseloads and the realities of multiple patients per therapist during sessions, mental imagery can be an effective tool for maintaining the involvement of the client in the activity even when the therapist is attending to other patients.

Role of Sleep in Motor Learning

Newly acquired motor memory becomes more stable (more resistant to disruption or interference) during sleep.[256] The procedural memory consolidation process appears to reduce the need for neocortical (prefrontal lobe) input into the neuronal representation of the movement, making it easier to recall the movement and increasing efficacy of retention.[257] Although early research suggested that consolidation during sleep actually improved learning (offline learning) and enhanced motor performance, more recent work proposes that it instead provides protection against forgetting by counteracting both physical and neuronal fatigue associated with practice.[258,259] Whichever perspective will prove to be accurate, it appears that sleep is a key component in the motor learning process.

The positive effect of sleep on the retention of newly learned skills appears to be true for motor skills that have been physically practiced as well as those reinforced by mental imagery both in persons who are healthy and in those with a pathologic condition of the CNS.[260,261] The opportunity for uninterrupted overnight sleep for offline consolidation of motor memory is a key component of the rehabilitation process for persons with stroke.[262,263] Individuals with prefrontal lobe damage (e.g., after traumatic brain injury), who typically are quite challenged by novel motor tasks presented during rehabilitation, appear to benefit significantly from

the opportunity for offline learning and memory consolidation that occurs during a night of sound sleep.[263]

However, sleep disturbances are quite common for people with traumatic brain injury (TBI) and mild traumatic brain injury/concussion (mTBI). These sleep problems lead to symptom exacerbations and difficulties participating in rehabilitation.[264,265] Animal model research suggests that sleep deprivation effects neuroplastic processes negatively, which could further affect functional motor recovery for those with TBI who are experiencing sleep disorders.[265] A coordinated interdisciplinary approach is needed to effectively treat sleep disorders so that persons with TBI or mTBI can benefit optimally from rehabilitation treatments. Rehabilitation professionals should pay particular attention to the sleep habits of clients who have TBI or mTBI and coexistent posttraumatic stress disorder (PTSD). This is common in war veterans. Sleep problems are a diagnostic feature of PTSD, and veterans with PTSD commonly experience sleep problems at a rate much higher than that of veterans without PTSD.[264] For best outcomes, motor learning interventions for these individuals will likely need to occur along with an interdisciplinary strategy that addresses sleep disturbances.

Importance of Patient/Client-Centered Goals

Rehabilitation goals focus on improving an individual's ability to participate in meaningful activities. One aspect of the motor learning process that is often taken for granted is the salience of the task to the learner; therapists may assume that the goals they have developed for a given patient (e.g., to walk 150 feet safely and efficiently using an assistive device and a prosthesis or orthosis) are consistent with the goals of the individual with whom they are working, when in fact there may be a mismatch.[266,267] Emerging evidence suggests that focusing on the tasks that are most meaningful to the individual enhances motivation and attention, necessary components of the motor learning process as well as facilitators of neural plasticity and recovery after brain injury.[11,268,269] A sense of empowerment and increasing self-efficacy contributes to efficacy of learning when an individual works toward a goal that is particularly meaningful to him or her.[11,270–273]

How does a rehabilitation professional help an individual identify salient personal goals and use these goals to inform the design of appropriate opportunities for motor learning (Fig. 3.9)? Framing goals at the level of activity and participation is the first step.[274] The next is to ensure that stated goals reflect consensus (as much as possible) of the patient and the health professional.[275] Such consensus is a key influence on the relationship between the patient and the health professional; being "on the same page" creates a level of trust that provides a solid foundation for risking failure in the rehabilitation learning environment.[275] Goals for motor learning are most effective if they reflect both expertise of the therapist and expectations of the individual beginning rehabilitation; at times, reaching consensus requires patient and family education as well as negotiation about priorities.[276–278] Effectively defined goals are (1) specifically related to the task to be accomplished or mastered; (2) measurable (i.e., use quantifiable metrics of distance, time, effort or difficulty, and frequency of performance); (3) ambitious yet achievable within the forecasted episode of care; (4) relevant, realistic, and congruent with the individual's potential and expectations; and (5) those that include a time line for achievement.[278] Establishing clearly stated and measurable goals provides a framework for assessment of outcomes of interventions as well as the revision or progression of activities that will further improve functional capacity and the individual's ability to participate in meaningful activity. Such attention to the early establishment of functional goals has been found to have a positive effect on outcomes of rehabilitation for children with cerebral palsy and persons with spinal cord injury, stroke, and traumatic brain injury.[279–284]

NEURAL PLASTICITY IN MOTOR CONTROL AND MOTOR LEARNING

Rehabilitation professionals are on the cusp of significant expansion in the understanding of the neurobiologic/physiologic basis of recovery after neurologic and neuromuscular injury.[285,286] The developing science suggests that we can use our understanding of motor control and motor learning to *drive neural plasticity* in both acute and chronic stages of many neurologic and neuromuscular diseases.[287–290] Learning-induced neuroplasticity involves three processes: (1) strengthening existing neural connections, (2) stimulating the formation of new neural connections, and (3) preferentially selecting neural connections and pathways, which is known as *pruning*.[46,159,160] This science also challenges us to reevaluate whether our interventions are sufficient—in terms of therapeutic approach, intensity, and duration—to trigger the neuroplastic changes that will improve function and quality of life.[291–293]

The term *neural plasticity* refers to the dynamic ability of the brain to structurally and functionally reorganize neural circuits in response to activity and environmental demand: such plasticity occurs during development in children, during adulthood as one masters new motor skills and builds knowledge base, as well as after any type of brain injury or insult.[288,293] Plasticity is driven by (i.e., is dependent on) the process of learning, whether it be focused on new knowledge or skills or relearning of skills disrupted by illness or injury. Although the mechanisms underlying neuroplastic change are not fully understood, exposure to learning opportunities of sufficient intensity and duration contributes to remapping of motor, perceptual, and communication areas within the brain.[288–291,294] Early in rehabilitation, as the effects of inflammation and edema associated with CNS infarct or injury diminish, therefore activity-based interventions may help to revive and restore function in neural structures that were initially compromised; this is *neural recovery*.[295] In addition to plasticity in the brain. New evidence suggests that activity-dependent plasticity was also seen in the spinal cord below the level of lesion in patients with spinal cord injury.[296] Even if there is potential for neural recovery, at times the effort required to activate recovering neural circuits is intensely difficult and frustrating. Without encouragement and opportunity to practice, function may continue to be compromised because of *learned nonuse* of a body part.[297] As rehabilitation progresses, continued activity-based interventions may facilitate the recruitment of intact neighboring neural

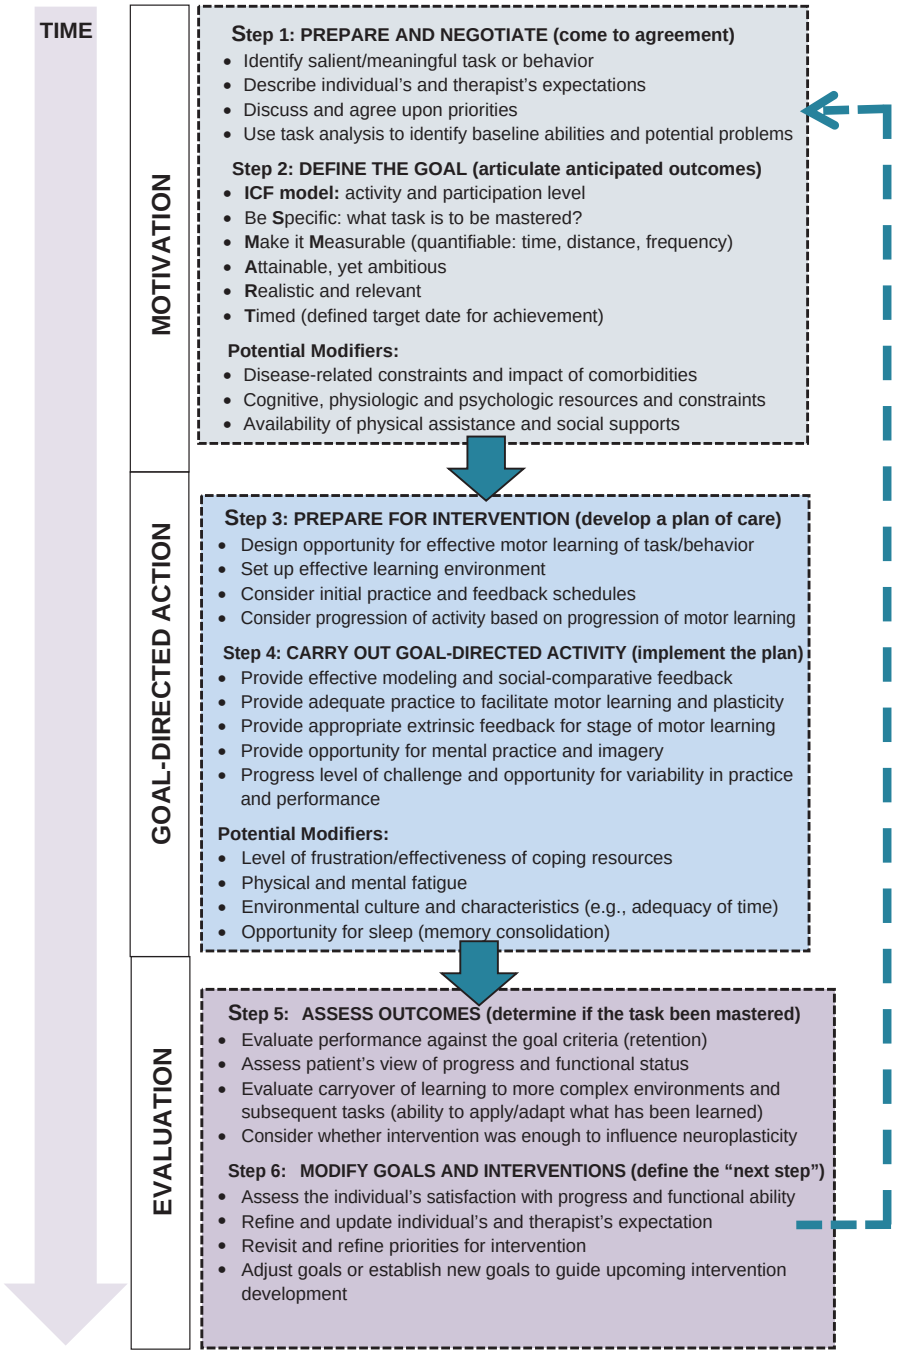

Fig. 3.9 A patient-centered model for setting goals for the effective motivation and facilitation of motor learning in rehabilitation. Initial efforts focus on building consensus between patient and therapist on the establishment of appropriate meaningful goals and on the articulation of such goals so that they can be later used to assess outcomes. Given understanding of motor learning, motor control, neuroplasticity, and recovery of function, the therapist then designs and implements task-specific, goal-directed rehabilitation interventions. Both the patient and therapist use agreed-upon goals as markers of efficacy of intervention; they modify or progress therapeutic activities and practice based on achievement of the goals.

structures to supplement the function of damaged brain structures. Even though this is actually a mechanism of *neural compensation*, it may be perceived by the individual, family, and rehabilitation professional as *functional recovery* at the International Classification of Functioning, Disability and Health (ICF) levels of body function and activity.[288] If brain injury has been so extensive that alternative ways of performing key functional tasks is necessary, retraining leads to *functional compensation*.[288]

Medical management of newly injured or compromised brains has traditionally focused on preventing or limiting secondary sequelae that result from insult, whether traumatic, ischemic, infectious.[163] Although evolving pharmacologic or interventional strategies (e.g., transcranial stimulation) now target recovery of function, rehabilitation based on principles of motor learning is currently the most powerful facilitator or neural plasticity.[287,298,299] The behavioral, sensory/perceptual, and cognitive aspects of functional and skilled movement appear to effectively trigger neuroplastic processes in damaged brains in ways similar to what occurs in developing brains.[287]

Kleim and Jones[287] have developed a set of 10 principles that translates current best evidence about experience-dependent neural plasticity from animal and human basic science studies to inform development of motor learning-based interventions for clinical rehabilitation practice. New evidence from multiple authors adds weight to these principles.[300–302] A recent study by

Table 3.2 Principles of Experience-Dependent, Use-Dependent, and Activity-Based Neural Plasticity

Principle	Description
Use it or lose it	Failure to drive specific brain functions can lead to functional degradation.
Use it and improve it	Training that drives a specific brain function can lead to enhancement of that function.
Specificity	The nature of the training experience dictates the nature of the plasticity.
Repetition matters	Induction of plasticity requires high levels of repetition.
Intensity matters	Induction of plasticity requires high-intensity training.
Time matters	Different forms of plasticity occur at different times during training.
Exercise matters	Different forms of plasticity occur with exercise prior to and following training.
Salience matters	The training experience must be sufficiently salient to induce plasticity.
Age matters	Training-induced plasticity occurs more readily in younger brains.
Transference	Plasticity in response to one training experience can enhance the acquisition of similar behaviors.
Interference	Plasticity in response to one experience can interfere with acquisition of other behaviors.
Success reinforcement	Both internal reinforcement and external validation of success are necessary.

Mawase et al. demonstrates that task success reinforcement is an additional principle to consider (Table 3.2).[303] Discussion of each principle follows.

Use It or Lose It

Basic science research has clearly demonstrated that impaired performance and eventual loss of skill and ability is likely if neural circuits are not consistently activated by functional activity. This is the underlying assumption of the learned nonuse theory that forms the foundation for constraint-induced therapy targeting upper extremity use for adults and children with hemiplegia.[304,305] A similar principle has been described as an explanation for decline in muscle performance and endurance associated with a sedentary lifestyle and bed rest.[306] Early in rehabilitation, individuals with CNS dysfunction or disease may discover compensatory or alternative movement strategies that are less difficult or frustrating, given their altered brain function and the resulting paresis or altered muscle tone.[12] Moving differently also impacts muscle performance and flexibility, making development of secondary impairments more likely. Thus, over time, not only does neural circuitry necessary for normal movement degrade, but also the individual's physical resources for movement change. Both of these factors reinforce the altered or abnormal movement pattern and the loss of premorbid skill and activity.

Use It and Improve It

Animal models consistently show that, in both nonimpaired and impaired circumstances, consistent or extended training induces cortical plasticity as evidenced by reorganization of cortical motor and sensory mapping and synaptogenesis.[307] The expectation is that behavioral experience will optimize neural plasticity in humans as well.[290] Participating in extended training (i.e., practice, experience) of specific skills and functions enhances performance in areas of the brain associated with those functions; this is the outcome expectation for constraint-induced therapy and task-specific paradigms used in stroke, brain injury, and spinal cord injury rehabilitation programs.[304,308,309]

Specificity Is Significant

In humans, the acquisition of particular motor skills (e.g., finger tapping) through physical practice leads to changes in neural activity only in particular areas of the motor cortex and cerebellum (e.g., areas mapped to hand and fingers) as evidenced on functional magnetic imaging.[310] This demonstrates that the training experience that leads to acquisition of a specific behavioral skill determines the resulting type and extent of plasticity. Task-specific training has been evaluated extensively as an intervention for recovery of upper extremity function and of locomotion after stroke.[311,312] It is important to note, however, that neuroplastic changes associated with training of one skill does not necessarily contribute to improvement in other skills or changes in other areas of the brain. Nonskilled movement appears to have little, if any, impact on neural plasticity.

Repetition, Repetition, Repetition

One successful performance of a motor task does not mean that the task has been skillfully mastered. In motor learning, evidence of mastery is the transition to automaticity.[113,174] An individual moves toward automaticity only after many practice sessions. Sufficient repetition of new or relearned behaviors is necessary for neuroplastic changes to become well established.[186] The underlying assumption is that the outcome of such repetition is the establishment of neural circuitry that makes the effectively learned behavior less likely to decay over time when practice is infrequent.[287] The role of repetition for driving learning and neural plasticity is a critical one. Body weight–supported treadmill (TM) training is designed to provide opportunity for repeated practice of locomotion that would not be possible in overground walking early in rehabilitation after stroke and spinal cord injury.[313,314] TM training has the added benefit of inducing cardiopulmonary/cardiovascular fitness, adding to overall resources for movement available to the individual whose CNS dysfunction may carry an associated secondary risk of deconditioning.

Intensity Is Important

In persons without brain injury, training intensity (dose, number of repetitions, number of practice sessions) influences both degree and stability of the neuroplastic change induced by practice.[287] Both constraint-induced therapy for upper extremity rehabilitation and TM training for the recovery of locomotion are high-intensity interventions. Although the optimal "dosage" for rehabilitation intervention is not well defined and may differ across diagnoses, it is clear that outcomes of intervention are influenced by dose, with high-intensity programs having the largest effect.[315] Intensity includes a high number of repetitions and high frequency of practice sessions.[183,300] Current rehabilitation practice models do not always provide the number of repetitions or dose intensity that might be necessary to induce neural plasticity and cortical reorganization.[316] Much of the research on intensity of intervention has involved persons who are medically stable and in the chronic period after their neurologic event. These individuals appear to tolerate intense interventions with little adverse consequence. What is not well understood, however, is whether there may be sensitivity to overuse in newly injured brains that is detrimental after a threshold level of repetitions is exceeded.[287,317] In the absence of guidelines about level intensity for persons with recent CNS insult, careful monitoring for signs of activity intolerance of the brain and body (e.g., fatigue, irritability, distractibility, change in attention or alertness, as well as a greater-than-anticipated decrement in performance, among others) may assist the therapist in keeping the intensity of intervention within safe ranges.

Time and Timing

There are many molecular, cellular, structural, and physiologic contributors to the process of neuroplasticity; the relationships and timing of changes at each of these levels continues to be explored.[287] Consolidation of motor memory, for example, requires "offline" time after practice for a newly learned skill to be effectively retained.[299] As in development, there may be windows of opportunity within the typical pattern of recovery when interventions targeting neuroplasticity are likely to be most effective.[317,318] Delaying intervention (or providing intervention at suboptimal levels of intensity) may allow abnormal compensatory movement patterns to become established, thus rendering rehabilitation less effective.[287] Certainly, there is much more investigation needed regarding when neuroplasticity focused rehabilitation intervention would be best implemented during the course of recovery following CNS insult.

Salience Is Substantial

Even a well-practiced activity will not successfully induce neural plasticity unless the individual perceives it to be as meaningful and important. Motivation, attention, and the ability to learn are influenced by the relevance of and perception of potential reward associated with a movement task.[319,320] Participation in rehabilitation interventions modeled on motor learning in the context of neural plasticity requires considerable investment and effort on the part of the patient. If the goal and level of effort needed to achieve it outweigh the perceived potential benefits or rewards of participation, is it any wonder that little will be accomplished in terms of skill development or facilitation of neural plasticity? It is essential that there be discussion and, optimally, consensus between the individual and the therapist about the likelihood of improved functional performance at a level that the individual perceives as valuable and important as a result of intervention. Increased motivation is noted in patients who are allowed some choice and control over interventions and when collaboration with the therapist is embedded into treatment planning.[11] Attention to task and intrinsic motivation strengthen learning when individual goals are connected to tasks.[300] Salience (meaningfulness) appears to impact motor learning and recovery via the cholinergic system of the basal forebrain.[321]

Considering the Life Span

Although the brain is clearly most "plastic" in early life—during periods of rapid motor, perceptual, and cognitive development—the brains of older adults continue to be responsive to experience-driven catalysts of neural plasticity.[322–324] Rich physical, emotional, and cognitive experiences over the life span appear to protect the older individual against decrements in brain function typically thought to be the result of aging.[325,326] There are differences in the process of motor learning and neural plasticity, however, at both ends of the life span. Children may require longer periods of practice and a more gradual reduction in frequency of feedback for effective motor learning than adults to effect neuroplastic change and the consolidation of newly learned skills.[327] Older adults also require longer periods of practice and increased number of repetitions, especially when they are attempting to replace competing compensatory movement strategies after CNS insult.[328] When such individuals are compared with younger adults, the efficacy of the motor learning process (and by extension, neural plasticity) appears to be somewhat less for older adults in both acquisition and retention of skilled sequential movements and retention.[329] This may be associated with age-related declines in visuospatial working memory and of attentional focus.[330] Increased age in patients with Parkinson disease appeared to be a factor for citing more barriers to exercise than younger patients with similar diagnosis.[302] Nevertheless, older adults with stroke and other CNS diseases do respond to appropriately targeted complex motor skill training, demanding environmental contexts and exercise interventions in both the acquisition and reinforcement of skilled movement.[313,331–333]

Transference

Kleim and Jones[287] describe transference as the ability of plastic changes in one set of neural circuits to enhance concurrent or future neuroplastic changes in other neuronal circuits. Adding repetitive transcranial magnetic stimulation to physical practice of salient motor skills appears to enhance acquisition and retention of motor skills and promote more extensive return of function during acute and chronic stages while a person is recovering from a stroke.[334,335] Animal studies suggest that living and functioning in complex enriched environments may also

potentiate neuroplastic changes in the cortex after brain injury.[336] In humans, both enriched environments and physical exercise appear to have a potentiating neuroplastic effect on the damaged brain, brain stem, cerebellum, and spinal cord, contributing to angiogenesis mediated by the release of brain-derived neurotrophic factors during activity.[337,338] Repetitive physical activity and exercise during rehabilitation has the potential to enhance neural plasticity and to improve muscle performance and cardiovascular/cardiopulmonary conditioning.

Interference

Just as some neuroplastic changes enable reorganization in the process of transference, they also may block, interfere with, or otherwise impede operation or reorganization of other circuits, with a negative impact on the ability to learn.[287] Kleim and Jones[287] define interference as the ability of plasticity in a particular neural circuit to impede the generation of novel circuits or enactment of established circuits. How does this translate into rehabilitation? The clearest example is the detrimental impact that self-discovered compensatory movement strategies (a neuroplastic change in which persons with stroke have learned to move functionally using alternate movement strategies) have on learning more effective strategies of movement during therapy.[339,340] This interference has also been demonstrated in persons with acute or chronic pain who have learned to move in ways that avoid discomfort but are not kinematically effective and are associated with likelihood of additional dysfunction.[341,342]

Neuroplastic interference as described by Kleim and Jones[287] is a different concept than the contextual interference that occurs during random practice discussed earlier in the chapter as a facilitator of motor learning. Contextual interference occurs as a result of the need to keep many options that might solve a motor problem available in working memory over time.[182,203] The increased attentional demand associated with contextual interference appears to augment, rather than interfere with, the learning (and hence the neuroplastic) process.[208–210] From a motor learning perspective, neuroplastic interference might occur if the type of practice or feedback provided during a rehabilitation session is not appropriate for a learner's specific needs or characteristics.[343,344] Another example of neuroplastic interference might be the impact of learning of an additional novel complex motor task soon after practice of a newly learned complex motor task; having little offline time may interfere with motor memory consolidation of the newly learned task.[345,346]

A history of trauma can add an additional layer of neuroplastic interference when people are trying to reestablish normal motor control. Recent understanding of brain function includes a model of the brain as a predictive processor, continually comparing hypotheses about sensory input to actual input.[347] In persons with FMD, learning is negatively affected because of the influence of priors, or past trauma, on the active inference process. "Top-down" predictions about "bottom-up" sensory input become invalid; there is a failure of inference.[347] The resulting movement does not match neuroanatomic or physiologic constraints and looks as if it were purposeful. However, the person with FMD self-reports an absence of agency related to the movement.[50] The rehabilitation professional is challenged with selecting the best task, environment, and feedback to promote the reestablishment of normal motor control. Because FMD requires attention to manifest, current literature recommends diverting attention away from the motor task in question during rehabilitation interventions.[50,52]

Task Success Reinforcement

One additional principle has been identified by Mowase et al. in a 2017 study.[303] When a person receives internal reinforcement through successful performance of a newly learned motor task during trials, plasticity changes occur in the motor cortex. This was termed "use-dependent plasticity" (UDP). UDP was noted significantly more in participants who experienced success reinforcement than in those who did not.[303] This may suggest that successful performance during learning trials reinforces the learning, which in turn increases plasticity.

AEROBIC EXERCISE, NEUROPLASTICITY, AND NEUROPROTECTION

Exercise may be a rehabilitation professional's most potent tool for facilitating neural plasticity. Fitness (aerobic) exercise causes a cascade of events, at both molecular and cellular levels, that support the health and development of neural circuits.[348] This is thought to be due to the interplay of central and peripheral mechanisms supporting energy metabolism and homeostatis.[349,350] During and for a short time following a bout of aerobic exercise, the level of circulating neurotrophic factors increases and is more available for support of neuroplastic and neuroprotective changes in the brain.[46,348,351] Resistance (strengthening) exercise does not lead to the degree of increase in neurotrophic factors that aerobic exercise does.[352] Although rehabilitation professionals typically endorse aerobic exercise as a means of building functional capacity and activity tolerance, we may not be as aware of the role that aerobic exercise may play in readiness of the brain to learn. As was stated earlier in the chapter, exercise that happens immediately before motor task practice assists with improved detection and encoding of information relevant to the motor task, and exercise that happens immediately following motor task practice strengthens the motor memory process.[46] These are two powerful reasons that aerobic activity should be included in plans of care for all persons with CNS dysfunction as well as any individual who must develop new motor skills (e.g., learning to walk with a prosthesis).

Participation in TM training during rehabilitation after stroke or incomplete spinal cord injury enhances motor learning and neural plasticity in several ways: it is task-specific, provides repetitive practice at high dosage, builds cardiovascular/cardiopulmonary fitness, and (as a result) readies the brain for functional modification of neural circuits.[313,348] Aerobic fitness is associated with greater neuroplasticity and better cognitive performance in persons with multiple sclerosis.[353,354] There is growing evidence that aerobic exercise can enhance motor performance, improve quality of life, decrease caregiver burden,[355] and possibly slow progression of mobility impairment in persons

with Parkinson disease.[356–358] Current animal model research demonstrates upregulation of neurotrophic factors through aerobic exercise that may contribute to dopaminergic survival in those with Parkinson disease. It is not yet clear whether forced intensity of aerobic exercise provides more benefit than self-selected intensity in terms of sustained improvements in motor performance and function for persons with Parkinson disease.[359,360] A bout of fitness exercise appears to transiently improve cognitive function in older adults, and participation in habitual cardiovascular fitness training appears to have a neuroprotective effect on cognition and the ability to learn in later life.[361–363] The neuroplastic and neuroprotective effect of aerobic conditioning also appears to improve or stabilize cognitive function and learning in persons with mild cognitive impairment and dementia.[364–368]

Given current evidence about the ability of aerobic exercise to potentiate and protect brain health and function, rehabilitation programs that fail to incorporate a fitness or conditioning component may miss the opportunity to enhance motor learning and recovery of function. This applies to persons with neurologic problems as well as those who may be learning to use an orthosis or prosthesis as a result of neuromuscular and musculoskeletal impairment from trauma, overuse, or disease.

Application: Case Examples

The following case examples are presented as opportunities for readers to apply the information presented in this chapter. Readers are urged to take time to develop an appropriate plan of care/therapeutic intervention within the framework of the ICF model, using the interactive person-task-environment (systems model) framework of motor control and the context of the modified version of Gentile's Taxonomy of Movement Tasks presented in the chapter. Additionally readers are urged to consider the principles of exercise/activity-driven neuroplasticity, including relevant goal setting for engagement of the patient, practice conditions for appropriate intensity challenge, and feedback for effective motor learning/acquisition of skills and development of self-efficacy that have been discussed.

QUESTIONS TO CONSIDER

The authors suggest that readers consider the following strategies and questions to guide their planning.

Functional Considerations

- What tasks or activities are most appropriate or important to address in developing a physical therapy plan of care for the individual described in the case? (Prioritize three or four tasks to be targeted by physical therapy intervention.)
- How can the therapist incorporate the goals and priorities of the person into the development of goals and plan of care to make it salient?
- Motor control considerations
- What resources/buffers and impairments/constraints does this individual bring to the situation? In what ways are these helpful or constraining, given the person's neuromotor and musculoskeletal condition, cognitive and emotional status, and level of fitness?
- What is the nature of the tasks that have been selected (stability, mobility, or quasimobility with or without object manipulation)? What are the foundational skills necessary to perform the task? What skills or abilities may be difficult, given the impairments/constraints described in the case? What skills are most feasible to improve to increase patient competence?
- Under what environmental conditions would this individual be best able to function at this time (closed/predictable versus open/variable)? In what type of environment does this individual need to be able to eventually function? How might you manipulate activities and environmental conditions to achieve function in the real environment to set an appropriate level of challenge?
- What is the emotional context of the environment? Can you manipulate the emotional context to facilitate better learning conditions? Does your patient require more "emotional press" to problem solve with you on the task? Does your patient require a stressful environmental context to be reduced to have an appropriate ready-to-learn context? Does the patient require encouragement and validation of success to increase confidence?
- How might you organize/prioritize a sequence of activities, using the modified Gentile's Taxonomy of Movement Tasks (stability/transitional/mobility), to prepare or progress the individual toward safe independent function in the least restrictive environment?

Motor Learning Issues

Identify the purpose of the task trials that will be designed by the therapist.

- Is this a task that needs to be acquired (or reacquired postamputation or postincidence), or is this a task that needs to be refined?
- At what stage of motor learning is the individual in relation to the defined task?
- Does the individual have an understanding or familiarity with the task, or is it completely novel?
- Is current task performance sufficient for the task to be functional?
- Is performance efficient or optimal?
- Is performance automated, and does it demonstrate desired variability? Can the individual use a variety of motor strategies to accomplish or address this task under changing environmental demands?
- Can this task be broken into discrete parts? Would it be better to practice the task as a whole? Why or why not?
- Is performance of a particular part of the task problematic (mechanics of the task, fluidity between the components of the task)?
- Is performance of the task as a whole problematic (completion, speed, endurance)?

- On the basis of your thoughts about the task trials, identify the best practice conditions for achieving the desired outcome.
- Is the primary goal of practice *retention (learning)* of motor behavior across practice sessions or *improving performance* within a practice session?
- Which practice condition or combination of practice conditions (blocked, random, or serial; massed or distributed; part- or whole-task training) would you use to assist retention of the skill? Why have you chosen these strategies?
- Which practice condition or combination of practice conditions (blocked, random, or serial; massed or distributed; part- or whole-task training) would assist improved performance *(competence)*? Why have you chosen these strategies?
- How might contextual interference influence the learning process?
- What type of augmented information should be included during practice of the tasks to achieve the desired outcome?
- What modes of information should be used for this individual (visual cues and demonstration, verbal prompting, physical prompt/facilitation)? Why has this augmented information strategy or combination of strategies been selected?
- What effect will the information have on the client's ability to recognize errors and self-correct motor behavior *(intrinsic feedback)*?
- What delivery scheme (KR or KP) should be used to provide augmented feedback?
- What is the anticipated effect of the selected delivery scheme (KR or KP) on retention versus performance of the motor skill being targeted?
- Can visual imagery or mental practice enhance the performance? What images would a rehabilitation professional want the client to visualize? What effect will imagery have on performance and on retention of the motor skill?
- What components can the client practice mentally? What effect will mental practice have on performance and on retention of the motor skill?
- How can the therapist incorporate understanding of neural plasticity into goal-directed activity and intervention? What strategies can be used to validate success and increase self-efficacy?
- Are the activities and tasks included in the plan of care sufficient in repetition and intensity to appropriately challenge the patient and influence neural plasticity?
- What evidence is available to guide decisions about potential windows of opportunity to time intervention for optimal neuroplastic effect in patients with similar diagnoses?
- How should the plan of care be influenced by the age of the patient in terms of facilitation of motor learning and neural plasticity?
- What additional medical interventions, environmental conditions, or principles of exercise can potentiate motor learning and neural plasticity for recovery of function?

Summary

This chapter explores the concepts that shape current understanding of human motor control, focusing on the dynamic and adaptive characteristics of the body as a biologic system. Rehabilitation professionals use their understanding of (1) an individual's resources and characteristics, (2) environmental conditions, and (3) the nature and constraints of functional tasks to develop appropriate interventions aimed at improving or adapting individuals' abilities to move effectively in ways that are safe and efficient in order to accomplish what is important for them to do.

The chapter also considers the process of motor learning, the ways in which individuals come to understand and approach a novel task or adapt a familiar task in differing environmental conditions or following an injury or illness that changes personal resources. Using their understanding of the stages of motor learning, the purpose of augmented information, types and timing of feedback/feedforward information, and types of practice conditions and other factors that enhance motor learning, physical therapists and other rehabilitation professionals can construct interventions that will effectively enhance the retention of motor learning or refine performance for persons with movement dysfunction.

The chapter concludes with a discussion of the emerging field of neuroplasticity, which links recovery of motor control and motor learning, considering rehabilitation as a mechanism to trigger neural plasticity and recovery of function after insult or injury to the CNS. As understanding of neuroplasticity grows, rehabilitation professionals must re-evaluate whether the interventions designed to enhance motor learning are sufficient to also drive neural plasticity and recovery of function for persons recovering from events and diseases that impact the structure and function of the brain.

Case Example 3.1 **Adult With Right Hemiparesis Who Is Learning to Use an Ankle-Foot Orthosis and Ambulatory Assistive Device**

A. F. is a slightly obese 78-year-old African American woman with a history of type 2 diabetes mellitus; she had an ischemic stroke of the left middle cerebral artery 3 weeks earlier. A computed tomography scan revealed a lacunar-shaped infarct from an embolic occlusion of a deep branch of the middle cerebral artery serving the internal capsule. A. F. was recently transferred to a skilled nursing facility for rehabilitation, particularly to address transfers and ambulation. She had received a prefabricated solid ankle-foot orthosis (AFO) just before her arrival. She says that the brace is intended to help control her "bad knee" and "lazy foot" position so she can walk better. She has not had much opportunity to use the orthosis and is concerned that it may actually make it more difficult for her to walk. She indicates that she prefers to use a rolling walker, although her therapist in the hospital insisted that she use a straight cane.

Chart review, interview, and physical therapy examination reveal the following:

- *Psychosocial*: A. F. lives alone in a two-story walk-up apartment. Her immediate family lives out of state. She retired 10 years ago from a position as a legal secretary and is heavily involved in the outreach ministry of her evangelical church.
- *Baseline vital signs*: heart rate: 82 beats/min; blood pressure: 132/94 mm Hg; respiratory rate: 16 breaths/min.
- *Cognitive status*: alert and oriented times 3.
- *Communication*: some slurring of words; has trouble finding the words she wants to say, but comprehension appears intact.
- *Vision*: intact; typically wears trifocals.
- *Sensory system*: cranial nerves intact; normal responses to light touch, pin prick, proprioception in all extremities.
- *Neuromotor status:*
  - *Tone*: moderate spasticity of right (R) upper extremity (UE) and lower extremity (LE); 1+ on the Modified Ashworth Scale.
  - *Range of motion (ROM)*: Passive ROM within normal limits for all extremities.
  - *Strength:* L extremities 4+/5 throughout.
  - *R UE:* shoulder elevation 2+/5; hand grip 2/5; elbow flexion 2/5; *R LE:* function strength grades include ankle plantar flexion 3/5; ankle dorsiflexion 1/5; knee extension 2+/5; knee flexion 3/5; hip flexion 3/5; hip extension 3/5; hip abduction 3/5; and hip adduction 3+/5.
  - *Postural control*: able to sit upright against gravity, asymmetric weight distribution with more weight borne on left side. Anticipatory posture changes are adequate when reaching toward right, inadequate when reaching toward left. Stands with supervision; requires verbal and tactile cues to bear weight on R LE.
  - *Functional activities*: rolls independently to both sides; supine to sit over edge of bed with supervision; transfers from bed to wheelchair with supervision; sit to stand transitions with supervision.
  - *Ambulation:* uses straight cane with moderate assist, requiring both verbal cueing and physical prompt to improve loading response on right leg and to minimize genu recurvatum during forward advancement over right foot.

Goal: Design a physical therapy plan of care that will focus on the development of motor skills necessary for safe and efficient locomotion using the AFO and straight cane.

Case Example 3.2 **Child With Cerebral Palsy Who Has Just Received New (Bilateral) Articulating Ankle-Foot Orthoses**

T. D. is a delightful 2{1/2}-year-old-boy with cerebral palsy ad spastic diplegia of moderate severity. He was born prematurely at 27 weeks' gestation and remained in the neonatal intensive care unit for 10 weeks. By the time he was 18 months old, there were increasing indications of developmental delay and abnormal motor control. He currently attends an early intervention program (EIP), receives individual home visits from a physical therapist, and attends a therapeutic play group run by an educator and occupational therapist weekly.

EIP examination findings include the following:

- *Social:* T. D. lives with both parents and an older brother in a two-story, single-family home. He interacts well with his family members and is on target for social development. He plays side by side with peers and occasionally interacts with them appropriately.
- *Cognition:* T. D. scores age appropriately for cognitive tasks including cause and effect, object permanence, means to end, early numeration, and sorting by categories. His play with objects includes variety and imagination.
- *Language:* T. D.'s comprehension, expression, and pragmatic use of language are on target for his age. He has an extensive vocabulary and uses language appropriately in various situations.
- *Fine motor/activities of daily living (ADLs):* T. D.'s reach, grasp, and release skills are within the age-expected range. Bimanual skills and object manipulation are also on target. Feeding skills are appropriate; T. D. uses utensils and drinks from a cup as expected for his age. His dressing skills are slightly below age expectations largely because of balance concerns in standing for putting on pants.
- *Gross motor:* T. D.'s gross motor skills fall below age expectations. He has been walking independently with bilateral solid ankle-foot orthoses (AFOs) for 6 months. He can walk on multiple terrains including tile or wood floors, carpets, grass, asphalt, and wood chips. He has some difficulty with stairs, requiring a railing or one hand held. Tripping and falling are issues with increasing speeds during ambulation and with attempts at running. T. D.'s mother is most concerned about his safety in ambulation at this point.

T. D. was having increasing difficulty with squatting and transitions into and out of standing from the floor. The rehabilitation team, discussing the problem, decided that articulating AFOs would increase the availability of ankle range of motion for these transition tasks. T. D. just received bilateral articulating AFOs with a plantarflexion stop set at 10 degrees. He is currently having trouble descending stairs in the new orthoses, refusing to go down stairs unless both hands are held. He also has increased frequency of tripping outside while ambulating on the grass and rock driveway at home.

Goal: Design a physical therapy plan of care to help T. D. master locomotion and transitional activities with the less constraining articulating AFOs in the environments of a typical 2{1/2}-year-old child.

Case Example 3.3 **Child With Congenital Upper Limb Deficiency Learning to Use a Myoelectric Prosthesis**

T. L. is a 3-year-old girl who has had a congenital right upper extremity limb deficiency since birth. She has an intact humerus and musculature of the upper limb with a functional elbow joint. Her forearm is incomplete, with a shortened ulna, missing radius, and no wrist or hand complex. T. L. has been wearing a prosthesis with a passive terminal device since she was 6 months old and uses her prosthesis well in mobility tasks and to stabilize objects against her body or a support surface during bimanual activities. T. L. began a preschool program 2 months ago and has adjusted well to socialization. She engages in play with her peers appropriately. She has good functional use of her left upper extremity (intact limb) and uses the residual limb to assist herself in tasks, particularly for stabilizing objects.

T. L. has been working with her prosthetist and therapists to learn to use a two-channel (voluntary closing/voluntary opening) myoelectrically controlled terminal device for the past 2 weeks. When she wears the myoelectric prosthesis throughout the day, she primarily uses it as she did her previous passive prosthesis. She has not attempted to use the "hand" for play or activities of daily living unless prompted by her parents or therapists. During her therapy sessions, she is intrigued with her new ability to open and close her "hand" but is inconsistent in controlling force of grasp and has difficulty initiating release. In today's session, she practiced picking up 1-inch blocks and placing them in a bowl, achieving the desired result in two of five trials. She was unsuccessful (and became frustrated) at picking up pegs that were much narrower than the blocks. The rehabilitation team's goals for T. L. include functional use of the prosthesis for grasp and release of household objects for feeding and self-care and school objects for play and participation in preschool activities. The team would like to increase the use of bimanual manipulation of various-sized objects.

Goal: Design a rehabilitation plan of care to help T. L. master grasp and release of objects of various sizes and levels of durability in activities meaningful for a 3-year-old child.

Case Example 3.4 **Adolescent With Transtibial Amputation Working on Returning to Competition in Track Events**

W. P. is a 16-year-old junior in high school who has been a star track athlete since he was a freshman. He currently holds his high school records in the 100-m and 200-m events, which he achieved during his sophomore year. He also finished third in the state championships that same year.

Three months ago, during the summer, W. P. was seriously injured when the garden tractor/lawnmower he was operating rolled over and down an embankment as he was making a fast turn while mowing the lawn. He sustained deep lacerations to his right foot and lower leg from the mower's blade as well as third-degree burns from the muffler. His injured limb was pinned under the tractor in a pile of leaves and debris. In the emergency department, trauma surgeons concluded that he did not meet the criteria for limb salvage and performed a long open transtibial amputation. After an intensive course of antibiotics, W. P. returned to the operating room a week later for closure to the standard transtibial level with equal anterior/posterior flaps. When his residual limb healed without difficulty, W. P. was fitted with a patellar tendon–bearing prosthesis with a sleeve and pin suspension and a Seattle Systems dynamic response foot. He quickly mastered ambulation without an assistive device and returned to school in the winter of his junior year.

W. P. is eager to return to track for his senior year. His prosthetist has fabricated a special prosthesis for him to wear in competition, an Otto Bock Healthcare Sprinter prosthetic foot designed for track-and-field athletes. He has begun training for his events and is pleased that he can run again. He has two goals: to decrease his performance time (hoping to meet the records he set the previous year) and to become much more efficient at leaving the starting block. He wants to master the new prosthesis this year so that he can concentrate on conditioning for his senior year.

Goal: Develop a prosthetic training regimen focusing on improving W. P.'s performance as he prepares to return to track competition.

4 Evidence-Based Approach to Orthotic and Prosthetic Rehabilitation☆

JEREMY E. HILLIARD, KEVIN K. CHUI, TABITHA D. GALINDO, and MICHELLE M. LUSARDI

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Describe the basic principles of evidence-based practice and apply these principles to orthotic and prosthetic rehabilitation.
2. Ask well-formulated, clearly defined, and clinically important questions applicable to orthotic and prosthetic rehabilitation.
3. Efficiently locate meaningful research specific to orthotic and prosthetic rehabilitation.
4. Critically appraise the evidence for validity and clinical importance.
5. Use the orthotic and prosthetic research evidence to make evidence-based clinical judgments that affect your practice.
6. Describe strategies to encourage practitioners to engage in greater use of evidence to inform their clinical decision making and thus practice.

What Is Evidence-Based Practice?

Providing effective health and rehabilitative care requires that practitioners be well informed about advances in assessment, medical management, technology, theory, and rehabilitation interventions. Relying on past experience or on the opinion of experts is not enough. An effective health care provider must also regularly update his or her knowledge base by accessing the ever-growing information generated by clinical researchers and their basic science colleagues.[1] However, providers in all health care disciplines face a number of challenges in efficiently and accurately locating, appraising, and applying scientific evidence in the midst of their increasingly hectic clinical practice schedules.[2-4] Health care providers who routinely use such skills and strategies demonstrate an evidence-based approach to patient care. This chapter provides guidance to the practitioner in overcoming these challenges to engaging in evidence-based practice (EBP).

David Sackett, MD, the father of evidence-based medicine, described this approach as the "integration of best research evidence with clinical expertise and patient values."[4] EBP is a broader concept that applies Sackett's physician-oriented concepts to a wide range of health professions.[4] Both models identify three major elements of evidence that are interactive and valuable, as well as a set of skills necessary to integrate each resource into an effective and informed clinical decision (Fig. 4.1). The three major elements are the following:

1. Best available information from up-to-date, clinically relevant research
2. The skilled and experienced practitioner who can accurately perform diagnostic procedures and interventions, integrate findings to efficiently determine correct diagnosis, and engage in reflective clinical practice
3. The integration of the patient's and family's issues, concerns, and hopes into the care plan

All three elements are equally important for an effective clinical decision-making process; optimal health care outcomes are grounded on integration of perspectives and priorities that each source of information brings to bear.

To make an informed clinical decision, the evidence-based rehabilitation professional must possess the skills to do the following:

1. Effectively search for and access relevant scientific evidence in the professional literature.[5]
2. Assess the strength and value of the scientific evidence that will support the decision to be made.[6]
3. Apply results of an accurate clinical examination, as well as the evidence from the literature, in the process of diagnosis, evaluation, prognosis, and development of an appropriate plan of care.[7]
4. Assess and incorporate the patient's or client's values, knowledge, preferences, and motivation into the intervention and anticipated outcomes.[8]

☆The authors extend appreciation to Rita A. Wong, whose work in prior editions provided the foundation for this chapter.

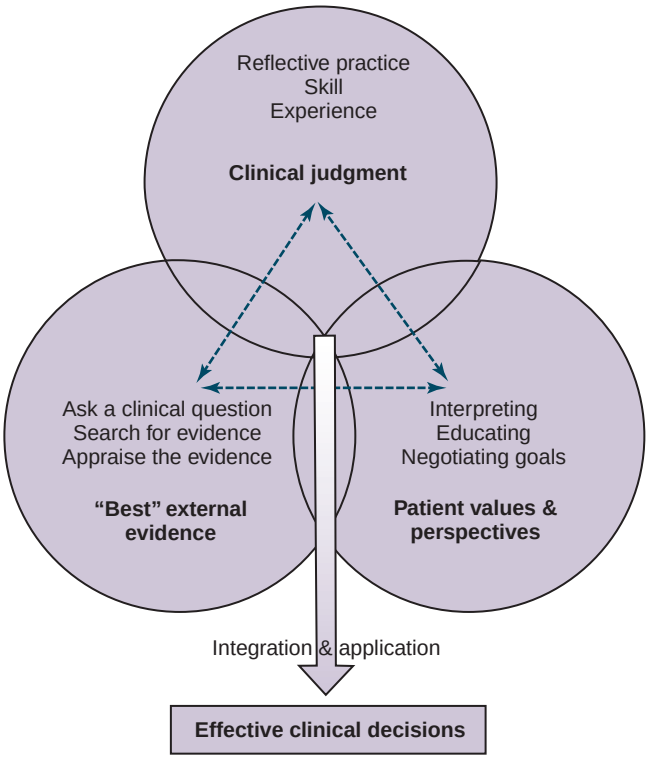

Fig. 4.1 Model of three essential and interactive components necessary for effective evidence-based health care approach to guide clinical decision making, as well as the dimensions of each.

Process of Evidence-Based Practice

EBP is essentially an orientation to clinical decision making that incorporates the best available sources of evidence into the process of assessment, intervention planning, and evaluation of outcomes. The skill set necessary for effective EBP develops over time, with practice and experience.

An EBP approach to the scientific literature is a systematic process with four primary steps[1,4,9]:

1. Posing a well-formulated, clinically important question
2. Locating meaningful research that is well targeted to the question (i.e., developing effective and efficient search strategies)
3. Critically appraising the available evidence for validity and clinical importance
4. Using the findings to make an evidence-based clinical judgment about examination or intervention options on the basis of the clinical relevance of the information applied to the needs of the individual patient

Step 1: Formulating an Answerable Clinical Question

The questions posed by researchers and the questions posed by clinicians, although similar in many respects, are asked and answered at quite different levels. Research questions combine information from groups (samples) of individuals to develop evidence about relationships among characteristics, effectiveness of examination strategies, or effectiveness of intervention strategies for the group as a whole.[10] In contrast, clinical questions seek to apply this knowledge to a single person with individual characteristics.[4,5,9] For example, clinicians ask, "Which examination strategy will provide the information most important for the clinical decision-making process for this particular individual?" and "Which intervention is likely to have the optimal outcome for this particular individual?"

The first essential step in the EBP process is developing a well-formulated, clinically important question. Sackett identifies two categories of clinical questions: broad background questions and specifically focused foreground questions.[4] *Background questions* expand our knowledge or understanding of a disorder, impairment, or functional limitation; they are often concerned with etiology, diagnosis, prognosis, or typical clinical course. Patients and their family members often ask health care practitioners background questions. Answers to background questions expand the general knowledge base used in clinical decision making. Students and novice clinicians ask many background questions as they develop expertise in their field. Even expert clinicians routinely need to seek answers to basic background questions when they encounter an unfamiliar pathologic condition or novel category of intervention. However, answers to background questions do not provide the specific evidence necessary to make individualized patient care decisions. Examples of broad background questions that might be asked by clinicians providing prosthetic and orthotic rehabilitation care include the following:

- What is the typical postsurgical rehabilitation program following a dysvascular transtibial amputation?
- What is peripheral arterial disease, and why can it lead to limb amputation?
- What neurologic functions are affected with a C7 spinal cord injury?
- What are the typical motor milestones of the first 2 years of life, and when is the achievement of these milestones considered delayed?

Foreground questions, in contrast, seek specific information to help guide management for an individual patient.[4,5,9] The most effective way to frame an answerable foreground clinical question follows the PICO model (Fig. 4.2). It identifies

P	Patient	Patient diagnostic category or key characteristic
I	Intervention	Treatment group, diagnostic tool, or prognostic marker
C	Comparison	Applicable if comparison is wanted between or among interventions, diagnostic tools, or prognostic markers
O	Outcome	What is the outcome of interest: presence of disease? Impairment? Functional limitation? Disability?

Fig. 4.2 The PICO system for formulating clinical questions includes consideration of the patient *(P)* who is receiving care; the intervention *(I)* being considered; and, if available, the reference standard with which it is being compared *(C)* and the anticipated outcomes *(O)* (positive and negative) of the intervention being considered.

the patient population of interest (P), noting specific characteristics (e.g., age, gender, diagnosis, acuity, severity) that will link the evidence to the patient care situation prompting the question. It then identifies the predictive factor, examination, or intervention (I) that is being considered. If appropriate, it identifies what comparisons (C) are being made to inform choice of examination or intervention. Finally, it clearly defines the outcomes (O) that might be expected for the given patient on the basis of the best available evidence. Using the PICO model, foreground questions that rehabilitation professionals might ask as they care for a specific individual in need of a prosthesis or orthosis include the following:

- How much does advanced age (I) affect the ability to become a functional ambulator (O) in an individual who has a dysvascular transtibial amputation (P)?
- Does supported treadmill gait training (I) improve ambulation endurance with a prosthesis (O) in older patients with dysvascular transtibial amputation (P)?
- Does the addition of functional neuromuscular stimulation (I) to a typical early rehabilitation intervention (C) enhance active muscle control (O) in individuals with incomplete spinal cord injury (P)?
- What factors predict (I) ambulation ability (O) in a young child with spastic diplegic cerebral palsy (P)?

PATIENT CHARACTERISTICS

A well-focused clinical question narrows the scope of possible patient characteristics to ones most applicable to a specific clinical problem or situation.[4,9] It defines the key characteristics that will best differentially guide the search for evidence. Characteristics or categories that help to focus a clinical question related to orthotic or prosthetic management are summarized in Table 4.1.

INTERVENTION

The term *intervention* is used broadly in the evidence-based literature. In the EBP paradigm, the intervention (I) and comparison intervention (C), described according to the PICO system, refer to the central issue for which the clinician is seeking an answer. This issue can typically revolve around an intervention, a diagnosis, or a prognosis.

Table 4.1 Patient Characteristics That May Be Used to Help Focus Literature Searches for Prosthetic and Orthotic Rehabilitation

Domain	Characteristics	Search Terms
Underlying condition	Etiology	Acquired (traumatic injury, infectious process, autoimmune disease, ischemia, vascular disease, neoplasm, cancer) Congenital condition Developmental delay Hereditary disease
	Systems affected	Musculoskeletal Neuromuscular Cardiovascular Pulmonary, respiratory Integumentary Endocrine Systemic physiologic
	Nature of condition	Chronic Progressive Degenerative Developmental Requiring remediation Requiring accommodation
	Comorbid conditions	Peripheral vascular disease Diabetes mellitus Systemic infections Cancer care, chemotherapy, radiation Heart disease Pulmonary disease Obesity Depression, anxiety Cognitive dysfunction Smoking
	Confounding factors	Alcohol use Other substance abuse Nutritional status
Family and lifespan development	Age category	Infant Toddler School-age child Adolescent Young adult Midlife adult Older adult

Continued on following page

Table 4.1 Patient Characteristics That May Be Used to Help Focus Literature Searches for Prosthetic and Orthotic Rehabilitation (Continued)

Domain	Characteristics	Search Terms
	Family system	Roles Responsibilities Caregiver
Fitness/conditioning	Level of activity	Frail Sedentary Active Elite athlete
Mobility	Use of assistive device	None Ambulatory aid (cane, crutch, walker) Wheelchair Adaptive equipment Requiring human assistance
Environmental issues	Environment	School Home Work Leisure Accessible/inaccessible
	Living arrangements	Community dwelling (alone, independent, with caregivers or family) Assisted living setting Skilled nursing

1 Intervention: a procedure or technique (e.g., a physical modality, surgical procedure, medication) (I) that is compared with alternative procedures or techniques (C).[11,12]
2 Diagnostic test: a test or measure (e.g., a bone mineral density test for identification of osteoporosis; the Berg Balance Scale for identification of fall risk) (I) that correctly differentiates patients with and without a specific condition (C).[13,14]
3 Prognostic marker: a specific set of characteristics or factors (I) that effectively predicts an outcome (O) for a given patient problem (P).[15]

DEFINING THE OUTCOME

A good clinical question focuses on the outcome that is most relevant to the patient care situation at hand. The Nagi model of disablement or the World Health Organization International Classification of Function (ICF) model provides a framework for clinicians to define the outcome they are most interested in: pathology or disease at the cellular level, impairment of a physiologic system, functional limitation at the level of the individual, or disability or handicap that interferes with the normal social role (Fig. 1.3).[16,17]

Case Example 4.1 **Elderly Woman With Recent Transtibial Amputation**

F. H. is an 89-year-old woman who had an elective transtibial amputation 4 days prior due to peripheral artery disease (PAD) unrelated to diabetes. Her postoperative pain is being managed with a narcotic, and she has been mildly disoriented and distractible during rehabilitation visits. At present, she requires moderate assistance in rising to standing and minimal assistance and directive cues to ambulate in a "hop to" pattern with a rolling walker. Her medical history includes mild congestive heart failure managed effectively with diuretics, hypertension managed effectively with beta-blockers, and a compression fracture (2 years ago) of the midthoracic spine secondary to osteoporosis. She recently had lens implants for cataracts. Before her hospitalization, she lived somewhat independently in an assisted living complex, walking long functional distances within the sprawling facility using a straight cane and eating her noon and evening meals in the communal dining room. She served as vice-chair of the Resident Council and was the organizer of an active bridge club and book discussion group. Her nearest living relative is a granddaughter who is finishing medical residency at the hospital.

The amputation/prosthetic clinic team has been charged with developing a plan for prosthetic rehabilitation, including determining her potential for prosthetic use, the optimal setting for rehabilitation intervention, the likely duration of rehabilitative care, and preliminary prosthetic prescription.

QUESTIONS TO CONSIDER

Possible clinical questions that the team would ask to guide her plan of care include the following:

- Which strategies (pharmacologic and nonpharmacologic) for postamputation pain management (I, C) will minimize risk of delirium and assist motor and cognitive learning (O) in elderly individuals with multiple comorbidities (P)?
- Which functional and cognitive characteristics (I) provide the best indication of potential for prosthetic use (O) in elderly individuals with multiple comorbidities?
- What intrinsic and extrinsic factors (I) influence the duration of preprosthetic and prosthetic care (O) for older adults with recent transtibial amputation (P)?
- Which prosthetic foot option (nonarticulating, articulating, or dynamic response) (C, I) and suspension system (silicone suspension sleeve with pin, supracondylar cuff, waist belt, and forked-strap extension aid) (C, I) would maximize potential for safe community ambulation (O) in older patients with transtibial amputation, impaired postural control, and limited cardiovascular endurance (P)?

Case Example 4.2 **Young Adult With Incomplete Spinal Cord Injury**

S. K. is a 19-year-old with incomplete C7 level spinal cord injury who has just been admitted to the rehabilitation facility, 2 weeks after injury. S. K. was a backseat passenger injured in a driving-under-the-influence motor vehicle accident following a Thanksgiving homecoming football game victory at his high school. He was unconscious at the scene and for several hours afterward. He was given methylprednisolone in the emergency department 2 hours after injury. Radiographs revealed an anterior wedge fracture of C6 vertebra. After intubation, he was admitted to the neurologic intensive care unit; 2 days later he had surgical fusion of C4 through C7 with immobilization in a cervical halo. During the postoperative period, pneumonia developed and has since resolved. Sensation is intact in all sacral and lumbar 3 to 5 dermatomes, and he has 2/5 strength in dorsiflexion and plantar flexion bilaterally, with hyperactive deep tendon reflex at the knee. He can tolerate sitting in a bedside recliner or high-back reclining wheelchair for approximately 45 minutes. He is anxious to know whether he will be able to walk again and, although frightened by what has occurred, appears to be motivated to begin his rehabilitation.

Before his injury, S. K. lived at home while attending a nearby state university as a biology major. His intention was to eventually apply to medical school to become an orthopedic surgeon. His parents and younger sister are involved in his care; a family member is with him for most of the day. He has a cousin, now in law school, who was born with spina bifida and uses a wheelchair for primary mobility.

QUESTIONS TO CONSIDER

Possible clinical questions that the team might ask to guide his plan of care might include the following:

- What are the most powerful indicators (I) of potential for return to functional ambulation (O) in patients with incomplete cervical spinal cord injury (P)?
- Which physical therapy interventions (I, C) will best improve functional lower extremity strength (O) in patients with incomplete cervical spinal cord injury who are immobilized in a cervical halo (P)?
- What strategies (pharmacologic and nonpharmacologic) (I, C) are effective in managing abnormal tone without compromising potential for strengthening (O) in patients with incomplete cervical spinal cord injury (P)?
- Will functional neuromuscular stimulation (I) reduce orthotic need and improve quality of gait (O) in patients with incomplete cervical spinal cord injury (P)?

Case Example 4.3 **Toddler With Spastic Diplegic Cerebral Palsy**

E. C. is an 18-month-old with spastic diplegic cerebral palsy being cared for by an interdisciplinary early intervention team. E. C. was born prematurely at 34 weeks of gestation after her mom's high-risk first pregnancy. Her course in the neonatal intensive care unit was relatively uneventful: She did not require ventilatory assistance but did have periodic episodes of apnea and bradycardia until she reached a weight of 4 lb. She was discharged to home at 3 weeks of age and appeared to be developing fairly typically until approximately 8 or 9 months of age. Her parents noted increasing "stiffness" of her lower extremities when in supported standing, a tendency toward "bunny hop" rather than reciprocal creeping, and over-reliance on upper extremities to pull to stand (as compared with her cousins and babies in her playgroup). Her pediatrician referred the family to a pediatric neurologist, who found mild to moderate hyperreflexia and decorticate pattern hypertonicity in her lower extremities. She has been followed in the early intervention program for 7 months; the team is charged with determining whether this is an appropriate time for orthotic intervention because she is ready to begin gait training.

QUESTIONS TO CONSIDER

Questions that might be asked to guide her plan of care include the following:

- What are the minimal levels of muscle performance and range of motion at the hip and knee (I) necessary for effective ambulation with an articulating ankle-foot orthosis (AFO) (O) in children with spastic diplegic cerebral palsy (P)?
- Which type of therapeutic activity or approach (e.g., neurodevelopmental [NDT], sensory integration, proprioceptive neuromuscular facilitation [PNF]) (I) is most effective in assisting dynamic postural control of the lower trunk and lower extremities during transitional and locomotor tasks (O) in children with spastic diplegic cerebral palsy (P)?
- What accommodations or adaptations of the home environment (I) will best assist safety, as well as developmental progression (O), in children with spastic diplegic cerebral palsy (P)?

Step 2: Locating and Accessing the Best Evidence

Once the clinical question has been clearly identified and articulated, the next step is to search the rehabilitation research literature for relevant information. The second step is to access full text articles, access their quality, and read those that might inform decision making.[18-21] Among the many ways to find citations and (hopefully) the full text of the article are the following:

- Regularly visit key journal websites to review what has been recently published or published ahead of print that might be relevant to the question. For example, the *Journal of Prosthetics and Orthotics* (https://www.oandp.org/page/jpo_nm) allows full access to any journal article published in the years previous to the current year. This strategy can be somewhat "hit or miss" in terms of effectiveness.
- Use the index in the back of up-to-date textbooks as a reliable secondary source of information; this can be especially useful to answer background questions.

- Use an internet search engine such as Google Scholar (http://scholar.google.com; free access), which provides both unjuried and juried resources and requires the ability to carefully assess the quality of the source and of the information that has been located.
- Use electronic databases of peer-reviewed journals such as PubMed/Medline/OVID (http://www.ncbi.nlm.nih.gov/pubmed; free access) or the Physiotherapy Evidence Database (PEDro; http://www.pedro.org.au/; free access) using appropriate key words. Professional organizations such as the American Physical Therapy Association (APTA) provide links to search engines (http://www.ptnow.org/ArticleSearch) or synthesized evidence (http://www.apta.org/PTNow) for organization members. Many medical libraries maintain subscriptions to multiple medical databases through services such as EBSCO (http://health.ebsco.com; subscription access) or ProQuest (http://www.proquest.com/products-services/pq_health_med_comp.html), among others.
- Subscribe to electronic table of content (eTOC) alerts from research journals relevant to their practice areas. For example, *Physical Therapy* (http://academic.oup.com/ptj), the *Journal of Geriatric Physical Therapy* (http://www.jgpt.org), the *Journal of Neurologic Physical* (http://www.jnpt.org), *Clinical Biomechanics* (http://www.clinbiomech.com), and the *Archives of Physical Medicine and Rehabilitation* (http://www.archives-pmr.org), among many others will send table of contents for current issues to email, cellular phones, tablets, e-readers, and other devices.

Each strategy has pros and cons in terms of efficiency and availability. Health professionals who use an evidence-based approach to patient care develop, over time, an information-seeking strategy that works within their time constraints and accessible resources.[22-24]

SOURCES OF EVIDENCE

Clinicians can access information from the research literature in a variety of formats and from a variety of sources. One of the most accessible formats is a journal article.[25,26] Table 4.2 provides a list of the journals particularly relevant

Table 4.2 Journals Relevant to Orthotic and Prosthetic Rehabilitation

Journal Title	Abbreviation

to orthotic and prosthetic rehabilitation. These journals often contain original clinical research, reviews of the literature, and case reports focused on issues most relevant to the particular professional group.

The medical literature is divided into primary and secondary sources of information. Primary sources are the reports of original scientific work commonly published as journal articles. Secondary sources are summary reviews of the primary literature on given topics. Secondary sources include textbooks, review articles, systematic reviews (such as meta-analyses, critical reviews of individual articles, clinical practice guidelines [CPGs]), and website summaries. Research studies are the foundation of meaningful evidence. Academic textbooks, biomedical journals, and internet websites aimed at health professionals and biomedical researchers are common sources of research evidence.

Textbooks

Academic textbooks can be a good starting point for locating background information, particularly for content areas that change slowly (e.g., gross anatomy or biomechanics). Evidence-based textbooks are well referenced, go through a review process, and are typically updated every 3 to 5 years. They summarize clinical studies and opinions of experts and analyze/synthesize the impact of the research and expert opinion on the topic. Some textbooks are currently available online, which provides the advantage of frequent updating of specific sections as new research evidence emerges and allows the reader to immediately hyperlink to primary research article sources. The website FreeBooks4Doctors! (http://www.freebooks4doctors.com) provides hyperlinks to many key medical textbooks free of charge online. Many other online textbooks are available for purchase. Box 4.1 lists key indicators of quality in academic textbooks.

Primary Sources: Journal Articles

Journal articles may serve as either primary or secondary literature sources. They can be useful for both background and foreground clinical questions. Primary research articles are those in which the author presents the findings of a specific original study.[27,28] It is best to use this category of evidence when dealing with rapidly evolving areas of health care (which many clinical practice questions fall into). Identifying two or three high-quality primary research articles that generally provide similar supporting evidence offers strong evidence on which to base a clinical decision. Searching, critiquing, and synthesizing primary research sources is a time-intensive task.

Secondary Sources: Integrative and Systematic Review Articles

Use of high-quality secondary source journal articles to guide evidence-based determinations can be a time-efficient strategy for clinicians.[29,30] Quality indicators for secondary source articles include a comprehensive search of the literature (using an explicit search strategy) to identify existing studies, an unbiased analysis of these studies, and objective conclusions and recommendations on the basis of the analysis and synthesis.[31] Secondary sources are available in a variety of formats: integrative narrative review, systematic review, meta-analysis, and CPG. Each of these summative resources can be an effective and time-efficient method to obtain a critical assessment of a specific body of knowledge. However, there are benefits and drawbacks associated with each type of summative resource.

In an *integrative review article*, the author reviews and summarizes, and sometimes analyzes or synthesizes, the work of a number of primary authors.[32] These narrative reviews are often broad in scope, may or may not describe how articles were chosen for inclusion in the review, and present a qualitative analysis of previous research findings. The quality (validity) of the narrative review varies with the expertise of the reviewer and requires careful assessment by the reader.

Systematic reviews are particularly powerful secondary sources of evidence that typically analyze and synthesize controlled clinical trials.[29,31,33] Well-done systematic reviews are valuable sources of evidence and should always be sought when initiating a search. Box 4.2 lists key indicators of a quality systematic review. Systematic reviews are typically focused on a fairly narrow clinical question, are based on a comprehensive search of relevant literature, and use well-defined inclusion and exclusion criteria to select high-quality studies (typically randomized controlled trials) for inclusion in the review. Each study included in the review is carefully appraised for quality and relevance to the specific clinical topic. The author attempts to identify commonalities among study methods and outcomes, as well as account for differences in approaches and findings. A good systematic review is labor intensive to prepare, thus only approximately 1.5% of all journal articles referenced in Medline are true systematic reviews.[34] Although the numbers are low, increasing numbers of systematic reviews are being published, including ones on topics relevant to orthotics and prosthetics. For example, a PubMed search from 2013 to January 2018 of the literature using the terms "'limb amputation' AND rehabilitation" combining the limits (1) review and (2) English yielded 33 applicable

Box 4.1 Quality Indicators for Textbooks and Internet Sources of Evidence

- Credentials of the authors
- Quality of references
- Recent/regular updating
- Endorsement by respected groups
- Peer reviewed
- Disclosure of funding source

Box 4.2 Quality Indicators for Systematic Review Articles

- Exhaustive search for evidence
- Clearly identified quality criteria for inclusion
- Multiple authors with independent judgments
- Impartial, unbiased summary
- Clearly stated conclusions: ready for clinical application
- If meta-analysis: statistical manipulation across studies

reviews (Appendix 4.1); by comparison, the same search from 2008 to January 2013 returned 20 reviews.

A *meta-analysis* is a type of systematic review that quantitatively aggregates outcome data from multiple studies to analyze treatment effects (typically using the "odds ratio" statistic) as if the data represented one large sample (thus with greater statistics power) rather than multiple small samples of individuals.[29,31,35] The limitation to performing a meta-analysis is that, to combine studies, the category of patients, the interventions, and the outcome measures across the studies must all be similar. Meta-analyses can provide more powerful statements of the strength of the evidence either supporting or refuting a given treatment effect than the separate assessment of each study. Because of the difficulty in identifying studies with enough similarity to combine data, only a small subset of systematic reviews has been carried to the level of a meta-analysis. One meta-analysis (and one systematic review) was identified in PubMed using the terms "'limb amputation' AND 'rehabilitation'" combined the limits (1) meta-analysis, (2) English, and (3) published in past 5 years.[36]

Secondary Sources: Clinical Practice Guidelines

Another secondary resource for clinicians may be CPGs that have been developed for application to clinical practice on the basis of the best available current evidence.[37] Most existing CPGs have been developed for screening, diagnosis, and intervention in medical practice. CPGs are intended to direct clinical decision making about appropriate health care for specific diseases among specific populations of patients. The best available evidence upon which CPGs are typically based combines expert consensus and review of clinical research literature.[38] Most are interpreted as prescriptive, using algorithms to assist decision making for appropriate examination and intervention strategies for patients with given characteristics. Examples of CPGs that may be relevant to orthotic and prosthetic rehabilitation are listed in Appendix 4.2. The National Guidelines Clearinghouse is the most comprehensive database in the United States for CPGs (http://www.guidelines.gov).

ELECTRONIC RESOURCES AND SEARCH STRATEGIES

A number of electronic databases can assist clinicians in quickly locating primary and secondary sources of evidence to guide clinical decision making (Table 4.3). When seeking articles, it is often helpful to use several different databases. The APTA provides access to many electronic resources described later as a service to APTA members via its ArticleSearch (formerly Open Door) portal on the website http://www.ptnow.org/ArticleSearch.

Using an electronic database effectively is a two-step process. First, the searcher must locate applicable citations that provide the title of the article, author, and other key identifying information (e.g., journal, issue, year, pages). Most often, these citations also provide an abstract of the article. Sometimes the searcher can gather enough information about the applicability of the article for his or her needs purely on the basis of the information found in the title and abstract. However, most often the searcher must access the full-text article to adequately assess the findings of the study. Citations and abstracts are readily available free of charge from numerous databases. However, access to the full text of articles often requires a paid subscription to search databases.

Table 4.3 Electronic Databases Used to Search for Relevant Evidence

Acronym	Database Information	Access
—	Academic Search Premier	By library access
Best Evidence	ACP Journal Club and Evidence-Based Medicine (critical and systematic reviews)	http://www.acpjc.org
CCTR	Cochrane Controlled Trials Register	By subscription or library access
CDSR	Cochrane Database of Systematic Reviews	By subscription or library access
CINAHL	Cumulative Index of Nursing and Allied Health Literature (citations and abstracts)	By subscription or library access (http://www.cinahl.com)
DARE	Cochrane Database of Abstracts of Reviews of Effectiveness	By subscription or library access
EBM Online	Evidence-based Medicine for Primary Care and Internal Medicine (critical reviews and systematic reviews)	By subscription (http://www.ebm.bmj.com)
Embase	Embase/Elsevier Science (citations and abstracts)	By subscription (https://www.elsevier.com/solutions/embase-biomedical-research)
—	PTNow/American Physical Therapy Association (citations, abstracts, annotations)	By membership in American Physical Therapy Association (http://www.apta.org/ptnow)
Medline	National Library of Medicine (abstracts)	By library access
NIH	National Institutes of Health Library	https://www.nih.gov/research-training/library-resources
OVID	A collection of health and medical subject databases (abstracts and full text)	By subscription or library access (http://www.ovid.com)
PEDro	The Physiotherapy Evidence Database (systematic reviews)	http://www.pedro.org.au
PubMed	National Library of Medicine (abstracts)	http://www.ncbi.nlm.nih.gov/pubmed (no charge)

Locating Citations

The National Library of Medicine, through the database PubMed, produces and maintains Medline, the largest publicly available database of English language biomedical references in the world. PubMed references more than 4600

journals, including many key non–English language biomedical journals. These journals, in the aggregate, include more than 15 million individual journal article citations. This database is also a rich source of citations for quality systematic reviews. Journals indexed in PubMed must meet rigorous standards for their level of peer review and the quality of the articles published in the journal; this gives the searcher some confidence in the information that is located through PubMed. PubMed can be accessed through the National Library of Medicine's website (http://www.nlm.nih.gov). OVID is another Medline resource; it is typically accessed via library subscription and often links full text articles.

The Cumulative Index of Nursing and Allied Health Literature (CINAHL) includes journal citations from a larger pool of nursing and allied health fields than is found in Medline. Many of these journals have a much smaller circulation than the typical Medline-cited journals, and the quality of these smaller circulation journals may not meet PubMed requirements. Thus the reader must be aware that closer scrutiny of validity and methodologic quality may be necessary. However, the greater inclusion of rehabilitation-focused journals in the CINAHL database makes this an important database for rehabilitation professionals. This database is available only to paid subscribers (library or individual subscriptions).

PTNow is a database of the APTA that can facilitate the knowledge translation process and is available free of charge to members of the association (http://www.ptnow.org).[39–41] Resources in PTNow have been reviewed, synthesized, and summarized by physical therapy academicians, researchers, and clinicians. Here an evidence-based practitioner may search for articles directly using ArticleSearch or review secondary sources including "Clinical Summaries," "CPGs," or "Cochrane Reviews."

Clinical Summaries offer a synthesis of evidence, called "Clinician's QuickTakes," regarding the management of specific conditions in different populations, including information on incidence and prevalence, classification, screening, examination, diagnosis, prognosis, intervention, medical management, and cases.[42] The full version of a clinical summary can also include information pathoanatomic features, risk factors, and impact on daily life. Clinical summaries that include information on orthotics or prosthetics include Spina Bifida: Myelomeningocele,[43] Cerebral Palsy,[44] Down Syndrome,[45] Guillain-Barré Syndrome,[46] Knee Osteoarthritis,[47] Multiple Sclerosis,[48] Patellofemoral Pain,[49] Spinal Cord Injury in Children and Adolescents,[50] Spinal Cord Injury in Adults,[51] Stroke,[52] and Traumatic Brain Injury in Civilian and Military Populations.[53]

Practitioners can print a full or a portable clinical summary. Current practice-changing information relevant to physical therapy, sports medicine, occupational therapy, and speech therapy can be found in "Rehab Reference Center" (RRC). There is also a section on "Tests" that includes tests and measures cited in Clinical Summaries and APTA section-generated CPGs that can be used in functional limitation reporting.

PEDro is a database of the Centre for Evidence-Based Physiotherapy at the University of Sydney, Australia, and is available to the public free of charge (http://www.pedro.org.au). PEDro lists CPGs, systematic reviews, and clinical trials. An advanced search allows the searcher to select the type of therapy, problem, body part, and subdiscipline. Both the PTNow and PEDro databases focus on high-quality studies related to physical therapy. Their benefit is ease of identifying citations applicable to physical therapy and rehabilitation. To search either database successfully, the research question should be fairly broad, using synonyms that represent words in the title. Both databases contain only a fraction of the citations found in PubMed; however, all of the citations are directly applicable to rehabilitation. A search of PEDro using "orthoses" identified one practice guideline, 31 systematic reviews, and 30 clinical trials, all relevant to physical therapy (Appendix 4.3). A similar search in ArticleSearch identified 7306 articles published since 2013.

The Cochrane Database of Systematic Reviews (http://www.cochranelibrary.com) is widely accepted as the "gold standard" for systematic reviews. Groups of experts perform comprehensive and quantitative analysis and synthesis of the existing research on well-focused topics and distill the findings into scientifically supported recommendations. Cochrane reviews use a standardized format and carefully follow rules to decrease bias in the choice of articles to review and in the interpretation of the evidence. Although few address physical therapy exclusively, rehabilitation procedures and approaches are a component of many of these reviews. The findings are reported in structured abstracts that summarize the key aspects of the full review including the authors' conclusions about the strength of the evidence and their recommendations. These structured abstracts are available free online. However, access to full-text review articles requires a paid subscription.

Finding valuable secondary references on the web is increasingly possible. However, searchers must carefully scrutinize these materials because there is wide variability in accuracy and objectivity of the published information.[54] This evidence represents such varied sources as reports of original research, research reviews from trusted experts, student summaries that are non–peer reviewed, marketing advertisements (sometimes presented visually to appear to be a peer-reviewed research report), and lobbying groups' perspectives and persuasive arguments. There are many patient-focused sites and fewer practitioner-focused ones. The quality indicators identified in Table 4.2 are applicable to internet websites and textbooks.

Executing Search Strategies

Often, the first search for citations results in one of two extremes: hundreds or thousands of citations with only a few related to the clinical question being asked, or almost no citations focused on the topic of interest.[18,55,56] Searchers should look carefully at the citations that result from a search. In the search that is too broad, the searcher must examine closely what he or she is really looking for, comparing titles and key words that have resulted from the search. Often, the search is repeated by rewording or setting limiters to narrow results and omit the previously identified unrelated citations. A searcher who uses the search term *prosthesis* may find that the results include articles about such diverse topics as joint prostheses, dental prostheses, and skin prostheses, as well as limb prostheses. Search

terms should be as applicable to the specific clinical question being posed as possible; using more precise search terms such as *limb prosthesis, leg prosthesis, arm prosthesis,* or *artificial limb* may be more effective.

Searchers should recognize that the search engine is simply matching the search words that the searcher has entered with subject headings linked to the article by the database administrator or librarian using predefined medical subject heading names or words included in the title or abstract. Searchers may need to adjust search terms to find applicable references. For example, a PubMed (http://www.ncbi.nlm.nih.gov/pubmed/) search of the English language literature published in the past 5 years (between January 2013 and January 2018) using the search terms *below-knee amputation* combined with the search term *prosthetic rehabilitation* yielded 19 citations. The same search using the term *transtibial amputation* rather than *below-knee amputation* yielded 143 citations, with five citations overlapping between the two searches. A third search using the term *trans-tibial amputation* in place of *transtibial amputation* yielded 15 citations, none of which overlapped with the first or second searches.

A search can be unforgiving to misspellings or, as described earlier, slight differences in search terms. If the searcher finds one citation that is on target for the topic of interest, repeating the search using terms from that article's title or abstract, as well as subject headings (key words), may yield additional appropriate citations. Using a variety of synonyms or Medical Subject Headings (http://www.ncbi.nlm.nih.gov/mesh) when repeating the search can help the searcher to be more confident that the correct concepts are being targeted. Searchers should note the search terms that result in successful searches so that future searches can be most efficient. Searchers using PubMed can set up a permanent search by establishing a "cubby." This service is free and fully available via internet connection to PubMed. Online directions help users set up cubbies that save search terms. Searchers can periodically check their cubbies and ask for literature updates on the topic.

In addition to the search topic, a good clinical question will often focus on one of three broad categories of clinical questions: treatment/intervention/therapy, diagnosis, or prognosis.[57] Searchers can use these terms to narrow their search as needed. Searchers must recognize that each database uses its own set of key words and may (or may not) include the title words, abstract words, or common sense clinical terms in their electronic search process. Familiarity with key headings used by the database can minimize frustration during the search process; combining words from the title or abstract (e.g., by using Boolean operators such as "AND," "OR," or "NOT"), as well as using synonyms for the clinical terms or concepts of interest, can also assist the search process. In many databases, searchers can choose to limit the search to systematic reviews addressing their topic of interest.

Searching for Interventions

Words that are likely to limit the search to studies that focus on interventions include the following[58]:

- Therapeutic use
- Clinical trials
- Therapy
- Comparative studies
- Randomized controlled trial (to limit search to articles of highest quality, only if there are many relevant articles)
- Rehabilitation

Examples of search terms for therapeutic interventions commonly used in prosthetics and orthotics include the following:

- Prosthetic rehabilitation
- Orthotic use
- Physical therapy techniques
- Prosthetic fitting
- Prosthetic training
- Gait training
- Therapeutic exercise
- Edema management
- Balance training
- Skin care
- Strength training

Diagnosis as the Intervention

If the primary clinical question relates to making an accurate and efficacious diagnosis about some aspect of the patient's condition or to screening patients to determine the need for more specific assessment, the health practitioner may search the "diagnosis" literature for relevant studies. General search terms that help limit the search to general studies focusing on diagnosis include the following[57]:

- Diagnosis (actual disease or disorder)
- Diagnostic use (tool used in diagnosis)
- Diagnosis, differential
- Sensitivity
- Specificity
- Accuracy
- Predictive value
- Construct validity

Natural History or Prognosis

Studies of the prognosis of medical pathologic conditions and impairments are becoming increasingly available. Such studies attempt to predict who is most likely to benefit from specific treatment interventions or determine whether specific characteristics of patients or their environment predict outcomes. Search terms that are likely to limit the citations to those focused on the general category of prognosis include the following[58]:

- Experimental cohort studies
- Prognosis
- Prognostic factors
- Disease progression
- Recurrence
- Morbidity
- Mortality
- Incidence
- Prevalence
- Clinical course
- Outcomes

Systematic Review

Currently, PubMed does not identify systematic review as a specific "publication type." The searcher must use the limits "meta-analysis" or "review" under the Type of Article option. When "systematic review" is used as a search term, several types of reviews are retrieved, not limited to actual systematic reviews. Articles commonly identified as review-academic, CPGs, review-tutorial, meta-analysis, guideline, and consensus development conference are all categorized in PubMed under the term systematic review. Search terms that are likely to limit the citations to ones focused on true systematic reviews include the following:

- Systematic review (as a title word [tw])
- Systematic (as a key word)
- Meta-analysis
- Development
- Validation
- Cochrane database of systematic reviews (as a journal name [jn])

LOCATING FULL-TEXT ARTICLES

Once appropriate citations have been found via a search of the literature, the next step is to locate the full text of articles that appear to be most closely related to the clinical question of concern. Individual journals are published and owned by publishing companies that support themselves by paid journal subscriptions. Each journal has its own mechanism for providing access to the articles it contains. If the journal is published by a specific professional organization, members of that organization typically have access to a delivered hard copy of the journal or access via the organization's website (by entering an assigned user name and password).

Libraries purchase hard copy and online access to specific journals, either bundled together as part of an intermediary company service (e.g., EBSCO or ProQuest), as stand-alone subscriptions, or as a publisher aggregated offering of several or all of its journals at a specified price. Libraries make the online copies of these journals available to their library patrons, either free of charge or for a specified library fee. Some journals provide full text free to the public via the internet, either for all issues or for articles published after a certain period of time (e.g., 1 to 2 years after publication). Most journals provide full text of individual articles for a fee; this fee may be as much as $20 to $25 per article. One benefit of searching the literature on PubMed is that this database provides a link to any online access to a specific citation, both those with free access sources and those with a fee attached. The website http://www.freemedicaljournals.com lists the various biomedical journals that provide full text free, provides the hyperlink to the journal website, and identifies any limitations to free access (often time since publication). Health care practitioners should search out the availability of full-text biomedical journal articles (either hard copy or online) from the libraries to which they have regular access. Access will vary widely on the basis of the work setting and the mission of the library at the health facility or in the community.

Step 3: Critically Appraising the Evidence

Once the clinician has located and screened the article to ensure that it is reasonably focused on the clinical research question of interest and applicable to the patients in his or her clinical practice, the clinician must critically appraise the methodologic and analytic quality of the research process used in the study.[59] This is a skill that clinicians can develop with consistent practice, over time, and is well worth the effort involved.[22,23] Participation in study groups or journal clubs often helps development of this useful EBP skill.[60,61]

OVERALL METHODOLOGIC QUALITY

The best-quality research evidence comes from studies with a carefully articulated research question, an appropriate design and methodology, and a sample representative of the population of interest. No clinical research study or article is perfect, and the critical appraiser of the research literature must develop skills to *weigh the evidence* that an article provides to determine whether the information is accurate, relevant, and clinically important for his or her patients.[59,62] Just because something is published and in print does not ensure that it provides valuable or accurate information. Whether the clinical study focuses on treatment/intervention, prognosis, or diagnosis, the overall purpose of critical appraisal is to determine the extent to which threats to internal and external validity of the study bias, and potentially invalidate, the findings of the study.[63] The clinician is interested in determining whether, and to what degree, the findings of the study truly represent the answer to the research question asked in the study. Box 4.3 lists a series of questions about the overall quality and applicability of primary research studies. Some questions are applicable across all categories of primary research; others are specific to certain categories. Box 4.4 identifies quality assessment questions applicable to the secondary source category of systematic review.

Sample: Adequacy and Appropriateness

Sample size must be considered when making judgments about the methodologic quality of a study. In studies with small sample sizes, a few nonrepresentative subjects can skew data substantially and lead to statistical findings that are nonrepresentative of the parent group.[64] In addition, the natural variability between subjects may end up masking real differences when sample size is low. There is no absolute minimum number of subjects identified quantitatively as the minimum needed for a legitimate study. However, research textbooks often recommend 8 to 15 subjects per group as a minimum number to ensure that the statistical analysis has at least a reasonable opportunity of demonstrating real differences or real relationships if they are present.[10,65] The larger the sample size, the more likely that the sample will represent the population from which it has been drawn.

Researchers, as well as readers of research articles, can use a power analysis to evaluate adequacy of the sample size. A power analysis provides an objective estimate of the minimum sample size necessary to demonstrate real differences or relationships between and among groups.[66-68]

Box 4.3 Questions to Consider in the Critical Appraisal of a Research or Review Article

For All Studies

- What criteria were in place in the database used to find the study (e.g., journals referenced in PubMed have met stringent quality criteria)?
- How up to date (recent) is the study?
- Is the purpose of the study clearly stated? How closely does the purpose of the study address the clinical question of concern?
- How comprehensive is the review of the literature? How up to date and relevant are the references cited in the article? Does the review of the literature support the need for the study that is being reported?
- Are the outcome measurement tools used in the study described sufficiently? Are they appropriate to the clinical question of concern?
- Is evidence of the reliability and validity of each outcome measurement tool presented? Is the evidence adequate for the clinical question of concern?

For Studies of Interventions/Treatments/Therapy

- Have subjects been randomly assigned to groups?
- Is there a control group (or placebo or standard care group) used to compare with the experimental group?
- Are the researchers collecting outcome data blind to subject group assignment?
- As feasible, are subjects blinded to their group assignment?
- How similar are the experiment and control groups? Optimally, the only difference should be the intervention.
- Do confounding variables make the groups different before intervention?

For Studies Concerned With Prognosis

- Are the researchers collecting outcome data blind to each subject's score on prognostic factors?
- Is the period of follow-up sufficiently long to ensure that the outcome of interest is captured?
- Is there evidence from repeated analysis with a second group of subjects with similar results to provide confirmation of the prognostic factors being investigated?

For Studies Concerned With Diagnosis

- Has the new diagnostic test been compared with an accepted reference standard?
- Is the researcher performing the new diagnostic test blind to each subject's score on the reference standard?
- Is there evidence from repeated analysis with a second group of subjects with similar results to provide confirmation of the accuracy of the new diagnostic test?

Box 4.4 Questions Used to Assess Quality of a Systematic Review

Formulation of Objectives

- Is the topic (purpose of the review) well defined?
- Intervention
- Patients
- Outcomes of interest

Literature Search for Studies

- Was the search for papers thorough?
- Use of search terms that fully capture key concepts
- Identification of databases or citation sources used
- Search methods exhaustive, international in scope
- Search methods described in enough detail to replicate
- International in scope
- Search terms that fully capture search concepts

Study Selection

- Were study inclusion criteria clearly described and fairly applied?
- Explicit inclusion and exclusion criteria
- Criteria should be applicable to the topic
- Selection criteria are applied in a manner that limits bias
- Account for studies that are rejected

Assessing Quality of Design and Methods

- Was study quality assessed by blinded or independent reviewers?
- Was missing information sought from the original study investigators?
- Do the included studies seem to indicate similar effects?
- Were the overall findings assessed for their robustness?
- Was the play of chance adequately assessed?

Data Gathering

- Was information from each article extracted using a standardized format?
- Does the information gathered from each article include the following?
  - Type of study (e.g., randomized, controlled trial)
  - Characteristics of the intervention for experimental and control groups
  - Key demographics of all subjects
  - Primary outcome of importance
  - An accounting for missing data

Pooling Method

- Are selected studies similar enough to be pooled for analysis?
- In design
- In interventions
- In operational definition of outcome variable

Discussion, Conclusions, Recommendations

- Are recommendations based firmly on the quality of the evidence presented?
- Are conclusions and recommendations justified on the basis of the analysis performed?

Inclusion of a power analysis as a standard part of the research design is a fairly new concept. Thus, although the presence of a power analysis is helpful in assessing the adequacy of the sample size, lack of a specifically identified power analysis—particularly in older studies—does not necessarily indicate a weak study.

A power level (β) of 0.8 (80%) is generally considered acceptable in ensuring that, if real group differences (or

relationships) are present, the study design is sensitive enough to pick them up. A power analysis considers five factors in the determination of power. Knowing any four of these five factors allows the reader to calculate the final factor.[67] The five factors include the following:

1 The significance level (α coefficient) set for the statistical analysis of the outcome variable
2 Anticipated variance (e.g., standard deviation) within each group of subjects related to the outcome variable
3 Sample and group size
4 The anticipated effect size for the intervention or relationship; how large a difference or a correlation does there need to be to ensure that the outcome under review is important or clinically meaningful?
5 The desired level of power (β coefficient), an estimate of the likelihood that a real difference between groups will be demonstrated if it exists (avoiding a type II error)

Power analysis performed in preparation for a study (i.e., before subject recruitment, data collection, or analysis) identifies the ideal number of subjects that should be in each group.[29] When a power analysis is performed after the data analysis has been completed, it is used to determine the likelihood that small sample size affected the statistical analysis when insignificant findings occurred.[69]

When a power analysis is performed before implementation of a study, most use a significance level of $\alpha = 0.05$ or lower and the power level of $b = 0.8$ or higher. The score for effect size and anticipated group variance will be study specific. Typically, researchers provide references from prior research or their own pilot data to justify their choices of effect size and variance. This use of power analysis provides evidence of a rigorous research design and helps the clinician to trust the findings of the study.

The next important appraisal of the sample concerns its representativeness: to what extent are the subjects in the sample similar to (and therefore representative of) the "population" of interest and to the individual for whom the clinician is caring? The goal of all research studies is to make decisions about a general population of people on the basis of the findings of a representative sample from that population. How well a sample represents the larger group to which results will be generalized is a function of subject recruitment, selection, and retention.[70,71] In appraising an article to use as evidence for clinical decision making, the health professional must consider how subjects were selected and assigned to groups (hopefully randomly), what criteria were used to determine whether a possible subject was included or excluded from the study, and the reasons that subjects who started the study may have dropped out before data collection was completed. Study results will be biased if the sample used for the study is not representative of the underlying population. Small variations randomly occurring across all subject groups may be acceptable. Larger variations, particularly ones that systematically affect one subject group more than others, may introduce unacceptable amounts of bias.

As a critical appraiser of the research, the evidence-based practitioner must be on the alert for sampling bias.[72,73] In the ideal world, any subject in the patient population of interest should be equally likely to be chosen to be a subject in the study. Realistically, this is rarely the case. No one researcher has access to each older adult who has had a transtibial amputation, each child with cerebral palsy, or each young adult with an incomplete spinal cord lesion. The researcher should provide enough evidence in his or her discussion of the study's methodology that the reader can be reasonably comfortable that the methods implemented for choosing subjects provided access to subjects reasonably representative of the breadth of subjects with the target characteristics under investigation.

The article typically provides descriptive evidence from previous studies of the common characteristics of patients with the pathologic condition of interest. The researcher then compares these known characteristics with the descriptive characteristics of subjects in their particular study. Any differences should be identified and discussed in the article. The critical appraiser must use professional judgment to determine the extent to which potential biasing factors influence the methodologic rigor of the study. If inequalities were detected, it is possible to add steps to the statistical analysis to account for the inequality. This should be reported in the study.

Attrition (subject dropout rate) also influences the researcher's ability to generalize the findings of the study to the larger population of individuals with the diagnosis or impairment. A useful rule of thumb for readers who are critically appraising an article is that, if more than a 20% dropout rate has occurred, then findings of the study are likely suspect. In a strong research article, the researchers explain why and when subjects were lost. Evidence-based practitioners want to know whether subjects chose to leave the study because intervention made them worse or because the intervention was too difficult or painful to overcome its potential benefits. Another situation that may lead to attrition is based on a research design so burdensome or difficult that subjects were unable to meet participation requirements (so that only the most persistent individuals in the sample completed the study). Researchers attempt to account for dropouts either by performing an "intention-to-treat" analysis or presenting descriptive statistics that compare key characteristics of subjects who completed the study with those who did not complete the study.[74] If the researcher can confirm that both groups of subjects are not significantly different, particularly in terms of any characteristic that might bias outcomes, then a study may still be identified as having adequate methodologic quality.

In an intention-to-treat analysis, all subjects who started a study but did not finish it are assigned the most negative outcome likely to occur with the measurement tool for the purposes of statistical analysis.[75] If a statistically significant finding still occurs in the presence of an intention-to-treat analysis, then even assuming that all dropouts had a bad outcome, the study still demonstrated significant effects.

Outcome Measures

In assessing methodologic quality of a study's outcome measurement tools, three questions must be addressed:

- Are the outcome tools described well enough for the evidence-based practitioner to make an informed and realistic judgment about their appropriateness for assessing the variables of interest for this study?

- Are the outcome tools reasonably valid and reliable?
- Are the outcome tools reasonably responsive and sensitive to change?

A high-quality study describes the outcome measures in enough detail for the reader to understand exactly what was measured and to determine whether the tools are appropriate to answer the research questions addressed in the study.

The article should also provide sufficient detail to confirm reliability and validity of each outcome measurement tool. Reliability represents the consistency with which scores are reproduced given repetition of the test with the same tester or across numerous testers.[76,77] Validity represents the accuracy with which the measurement tool taps into the construct or characteristics that the test is purported to measure.[76,78-80] Table 4.4 lists the various aspects of reliability and validity.

If a test is reliable, it should perform consistently under similar testing situations regardless of who performs the test. Studies of reliability usually report either correlation coefficients or intraclass correlation coefficients as the statistical measure of the accuracy with which scores are reproduced.[81] There is no absolute standard of minimally acceptable reliability.[82] A score of 1 indicates a complete reliability (and is rarely achieved); a score of 0 represents a complete lack of reliability. A general benchmark is that a score of $r = 0.9$ or better is strong evidence of reliability of that measure. Coefficients between 0.75 and 0.89 suggest that the measure has moderate risk of error but may be acceptable. Correlations of less than $r = 0.75$ are not typically perceived as having acceptable reliability.

The researchers who are reporting their study should provide an adequate description of the methodology of the study for the critical appraiser to determine which aspects of reliability are most important in this study (and therefore to determine whether the authors provided evidence of the appropriate reliability). Intertester reliability should be reported when more than one tester measures the same

Table 4.4 Validity and Reliability

DETERMINATION OF A TEST OR MEASURES RELIABILITY

Type of Reliability	Question Being Addressed
Intrarater	Will the same examiner make consistent ratings of the same individual?
Test-retest	Is the measure stable/accurate over time?
Interrater	Will different examiners make consistent ratings of the same individual?
Internal consistency	How well do each of the items contribute or reflect what the test intends to measure (how well do the items hang together)?
Parallel forms	Are different versions of the test or measure equivalent?

RELIABILITY COEFFICIENTS

Parametric Analyses		Nonparametric Analyses		
Strategies for Continuous Measures	Types of Reliability Evaluated	Strategies for Nominal Measures	Strategies for Ordinal Measures	Types of Reliability Evaluated
Pearson product moment (Pearson *r*) (association) (0.0 to 1.0)	Intrarater Test-retest Interrater Parallel forms	Percent agreement (includes chance agreement)	Percent agreement (includes chance agreement)	Intrarater Test-retest Interrater Parallel forms
Coefficient of Variation (standard deviation/mean) (<10% suggests reliability)	Intrarater Interrater	Kappa coefficient (agreement beyond chance)	Weighted percent agreement (magnitude of disparity) (includes chance agreement)	Intrarater Test-retest Interrater Parallel forms
Intraclass correlation coefficient (ICC) (association and agreement)	Intrarater Test-retest Interrater Parallel forms		Weighted kappa (agreement beyond chance)	Intrarater Test-retest Interrater Parallel forms
Cronbach alpha	Internal consistency			

DETERMINATION OF A TEST OR MEASURE'S VALIDITY

Type of Validity	Question Being Addressed	Continuous Measures
Content	How well are items on the test sample from the domain being evaluated?	Content expert review of items
Concurrent or Criterion	How well does the measure reflect a particular event, characteristic, or outcome?	Correlation (with reference standard measure of characteristic or construct)
Predictive	How well does the measure predict a future event or outcome?	Correlation (with outcome variable, measured after a period of time)
Construct	Does the test measure a single underlying theoretical concept or construct?	Correlation (with variables theoretically related to the construct of interest)
	How many underlying constructs are included in the measure?	Confirmatory factor analysis
Discriminant or Divergent	How well does the test or measure differentiate between/among groups?	*t*-Test or analysis of variance

outcome, and intratester reliability should be reported when the same tester measures outcomes on more than one occasion. Test-retest reliability provides evidence that the test performs consistently when repeated under similar conditions.

In addition, readers are interested in whether the validity of the measure has been assessed. To be considered valid, there must be sufficient evidence to demonstrate that the test or tool measures what it is purported to measure.[78-80] The researchers who have written the article must provide this evidence about the measure so that the critical appraiser can be comfortable that concerns about validity have been adequately addressed. Just because a tool is reliable (consistent in its measurement properties) does not mean that it is also valid (measures what it intends to measure). However, a tool cannot be valid if it is not reliable in its measurement.[76] Ideally, the tests or measures used in the study demonstrate great consistency with high reproducibility (i.e., reliability) and accurately assess the targeted characteristic (validity).

Evidence of validity is especially important when the test or tool measures an abstract concept (e.g., quality of life or functional independence) rather than a physiologic phenomenon (e.g., heart rate, range of motion). A valid test or measure contains enough items or questions related to the concept or characteristic being evaluated that the clinician can be confident that the results of testing will represent the subject's status in relationship to the construct being assessed. A test or measure found to be reliable in one patient population is not automatically reliable in other populations.[76]

Step 4: Applicability to Patients and Clinical Practice

The final component of an EBP approach to rehabilitative care is just as essential to provision of quality care as the ability to access and use available evidence and clinical expertise. Without consideration of the unique goals, expectations, values, and concerns that an individual in our care brings to the health care encounter, even the "perfect" plan of action will not be as efficacious as it might otherwise be. An individual's perspective and values are influenced by a number of factors, including developmental issues and their position in the lifespan, their family system and culture, their work roles and responsibilities, their coping styles and strategies, their willingness or ability to access whatever resources might be available in their social support network, and their socioeconomic and educational resources.[83,84] To be as effective as possible in providing care, evidence-based practitioners must consider what the pathologic condition, impairment, functional limitation, or disability means to the individual with respect to self-concept and sociocultural roles.[85]

CLINICAL RELEVANCE

Assessing clinical importance of a study has both objective and subjective considerations. The clinician must look beyond the statistical significance of the findings.[86] Often this assessment is based on professional judgment about the impact of the extent of change. Does a statistically significant change in a functional test score or pain level translate into a change that the patient will perceive as important in daily life? Does long-term follow-up occur? That is, does the author examine the effectiveness of a given intervention 3 months, 6 months, or 1 year following the intervention? If the article only provides evidence of short-term benefits of the intervention, are these short-term benefits worth the time and effort in the long run? Would other interventions have had a better long-term outcome?

Making the decision to implement new approaches to care supported by the research literature requires the evidence-based practitioner to answer several questions related to his or her specific clinical environment[87]:

- How similar are the subjects used in the study to those in his or her clinical practice?
- How do the patient's values and expectations interact with or relate to effort, risks, and likely outcomes of the intervention being considered?

For studies of interventions/therapy/treatment, consider the following:

- How likely is it that the patient will be willing and able to comply with intervention activities suggested in the study?

For studies of diagnosis, consider the following:

- Is the diagnostic test adequately available, affordable, accurate, and precise for use in the clinician's setting?
- Is it likely that the patient will be willing and able to comply with the testing procedures?

For studies of prognosis, consider the following:

- Will knowing the predictor factors make a clinically important difference in the way the clinician will care for his or her patients?

Integrating Clinical Expertise and Skill

Although research literature is a valuable and important resource for evidence-based decision making, using evidence from the literature is not sufficient for effective EBP. Practitioners must also have strong examination, evaluation, and diagnostic skills and should be able to incorporate these skills into reflective past experience and current research findings.[88]

What is clinical expertise? In rehabilitation, it is the combination and integration of (1) a multidimensional knowledge base that is grounded in basic science, medical science, psychologic/sociocultural sciences, and movement sciences; (2) effective clinical reasoning skills and an orientation toward function; (3) well-developed and efficient psychomotor skills for examination and intervention; and (4) the desire or commitment to provide patient-centered care (see Fig. 4.3).[89-91]

The first chapter of this text explores the educational preparation, roles, and responsibilities of individual health professionals involved in orthotic and prosthetic rehabilitation. Each has a particular body of knowledge to bring to

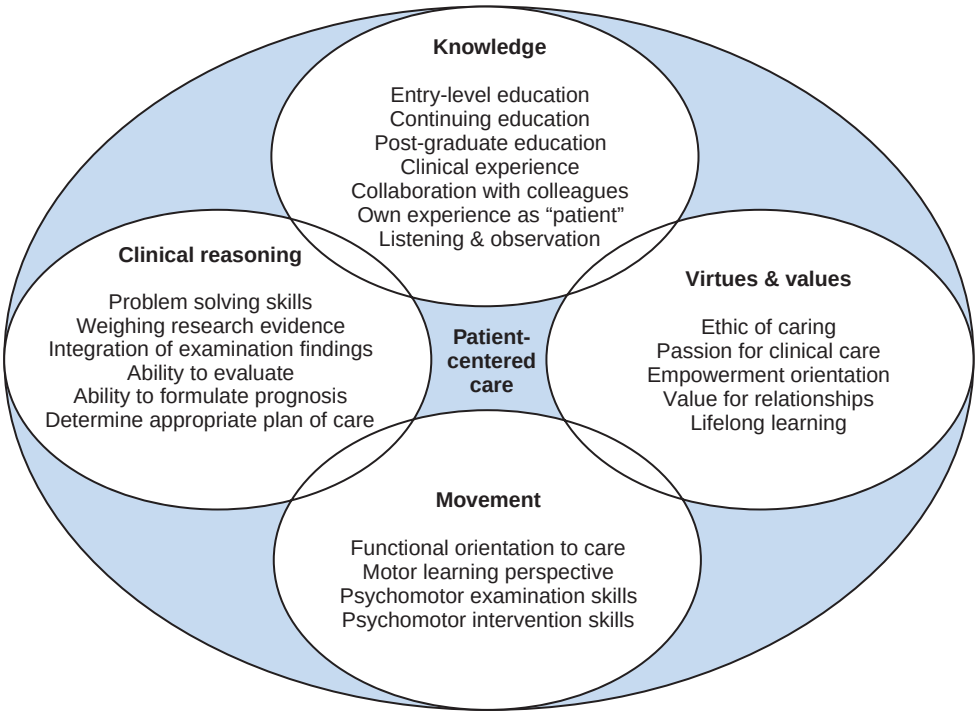

Fig. 4.3 Expert patient-centered physical therapy practice requires integration and interaction of a provider's underlying knowledge, values, examination, and intervention skills as well as clinical reasoning.

the care of individuals needing a prosthesis or orthosis, as well as shared understanding (albeit at various depths) of anatomy, kinesiology, biomechanics, gait analysis, mobility training, motor control and motor learning, and principles of exercise. The authors have established that effective interdisciplinary teaming, in which each profession's perspective interacts so that the team becomes "more than the sum of its parts," is an essential component in the provision of successful orthotic or prosthetic rehabilitative care.

The background knowledge important in orthotic and prosthetic rehabilitation that enables clinicians to ask sound clinical questions and apply evidence to patient care includes a strong foundation in the following areas:

- Anatomy and physiology of the musculoskeletal, neuromuscular, cardiovascular, and cardiopulmonary systems
- Kinesiology and biomechanics of the human body
- Properties of orthotic and prosthetic materials
- Principles of motor control and motor learning
- Lifespan development
- Exercise prescription and assessment of exercise tolerance
- Determinants of normal gait and methods of gait assessment

How does the clinician gain knowledge necessary for expert practice? Entry-level professional education is the baseline, and on-the-job experience via trial-and-error practice and discussion/debate/collaboration with colleagues moves clinicians from students toward novices.[89,91] They become more competent in their roles and responsibilities as their experience grows; they support and enhance their developing mastery and expertise with continuing education, participation in journal clubs and perusal of the clinical research literature, and postgraduate education. Another important component of increasing competence and developing expertise is the ability to actively listen to the hopes and concerns of those they work with and incorporate these into decision making and plans of care.

Clinical expertise, then, allows health care providers to quickly and efficiently identify an individual's rehabilitation diagnosis and, based on their constellation of impairments and functional limitations, select the strategies for remediation or accommodation that will assist the individual's return to a preferred lifestyle.

STAYING CURRENT WITH THE LITERATURE

One proactive way that a clinician can keep informed about new studies focused on his or her area of practice is to sign up for an online service that automatically sends weekly or monthly electronic updates of new articles from journals that the clinician feels are important to read or content areas that he or she wants to stay informed about. Professional organizations often offer this service as a membership benefit. Many journals allow readers to sign up for a service that electronically sends the table of contents via email whenever a new issue of the journal is released. Another valuable service (without charge) for evidence-based practitioners is available from an information management company, Amedeo (http://www.amedeo.com). When an evidence-based practitioner subscribes to Amedeo, he or she chooses from a list of topics for notification of newly published articles linked to those selected topics. Amedeo topics include rehabilitation, pain management, vascular surgery, and stroke, among many others. Amedeo routinely searches a large variety of high-quality journals for new publications on the topics selected by subscribers and sends weekly updates via email. This is a valuable resource for busy clinicians who may not have ready access to a medical library.

Two strategies, if routinely used, help health professionals to update and expand their expertise. The first is to select two or three journals (see Table 4.2) that are particularly appropriate for the clinician's area of professional interest and practice and arrange (via the journal's website) to receive an electronic copy of the table of contents of each issue. When the update arrives, it will be well worth the clinician's time and effort to scroll through the listing of articles and authors to determine which would be worth tracking down to read. The second strategy is to use whatever electronic literature update service is available through professional organizations, PubMed cubby, or Amedeo to arrange to be notified regularly of research reports published in the clinician's area of interest. The final step is to actually (and consistently) make time to read the resources that have been identified and discuss and debate them with colleagues to effectively integrate the new information into clinical practice.

Summary

This chapter explores the concepts underlying evidence-based health care practice and illustrates strategies to develop clear clinical questions that are relevant to an individual patient who is receiving care. The chapter also identifies various sources of evidence available to clinicians and illustrates how electronic databases can assist the search process. The authors suggest strategies that clinicians can use to develop critical appraisal skills and to update and expand their clinical expertise. Although much of the chapter focuses on evidence available in the research literature, it is the integration of the best available scientific evidence; clinical expertise and judgment; and the concerns, values, and expectations of the individual who the clinicians care for that determines the effectiveness of clinical decision making.

Gait analysis: clinical facts	Baker R, Esquenazi A, Benedetti MG, Desloovere K	Eur J Phys Rehabil Med 2016;52(4):560–574
Measuring community integration in persons with limb trauma and amputation: a systematic review	Resnik L, Borgia M, Silver B	Arch Phys Med Rehabil 2017;98(3):561–580.e8
Multimodality imaging review of the post-amputation stump pain	Subedi N, Heire P, Parmer V, Beardmore S, Oh C, Jepson F, Ali SI	Br J Radiol 2016;89(1068):20160572
The role of pressure offloading on diabetic foot ulcer healing and prevention of recurrence	Bus SA	Plast Reconstr Surg 2016;138(3 Suppl):179S–187S
Comparison of bone-anchored prostheses and socket prostheses for patients with a lower extremity amputation: a systematic review	Leijendekkers RA, van Hinte G, Frölke JP, van de Meent H, Nijhuis-van der Sanden MW, Staal JB	Disabil Rehabil 2017;39(11):1045–1058
Risk factors for falls in people with a lower limb amputation: a systematic review	Hunter SW, Batchelor F, Hill KD, Hill AM, Mackintosh S, Payne M	PM R 2017;9(2):170–180.e1
Pediatric traumatic limb amputation: the principles of management and optimal residual limb lengths	Khan MA, Javed AA, Rao DJ, Corner JA, Rosenfield P	World J Plast Surg 2016;5(1):7–14
Overview: mechanism and control of a prosthetic arm	Kulkarni T, Uddanwadiker R	Mol Cell Biomech 2015;12(3):147–195
The effects of mirror therapy on pain and motor control of phantom limb in amputees: a systematic review	Barbin J, Seetha V, Casillas JM, Paysant J, Pérennou D	Ann Phys Rehabil Med 2016;59(4):270–275
Physical and social factors determining quality of life for veterans with lower-limb amputation(s): a systematic review	Christensen J, Ipsen T, Doherty P, Langberg H	Disabil Rehabil 2016;38(24):2345–2353
Innovations in diabetic foot reconstruction using supermicrosurgery	Suh HS, Oh TS, Hong JP	Diabetes Metab Res Rev 2016;32 (Suppl 1):275–280
Acute limb shortening for major near and complete upper extremity amputations with associated neurovascular injury: a review of the literature	Kusnezov N, Dunn JC, Stewart J, Mitchell JS, Pirela-Cruz M	Orthop Surg 2015;7(4):306–316
Biomechanical design considerations for transradial prosthetic interface: a review	Sang Y, Li X, Luo Y	Proc Inst Mech Eng H 2016;230(3):239–250
Current concepts in total femoral replacement	Ramanathan D, Siqueira MB, Klika AK, Higuera CA, Barsoum WK, Joyce MJ	World J Orthop 2015 18;6(11):919–926
Management of major traumatic upper extremity amputations	Solarz MK, Thoder JJ, Rehman S	Orthop Clin North Am 2016;47(1):127–136

Prosthetic rehabilitation for older dysvascular people following a unilateral transfemoral amputation	Cumming J, Barr S, Howe TE	Cochrane Database Syst Rev 2015;1:CD005260
Pedorthic management of the diabetic foot	Janisse D, Janisse E	Prosthet Orthot Int 2015;39(1):40–47.
Development of a control system for artificially rehabilitated limbs: a review	Bhuiyan MS, Choudhury IA, Dahari M	Biol Cybern 2015;109(2):141–162
Pediatric limb differences and amputations	Le JT, Scott-Wyard PR	Phys Med Rehabil Clin North Am 2015; 26(1):95–108

Appendix 4.2

Examples of Clinical Practice Guidelines Available from the National Guideline Clearinghouse (http://www.guideline.gov)

Title (year)	NGC#	Sponsoring Professional Organization(s) *Type of Organization*
SEARCH TERMS: (ORTHOSIS OR ORTHOTIC) AND REHABILITATION, Publication Date from 2013 to 2016, sorted by date beginning with most recent		
Low back pain and sciatica in over 16s: assessment and management. (2016)	NGC:011116	National Guideline Centre *Nonprofit Organization*
Congress of Neurological Surgeons systematic review and evidence-based guideline on the role of cranial molding orthosis (helmet) therapy for patients with positional plagiocephaly. (2016)	NGC:011098	Congress of Neurological Surgeons *Medical Specialty Society*
Congress of Neurological Surgeons systematic review and evidence-based guideline for the management of patients with positional plagiocephaly: the role of physical therapy. (2016)	NGC:011097	Congress of Neurological Surgeons *Medical Specialty Society*
Cervical and thoracic spine disorders. (2016)	NGC:011174	American College of Occupational and Environmental Medicine *Medical Specialty Society*
Lower extremity injury medical treatment guidelines. (2016)	NGC:011050	Colorado Division of Workers' Compensation *State/Local Government Agency [U.S.]*
American Academy of Orthopaedic Surgeons clinical practice guideline on management of carpal tunnel syndrome. (2016)	NGC:010928	American Academy of Orthopaedic Surgeons *Medical Specialty Society*
Low back disorders. (2016)	NGC:011173	American College of Occupational and Environmental Medicine *Medical Specialty Society*
Motor neurone disease: assessment and management. (2016)	NGC:010919	National Guideline Centre *Nonprofit Organization*
Fractures (complex): assessment and management. (2016)	NGC:010914	National Guideline Centre *Nonprofit Organization*
Fractures (non-complex): assessment and management. (2016)	NGC:010915	National Guideline Centre *Nonprofit Organization*
IWGDF guidance on the prevention of foot ulcers in at-risk patients with diabetes. (2016)	NGC:011052	International Working Group on the Diabetic Foot *Disease Specific Society*
IWGDF guidance on footwear and offloading interventions to prevent and heal foot ulcers in patients with diabetes. (2016)	NGC:011053	International Working Group on the Diabetic Foot *Disease Specific Society*
Diabetic foot problems: prevention and management. (2011, Revised 2015)	NGC:010790	National Institute for Health and Care Excellence (NICE) *Independent Public Body*
American Academy of Orthopaedic Surgeons clinical practice guideline on the treatment of pediatric diaphyseal femur fractures. (2009, Revised 2015)	NGC:010775	American Academy of Orthopaedic Surgeons *Medical Specialty Society*
Evidence-based guideline summary: evaluation, diagnosis, and management of congenital muscular dystrophy: report of the Guideline Development Subcommittee of the American Academy of Neurology and the Practice Issues Review Panel of the American Association of Neuromuscular and Electrodiagnostic Medicine. (2015)	NGC:010825	American Academy of Neurology *Medical Specialty Society*; American Association of Neuromuscular and Electrodiagnostic Medicine *Medical Specialty Society*
Cervical spine collar clearance in the obtunded adult blunt trauma patient: a systematic review and practice management guideline from the Eastern Association for the Surgery of Trauma. (2015)	NGC:010633	Eastern Association for the Surgery of Trauma *Medical Specialty Society*

Type of Study	Title	Authors	Source
Clinical Practice Guideline	The Italian Society of Physical and Rehabilitation Medicine (SIMFER) recommendations for neck pain	Monticone M, Iovine R, de Sena G, Rovere G, Uliano D, Arioli G, Bonaiuti D, Brugnoni G, Ceravolo G, Cerri C, Dalla Toffola E, Fiore P, Foti C	Giornale Italiano di Medicina del Lavoro ed Ergonomia 2013;35(1): 36–50
Systematic Review	Treadmill interventions in children under six years of age at risk of neuromotor delay	Valentin-Gudiol M, Mattern-Baxter K, Girabent-Farres M, Bagur-Calafat C, Hadders-Algra M, Angulo-Barroso RM	Cochrane Database Syst Rev 2017;Issue 7
Systematic Review	Braces and orthoses for treating osteoarthritis of the knee	Duivenvoorden T, Brouwer RW, van Raaij TM, Verhagen AP, Verhaar JAN, Bierma-Zeinstra SMA	Cochrane Database Syst Rev 2015;Issue 3
Systematic Review	Knee orthoses for treating patellofemoral pain syndrome	Smith TO, Drew BT, Meek TH, Clark AB	Cochrane Database Syst Rev 2015;Issue 12
Systematic Review	The effectiveness of braces and orthoses for patients with knee osteoarthritis: a systematic review of Japanese-language randomised controlled trials	Mine K, Nakayama T, Milanese S, Grimmer K	Prosthetics and Orthotics International 2017 Apr;41 (2):115–126
Systematic Review	Effectiveness of foot orthoses and shock-absorbing insoles for the prevention of injury: a systematic review and meta-analysis	Bonanno DR, Landorf KB, Munteanu SE, Murley GS, Menz HB	British Journal of Sports Medicine 2017 Jan;51(2):86–96
Systematic Review	Effectiveness of surgical and non-surgical management of crouch gait in cerebral palsy: a systematic review	Galey SA, Lerner ZF, Bulea TC, Zimbler S, Damiano DL	Gait & Posture 2017 May;54:93–105
Systematic Review	Shoulder orthoses for the prevention and reduction of hemiplegic shoulder pain and subluxation: systematic review	Nadler M, Pauls MMH	Clinical Rehabilitation 2017 Apr;31(4):444–453
Systematic Review	Counterforce orthosis in the management of lateral epicondylitis	Vellilappilly DV, Rai HR, Varghese J, Renjith V	Journal of Ayub Medical College, Abbottabad 2017 Apr-Jun;29(2):328–334
Systematic Review	Physical and mechanical therapies for lower-limb problems in juvenile idiopathic arthritis: a systematic review with meta-analysis	Fellas A, Coda A, Hawke F	Journal of the American Podiatric Medical Association 2017 Sep–Oct;107(5):399–412
Systematic Review	(A review study on various conservative management strategies for patellofemoral pain syndrome: what is the best intervention?) [Persian]	Mazloum V, Sahebozamani M	Journal of Kerman University of Medical Sciences 2016 Jan–Feb;23(1):116–136
Systematic Review	The effectiveness of physical agents for lower-limb soft tissue injuries: a systematic review	Yu H, Randhawa K, Cote P	The Journal of Orthopaedic and Sports Physical Therapy 2016 Jul;46(7):523–554
Systematic Review	The influence of orthosis options on walking parameters in spinal cord-injured patients: a literature review	Arazpour M, Samadian M, Ebrahimzadeh K, Ahmadi Bani M, Hutchins SW	Spinal Cord 2016 Jun;54(6):412–422
Systematic Review	Functional electrical stimulation versus ankle foot orthoses for foot-drop: a meta-analysis of orthotic effects	Prenton S, Hollands KL, Kenney LP	Journal of Rehabilitation Medicine 2016 Sep;48 (8):646–656
Systematic Review	Hand therapy versus corticosteroid injections in the treatment of de Quervain's disease: a systematic review and meta-analysis	Cavaleri R, Schabrun SM, Te M, Chipchase LS	Journal of Hand Therapy 2016 Jan–Mar;29(1):3–11
Systematic Review	A systematic review of the effect of foot orthoses and shoe characteristics on balance in healthy older subjects	Aboutorabi A, Bahramizadeh M, Arazpour M, Fadayevatan R, Farahmand F, Curran S, Hutchins SW	Prosthetics and Orthotics International 2016 Apr;40 (2):170–181

Type of Study	Title	Authors	Source
Systematic Review	Effectiveness of stretch interventions for children with neuromuscular disabilities: evidence-based recommendations	Craig J, Hilderman C, Wilson G, Misovic R	Pediatric Physical Therapy 2016 Fall;28(3):262–275
Systematic Review	Conservative treatment of thumb base osteoarthritis: a systematic review	Spaans AJ, van Minnen LP, Kon M, Schuurman AH, Schreuders ART, Vermeulen GM	The Journal of Hand Surgery - American Volume 2015 Jan;40(1):16–21
Systematic Review	Effectiveness of orthotic devices in the treatment of Achilles tendinopathy: a systematic review	Scott L, Munteanu S, Menz H	Sports Medicine 2015 Jan;45(1):95–110
Systematic Review	Static progressive versus dynamic splinting for posttraumatic elbow stiffness: a systematic review of 232 patients	Veltman ES, Doornberg JN, Eygendaal D, van den Bekerom MPJ	Archives of Orthopaedic and Trauma Surgery 2015 May;135(5):613–617
Systematic Review	The efficacy of conservative treatment of osteoporotic compression fractures on acute pain relief: a systematic review with meta-analysis	Rzewuska M, Ferreira M, McLachlan AJ, Machado GC, Maher CG	European Spine Journal 2015 Apr;24(4):702–714
Systematic Review	Custom made finger orthoses have fewer skin complications when compared to prefabricated finger orthoses in management of mallet injury: a systematic review and meta-analysis	Witherow EJ, Peiris CL	Archives of Physical Medicine and Rehabilitation 2015 Oct;96(10):1913–1923
Systematic Review	Systematic review and meta-analysis of effects of foot orthoses on pain and disability in rheumatoid arthritis patients	Sena da Conceicao C, Gomes Neto M, Mendes SMD, Nunes Sa K, Fontes Baptista A	Disability and Rehabilitation 2015;37(14):1209–1213
Systematic Review	Peroneal stimulation for foot drop after stroke: a systematic review	Dunning K, O'Dell MW, Kluding P, McBride K	American Journal of Physical Medicine & Rehabilitation 2015 Aug;94(8):649–664
Systematic Review	The efficacy of foot orthoses on alteration to center of pressure displacement in subjects with flat and normal feet: a literature review	Aboutorabi A, Arazpour M, Hutchins SW, Curran S, Maleki M	Disability and Rehabilitation: Assistive Technology 2015;10(6):439–444
Systematic Review	Investigation of the effect of conservative interventions in thumb carpometacarpal osteoarthritis: systematic review and meta-analysis	Bertozzi L, Valdes K, Vanti C, Negrini S, Pillastrini P, Villafane JH	Disability and Rehabilitation 2015;37(22):2025–2043
Systematic Review	Effects of ankle foot orthoses on body functions and activities in people with floppy paretic ankle muscles: a systematic review	van der Wilk D, Dijkstra PU, Postema K, Verkerke GJ, Hijmans JM	Clinical Biomechanics 2015 Dec;30(10):1009–1025
Systematic Review	Efficacy of orthoses for children with hypotonia: a systematic review	Weber A, Martin K	Pediatric Physical Therapy 2014 Spring;26(1):38–47
Systematic Review	Technical devices in children with motor disabilities: a review	Montero SM, Gomez-Conesa A	Disability and Rehabilitation: Assistive Technology 2014;9(1):3–11
Systematic Review	Spinal cord injury rehabilitation: which way forward?	Karimi M, Omar AHH, Fatoye F	Neurorehabilitation 2014;35(2):325–340
Systematic Review	Psychological care, patient education, orthotics, ergonomics and prevention strategies for neck pain: an systematic overview update as part of the ICON project	Gross AR, Kaplan F, Huang S, Khan M, Santaguida PL, Carlesso LC, MacDermid JC, Walton DM, Kenardy J, Soderlund A, Verhagen A, Hartvigsen J	The Open Orthopaedics Journal 2013 Sep 20;7:530–561
Systematic Review	Nonoperative management of cervical myelopathy: a systematic review	Rhee JM, Shamji MF, Erwin WM, Bransford RJ, Yoon ST, Smith JS, Kim HJ, Ely CG, Dettori JR, Patel AA, Kalsi-Ryan S	Spine 2013 Oct 15;38(22):S55–S67
Clinical Trial	Podiatry intervention versus usual care to prevent falls in care homes: pilot randomised controlled trial	Wylie G, Menz HB, McFarlane S, Ogston S, Sullivan F, Williams B, Young Z, Morris J	BMC Geriatrics 2017 Jul 12;17(143):Epub

Type of Study	Title	Authors	Source
Clinical Trial	Effectiveness of foot orthoses versus rocker-sole footwear for first metatarsophalangeal joint osteoarthritis: randomized trial	Menz HB, Auhl M, Tan JM, Levinger P, Roddy E, Munteanu SE	Arthritis Care & Research 2016 May;68(5):581–589
Clinical Trial	A randomized controlled trial of custom foot orthoses for the treatment of plantar heel pain	Wrobel JS, Fleischer AE, Crews RT, Jarrett B, Najafi B	Journal of the American Podiatric Medical Association 2015 Jul-Aug;105(4):281–294
Clinical Trial	Prevention of recurrent foot ulcers with plantar pressure-based in-shoe orthoses: the CareFUL prevention multicenter randomized controlled trial	Ulbrecht JS, Hurley T, Mauger DT, Cavanagh PR	Diabetes Care 2014 Jul;37(7):1982–1989
Clinical Trial	Cryoultrasound therapy in the treatment of chronic plantar fasciitis with heel spurs. A randomized controlled clinical study	Costantino C, Vulpiani MC, Romiti D, Vetrano M, Saraceni VM	European Journal of Physical and Rehabilitation Medicine 2014 Feb;50(1):39–47
Clinical Trial	Brain-machine interface in chronic stroke rehabilitation: a controlled study	Ramos-Murguialday A, Broetz D, Rea M, Laer L, Yilmaz O, Brasil FL, Liberati G, Curado MR, Garcia-Cossio E, Vyziotis A, Cho W, Agostini M, Soares E, Soekadar S, Caria A, Cohen LG, Birbaumer N	Annals of Neurology 2013 Jul;74(1):100–108
Clinical Trial	Foot exercises and foot orthoses are more effective than knee focused exercises in individuals with patellofemoral pain	Molgaard CM, Rathleff MS, Andreasen J, Christensen M, Lundbye-Christensen S, Simonsen O, Kaalund S	Journal of Science and Medicine in Sport 2018 Jan;21 (1):10–15
Clinical Trial	Early or delayed provision of an ankle-foot orthosis in patients with acute and subacute stroke: a randomized controlled trial	Nikamp CDM, Buurke JH, van der Palen J, Hermens HJ, Rietman JS	Clinical Rehabilitation 2017 Jun;31(6):798–808
Clinical Trial	Cohort randomised controlled trial of a multifaceted podiatry intervention for the prevention of falls in older people (the REFORM trial)	Cockayne S, Adamson J, Clarke A, Corbacho B, Fairhurst C, Green L, Hewitt CE, Hicks K, Kenan A-M, Lamb SE, McIntosh C, Menz HB, Redmond AC, Richardson Z, Rodgers S, Vernon W, Watson J, Torgerson DJ, on behalf of the REFORM study	PLoS One 2017 Jan;12(1):e0168712
Clinical Trial	Foot orthoses in the treatment of symptomatic midfoot osteoarthritis using clinical and biomechanical outcomes: a randomised feasibility study	Halstead J, Chapman GJ, Gray JC, Grainger AJ, Brown S, Wilkins RA, Roddy E, Helliwell PS, Keenan AM, Redmond AC	Clinical Rheumatology 2016 Apr;35(4):987–996
Clinical Trial	Effectiveness of footwear and foot orthoses for calcaneal apophysitis: a 12-month factorial randomised trial	James AM, Williams CM, Haines TP	British Journal of Sports Medicine 2016 Oct; 50(20):1268–1275
Clinical Trial	Effectiveness of customised foot orthoses for Achilles tendinopathy: a randomised controlled trial	Munteanu SE, Scott LA, Bonanno DR, Landorf KB, Pizzari T, Cook JL, Menz HB	British Journal of Sports Medicine 2015 Aug; 49(15):989–994
Clinical Trial	Additional effects of an individualized risk factor-based approach on pain and the function of patients with patellofemoral pain syndrome: a randomized controlled trial	Halabchi F, Mazaheri R, Mansournia MA, Hamedi Z	Clinical Journal of Sport Medicine 2015 Nov; 25(6):478–486
Clinical Trial	The clinical impact of orthotic correction of lower limb rotational deformities in children with cerebral palsy: a randomized controlled trial	Abd el-Kafy EM	Clinical Rehabilitation 2014 Oct;28(10):1004–1014
Clinical Trial	A randomized clinical trial comparing extensible and inextensible lumbosacral orthoses and standard care alone in the management of lower back pain	Morrisette D, Cholewicki J, Logan S, Seif G, McGowan S	Spine 2014 Oct 1;39(21): 1733–1742
Clinical Trial	Rigid versus semi-rigid orthotic use following TMC arthroplasty: a randomized controlled trial	Prosser R, Hancock MJ, Nicholson L, Merry C, Thorley F, Wheen D	Journal of Hand Therapy 2014 Oct–Nov;27(4): 265–271

Type of Study	Title	Authors	Source
Clinical Trial	Clinical effectiveness and cost-effectiveness of a multifaceted podiatry intervention for falls prevention in older people: a multicentre cohort randomised controlled trial (the REducing Falls with ORthoses and a Multifaceted podiatry intervention trial)	Cockayne S, Rodgers S, Green L, Fairhurst C, Adamson J, Scantlebury A, Corbacho B, Hewitt CE, Hicks K, Hull R, Keenan A-M, Lamb SE, McIntosh C, Menz HB, Redmond A, Richardson Z, Vernon W, Watson J, Torgerson DJ	Health Technology Assessment (Winchester, England) 2017 Apr;21(24):1–198
Clinical Trial	Bespoke versus off-the-shelf ankle-foot orthosis for people with stroke: randomized controlled trial	Tyson SF, Vail A, Thomas N, Woodward-Nutt K, Plant S, Tyrrell PJ	Clinical Rehabilitation 2017 Aug 1:Epub ahead of print
Clinical Trial	Integrated effect of treadmill training combined with dynamic ankle foot orthosis on balance in children with hemiplegic cerebral palsy	Sherief AEAA, Abo Gazya AA, Abd el Gafaar MA	Egyptian Journal of Medical Human Genetics 2015 Apr;16(2):173–179
Clinical Trial	Treatment of proximal interphalangeal joint flexion contracture: combined static and dynamic orthotic intervention compared with other therapy intervention: a randomized controlled trial	Cantero-Tellez R, Cuesta-Vargas AI, Cuadros-Romero M	The Journal of Hand Surgery - American Volume 2015 May;40(5):951–955
Clinical Trial	Day versus day-night use of ankle-foot orthoses in young children with spastic diplegia: a randomized controlled study	Zhao X, Xiao N, Li H, Du S	American Journal of Physical Medicine & Rehabilitation 2013 Oct;92(10):905–911
Clinical Trial	Efficacy of low-level laser therapy associated to orthoses for patients with carpal tunnel syndrome: a randomized single-blinded controlled trial	Barbosa RI, Fonseca MCR, Rodrigues EKS, Tamanini G, Marcolino AM, Mazzer N, Guirro RRJ, MacDermid J	Journal of Back and Musculoskeletal Rehabilitation 2016;29(3):459–466
Clinical Trial	Foot orthoses in the management of chronic subtalar and talo crural joint pain in rheumatoid arthritis	Gatt A, Formosa C, Otter S	The Foot 2016 Jun;27: 27–31
Clinical Trial	Long-term follow-up to a randomized controlled trial comparing peroneal nerve functional electrical stimulation to an ankle foot orthosis for patients with chronic stroke	Bethoux F, Rogers HL, Nolan KJ, Abrams GM, Annaswamy T, Brandstater M, Browne B, Burnfield JM, Feng W, Freed MJ, Geis C, Greenberg J, Gudesblatt M, Ikramuddin F, Jayaraman A, Kautz SA, Lutsep HL, Madhavan S, Meilahn J, Pease WS, Rao N, Seetharama S, Sethi P, Turk MA, Wallis RA, Kufta C	Neurorehabilitation and Neural Repair 2015 Aug;29 (10):911–922
Clinical Trial	The effects of peroneal nerve functional electrical stimulation versus ankle-foot orthosis in patients with chronic stroke: a randomized controlled trial	Bethoux F, Rogers HL, Nolan KJ, Abrams GM, Annaswamy TM, Brandstater M, Browne B, Burnfield JM, Feng W, Freed MJ, Geis C, Greenberg J, Gudesblatt M, Ikramuddin F, Jayaraman A, Kautz SA, Lutsep HL, Madhavan S, Meilahn J, Pease WS, Rao N, Seetharama S, Sethi P, Turk MA, Wallis RA, Kufta C	Neurorehabilitation and Neural Repair 2014 Sep;28 (7):688–697
Clinical Trial	Mechanical effectiveness of lateral foot wedging in medial knee osteoarthritis after 1 year of wear	Barrios JA, Butler RJ, Crenshaw JR, Royer TD, Davis IS	Journal of Orthopaedic Research 2013 May; 31(5):659–664
Clinical Trial	Effect of patellar strap and sports tape on pain in patellar tendinopathy: a randomized controlled trial	de Vries A, Zwerver J, Diercks R, Tak I, van Berkel S, van Cingel R, van der Worp H, van den Akker-Scheek I	Scandinavian Journal of Medicine & Science in Sports 2016 Oct;26(10):1217–1224
Clinical Trial	A comparison study on the efficacy of SpinoMed and soft lumbar orthosis for osteoporotic vertebral fracture	Li M, Law S-W, Cheng J, Kee H-M, Wong MS	Prosthetics and Orthotics International 2015 Aug;39 (4):270–276
Clinical Trial	Role of three side support ankle-foot orthosis in improving the balance in children with spastic diplegic cerebral palsy	Olama KA, el-Din SMN, Ibrahem MB	Egyptian Journal of Medical Human Genetics 2013 Jan;14(1):77–85
Clinical Trial	Effects of AFO use on walking in boys with Duchenne muscular dystrophy: a pilot study	Townsend EL, Tamhane H, Gross KD	Pediatric Physical Therapy 2015 Spring;27(1): 24–29

[a]Keyword: orthoses (limited to articles/abstracts published January 2013–January 2018).

5 Clinical Assessment of Gait☆

OLFAT MOHAMED and HEATHER APPLING

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Describe the major functional tasks of the gait cycle and their corresponding subphases.
2. Identify the muscle activity, ground reaction forces, and joint angles during each of the subphases of the gait cycle.
3. Define the time and distance parameters used to describe and assess normal gait.
4. Describe common pathological gait patterns, including contributing factors, compensatory deviations, and when these are likely to occur in the gait cycle.
5. Compare and contrast the type and quality of information gathered with various quantitative, qualitative, instrumented, and function-based gait assessment tools.
6. Differentiate between pathological and compensatory gait characteristics typically observed in individuals with lower motor neuron disease, hemiplegia, spastic diplegic cerebral palsy, and spina bifida.
7. Discuss how prosthetic components and alignment influence the efficacy and quality of gait for individuals with amputation at the transtibial and transfemoral levels.

Normal Gait

Walking requires numerous physiological systems (neurologic, musculoskeletal, cardiopulmonary, and cognition) to work congruently. Understanding normal gait is a prerequisite to understanding pathological gait, as it will provide the standard against which the gait pattern (GP) of an individual could be compared. Normal walking requires stability to provide body weight support against gravity during stance, mobility of body segments, and motor control to sequence multiple segments while transferring body weight from one limb to the other. The primary goal in gait is forward progression by using a stable kinetic chain of joints and limb segments working congruently to transport its passenger unit, consisting of the head, arms, and trunk in a continuously changing environment and task demands.

Clinical gait assessment identifies primary or pathological gait problems and helps differentiate them from compensatory strategies. It is necessary for selection of appropriate orthotic or prosthetic components, alignment parameters, and identification of other variants that might enhance an individual's ability to walk. Clinical gait assessment also contributes to the development of a comprehensive treatment plan, with the ultimate goal of optimal energy efficiency and appropriate pathomechanical control, balancing cosmesis, and overall function.

A comprehensive system to describe normal and abnormal gait has been developed by the Pathokinesiology and Physical Therapy Departments at Rancho Los Amigos Medical Center over the past several decades.[1,2] Adams and Cerny have recently published a comprehensive manual for normal and pathological observational gait analysis that compliments the Perry and Burnfield book and offers a practical guide for clinical gait assessment.[3]

Kinetic and Kinematic Descriptors of Human Walking

The mechanics of human movement and related biomechanical behavior is studied by individuals desiring to know more about the loading experienced by the body, the body's response to loading, overall motion of the body as well as the motions of its unique body segments, and ultimately the forces required to produce motion. The study of kinetics and kinematics are independent and related; when studied alone and in unison the knowledge and understanding of human movement is far-reaching and comprehensive. *Kinematics* is the study of motion, whereas *kinetics* is the study of the forces that produce motion.

Step length, stride length, cadence, and velocity are important quantitative, interrelated kinematic measures of gait. Step length and stride length are not synonymous. *Step length* is the distance from the floor-contact point of one (ipsilateral, originating) foot in early stance to the floor-contact point of the opposite (contralateral) foot—in normal individuals, the distance from right heel contact to left heel contact. *Stride length* is the distance from floor contact on one side to the next floor contact on that same side—the distance from right heel contact to the next right heel contact. A reduction in functional joint motion or the presence of pain or muscle weakness can result in decreased stride or step length, or both. Pathological gait commonly produces asymmetries in step length between the two lower limbs.

☆The authors extend appreciation to Dana Craig, Heather Worden, and Edmond Ayyappa, whose work in prior editions provided the foundation for this chapter.

Cadence is the number of steps taken in a given unit of time, most often expressed in steps per minute. *Velocity* is the distance traveled in a given unit of time (the rate of forward progression) and is usually expressed in centimeters per second or meters per minute. Velocity is the best single index of walking ability. Decreased joint motion, pain, and/or muscle weakness can reduce cadence or velocity or both. Velocity can also be qualitatively categorized as free, slow, or fast. Free walking (self-selected) speed is an individual's normal self-selected (comfortable) walking velocity. Fast walking speed (WS) describes the maximum velocity possible for a given individual while being safe. Slow WS describes a velocity below the normal self-selected WS. For healthy individuals, a fast walk velocity may be as much as 44% faster than free or self-selected WS.[4] In people with musculoskeletal and neuromuscular impairments that affect gait, often much less difference is found between free and fast gait velocity.

Double limb support is the period of time when both feet are in contact with the ground. It occurs twice during the gait cycle, at the beginning and the end of each stance phase. As velocity increases, double limb support time decreases. When running, the individual has rapid forward movement with little or no period of double limb support. Individuals with slow WSs spend more of the gait cycle in double support.

Step width, or width of the walking base, typically measures between 5 and 10 cm from the heel center of one foot to the heel center of the other foot.[5] A wide walking base may increase stability but also reduces energy efficiency of gait.

Ground reaction force (GRF) in gait is established between the contact of the limb and the supporting surface; the point of application of the GRF and the supporting surface is called the *center of pressure*. The GRF is a vector quantity comprised of both magnitude and direction and can be resolved into perpendicular force vectors, normal force, and tangential force components, respectively. The magnitude is a result of the combination of the gravitational and inertial effects on all the body segments while the foot is in contact with the ground, and the direction is the result of the angle of application of the combination of gravitational and inertial forces when the foot is in contact with the ground.[6] Kinetic and kinematic measurements can be assessed through the combination of force plates, electromyography (EMG), and motion capture analysis. *Force plates* are platforms set on or into the ground that a person is traversing. The force plates measure the amount of force exerted on them during the respective steps taken across the platforms.[5] *EMG* captures the electrical signals produced by muscle activation. EMG data is implied from muscle activation patterns and when compiled with correlating force plate data; the combination of force plate and EMG data directly produces kinetic data in real time.

The spatial relationship between the GRF and a given joint center influences the direction of its rotation and measurements. The rotational potential of the forces that act on a joint is called a *torque* or *moment*. *Torque (or moment)* is the tendency to produce rotational motion as a result of a force being applied across a distance from the pivot point. Torque produces displacement of the lever or limb segment with a particular angular velocity. The measure that assesses the quantity of work occurring over a particular time or the rate of change of energy in a particular system is known as *power*. Power is useful in both kinetic and kinematic assessments of joint motion. Joint power is found by multiplying the magnitude of torque and the angular velocity for the respective joint.

Kinetic and kinematic descriptors of human motion are not only helpful in describing motion but also in the quantification and qualification of both static and dynamic assessment, providing feedback to the client and clinician informing modification to both technique and equipment, respectively—producing adequate evaluation to improve performance and reduce the risk of injury ultimately.

Gait Cycle

The *gait cycle* is the time interval between two successive occurrences of one of the repetitive events of walking. Conventionally the time from initial contact to initial contact of the same foot is selected as the starting and completing event of a single cycle of gait. Each cycle is divided into two periods: stance phase and swing phase. *Stance* is the time when the foot is in contact with floor during one gait cycle (0%–62%).[1] For adults, it constitutes approximately 62% of the gait of the gait cycle. *Swing* denotes the time when the foot is in the air during one gait cycle and constitutes the remaining 38% of the gait cycle. There are five subphases within the stance period: initial contact (IC), loading response (LR), midstance (MSt), terminal stance (TSt), and preswing (PSw). Swing phase is divided into three subphases: initial swing (ISw), mid swing (MSw), and terminal swing (TSw). Single limb support (SLS) is the time when only one foot is in contact with the ground during one gait cycle. Double Limb Stance is the time when both feet are in contact with the ground during one gait cycle. A variety of conceptual approaches describe the walking process. Saunders and colleagues define the functional task of walking as translation of the center of gravity through space in a manner that requires the least energy expenditure.[7] They identify six determinants, or variables, that affect energy expenditure in sustained walking: pelvic rotation, pelvic tilt, knee flexion in stance phase, foot interaction with the knee, ankle interaction with the knee, and lateral pelvic displacement. Individually and collectively, these determinants have an impact on energy expenditure and the mechanics of walking. Although they help us understand the process of walking, the determinants do not themselves offer a practical clinical solution to address the problems of gait assessment. Three functional tasks are achieved during these eight gait phases: weight acceptance in early stance, SLS in MSt to TSt, and limb advancement during swing (Fig. 5.1).

FUNCTIONAL TASK 1: WEIGHT ACCEPTANCE

IC and LR are the subphases of stance where weight acceptance is accomplished. Effective transfer of body weight onto the limb as soon as it makes contact with the ground requires initial limb stability, shock absorption, and the preservation of forward momentum.

Initial Contact

IC is the instant that the foot of the leading lower limb touches the ground. Most motor function during IC is preparation for LR. At IC, the ankle is in neutral position, the knee is close to full extension, and the hip is flexed 30 degrees. The sagittal plane GRF vector lies posterior to the

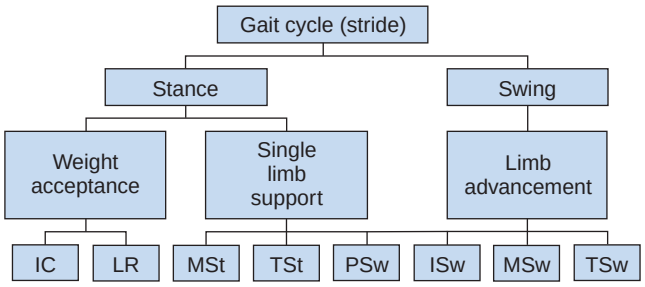

Fig. 5.1 A complete gait cycle divided into three functional tasks of weight acceptance, single limb support, and limb advancement. The gait cycle can also be described in phasic terms of initial contact *(IC)*, loading response *(LR)*, midstance *(MSt)*, terminal stance *(TSt)*, preswing *(PSw)*, initial swing *(ISw)*, midswing *(MSw)*, and terminal swing *(TSw)*. The PSw phase is a transitional phase between single limb support and limb advancement.

ankle joint, creating a plantar flexion moment (Fig. 5.2A). Eccentric contraction of the pretibial muscles (tibialis anterior and long toe extensors) holds the ankle and subtalar joint in neutral position. At the knee, the GRF vector is anterior to the joint axis, which creates a passive extensor torque. Muscle contraction activity of the three vasti of the quadriceps and hamstring muscle groups continues from the previous TSw to preserve the neutral position of the knee joint. A flexion moment is present around the hip joint because the GRF vector falls anterior to the joint axis. Gluteus maximus and hamstring muscles are activated to restrain the resultant flexion torque.

Loading Response

LR occupies approximately 10% of the gait cycle and constitutes the period of initial double limb support (see Fig. 5.2B).

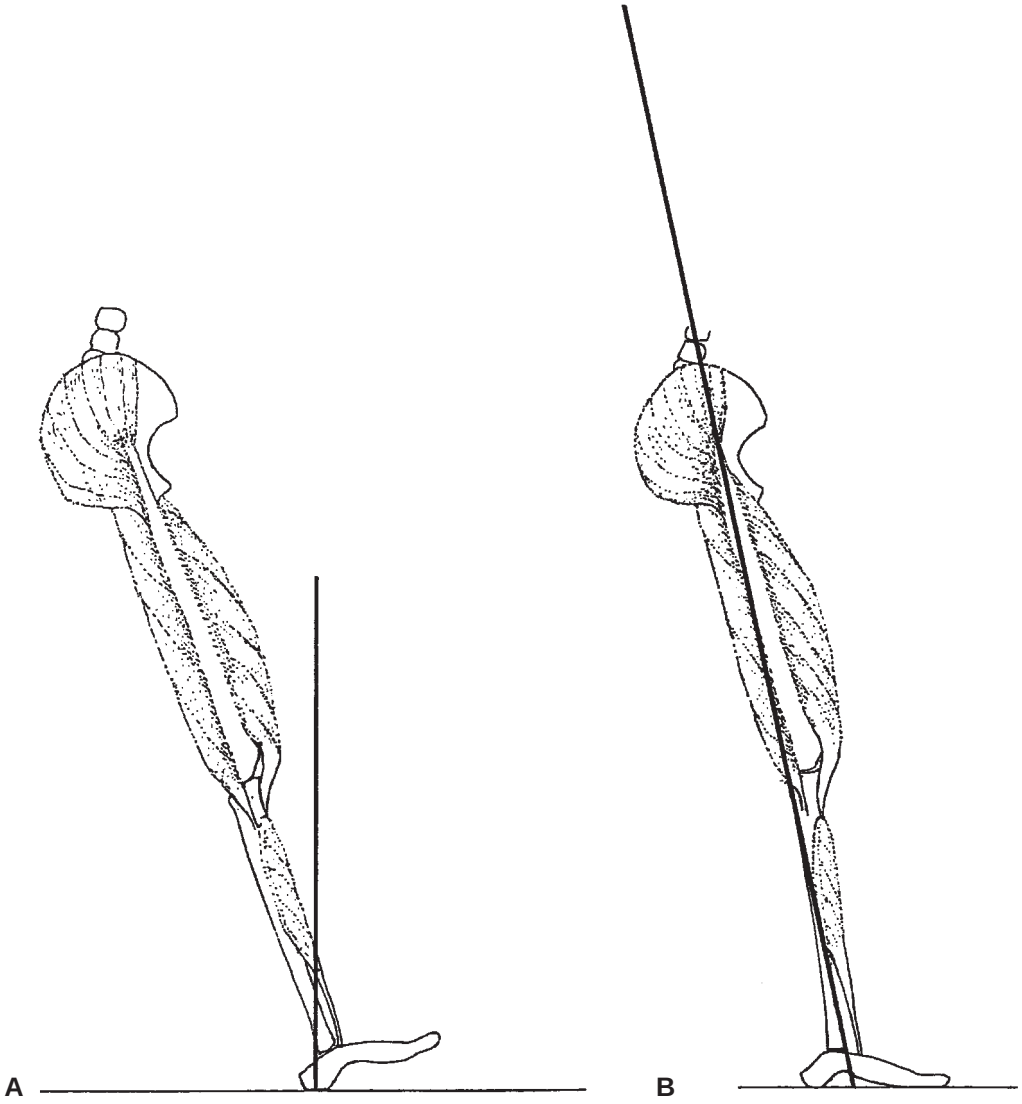

Fig. 5.2 The two subphases of gait involved with the functional task of weight acceptance are initial contact (IC) and loading response (LR). (A) At IC, the ground reaction force (GRF) line is posterior to the ankle and anterior to the knee and hip with activation of pretibial, quadriceps, hamstring, and gluteal muscles. Note that the length of the GRF line represents its magnitude. (B) The LR phase results in an increased magnitude of the vertical force, which ultimately exceeds body weight. Activity of the same muscle groups elicited at IC increases steadily with the vertical force.

Two functional tasks occur during LR: controlled descent of the foot toward the ground and shock absorption as weight is transferred onto the stance limb.

The momentum generated by the fall of body weight onto the stance limb is preserved by the *heel rocker* (first rocker) of stance phase.[5] Normal IC at the calcaneal tuberosity creates a fulcrum about which the foot and tibia move. The bony segment between this fulcrum and the center of the ankle rolls toward the ground as body weight is loaded onto the stance foot, preserving the momentum necessary for forward progression. Eccentric action of the pretibial muscles regulates the rate of ankle plantar flexion, and the quadriceps vasti contract to limit knee flexion. The action of these two muscle groups provides controlled forward advancement of the lower extremity unit (foot, tibia, and femur). During the peak of LR, the magnitude of the vertical GRF exceeds body weight. To absorb the impact force of body weight and preserve forward momentum, the knee flexes 15 to 18 degrees and the ankle plantar flexes to 10 degrees. The hip maintains its position of 30 degrees of flexion. Contraction of the gluteus maximus, hamstrings, and adductor magnus prevents further flexion of the hip joint.

FUNCTIONAL TASK 2: SINGLE LIMB SUPPORT

Two phases of stance are associated with SLS: MSt and TSt. During this period, the contralateral foot is in swing phase, and body weight is entirely supported on the stance limb. Forward progression of body weight over the stationary foot while maintaining stability must be accomplished during these two subphases of stance.

Midstance

MSt begins when the contralateral foot leaves the ground and continues as body weight travels along the length of the stance foot until it is aligned over the forefoot at approximately 20% of the gait cycle (Fig. 5.3A). This pivotal action of the *ankle rocker* (second rocker) advances the tibia over

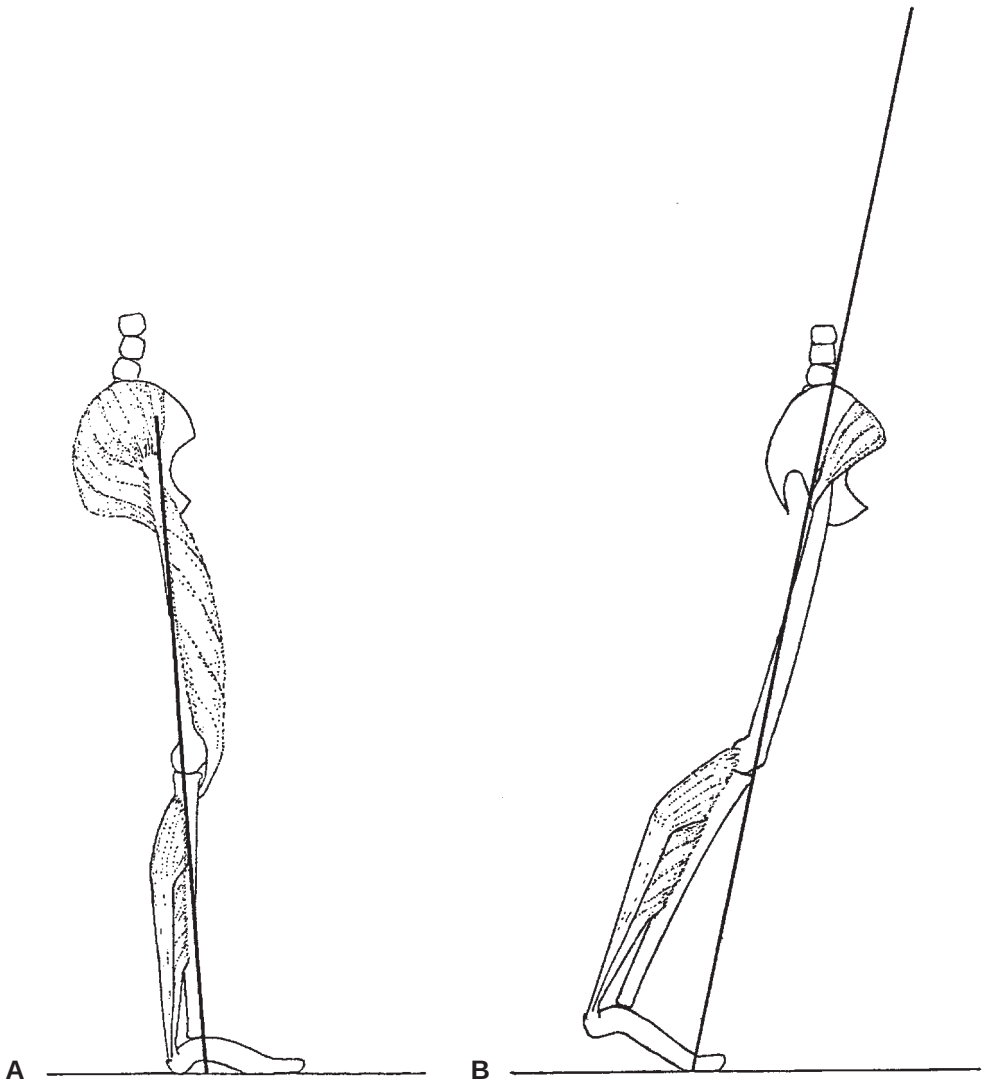

Fig. 5.3 The subphases of gait involved in the functional task of single limb support are midstance (MSt) and terminal stance (TSt). (A) In early MSt, the vertical force begins to decrease and the triceps surae, quadriceps, and gluteus medius and maximus are active. (B) During TSt, there is a second peak in vertical force, exceeding body weight, with high activity of the triceps surae, which maintain the third rocker. The tensor fascia lata restrains the increasing posterior hip vector.

the stationary foot.[5] Forward movement of the tibia over the foot is controlled by the eccentric contraction of the soleus assisted by the gastrocnemius.

During this phase, the ankle moves from its LR position of 10 degrees of plantar flexion to approximately 5 degrees of dorsiflexion. The knee extends from 15 degrees of flexion to a neutral position. The hip joint moves toward extension, from 30 to 10 degrees of flexion. With continued forward progression, the body weight vector moves anterior to the ankle, creating a dorsiflexion moment. Eccentric action of the plantar flexors is crucial in providing limb stability as contralateral toe-off occurs, transferring body weight onto the stance foot. By the end of MSt, the body weight vector moves anterior to the knee (creating passive extensor stability at the knee) and posterior to the hip (reducing the demand on the hip extensors). The gluteus maximus, active in early MSt, ceases its activity and now stability relies on passive structures as the hip nears vertical alignment over the femur. Vertical GRF is reduced in magnitude at MSt because of the upward momentum of the contralateral swing limb. In the coronal plane, activity of hip abductors during MSt is essential to provide lateral hip stability and almost a level pelvis.

Terminal Stance

TSt, the second half of SLS, begins with heel rise of the stance limb and ends when the contralateral foot makes contact with the ground. As the body vector approaches the metatarsophalangeal joint, the heel rises, and the phalanx dorsiflexes (extends). The metatarsal heads serve as an axis of rotation for body weight advancement (see Fig. 5.3B). This is referred to as the *forefoot rocker* (third rocker).[5] The forefoot rocker serves as an axis around which progression of the body vector advances beyond the area of foot support, creating the highest demand on calf muscles (gastrocnemius and soleus). During TSt, the ankle continues to dorsiflex to 10 degrees. The knee is fully extended, and the hip moves into slight hyperextension. Forward fall of the body moves the vector further anterior to the ankle, creating a large dorsiflexion moment. Stability of the tibia on the ankle is provided by the eccentric action of the gastrocnemius and soleus muscles.

The trailing posture of the limb and the presence of the vector anterior to the knee and posterior to the hip provide passive stability at hip and knee joints. The tensor fascia latae serves to restrain the posterior vector at the hip. At the end of TSt, the vertical GRF reaches a second peak greater than body weight, similar to that which occurred at the end of LR.

FUNCTIONAL TASK 3: LIMB ADVANCEMENT

Four phases contribute to limb advancement: PSw, ISw, MSw, and TSw. During these phases, the stance limb leaves the ground, advances forward, and prepares for the successive IC.

Preswing

PSw, the second period of double limb support in gait, comprises the last 10% of the stance phase. It begins when the contralateral foot makes contact with the ground and ends with ipsilateral toe-off. During this period, the stance limb is unloaded, and body weight is transferred onto the contralateral limb (Fig. 5.4A). This is referred to as the *toe rocker* (fourth rocker). The toe rocker, the most anterior aspect of the medial margin of the forefoot and the great toe, serves as the base for accelerated limb advancement.[5] The ankle moves rapidly from its TSt dorsiflexion into 20 degrees of plantar flexion. During this subphase, plantar flexor muscle activity decreases as the limb is unloaded. Toward the end of PSw, the vertical force is diminished such that plantar flexors rapidly decrease their activity to complete quiescence. There is no active muscle contraction for "push off" in normal reciprocal free walk bipedal gait.[8] The knee also flexes rapidly to achieve 35 to 40 degrees of flexion by the end of PSw.[9] The GRF vector is at the metatarsophalangeal joints and posterior to the knee, creating passive knee flexion with toe clearance. Knee flexion during this phase prepares the limb for toe clearance in the swing phase. PSw hip flexion is initiated by the rectus femoris and the adductor longus, which also decelerates the passive abduction created by contralateral body weight transfer. The sagittal vector extends through the hip as the hip returns to a neutral position.

Initial Swing

Approximately one third of the swing period is spent in ISw. It begins the moment the foot leaves the ground and continues until maximal knee flexion (60 degrees) occurs, when the swinging extremity is directly under the body (see Fig. 5.4B). Concentric contraction of pretibial muscles initiates foot dorsiflexion from its initial 20 degrees to 5 degrees of plantar flexion. This is necessary for toe and foot clearance as swing phase begins. Knee flexion, resulting from action of the short head of the biceps femoris, also assists in toe clearance. The knee continues to flex until it reaches a position of 60 degrees of flexion. Contraction of the iliacus advances the hip to 20 degrees of flexion. Contraction of the gracilis and sartorius muscles during this phase assists hip and knee flexion.

Midswing

During MSw, limb advancement and foot clearance continue. MSw begins at maximum knee flexion and ends when the tibia is vertical. Knee extension, coupled with ankle dorsiflexion, contributes to foot clearance while advancing the tibia (see Fig. 5.4C). Continued concentric activity of pretibial muscles ensures foot clearance and moves the foot toward the neutral position. Momentum creates an extension moment, advancing the lower leg toward extension from 60 to 30 degrees of flexion, with the quadriceps quiescent. Mild contraction of hip flexors continues to preserve the hip flexion position.

Terminal Swing

In the final phase, TSw, the knee extends fully in preparation for heel contact (see Fig. 5.4D). Eccentric contraction of the hamstrings and gluteus maximus decelerates the thigh and restrains further hip flexion. Activity of the pretibial muscles maintains the ankle at neutral to prepare for heel contact. In the second half of TSw, the rectus femoris is quiescent but the rest of the quadriceps vasti become active to facilitate full knee extension. Hip flexion remains at 30 degrees.

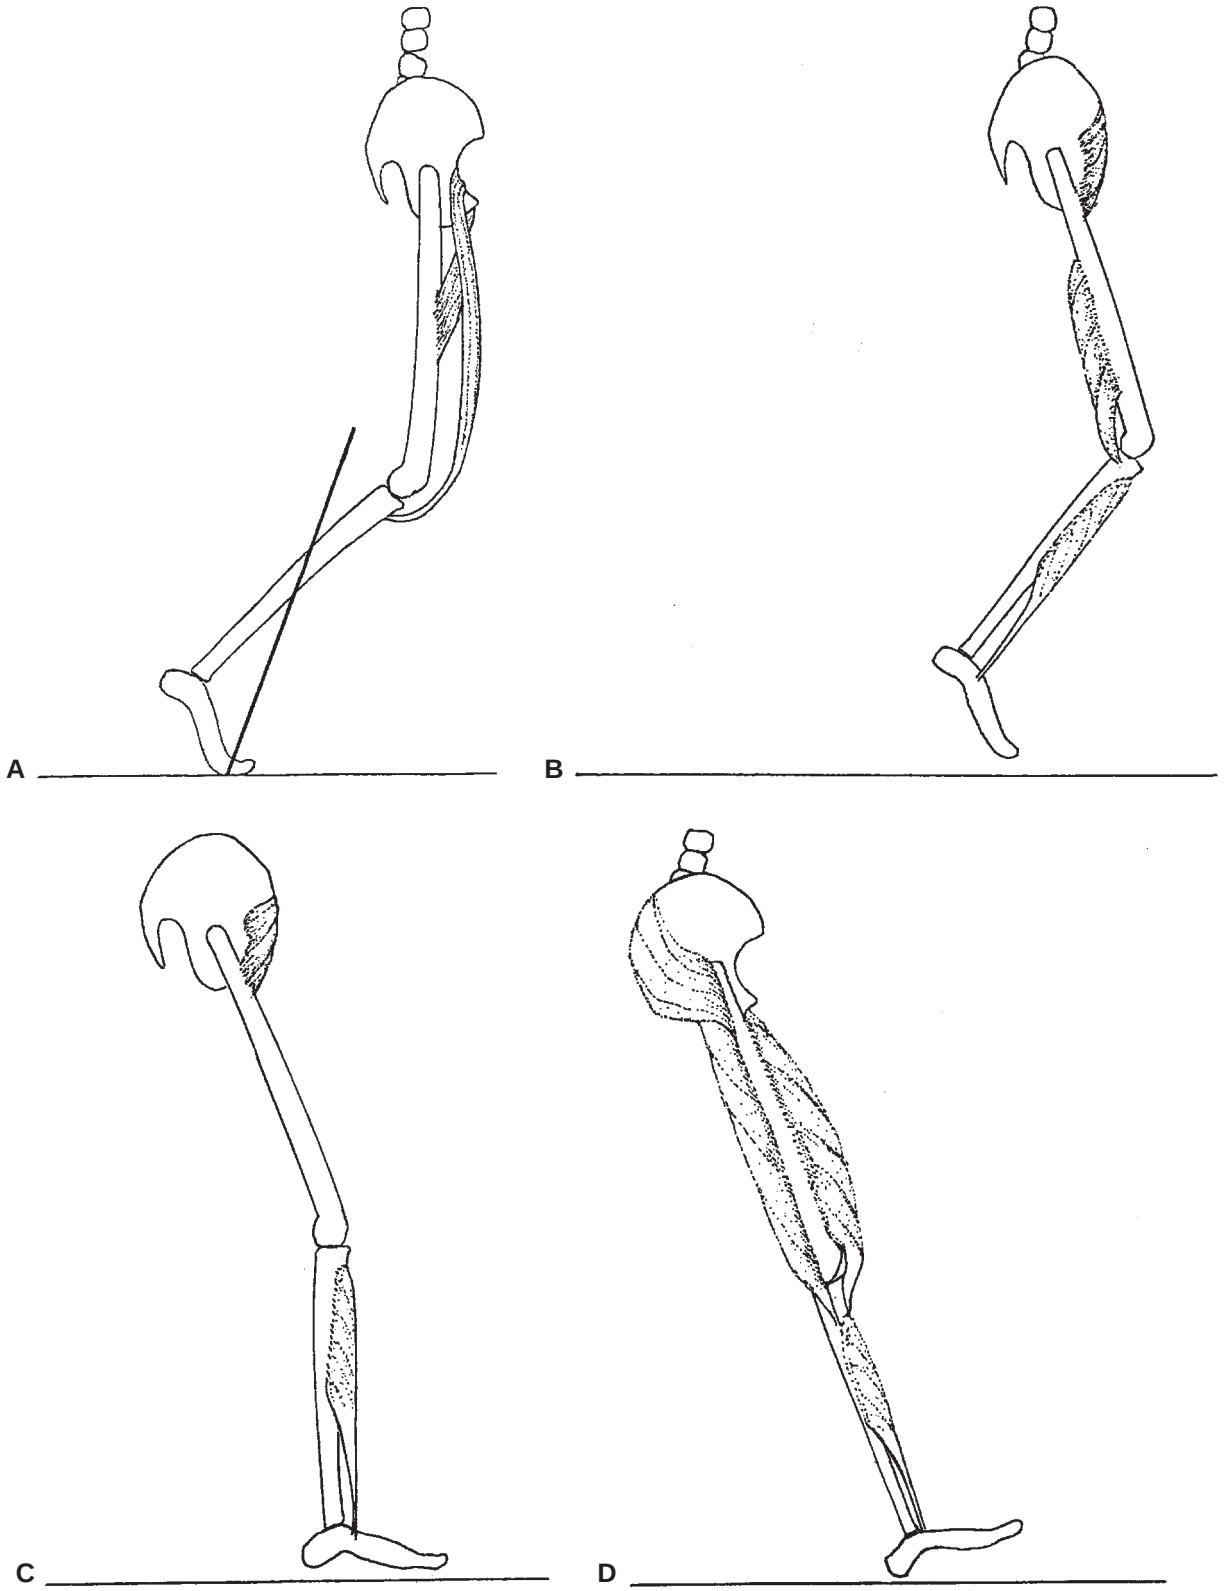

Fig. 5.4 The subphases of gait involved in the functional task of swing limb advancement include preswing (PSw), initial swing (ISw), midswing (MSw), and terminal swing (TSw). (A) During PSw, contralateral loading results in limited muscle activity in the limb transitioning from stance to swing. The rectus femoris and adductor longus initiate hip flexion. Knee flexion is passive, resulting from the planted forefoot and mobile proximal segments. (B) During ISw, the pretibial muscles, short head of the biceps femoris, and iliacus are active in initiating limb advancement and providing swing clearance. (C) A vertical tibia signals the end of the period of MSw. Here contraction of the iliacus preserves hip flexion while pretibial muscle activity maintains foot clearance. (D) At TSw, the gluteus maximus, hamstrings, quadriceps, and pretibial muscles are active to prepare for limb placement and the ensuing loading response.

A comprehensive system to describe normal and abnormal gait has been developed by the Pathokinesiology and Physical Therapy Departments at Rancho Los Amigos Medical Center over the past several decades.[1,2,10] Because velocity affects many parameters of walking, the description of normal gait assumes a comfortable self-selected velocity. At free walking velocity, the individual naturally recruits strategies and assumes the speed that provides maximum energy efficiency for their physiological system throughout the gait cycle.

Describing Pathological Gait

Qualitative descriptors are often used to characterize gait deviations and compensations. Some of these terms help identify specific primary impairments; others describe compensatory strategies adopted by individuals to address gait difficulties created by various primary impairments. Pathological gait mechanisms can be rooted in one of five primary areas. Dr. Perry identified these five functional categories as deformity, muscle weakness, sensory loss, pain, and impaired motor control.[5]

COMMON GAIT DEVIATIONS OBSERVED DURING STANCE

Gait deviations observed during stance can be a result of single impairment or a combination of deformity, muscle weakness, sensory loss, pain, and impaired motor control.

Increased contralateral pelvic drop or Trendelenburg gait pattern is seen in the stance phase of the gait cycle. This deviation can result from musculoskeletal complications or impaired motor control and is observed when the hip abductors are unable to generate sufficient torque to prevent excessive femoral adduction during LR. Increased contralateral pelvic drop is observed when the trunk leans to the same side as the hip pathology (ipsilateral lean), coupled with pelvic rotation. This is a compensatory strategy used when the gluteus medius muscle and its synergists (gluteus minimus and tensor fascia latae) cannot adequately stabilize the pelvis during stance.[11] Normally the drop of the contralateral pelvis is limited to 5 degrees by the eccentric control of the strong hip abductor muscles. To support the pelvis, the hip abductor muscles must generate a force that is about two times the body weight.[12] Weak or absent gluteus medius musculature leads to a postural substitution observed as an ipsilateral trunk lean over the weight-bearing hip joint. This reduces the external adductor moment created by a GRF line that falls medial to the joint center. Without this postural compensation, clearance of the distal portion of the contralateral limb becomes difficult in swing. Rarely, a positive Trendelenburg sign is caused by overactive hip adductors (adductors longus, magnus, brevis, and gracilis).

Vaulting may be a result of deformity or impaired motor control. Vaulting is observed through excessive plantar flexion of the stance foot, occasionally occurring with simultaneous stance limb hip and knee extension, with the goal of raising the pelvis to clear the contralateral swing limb.[13] It occurs when the functional length of the swing limb is relatively longer than that of the stance limb. It also occurs when swing limb advancement is impaired or delayed by inadequate motor control of hip or knee flexion, or both, or in the presence of a plantar flexion contracture of the swing leg. It may compensate for pelvic obliquity or leg length discrepancy.

Antalgic gait is a strategy used to avoid pain during walking. It is frequently observed in LR when the individual reduces SLS time on the affected limb. If the pain occurs during a particular interval in stance phase, that time interval is avoided. Antalgic gait caused by pain that originates around the hip might translate into a lateral lean to permit the individual to position the center of gravity over the support point, the head of the femur. If pain occurs during the extreme end range of a particular joint motion, that motion is diminished. For example, if full extension produces pain, the knee would be maintained in slight flexion throughout the gait cycle. It is important to note that while gait deviations are intended to lessen or avoid pain altogether, the compensatory movement patterns and altered mechanics can subsequently cause pain, dysfunction, and damage to the surrounding anatomy.[5]

COMMON GAIT DEVIATIONS OBSERVED DURING SWING

Circumducted gait may be a result of deformity, muscle weakness, or impaired motor control affecting ankle dorsiflexion, knee flexion, or hip flexion or a combination thereof. Circumduction is described as hip abduction combined with a wide arc of external pelvic rotation. Circumduction can be observed as a lateral arc of the foot in the transverse plane that begins at the end of PSw and ends at IC on the same limb, and the arc reaches the apex of its lateral movement at MSw. Most often, circumduction occurs as a compensatory pattern when there is a relatively longer swing limb compared with the stance limb. A plantar flexion contracture at the foot or a stiff knee or hip joint can necessitate a circumduction pattern during swing in an effort to achieve toe and foot clearance. The combination of abduction and pelvic rotation is a compensatory strategy to advance the limb through swing phase.

The typical pattern is a mixture of a wide base of support with the foot abnormally outset and may include an ipsilateral pelvic drop. In addition, it is possible for a contracture of the contralateral adductors to create this deviation by pulling the pelvis toward the contralateral femur and demanding a compensatory ipsilateral abducted position relative to the pelvis. A severe leg length discrepancy can result in an exaggerated pelvic tilt from the contralateral stance leg, which obligates the swing limb to an increased abduction position. Circumduction and abduction create a significant energy cost penalty, increasing lateral displacement of the center of gravity.

GAIT DEVIATIONS ASSOCIATED WITH ABNORMAL MUSCLE TONE

Gait deviations associated with abnormal muscle tone or weakness can be seen in both stance and swing phases and are also abnormalities produced by primary pathologies that present in the form of abnormal mechanics of one or more of the five functional areas (deformity, muscle weakness, sensory loss, pain, and impaired motor control).[5]

A variety of abnormal GPs are associated with abnormal muscle tone—most commonly spasticity, rigidity, hypotonicity, or abnormal motor control or muscle weakness.

Ataxic gait is a complication in gait that is seen as a failure of coordination or irregularity of muscular action of the limb segments commonly caused by cerebellar dysfunction. Ataxia often becomes accentuated when the eyes are closed, or vision is impaired or distracted.

Crouch gait is seen as excessive ankle dorsiflexion and exaggerated knee and hip flexion occurring throughout the stance phase of the gait cycle. Crouch gait is often seen in combination with toe-walking in children and adults with spastic diplegic cerebral palsy.[14] It has been attributed to a combination of overactivity of the hamstrings and weakness of calf muscles.

Scissor gait describes a pattern of poor control in limb advancement or tracking of the swing leg often characterized by the crossing, or scissoring (hip adduction, flexion, and medial rotation), of the lower limbs. It is most often observed in individuals with spastic or paretic pathological conditions such as hemiplegia, spastic diplegia, and cerebral palsy.[15]

Steppage gait occurs when there is weakness or paralysis of the dorsiflexor musculature, such as in persons with peroneal palsy or peripheral neuropathy, demanding exaggerated hip and knee flexion of the proximal joints to accomplish swing clearance; this gait deviation is most easily observed in late MSw.

Although orthosis use can successfully control abnormal motion in the sagittal plane as in steppage gait, orthoses are less effective in controlling the abnormal transverse, rotational, or coronal plane limb placement problems observed in ataxic, scissoring, or crouched GPs.

Qualitative Gait Assessment

Qualitative methods for identification and recording of gait deviations have played a role in patient care for decades. In 1925, Robinson described pathological GPs and attempted to correlate them with specific disease processes.[16] In 1937, Boorstein identified 14 disease processes that could be diagnosed with gait assessment.[17] He described seven major gait deficit groups, attributing the term *steppage gait* to the French physician Charcot and the identification of *waddling gait* in hip dysplasia to Hippocrates. In the late 1950s, Blair Hangar, the founder of Northwestern University's School of Prosthetics and Orthotics, and Hildegard Myers, a physical therapist at Rehabilitation Institute of Chicago, collaborated to develop the first comprehensive system of clinical gait analysis for persons with transfemoral amputation.[18] They identified 16 gait deviations and suggested numerous clinical and prosthetic causes for each. Their work, developed into an educational film and handbook in 1960, has since been a model for subsequent instructional videos and assessment systems in prosthetics.[19] Brunnstrom's comprehensive gait analysis form for hemiplegic gait, published in 1970, is a checklist of 28 deviations seen at the ankle, knee, and hip that are common after stroke.[20] Many other assessment tools have evolved; many are used but only a few have been assessed for validity and reliability. The Gait Assessment and Intervention Tool (GAIT) is a 31-item objective measure of the movements of persons following stroke that provides a comprehensive assessment of the coordinated components of gait pre- and postintervention.[21] This tool has been shown to be reliable and valid in the assessment of gait and the assessment of the success of intervention following neural injury.[22,23]

Early work in observational gait analysis received a significant impetus from Perry as an outgrowth of basic research data published in 1967.[24] In the late 1960s, Perry and a group of physical therapists from the Rancho Los Amigos Medical Center Physical Therapy Department developed an organized format for systematically applied observational gait analysis. Their work initially focused on the development of an in-house training program for students and personnel who were new to the rehabilitation hospital. The first Normal and Pathological Gait Syllabus was published by the Professional Staff Association of Rancho Los Amigos Hospital in 1977.[2,25] Subsequent revisions have included additional gait data and gait interpretation.[26] This syllabus uses parameters of normal gait as a comparative standard for abnormal or pathological gait. Recently Adams and Cerny have designed a similar but more simplified observational gait analysis form (KAKC's Observational Gait Analysis) that includes only major, most commonly, occurring gait deviations that interfere with the three gait functional tasks.[27] Problems in each of the major body segments are noted with a check in one of the bubbles, beginning with the ankle, calcaneus, toes, knee, thigh, pelvis, and trunk. This format allows the clinician to consider systematically critical questions to illuminate the deviations and complications present in each unique client presentation.[27] It focuses on identifying gait deviations that affect the three functional tasks of walking: weight acceptance, SLS, and swing limb advancement.

Qualitative gait assessment is an important component of preorthotic assessment because it assists the clinician in identifying the functional task and the subphase of gait that are problematic and can be addressed with orthotic intervention. Similarly, qualitative assessment can inform preprosthetic choices, as well as identify deviations observed during gait analysis, illuminating the need for adjustment of prosthetic design and alignment.

Instrumented Gait Analysis

Instrumented gait analysis records the process of walking with measurable parameters collected through the use of computerized equipment with the goal of enhancing the interpretive quality to clinical gait analysis. Such basic techniques would have enabled measurement of walking velocity (distance traversed per unit of time) and cadence (steps per unit of time). Marks, a New York City prosthetist, offered a more precise qualitative description of pathological gait in 1905, when he described the gait process in eight organized phases and discussed the implications of prosthetic component design on walking function. Marks praised "kinetoscopic" photography as a potential diagnostic tool for optimizing pathological gait.[28]

Today we record gait parameters with instruments as common as a stopwatch or as complex as the simultaneous integration of three-dimensional kinematics, kinetics, and

EMG methods. The primary emphasis of clinical assessment has been on accessible techniques and inexpensive technologies. A simple, inexpensive footprint mat has been used for decades to record barefoot plantar pressures. Clinics use individual or multiple mats to record step and stride length, as well as walking base width. Early on, video technology with slow-motion capabilities made more precise qualitative description of the gait cycle possible. The continued development of inexpensive video gait assessment software has made clinical quantitative applications more practical as well. Most quantitative and qualitative video systems, however, measure joint angles in two dimensions, which does not offer a complete analysis of the three-dimensional walking activity.

TECHNOLOGY IN GAIT ASSESSMENT

The high-tech side of quantitative gait analysis has traversed a surprisingly long road. The birth of instrumented kinematic, EMG, and temporal performance analysis began in the 1870s with E.J. Marey, who first performed movement analysis of pathological gait with photography.[29] He also developed the first myograph for measuring muscle activity and the first foot-switch collection system for measuring gait events related to the temporal parameters. The foot-switch system was an experimental shoe that measured the length and rapidity of the step and the pressure of the foot on the ground. Eadweard Muybridge, working at Stanford University in the 1880s, used synchronized multiple camera photography with a scaled backdrop to record on film and assess the motion of subjects walking.[30] Scherb made other major advances in instrumented gait analysis in 1920 by performing manual muscle palpation on individuals while using a treadmill. In addition, in 1925 Adrian advocated the use of EMG to study the dynamic action of muscles.[31]

Modern gait technology began in 1945, when Inman and colleagues initiated the systematic collection of gait data for individuals without impairment and with amputation in the outdoor gait laboratory at the University of California at Berkeley.[7] Since then, researchers and clinicians have increasingly used the wide array of gait technologies to measure the parameters of human performance in normal and pathological gait. A full-service gait laboratory gathers information on six performance parameters in walking: temporal, metabolic, kinematic, kinetic, EMG, and pressure.[32]

MEASURING TEMPORAL AND DISTANCE PARAMETERS

Temporal parameters (time and distance) enable the clinician to summarize the overall quality of an individual's gait. Temporal data collection systems might be one of the most effective components available for assessment in the clinical setting. In the gait laboratory, microswitch-embedded pads taped to the bottom of an individual's shoes or feet can record the amount of time that the individual spends on various anatomical landmarks over a measured distance. Portable pressure-sensitive gait mats, connected to a laptop computer with gait analysis software for time and distance parameters, are also commercially available to use in clinical settings.[33,34] For example, the GAITRite system, which consists of an electronic walkway connected to a computer, records the temporal and spatial characteristics of individuals while walking, as well as while performing other functional or occupational tasks. The GAITRite mat is flexible and can be rolled and transported in a hard case, which enables data collection at different clinics or sites. Rao and colleagues used the GAITRite system to collect temporal and spatial data to compare the effects of two unique and different ankle-foot orthosis (AFO) designs on the GP of individuals following acute hemiparetic cerebrovascular accidents (CVAs). In this study, they compared stride length, velocity, cadence, and step length, while also surveying the clients' perceptions between walking with no device, an off-the-shelf carbon AFO, and a custom plastic AFO. The GAITRite system data collection was consistent with the client perceptions; velocity, cadence, stride length, step length increase with either the carbon AFO or the custom plastic AFO compared to no AFO.[35]

Gait deviations related to excessive inversion, eversion, or prolonged heel-only time can be recognized and should be considered when modifying the alignment or components of prostheses or orthoses. A temporal data collection system is particularly cost effective and clinically meaningful. Temporal data are usually a product of another measuring system such as EMG or motion analysis. Temporal data systems are commercially available, covering a wide range of cost, technical sophistication, and time required to analyze the summarized data. Some of the temporal parameters, however, can be recorded to a lesser degree of accuracy using a stopwatch and basic video camera.[36]

ASSESSING THE ENERGY COST OF WALKING

Metabolic data reflect the physiological "energy cost" of walking. The traditional measures of energy cost are oxygen consumption, total carbon dioxide generated, and heart rate. Other relevant factors include volume of air breathed and respiratory rate. All these parameters are viewed in relation to velocity and distance walked over the collection period. Historically, metabolic data were collected while the individual walked on a treadmill, wearing umbilical devices. In recent years, because of the known influence of treadmill collection in altering normal gait velocity, energy cost data are more likely to be obtained on an open track of a measured distance with the individual ambulating in a free walk or natural cadence. With the cardiopulmonary device market continually growing and advancing, there is a wide array of versatile testing equipment to choose from. This equipment allows the individual to negotiate their normal environments with little or no interruption due to the testing and collection setups. Some of the newest products on the market couple the traditional oxygen and carbon dioxide (V_{O_2} and V_{CO_2}) measurement with the capability of collecting telemetry data, indirect calorimetry, and integrated electrocardiogram among other add-ons to standard systems. The primary limitation of energy cost as an assessment tool is that, although it can inform the investigator about body metabolism relative to the individual's gait, it cannot explain why or how an advantage or disadvantage was obtained. Dr. Weinert-Aplin found that through the analysis of the center of mass in all three plans for subjects

with amputations there could potentially be a correlation between metabolic cost and the center of mass positioning during gait. The study revealed the base of support and the medial-lateral positioning of the center of mass had the most significant correlation with the subject's metabolic requirements, suggesting that increases in base of support and medial-lateral center of mass displacement reduce walking efficiency.[37] Energy cost measures alone cannot easily identify between the impact of varieties of components, muscle activation, or a combination of both with regard to metabolic energy, whereas a combination of kinematic, kinetic, and EMG data typically can.[38] The COSMED K4b2 system has been used in many studies; in particular, one study utilized the wearable metabolic analysis system to assess the impact of new technologies in prosthetics and the associated energy requirements. The comparison was made between the standard energy storing prosthetic feet and the relatively new concept of crossover prosthetic feet.[39] The MetaMax 3B system was utilized to demonstrate that the movement of the center of mass, as well as the base of support, were significant indicators of the metabolic cost of walking in persons with amputations.[37]

Perhaps the best kept secret in the energy cost arsenal is the *physiological cost index* (PCI). It is easily calculated as follows:

$$\text{PCI} = (\text{walking pulse} - \text{resting pulse})/\text{gait speed}$$

The PCI is one of the most sensitive indicators of energy cost of gait. Tanabe and colleagues compared two different orthotic designs by measuring a wide variety of metabolic parameters as well as the PCI.[40] Their results demonstrated statistically significant difference in PCI between the two devices when all other measured parameters failed to produce such differences.

KINEMATIC AND KINETIC SYSTEMS

Most *kinematic* systems provide joint and body segment motion in graphic form. This information includes sagittal, coronal, and transverse motions that occur at the ankle, knee, hip, and pelvis. The individual is instrumented with reflective markers that are placed on well-recognized anatomical landmarks (Fig. 5.5). Typically, an infrared light source is positioned around or integrated into each of several cameras. This light is directed to the reflective spheres, which in turn are reflected into the cameras. Each field of video data is digitized, the markers are manually identified, and the coordinates of the geometric center of each marker are calculated with computer software. Resultant data are displayed as animated figures that represent the actual motions produced by the individual. The operator can freeze any frame and enlarge the image at any joint to examine GPs in greater depth. The operator can extract raw numbers that represent joint placement and motion in space or produce a printout showing joint motion in all planes plotted against the percentage of the gait cycle (Fig. 5.6). Angular velocities, accelerations, and joint and segment linear displacements can be calculated. Data from other systems (force platforms and EMG) collected during the same time sequence as the motion data are often integrated with the kinematics. Advanced systems like these can be a very expensive component of the gait lab, but the information collected provides some of the most in-depth and valid data. In the gait lab or a clinical lab, the motion system

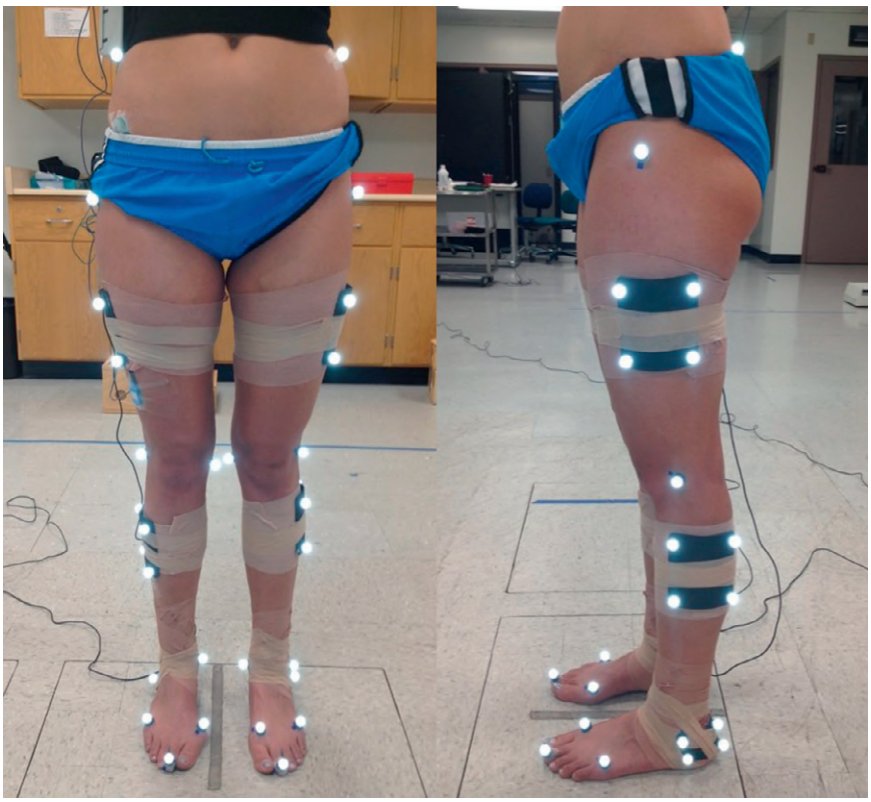

Fig. 5.5 This individual is wearing reflective spheres. An infrared camera system can track limb segment motion as the patient walks across the field of view.

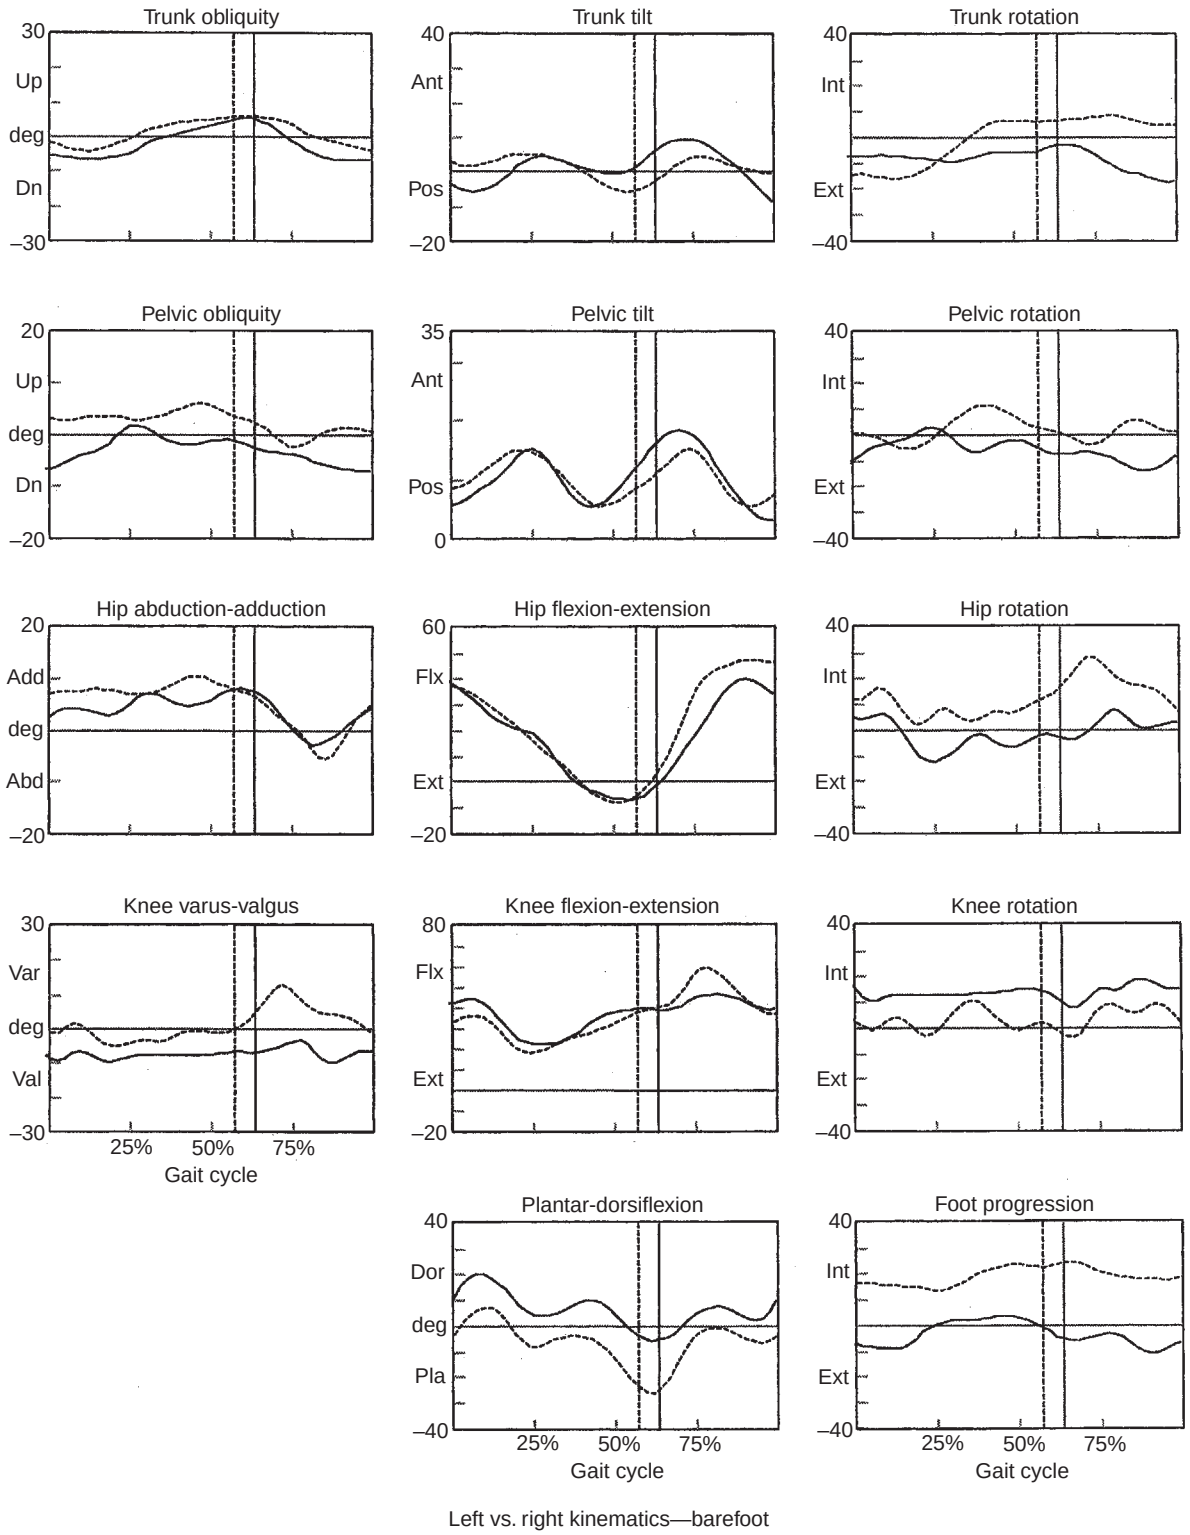

Fig. 5.6 The output generated by a computer-based motion analysis system includes graphs of the mean range of motion at each body segment or joint (trunk, pelvis, hip, knee, and ankle) in coronal *(left column)*, sagittal *(middle column)*, and transverse *(right column)* planes as the individual being evaluated progresses through multiple gait cycles. This is the output of an 8-year-old child with spastic diplegic cerebral palsy. (Courtesy the Center for Motion Analysis, Connecticut Children's Medical Center, Hartford, CT.)

setup serves as the technological core. A variety of Vicon motion systems have been used to evaluate the joint motion in individuals with spastic diplegic cerebral palsy and various other client populations.[41] Similarly, the EvaRT motion analysis system has been used to collect data comparing mechanical and microprocessor knees in individuals with gait and balance deficits associated with transfemoral amputations.[42]

The Dartfish system is another motion analysis tool that is used in gait laboratories and clinical settings.[43] The Dartfish system allows for two- and three-dimensional joint motion analysis. It is portable, less expensive, and requires less time to set up when compared with other motion analysis systems. In one study, the Dartfish system demonstrated excellent validity and reliability as well as agreement between 2D and 3D motion analysis in subjects demonstrating postural control of varying capabilities as well as balance deficits.[44]

When an individual takes a step, he is exerting force against the surface he is walking on. This kinetic information is obtained from one or more force platforms, which collect data on the three components of the GRF: vertical, fore-aft (anterior-posterior), and medial-lateral (Fig. 5.7). The contribution of kinetic data can be significant. Fore-aft shear is quite useful in establishing appropriate transtibial prosthetic alignment in the sagittal plane. For this purpose, the clinician would anticipate a balanced magnitude and timing of the braking and propulsive patterns. Data collection from two consecutive steps, one gait cycle, requires dual force plates. Some kinetic software packages also offer specialized programs for specific purposes such as stability analysis, which provides information about center of gravity shift relative to time.

Although the typical force platform system provides data about forces and moments occurring at the ground, or center of pressure progression, it can be combined with kinematic data to provide additional information. By combining these two data sets, the moments and powers acting at the joints can be calculated. This information is useful in measuring the dynamic joint control of an individual throughout stance, particularly when used in conjunction with EMG. Similarly, information about joint moments, sometimes referred to as *torque*, is also often reported as an outcome measure in research studies. Although this information can be potentially important in the evaluation of pathological gait, it is also necessary to have a basic understanding of how these values are derived. As mentioned, when a person ambulates, the individual exerts force on the walking surface; differing degrees of this force are similarly exerted on each of the joints in the lower extremity. With the exertion of these forces comes an associated moment that is also acting at the joint, along with a power value. In its most basic form, a moment is the result of a force multiplied by a distance or lever arm.[45] Joint power is then calculated by multiplying the moment acting at a joint by the joint's angular velocity. In addition, the moment acting on a particular segment is most frequently calculated with reference to the center of mass of that segment. This means that the lever arm is the distance from where the forces are acting at the joint to the center of mass of the segment. In order to calculate these values, the lower extremity must be broken down into segments—often the ankle, shank or calf, and thigh. By doing this, a link-segment model is being applied and the parameters of interest can be calculated. One study utilized a multilink segment model to evaluate the kinetics, kinematics, and energetics associated with energy storage and return (ESAR) prosthetic feet used in high impact sports. The study revealed there were some flaws in merging unaffected limb and affected limb parameters; this should be taken into consideration when studying the kinematics and kinetics of persons with unilateral amputations.[46]

To further illustrate the interrelated nature of these measures, the calculation path for forces, moments, and power is also presented in a flow chart (Fig. 5.8). It is important to note within the diagram where the different data sources originate. There are very few directly measured values that are then combined with biomechanical models to calculate these variables.

The calculation process begins with the determination of the GRFs, which are obtained through the direct measurement of an individual stepping on a force platform. Once that information is available, it is combined with kinematic data and derived from a two- or three-dimensional motion capture system for each lower extremity body segment so that the joint reaction forces can be calculated. As the forces at each of the joints are determined, then the associated moments acting on each segment can also be calculated. Ultimately, the power can be calculated as well (Fig. 5.9).

In many cases, instrumented kinetic and kinematic systems have included an inverse dynamics model that is applied to determine the forces acting at each of the lower extremity joints. Like virtually all biomechanics models, certain assumptions must be made in order for the calculation to be carried out in a practical manner. With assumptions come the opportunity for the introduction of additional error throughout the process. Because of the high potential for induced error, it is important to understand the limitations associated with them. A fundamental point is that frequently these calculations all rely upon data that are calculated using general body proportions and anthropometric models for whole bodied individuals. Because of this, certain assumptions are made about the mechanical properties of the segments and joints being evaluated. For example, many of the commonly used models assume that the subject has no limb deficiencies and essentially normal musculature. While this may be acceptable for evaluations of individuals without pathology, these assumptions can become a source of error when evaluating an individual with an amputation or other limb dysfunction. There is also the issue that the knee and ankle joints are frequently modeled as simple hinge joints. Doing this makes the calculations more practical to perform but does not completely represent the anatomical reality. Particularly in the case of the knee, the joint center does not stay in a fixed position during stance, but many of the models for calculating joint moments assume that it does (Fig. 5.10). As a result, there can be variation in the distance used to calculate the moment at the knee. Considering the physical location, even a small variation in the estimated joint center could result in a significant change in the value calculated. Because many of the calculations rely upon the model assumptions, the inherent errors can be easily compounded. This is not to say that these variables should be ignored, but that their value should be tempered with an understanding of the process for obtaining them.

ELECTROMYOGRAPHY

Muscle action beneath skin and subcutaneous tissue cannot be directly measured, but through the use of EMG, the activity can be approximated and studied in relation to the action, size of muscle, and signals obtained. EMG records the muscle activity by the electrical signal detected from

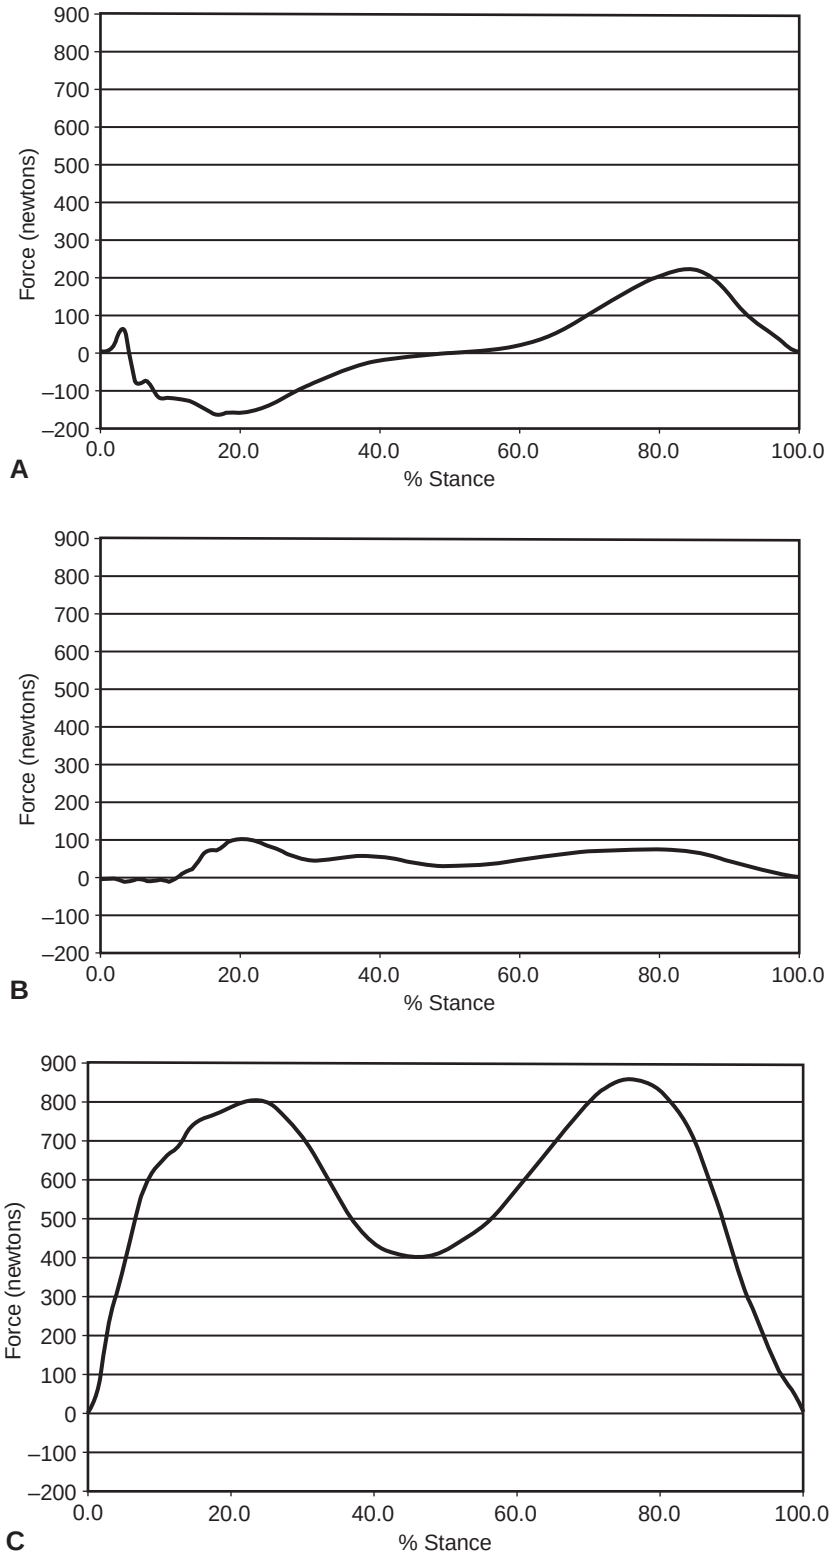

Fig. 5.7 Example of output generated by a force-plate as the individual being tested progresses through stance phase. (A) The anteroposterior component of the ground reaction force (GRF). (B) The medial lateral component of the GRF. (C) The vertical component of the GRF. (Output courtesy of the Motion Analysis Laboratory, Department of Physical Therapy and Human Movement Science, Sacred Heart University, Fairfield, CT.)

the contraction and chemical stimulation of the respective musculature.[47]

EMG instrumentation can vary, as is seen with surface EMG (sEMG) or fine-wire EMG. With sEMG, the electrode pad is adhered to the skin above the muscle being studied, while fine-wire EMG uses wire electrodes directly inserted into the belly of the respective muscle. Intrasocket EMG is a relatively new technique, employing traditional sEMG techniques as well as the use of transcutaneous electrical nerve stimulation (TENS) techniques to allow for EMG to be worn by amputees underneath their prosthesis. This technique allows for EMG information to be gathered on

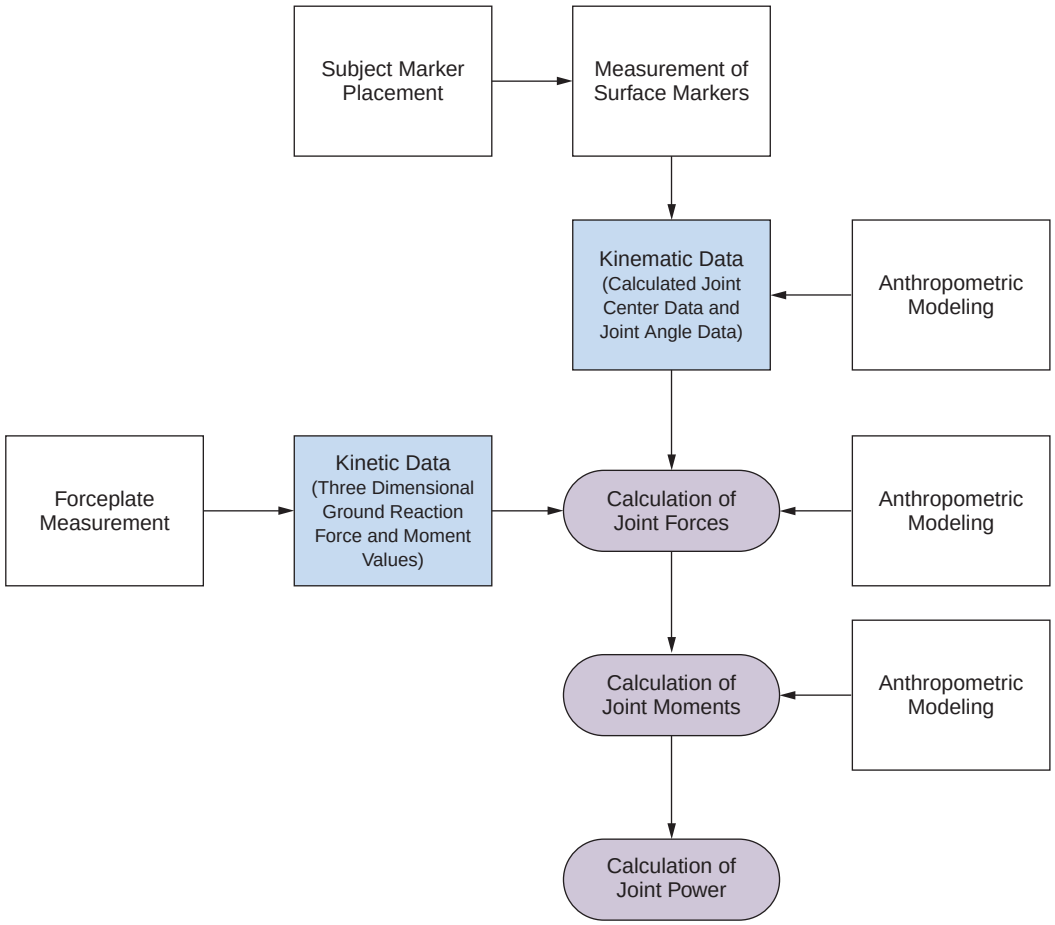

Fig. 5.8 Calculation flowchart: the kinematic data collected from the motion analysis system is entered into a series of calculations based on the person's anthropometric data to produce the instantaneous position of every joint and segment. These data are then combined with force plate data collected at the same time to calculate joint forces, moments, and powers.

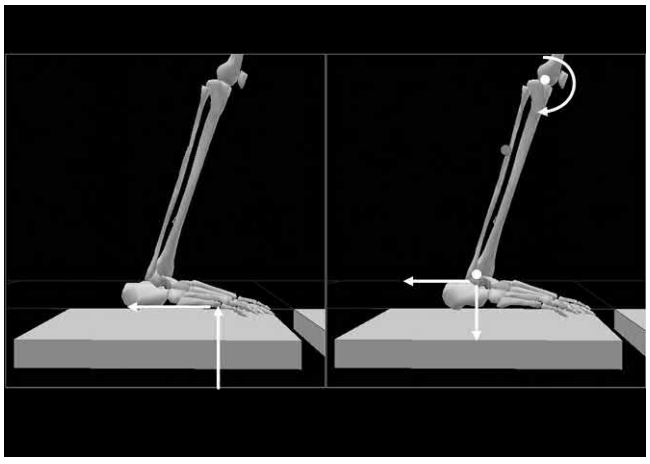

Fig. 5.9 Example of joint moment calculation. (A) Vertical and antero-posterior ground reaction forces recorded from a force plate. (B) Joint moments are calculated by combining ground reaction forces and kinematic data, taking into account the segment's center of mass.

amputees during walking and other dynamic activities, including the use of human intent and control of powered prosthetic devices.[48] EMG data may be the single most important technology in terms of understanding the direct physiological effect of gait variants.

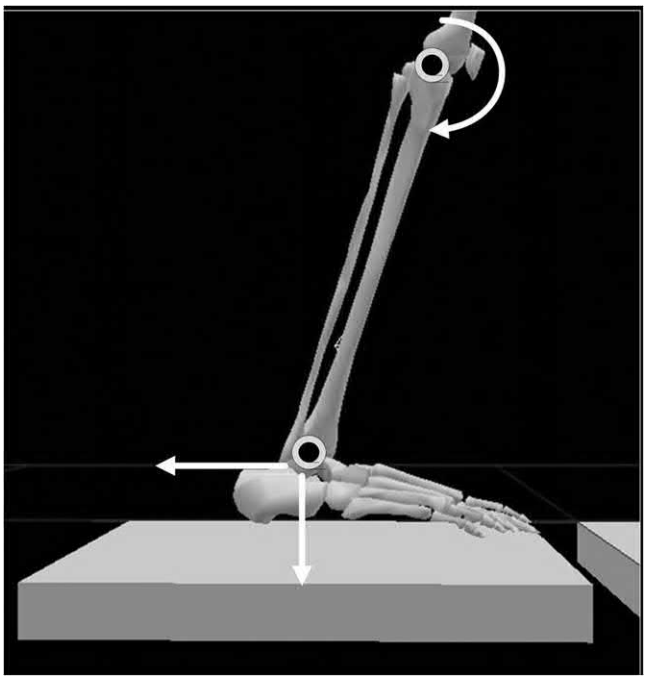

Fig. 5.10 Soft tissues and joint geometry differences between the anthropometric model and the actual individual being introduce a potential error in calculating joint moments. In this example, the outer circle indicates the potential range of location of the actual joint center, compared with where the model ultimately defines it *(inner circle)*.

EMG records the motor unit activation of muscle fibers in the specific muscle being studied. This is very useful but can be problematic with surface electrode applications in that they can pick up the signal from surrounding musculature during testing. EMG characterization allows for timing and relative intensity of muscular effort, as well as resultant muscle force, all of which are necessary to understand normal and pathological gait. EMG data are normalized against maximum contraction data for each respective muscle. Without normalization, the data collected may be invalid and can lead to erroneous interpretation. Maximum contraction is dependent on joint angle as well as the duration of the contraction, both of which are influential to the overall information extracted from analysis.

Patterns of muscle activity in individuals with abnormal gait are compared with well-established norms. Knowledge of the timing and intensity of the muscle activity throughout the gait cycle may guide gait training, orthotic or prosthetic prescription, and dynamic orthotic or prosthetic alignment aimed at reduction of excessive, ill-timed, or prolonged muscle activity. EMG is exceedingly adaptable with the most basic function of superficial muscle activity data to intramuscular fine-wire sensor technology, which is all cohesive to the implementation of many other complex clinical or gait lab technologies.[36] EMG data are also helpful in guiding decisions about surgical intervention (dorsal rhizotomy, tendon lengthening, or osteotomy) in children with cerebral palsy. Some myoelectric prosthesis users have benefitted from increased device control as a result of targeted muscle reinnervation (TMR). TMR procedures intend to create additional EMG sites in higher level upper extremity candidates (transhumeral or shoulder disarticulations), where the user would benefit from intuitive, physiological, and overall improved control of the myoelectric device.[49]

PRESSURE-SENSING TECHNOLOGY

Pressure-sensing technologies offer the clinician tremendous insights into the treatment of individuals at risk for amputation because of vascular disease and diabetic neuropathy. They can also assist vascular surgeons and orthopedic foot specialists in limb salvage through more appropriate custom-designed prophylactic orthoses. In some systems, a thin plastic array can slip nearly unnoticed between the plantar surface of the foot and an orthosis or insole of the shoe (Fig. 5.11). This array, connected to a computer by a lead wire or Bluetooth technology, can measure dynamic pressure patterns and record critical events throughout the walking cycle. A prosthetic version can provide various measurements at 60 individual sites within a socket and record those measurements during multiple events of the gait cycle. Pressure is expressed in terms of a force distributed over the area at which the force is acting.

$$\text{Pressure} = \text{Force}/\text{Area}$$

Plantar pressure and temperature measurements in the foot contribute to the identification of abnormal values and the risk for potential ulcers. These measurements transition critical feedback from subjective to objective clinical measurements offering a way to break out of the cycle of trial and error that is often necessary to find the correct solution to an individual's problem.[50] Currently, surface pressure measurement systems exist in various forms ranging from in-shoe, barefoot, seating and positioning, joint, and prosthetic and orthotic floor-based models. Over the years, Perry and colleagues have collected data on the most common types of pressure testing systems that consist of a "force plate" that uses ink and paper to record the areas of peak pressures during ambulation. This type of system is inexpensive and provides reliable, easily interpreted data. Instrumented insoles, however, are positioned inside the individual's shoes and worn during ambulation and activity performance. The insoles record pressures and various forces on the plantar surface of the foot through an integrated array of sensors.[47] The diversity of treatment applications has promoted these systems to be some of the most valuable in the laboratory setting.[36] An example of the application of pressure sensing technology is in the area of detecting plantar ulcers in the diabetic population. The compilation of data gathered from a six-camera motion capture system for kinematic data, kinetic data collected from two-force plates, data from a two-dimensional plantar pressure finite element model, and EMG data corresponding to the respective lower extremity musculature is used to predict the internal stresses experienced prematurely that ultimately present as plantar surface ulcers.[51] This area is one of the more recent and clinically promising technologies for future use in the clinical assessment setting.

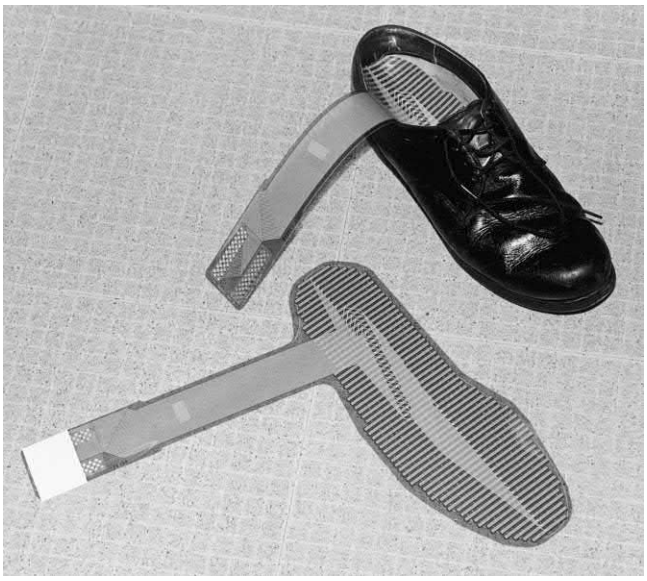

Fig. 5.11 An in-shoe pressure-sensing array can help identify areas of high pressure concentration. This information assists in the design of an orthosis to modify pressure dynamics during the stance phase of gait.

Choosing the Appropriate Assessment Tool

Over the past several decades, technologies have advanced and aided in providing a significantly improved understanding of pathological gait. They have also assisted clinicians in providing strong evidence for the efficacy of various treatment approaches and ultimately helped enhance patient

care. Advocates of a more universal application of the high-end technologies in the clinical setting have made a compelling case for implementation in gait laboratories and clinical settings alike across the field of rehabilitative care. Determining the extent and necessity for various high-end devices, such as full featured motion analysis systems, in the clinical setting can be a very extensive process requiring the evaluation of the advantages and disadvantages to both the individual and the clinic, particularly in the current climate of cost containment. Perhaps the strongest argument for gait technology in our present era lies in its use for outcome measurement to justify legitimate therapeutic treatment approaches, as well as orthotic and prosthetic applications.

Recognizing the need, benefits, and drawbacks of technology in the clinical setting is very important. Appropriate instrumented evaluations will need to be made by the rehabilitation team to help optimize client outcomes.

Function-Based Assessment

Functional measures are performance-based tools directly related to specific activities and linked to "real-world" domains of function. For example, walking in the community requires meeting the demand of varied distance, terrain, illumination, obstacles, stair-climbing, and multitasking. The results of these functional measures are usually compared with established "norms," which characterize the full spectrum of a specific population. Results of functional measures help specify level of function, evaluate progress after intervention, and establish goals and benchmarks.

Holden and colleagues suggest that gait performance goals for individuals with neurological impairments are best measured against values from impaired rather than healthy subjects. Treatment goals are adjusted for the individual's diagnosis, etiologic factor, ambulation aid, and functional category. In separate studies, Brandstater and colleagues and Holden and colleagues found that individuals with the greatest number of gait deviations did not have the lowest temporal values.[52,53] A great deal of energy is often expended by physical therapists, prosthetists, and orthotists in an attempt to help individuals achieve optimal GPs. Holden and colleagues suggest that hard-won qualitative gait improvements may cause secondary losses in time-distance parameters, such as slower velocity and reduced step length.[52] The fundamental issue is whether temporal gait efficiency or cosmesis should be the preferred goal. Certainly, in cases in which individuals are nominal walkers and in which therapy, surgery, and orthotics or prosthetics have optimized, gait efficiency is far more important than reducing in compensatory gait deficits.

In the past, symmetry and reciprocal movement patterns have been significant treatment goals. Wall and Ashburn maintain that "an ideal objective in the functional rehabilitation of hemiplegia is the reduction of the asymmetrical nature of movement patterns."[54] Measuring pathological gait against normal gait values is a useful means of providing an overall clinical picture. In setting treatment goals, however, measuring an individual's performance against their own best possible outcome is more reasonable. How can a given individual's best possible outcome be anticipated? This requires collection of accurate data to establish pretreatment and posttreatment profiles for a wide variety of involvement levels within each pathological condition. Olney and Richards suggest that large groups of instrumented studies be undertaken to identify clusters of biomechanical features associated with functional performance during walking.[55]

Time-distance parameters have enormous potential for setting outcome goals. Variations in time-distance values are often specific to pathological condition. Asymmetries in hemiplegia, for example, are obviously greater than in most other types of pathological conditions. Variables that are reported to affect temporal measurements in normal healthy subjects include age, gender, height, orthotic use, or type of assistive device. In separate studies of individuals with pathological conditions, Brandstater and colleagues and Holden and colleagues found no significant difference in temporal performance based on gender or age.[52,53]

Corcoran and colleagues measured temporal parameters of subjects with hemiplegia under two gait conditions: with and without their AFO. Individuals with hemiplegia had significantly faster gait velocity when wearing their orthoses than when walking without them.[56] Another similar study of healthy unimpaired subjects wearing AFOs found reduced step length. Apparently subjects without central nervous system involvement altered their movement strategy to decrease movements at the knee in an effort to minimize shearing forces in the AFO.[57] Reduced step length can minimize force exerted by the brace along the posterior aspect of the calf band.[58]

FUNCTIONAL MEASURES

Innumerable gait-specific functional measures have been developed to evaluate and quantify complex tasks essential to fully participate in everyday community life. These functional measures provide information about the ambulatory function of individuals with varying neuromuscular, musculoskeletal, cardiopulmonary, or metabolic diseases and conditions. Functional measures are commonly used to document current functional status, change over time, and response to interventions. Although Observational Gait Analysis is valuable in identifying gait deviations in all phases of the gait cycle, functional measures provide information about how these gait deviations affect function in the person's environment. Functional ambulation in the "real-world" involve complex gait tasks, including walking at a varying speed and distance, accelerating and decelerating pace as needed; negotiating changing terrains; navigating obstacles; and multitasking. Functional measures can be performed in most settings, as they do not require specialized equipment or instrumentation.

Commonly used gait-specific outcome measures include (1) WS, (2) Timed Up and Go Test (TUG), (3) Dynamic Gait Index (DGI), (4) Functional Ambulation Classification System (FAC), and (5) The Modified Gait Abnormality Rating Scale (GARS-M). Most of these measures require some degree of practice or training so that testers may develop accuracy in using the tool and can apply all of its psychometric implications. It is common that clinicians combine some of these measures to collect enough information to

make a clinical decision regarding functional level, safety, and/or need for a specific intervention.

Walking Speed

WS (or gait velocity) is the fundamental walking measure that defines the person's basic walking ability.[47] WS is the time required for a person to traverse a specific distance. The term *velocity* indicates not only the speed of travel but also the specific direction of travel. Since walking is usually measured in the forward direction, the distinction between speed and velocity is not significant. On level ground, people without pathology consistently walk at a preferred/comfortable or "self-selected" WS. This speed is the most efficient for that person; faster or slower speed will require more energy.[59,60] In the gait laboratory, this preferred speed is referred to as "free walking velocity" to be distinguished from "fast walking velocity."

WS as a functional measure is highly reliable and sensitive, regardless of the method of measurement.[61] In a group of frail elderly individuals, Van Iersel demonstrated that a 5% change in WS had a sensitivity of 92% to detect clinically relevant change.[62] WS also correlates with functional ability,[63] physiological changes,[63] and balance confidence.[64] Several studies demonstrated that WS can predict important aspects of health status and future events including hospitalization,[65] discharge location,[66,67] future health status,[68,69] and mortality.[70]

Numerous factors contribute to WS, including joint mobility, muscle strength, sensory function, neural control, cognitive status, and energy level, so it can reflect overall health. Fritz and Lusardi suggested considering WS as the "sixth vital sign" in older adults. Vital signs 1 to 5 include pulse rate, respiratory rate, blood pressure, pain, and temperature.[3] The National Institutes of Health (NIH) Toolbox for the Assessment of Neurological and Behavioral Function includes WS as a measure of motor function.[71]

In gait laboratory investigations, researchers have used a variety of state-of-the-art equipment including portable computerized walkways, motion analysis systems, and foot switch technology to measure WS. Clinicians, however, can reliably measure WS in almost any clinical setting using a stopwatch and a walkway. Most published reports measured WS for the middle 6-m of a 10-m walkway to avoid the acceleration and deceleration phases and capture the steady WS. Suggested walkway distance varied greatly between studies; however, a walkway as short as 6-m (recording zone is the central 4-m) is still a reliable measure.[71] Fritz and Lusardi suggest a 10-m test with added 5-m for acceleration and 5-m for deceleration.[72]

In people without pathology, several factors affect walking, including age, gender, lower extremity length, strength, and spontaneous variability between individuals.[72] To follow the International Standards of Measurement, gait speed should be expressed in m/s. Collectively, the range for normal WS for adults is between 1.2 and 1.4 m/s.[73] Others reported WSs in m/min to be compatible with other energy and cadence measurements. Waters and colleagues reported a similar average of 82 m/min for adults.[74]

Timed Up and Go

The original purpose of the TUG test was to assess general mobility and fall risk in frail older adults with limited mobility.[75] The American Geriatric Society recommends that TUG be utilized as a routine screening test for falls.[76] For the test, individuals are asked to rise from a seated position in a standard height chair, walk 3-m on a level surface, turn, walk back to the chair, and return to a seated position, moving as quickly as they are safely able. Although the original get-up-and-go test used a somewhat subjective 0 to 5 rating to score each component of the task, performance is now based on total time to complete the task.[77,78] In both versions, individuals being evaluated are instructed to move as quickly as they are safely able to move. It is important to note, the TUG is a measure of overall functional mobility, assessing the ability to transfer, walk, and change direction.

Several studies documented reference ranges for the TUG in community-dwelling older adults.[61,79–81] Bohannon consolidated data from 21 studies for meta-analysis on the TUG reference values in people older than 60 years of age.[82] The mean TUG time for individuals at least 60 years of age was 9.4 (8.9–9.9) seconds. When the data were divided into three age subgroups, the mean for those 60 to 69 years was 8.1 seconds, for 70 to 79 years was 9.2 seconds, and for 80 to 99 years was 11.3 seconds. Several other studies documented the higher mean of the TUG values as age increased and for women compared to men.[80,81] Intrarater and interrater reliability of the TUG is excellent, and Intraclass Correlation Coefficients range between 0.97 and 0.99.[61] Although the TUG does not specifically assess WS, it assesses the more functional components of mobility and transfer from sit to stand.[83]

The TUG times increased when healthy older adults were tested using an assistive device.[84,85] Reference range for the TUG times in individuals who use assistive devices is not available. Higher TUG times are associated with functional impairment in individuals with arthritis, amputation, hip fracture, and Parkinson disease.[86–92]

The TUG dual task tests have the same basic instructions as the TUG, where the participant simultaneously perform another task, either cognitive (TUG cognitive) or manual (TUG manual). In the TUG cognitive, the participant is asked to complete the test while counting out loud or verbally counting backward by threes from a randomly selected number between 20 and 100.[93,94] Similar to the TUG, the TUG dual task was tested in healthy individuals as well as in individuals with varying diagnoses.[93–95]

Dynamic Gait Index

The DGI tests the ability of the participant to maintain walking balance while responding to different task demands, through various dynamic conditions. It is a useful test in individuals with vestibular and balance problems.[96] It includes eight items, walking on level surfaces, changing speeds, head turns in horizontal and vertical directions, walking and turning 180 degrees to stop, stepping over and around obstacles, and stair ascent and descent. Each item is scored on a scale of 0 to 3, with 3 indicating normal performance and 0 representing severe impairment. The best possible score on the DGI is a 24. Several studies demonstrated its high intrarater and interrater reliability in older adults and in different client populations.[97–99] A score of less than 19 indicates a risk for falling.[98]

A short form of the DGI includes only four items: walking on level surfaces, changing speeds, and head turns in

horizontal and vertical directions.[100] Anything less than the maximum score of 12 on the short form identified individuals with balance deficit and those who scored less than 10 were at risk for falls.[83]

The Modified Dynamic Gait Index (mDGI) expands the original eight-item DGI expanding the range of possible scores. In addition to DGI scoring, it scores the level of assistance (LOA), GP, and time for each of the eight items.[101] The test has four environmental dimensions as well: temporal, postural, terrain, and density. The total possible mDGI score is 64 points, which is the sum of the scores of the three facets of the test; 24 points for time, 16 points for LOA, and 24 points for GP. Similar to the DGI, the mDGI was tested on healthy older adults as well as on varying client populations.[101,102]

Functional Ambulation Classification

The FAC is a walking test that classifies subjects into six functional categories based on the need for personal assistance, regardless of the use of assistive device during walking tasks.[52] Holden and colleagues suggest that grouping subjects by motor ability or functional category is more important than grouping by other indicators of gait.[52] Six functional categories are defined in their system. A score of 0 indicates nonfunctional ambulation. Individuals who require significant and constant assistance of another person for support and balance receive a score of 1. A score of 2 indicates that light touch or intermittent physical assistance is required, and 3 means that the individual needs verbal cueing or occasional safety assistance. To be scored as a 4, the individual must be independent in ambulation on level surfaces, and a score of 5 means the individual is independent in ambulation on level and nonlevel surfaces, including stairs and inclines. Although the FAC is a general ambulation test, its scores showed a positive linear relationship with such variables as gait velocity, step length and the 6-minute walk test.[103,104]

The FAC has been used most extensively in the assessment of functional locomotion and as a rehabilitation outcome measure for individuals recovering from stroke.[105–109] In a Rausch analysis of discriminant validity of measures used to assess outcome of stroke rehabilitation intervention, however, Functional Independence Measure (FIM) motor scores and WS were better discriminators of outcome than FAC scores.[110] The FAC has also been helpful in assessing concurrent reliability of new mobility measures in stroke rehabilitation and portable instrumented pressure-sensitive monitors.[111]

Modified Gait Abnormality Rating Scale

Wolfson and colleagues developed the original GARS in an effort to quantify abnormal gait performance of frail institutionalized older adults and identify those most at risk of falling.[112] The scale has since been modified (GARS-M) by Van Swearingen and colleagues for use in community settings.[113]

The GARS-M is a shorter (7-item) version of the original 16-item GARS; the 11 items were removed for several reasons including redundancy, inconsistent visual rating among raters, and not being an effective discriminator between fallers and nonfallers.[113]

To test the GARS-M, the individual is videotaped while walking at a self-selected pace on a level surface of about 8-m, then turns and walks back to the starting point. The evaluator then examines the videotape and scores the individual on seven dimensions: variability, guardedness, staggering, foot contact, hip range of motion, shoulder extension, and synchrony of arm movement and heel strike. The measure uses a four-point criterion-based rating scale (0–3). Total GARS-M scores range from 0 to 21, with high scores indicating less efficient or safe performance. Gait variability is one of the unique measures of the GARS-M, which has been linked to increased fall risk in older adults and in individuals with varying neurological disorders.[113–115] Huang and colleagues documented the validity of the GARS-M by comparing its scores with those recorded on a computerized walkway.[116] Evidence of interrater and intrarater reliability, and concurrent validity (compared with temporal and distance parameters of gait) and discriminate validity (between fallers and nonfallers), have been reported.[113,117]

Choosing an Assessment Strategy

Gait can be assessed in a myriad of ways depending on the objective of the assessment. Observational gait analysis is invaluable in systematically identifying phase-specific gait deviations. Instrumented gait analysis on the other hand provides quantitative kinematic and kinetic information about joint movement and forces. Performance-based measures attempt to document and quantify how gait deficiencies affect the individuals' ability to meet mobility demands of their environment. Functional measures are useful in documenting current functional status, change over time, and response to interventions.

Clinical Examples of Gait Deficiencies: Impact of Functional Tasks During Gait

Case Examples 5.1 to 5.6 illustrate gait deficiencies associated with pathological conditions that commonly alter gait performance: pretibial flaccid paralysis, hemiplegia, cerebral palsy, and spina bifida. As might be expected, each example demonstrates common gait characteristics specific to the particular pathological condition while presenting variants from that profile. The discussion is based on information gathered by foot-switch stride and kinematic and observational gait analysis.

CLINICAL CHARACTERISTICS OF GAIT IN HEMIPLEGIA

For most individuals who are recovering from stroke—a CVA—improvement in the quality of gait is related to the natural history of the pathological process and the impact of gait retraining in rehabilitation. In the weeks immediately following a CVA, only 53% of individuals are able to ambulate independently after intensive rehabilitation training.[118] After weeks of rehabilitation, approximately 75% of

Case Example 5.1 A Patient With Flaccid Paralysis of Pretibial Muscles

J.J. is a 37-year-old man with inherited sensorimotor neuropathy (Charcot-Marie-Tooth disease) who has been referred to the gait assessment clinic for evaluation of his orthotic intervention. Examination of muscle function and strength reveals relatively symmetrical distal impairment. Manual muscle test scores include "trace" activity of dorsiflexion muscles bilaterally, "poor" plantar flexion on the left, and "fair+" plantar flexion on the right. Knee and hip strength is "normal."

QUESTIONS TO CONSIDER

- Given J.J.'s pattern of weakness, what types of primary difficulties or deviations might you predict during the functional task of (1) weight acceptance (IC and LR), (2) SLS (MSt and TSt), and (3) swing limb advancement (PSw, ISw, MSw, and TSw)?
- Given J.J.'s pattern of weakness, what compensatory strategies (pathological gait deviations) might he use to accomplish these functional tasks of gait?
- What quantitative measures, indicators of energy cost, qualitative measures, or function-based assessments would you use to determine whether a change in orthoses would be warranted? Why would you select those measures?

EXAMINATION AND EVALUATION

During a foot-switch stride analysis, J.J. walks without his usual orthoses. In the trailing left limb, the posterior compartment fails to support the forefoot lever arm so that the tibia progresses forward with limited heel-off in late stance (Fig. 5.12). This creates excessive knee flexion and limits the step length of the contralateral limb. The net effect of this inadequate forefoot rocker is a reduction in velocity. Lack of support of the trailing forefoot allows depression of the center of gravity. At the same time, dorsiflexion weakness on the right creates early, abrupt plantar flexion (foot slap) with premature contact of the first metatarsal. The variance between plantar flexor strength of the left and right limbs is demonstrated by difference in SLS times. The stronger right calf participates in 39.8% (0.416 s) of the gait cycle, whereas the weaker left calf commits itself to only 31.4% (0.328 s). This subtle timing discrepancy in gait was not readily identifiable in observational analysis.

In right MSw, while the left foot is in a supporting posture, the classical steppage gait characteristics of a flail forefoot are observed: Compensatory swing clearance is accomplished through excessive hip and knee flexion (see Fig. 5.9B).

When J.J. wears his orthoses (a dorsiflexion assist thermoplastic AFO on the right and a dorsiflexion stop–plantar flexion resist thermoplastic AFO on the left), results of foot-switch temporal analysis are quite different. Velocity, cadence, and stride length increase slightly. The asymmetry between right and left SLS times decreases because the AFO provides external support of the trailing left limb. The energy-inefficient steppage gait and unsightly foot slap are diminished as well.

QUESTIONS TO CONSIDER

- What specific problems do the examination and evaluation identify in each of the functional tasks of gait: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)?
- In what ways do J.J.'s orthoses address the functional problems observed when he walks without his orthoses in each of the functional tasks of the gait cycle: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)? In what ways do his orthoses potentially limit each of the functional tasks of gait? Do the benefits outweigh the limitations?

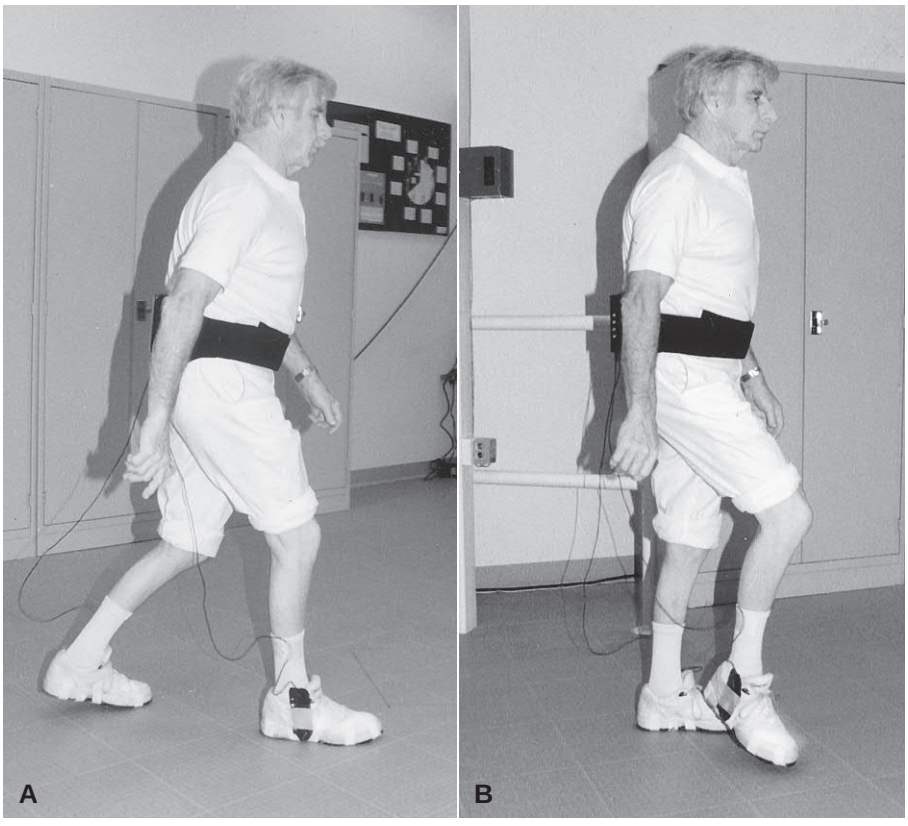

Fig. 5.12 A patient with Charcot-Marie-Tooth disease demonstrates shortened right stride length because of inadequate support at the foot and ankle in late stance of the left limb (A) and the use of a compensatory steppage gait to ensure swing clearance in the presence of dorsiflexion weakness (B).

individuals are able to walk without assistance, especially if using an assistive device, including AFOs and canes.[119] At the 6-month mark, more than 80% of individuals with a CVA are functionally independent in ambulation.[120]

The many variations of limb control observed during the gait of individuals who are recovering from a CVA can be explained by one or more of the following factors: primitive locomotor patterns, impaired postural responses, abnormal postural tone with various degrees of spasticity and rigidity, inappropriately timed muscle contractions, and diminished muscle strength. One of the primary determinants of gait dysfunction in post-CVA hemiplegia is whether the individual has some degree of selective control of specific muscles, rather than activation of abnormal synergy patterns (mass flexion or extension). Individuals with hemiplegia often have difficulty grading the magnitude of a particular muscle contraction with respect to other muscle contractions. Because of hyperactivity of muscle spindle/stretch reflex in the presence of spasticity, the ability to move toward dorsiflexion with forward progression of the tibia during stance may be counteracted by contraction of plantar flexors into a position of equinus. Spasticity, although difficult to measure, can be described for clinical purposes with the Modified Ashworth Spasticity Scale.[121] The baseline level 0 indicates no measurable tone. A designation of level 1, mild tone, is given when a muscle "catches" with an abrupt passive movement into flexion or extension. A level 2 designation indicates marked abnormal tone but flexible range of motion, and level 3 is characterized by pronounced tone and difficult passive movement. Level 4 denotes a limb that is held rigidly in either flexion or extension.

The orthotic goal for individuals with hypertonicity of the lower extremity after a CVA is to control ankle motion and preposition for tibial advancement. Two orthotic strategies are commonly used: (1) provision of an AFO with a locked ankle component set in slight dorsiflexion or (2) use of an articulated AFO that allows slight ankle motion around the neutral position. When ankle joint motion is limited or blocked by an orthosis, stability in stance improves; however, forward progression of the tibia is compromised, and step length is reduced. Modifications to the shoe, such as application of a rocker bottom sole or elevation of the heel, can compensate by mimicking the various rockers of gait, specifically the forefoot and toe rockers.[5]

Over the course of rehabilitation, the individual with hemiplegia often experiences changes in tone, joint flexibility, pain or discomfort, fear or confidence, motor strength or weakness, and quality of proprioception. Six stages of motor recovery in hemiplegia have been identified by Brunnstrom.[20] In the first stage, no voluntary movement of limbs is present. In the second, movement reappears but is limited by pronounced muscle weakness or spasticity, or both. The individual is usually not yet ready for functional ambulation. In the third stage, spasticity coexists with limb synergy motion. Typically, a mass extensor pattern is seen in the lower limb. As the individual continues to improve in the fourth stage, spasticity may be reduced as the individual begins to move out of stereotypical synergy patterns. In stage 5, selective control outside mass synergy patterns becomes more consistent and more functional. With recovery complete, in stage 6 the individual may achieve coordinated controlled movement. Because of the dynamic nature of the recovery process, the ability to adjust or alter orthotic alignment or characteristics is very desirable. It is not unusual that an orthosis prescribed early in rehabilitation becomes inappropriate or creates further gait dysfunction at a later stage. Once rehabilitation is complete and the individual has achieved stability in walking patterns, definitive biomechanical needs are identified, and the adjustability of the orthosis is less important.

The extension synergy pattern places the lower extremity in excessive extension at the hip and knee and the foot in equinovarus. This reduces the amount of knee flexion and dorsiflexion during swing, necessitating a compensatory strategy, such as circumduction, to provide swing phase clearance.[122] Rigidity of the ankle leaves the individual with inadequate dorsiflexion mobility, as well as vastly reduced plantar flexion excursion during PSw and early swing. Stance time is considerably reduced on the hemiplegic/paretic side, and the quadriceps, gastrocnemius, gluteus maximus, and semitendinous muscles are inappropriately active throughout stance.[123] Activity of lower limb muscle groups on the hemiplegic/paretic side is increased compared with normal patterns of muscle activation. Excessive hip flexion at MSt on the hemiplegic/paretic side shifts the GRF line anteriorly, producing a knee extension moment that interferes with forward progression. The hemiplegic/paretic side also displays less hip adduction in SLS, which compromises lateral shift toward the affected side.[124] Brandstater and Von Schroder describe reduced velocity, cadence, stride length, and SLS time on the affected side, with consequent increased SLS and reduced step length on the sound side.[53,125] The use of an appropriate AFO improves the quality of gait, increasing step length and stance time, as well as reducing swing time of the affected side, by correcting foot drop. Velocity of gait improves when the AFO is placed in slight dorsiflexion. When spasticity is not problematic, an AFO that permits some plantar flexion normalizes IC to LR timing and prevents an unstable knee flexion moment in early stance. Because knee extensor strength often equals or exceeds hip extensor strength after CVA, most individuals with hemiplegia can be effectively managed with an AFO rather than a knee-ankle-foot orthosis.[124] Muscle strengthening is less important in achieving improved walking characteristics in hemiplegia than is the retraining of normal movement patterns in gait.[126] Darekar and colleagues observed favorable effects related to the outcomes produced using virtual reality–based intervention with improving WS and the ability to deal with environmental challenges, which may ultimately facilitate independent community ambulation.[127]

CLINICAL CHARACTERISTICS OF GAIT IN SPASTIC DIPLEGIC CEREBRAL PALSY

Children with spastic diplegic cerebral palsy often have significant spasticity and marked weakness of the antigravity muscles in both lower extremities. This combination is a precursor of joint contracture. The clinical term often used to describe the typical gait of an individual with diplegia is *crouched gait*. In crouched gait, marked internal rotation of the femur and tibia occurs throughout the gait cycle, the knees remain in flexion throughout stance, and the

Case Example 5.2 **A Patient With Hemiplegia**

M.G. is a 67-year-old man referred to the gait laboratory for evaluation 13 months after a CVA damaged the sensorimotor cortex of the left hemisphere. Currently, he is a community ambulator (MGH functional ambulation classification level 6) who walks with the aid of an AFO and quad cane (FIM locomotion score 6). In the clinical examination, his spasticity becomes apparent when his ankle moves toward a neutral position (Ashworth spasticity scale level 3). The orthosis he received early in rehabilitation, and continues to use, is a traditional double upright, which locks his ankle in slight plantar flexion. Although this ankle angle delays tibial advancement and forward progression in stance, the individual has come to rely on its contribution to stability at proximal joints.

QUESTIONS TO CONSIDER

- Given M.G.'s pattern of spasticity and weakness, what types of primary difficulties or deviations might you predict when he is not wearing his orthosis during the functional task of weight acceptance (IC and LR)? Of SLS (MSt and TSt)? Of swing limb advancement (PSw, ISw, MSw, and TSw)?
- Given M.G.'s pattern of spasticity and weakness, what compensatory strategies (pathological gait deviations) might he use to accomplish these functional tasks of gait?
- What additional quantitative measures, indicators of energy cost, qualitative measures, or function-based assessments would you use to determine if a change in orthosis would be warranted? Why would you select those measures?

EXAMINATION AND EVALUATION

M.G.'s gait with the AFO is evaluated by foot-switch testing. Extensor synergy patterns contribute to function by providing a degree of stability in stance but also reduce efficiency of gait by limiting normal stance progression beginning with the first rocker period (Fig. 5.13). Duration heel-only time of the first rocker (IC to the foot-flat position at the end of LR) is approximately one-sixth of a second on the hemiplegic side, which is significantly less than normal heel-only time. Heel-only time on the intact side is roughly three times greater than that on the hemiplegic side. Forward progression during MSt is halted at the second rocker when spasticity prevents the necessary dorsiflexion of the ankle (see Fig. 5.10). As M.G. moves into TSt, when metatarsophalangeal break (concurrent with heel-off) should allow progression onto the forefoot, the third rocker is also relatively blocked. This lack of mobility of the metatarsophalangeal joints and inadequate third rocker result in a loss of knee flexion necessary for an effective PSw, for which the individual is unable to compensate. Of the 60 degrees of knee flexion necessary for the swing phase clearance, 35 degrees should be achieved passively during PSw. For individuals with hemiplegia, the loss of this positional flexion is an additional challenge to clearance beyond that produced by the equinus position of the ankle. Any attempts to compensate by "hip hiking" are likely to be inefficient and unsuccessful. These rocker limitations reduce step length of the sound side, leading to premature double limb support. The corresponding MSw knee flexion on the hemiplegic side is also reduced. MG demonstrates a much-reduced stance time on the affected side (62% gait cycle) versus the sound side (71% gait cycle) and a reduced SLS time on the affected side (28% gait cycle) versus the sound side (38% gait cycle).

QUESTIONS TO CONSIDER

- What specific problems has the examination and evaluation identified in each of the functional tasks of gait: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)? How do these problems relate to his abnormal tone and motor control?
- In what ways does M.G.'s orthosis address or constrain each of the functional tasks of the gait cycle: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)?

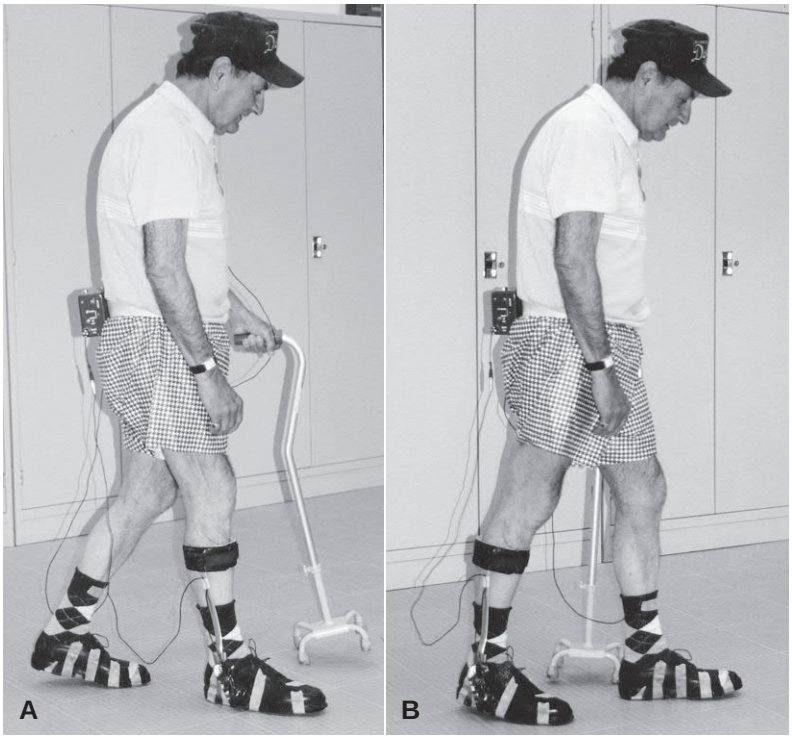

Fig. 5.13 A patient with hemiplegia after cerebral vascular accident, the first rocker from initial contact to foot flat (A) is abrupt as a result of extensor patterns and limb rigidity. Extensor pattern at the ankle (B) translates into a failure to yield into dorsiflexion toward the end of the second rocker. Third rocker heel elevation will also be reduced, and lack of mobility reduces the step length of the contralateral limb.

ankles remain in plantar flexion during stance (toe walking) and swing. Steele and colleagues concur that efficiency of flexed knee gait is not optimal; however, kinematics alone may not be the single most important indicator of increased energy consumption, although energy cost does increase with flexed knee gait.[128] The pathological combination of an equinus ankle, positive Trendelenburg hip, and stiff knee gait often produces various combinations of compensatory hiking of the pelvis, external rotation of the foot, and circumduction of the swing limb. This pattern has been attributed to tightness and overactivity of the distal hamstrings, alone or in combination with the hip flexors.[129,130]

Some individuals with diplegia ambulate with a *jump gait* pattern, using somewhat less hip and knee flexion than do individuals with crouch gait but with excessive ankle dorsiflexion rather than plantar flexion.[131] Jump gait is often a postoperative manifestation of bilateral Achilles tendon lengthening without concurrent release of hip and knee contractures. Common compensatory strategies in jump gait include vaulting and circumduction. In crouch and jump gait, the GRF line falls progressively behind the knee joint center during SLS of the stance phase. This creates an excessive demand on the quadriceps for stance phase stability. One surgical strategy used to correct jump gait combines hip flexion releases, hip flexion release lengthening of the distal hamstrings, and correction of external rotation. Postoperatively, the individual is fitted for floor reaction AFOs.[132] Ideally, the Achilles tendon is lengthened to neutral dorsiflexion position and the individual is protected in AFOs for 1 year postoperatively.

The *scissoring* pattern, which is also a common gait deviation in children with diplegia, is aggravated by spastic hip flexors and adductors because the smaller base of support reduces the efficiency of their line of pull. Orthotic solutions provide limited assistance in limb tracking and rotational control. Those that attempt to control rotation must cross the hip joint, adding significant weight and bulk and increasing difficulty in donning and doffing.

Case Example 5.3 **A Patient With Spastic Diplegic Cerebral Palsy**

K.E. is a 10-year-old boy with spastic diplegic cerebral palsy who has been referred to the gait laboratory for evaluation to assist his orthopedist in deciding whether corrective surgery is indicated. The boy currently ambulates independently, without assistive devices, wearing bilateral solid ankle AFOs (WeeFIM locomotion score of 6).

QUESTIONS TO CONSIDER

- Given K.E.'s pattern of spasticity and weakness, what types of primary difficulties or deviations might you predict when he is not wearing his orthoses during the functional task of weight acceptance (IC and LR)? Of SLS (MSt and TSt)? Of swing limb advancement (PSw, ISw, MSw, and TSw)?
- Given K.E.'s pattern of spasticity and weakness, what compensatory strategies (pathological gait deviations) might he use to accomplish these functional tasks of gait?
- What additional quantitative measures, indicators of energy cost, qualitative measures, or function-based assessments might help determine whether surgical orthopedic intervention is warranted? Why would you select those measures?

EXAMINATION AND EVALUATION

K.E. is fitted with reflective markers for three-dimensional motion analysis of this gait. A typical crouch gait pattern (GP) is observed during observational gait analysis while his gait is being recorded for more detailed kinematic and kinetic analysis by computer software. Foot-switch analysis confirms diminished heel contact with no heel-only time on the left and no heel contact at all on the right.

Clinical examination of K.E.'s lower extremity function reveals a combination of overactive hamstrings and weak gastrocnemius and soleus muscles (Fig. 5.14). The flexion of hips and knees increases the need for proximal stabilization, resulting in compensatory hyperextension of the trunk and posterior arm placement (see Fig. 5.11B). Because the ankles are held in equinus, the final rocker propels tibial advancement despite limitation in ankle mobility. K.E. spends most of the stance phase in TSt and PSw; consequently, double limb support time is vastly increased.

K.E. has not had previous surgical release of his gastrocnemius muscles. Even with surgery, impairment of motor control may continue to be problematic so that dorsiflexion may not work in concert with the knee flexion to provide a heel-toe GP. Gastrocnemius release without concurrent release of the hip and knee contractures usually leads to short step lengths with a compensatory increase in cadence. Spastic hip flexors, also serving as adductors, create a mild scissors effect during each swing limb advancement. Ambulation with bilateral AFOs, which the client prefers, increases step length and reduces knee flexion compared with ambulation with no orthosis.

QUESTIONS TO CONSIDER

- What specific problems does the examination and evaluation identify in each of the functional tasks of gait: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)? How do these problems relate to K.E.'s abnormal tone and motor control?
- In what ways do K.E.'s orthoses address or constrain each of the functional tasks of the gait cycle: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)? What is the interaction of his abnormal tone and impaired motor control with his orthoses on the efficacy and energy cost of his walking?

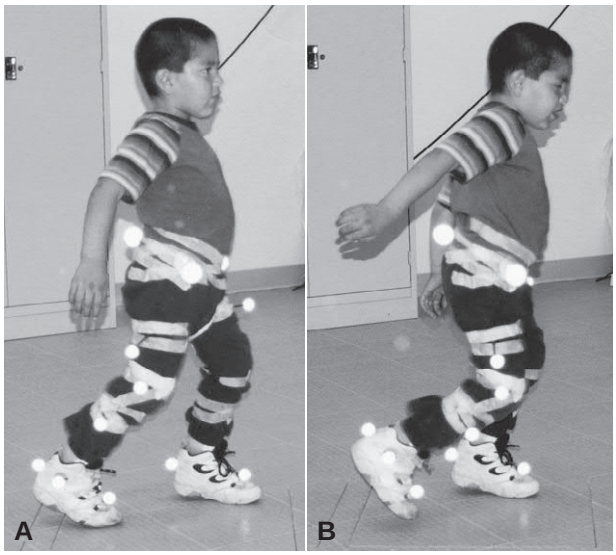

Fig. 5.14 A child with spastic diplegia, classic crouch gait (A) is characterized by increased hip and knee flexion in combination with toe walking. Postural substitutions in crouch gait (B) may include increased lumbar lordosis, trunk extension, and posterior arm placement.

CLINICAL CHARACTERISTICS OF GAIT IN CHILDREN WITH SPINA BIFIDA

Spina bifida (myelomeningocele) occurs when vertebral arches fail to unite very early in gestation. Clinically, this leads to partial or complete paralysis at or below the level involved. The most common impairment is a flaccid paralysis, with loss of proprioception and exteroception (pain, temperature sensation, light touch, and pressure sensation). Many children with spina bifida have significant ambulatory deficiencies; more than 50% require an orthosis of some kind to ambulate.[133] Assessment for orthotic support begins as soon as the child attempts to gain an erect posture.

Severity of gait dysfunction depends on the level of involvement of the spinal cord. When the L-5 and S-1 nerve roots are affected, the gluteus maximus, hip abductors, and triceps surae are lost; the hamstrings are present but weak; and sensory loss is limited to the plantar surface of the feet. The plantar flexor deficit requires setting limits to dorsiflexion range of motion through orthotic joint control. This limitation of dorsiflexion allows the individual to establish hip stability through hip extension accomplished with exaggerated trunk lordosis. Without it, the individual would fall forward unopposed. Lateral stability is achieved through crutches and a wide walking base.

When the L-3 and L-4 root nerves are affected, hamstring function, hip extension, knee flexion, plantar flexion, and dorsiflexion are completely lost. The resulting foot drop cannot be adequately compensated for in swing by hip and knee flexion. Hip flexion, adduction, and knee extension are intact but may be weak. At the L-3 level, weak knee flexion from the gracilis may also be present. These children benefit early from standing frames; later, they often are able to ambulate with orthotic assistance. Adequate stabilization of the foot and ankle is achieved through orthotic application of a locked ankle in neutral or slight dorsiflexion. Trunk lordosis is a compensatory strategy used to stabilize the hip during stance. The muscular imbalance at the hip increases the likelihood of flexion contracture, which in turn amplifies the need for even more compensatory lordosis. Extreme hip flexion contracture may ultimately preclude ambulation. If contractures at the hip, knee, and ankle are minimal and the child gains trunk control, he or she will be able to stand erect but will rely on trunk alignment for static balance and forearm crutches for further stability.

A child with lesions that involve L-1 and L-2 levels has little lower limb function other than weak hip flexors. Such children often begin upright function with a parapodium or swivel walker and can later progress to reciprocal gait orthoses. The swing-through gait with bilateral hip-knee-ankle-foot orthosis has been shown to be less efficient than a reciprocal gait orthosis for thoracic level spinal bifida.[134]

Gait Patterns in Individuals With Amputation

Qualitative observational gait analysis is a broadly accepted approach to achieving a clinically optimal gait in individuals with amputation. Instrumented gait analysis provides a more repeatable accurate assessment of prosthetic function. In its broadest scope, the data derived increasingly serve as foundation guidelines for both prosthetic design and clinical application. The daily practice of assessment and management of prosthetic gait, however, depends on the subjective skills of the prosthetist and the targeted treatment protocol of the therapist.

Case Example 5.4 **A Child With Spina Bifida**

N.P. is an active 9-year-old boy with myelomeningocele at L-5 who returns to the gait laboratory as part of an ongoing research study to document changes in gait characteristics over time. He currently ambulates wearing bilateral AFOs set in a neutral ankle position, using Loftstrand crutches in a four-point reciprocal GP.

QUESTIONS TO CONSIDER

- Given N.P.'s pattern of weakness and sensory loss, what types of primary difficulties or deviations might you predict when he is not wearing his orthoses, during the functional task of weight acceptance (IC and LR)? Of SLS (MSt and TSt)? Of swing limb advancement (PSw, ISw, MSw, and TSw)?
- Given N.P.'s pattern of weakness and sensory loss, what compensatory strategies (pathological gait deviations) might he use to accomplish these functional tasks of gait?
- What additional quantitative measures, indicators of energy cost, qualitative measures, or function-based assessments might help determine if surgical orthopedic intervention is warranted? Why would you select those measures?

EXAMINATION AND EVALUATION

Comparative foot-switch testing reveals that, without crutches, stride length and velocity are reduced. External rotation of both limbs is present throughout the gait cycle (Fig. 5.15). With or without crutches, he has no measurable fifth metatarsal or toe contact on either limb in his typical stance phase weight-bearing patterns. Passive external rotation is present at the hip as well as abducted limb placement as he advances over the forefoot. His abducted limb placement and wide-based gait provide increased stability at a cost of excessive loading on the posteromedial aspect of the feet (see Fig. 5.12B). Like many children with spina bifida, he spends excessive time in heel contact, largely to the exclusion of lateral forefoot weight bearing. This loading and shear pattern often leads to callusing and eventual neuropathic breakdown in adult life. His fastest gait velocity (55 m/min) is approximately 60% of normal free-gait velocity. During swing phase, external rotation of the limb is marked. The flail foot is held in slight dorsiflexion during TSw through the support of the AFO.

QUESTIONS TO CONSIDER

- What specific problems does the examination and evaluation identify in each of the functional tasks of gait: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)? How do these problems relate to N.P.'s flaccid paralysis and sensory impairment?
- In what ways do N.P.'s orthoses address or constrain each of the functional tasks of the gait cycle: weight acceptance (IC and LR), SLS (MSt and TSt), and swing limb advancement (PSw, ISw, MSw, and TSw)? What is the interaction of his flaccidity and sensory with his orthoses on the efficacy and energy cost of his walking?

Case Example 5.4 **A Child With Spina Bifida (Continued)**

Fig. 5.15 In this child with myelomeningocele, weakness at the hip results in external rotation of the limbs in both stance and swing phase (A), which contributes to altered forward progression from the heel to the medial forefoot, with minimal weight bearing on the lateral foot (B).

The University of California at Berkeley prosthetic project, which began in the mid-1950s, represented the most concentrated period of prosthetic advancement. The comprehensive basic gait studies and their application to the biomechanics of amputee gait for transtibial and transfemoral amputations established fundamental design criteria.[135] Contributions of subsequent investigators continue to be largely based on the Berkeley criteria.

Extensive calculations and interpretations were required to relate normal and prosthetic gait data to the problems of prosthetic design. Data reduction was a slow process before relatively recent technological advancements because all motion measurements had to be performed by hand. There were no automated film analyzers to identify the motion patterns and no computers to perform rapid data processing. Therefore, the number of subjects studied was limited. The project also had the additional depth of considering all three planes of motion, in contrast to prior studies that analyzed only the sagittal plane of gait progression.[47,136] Subsequent investigators, with the aid of more advanced instrumentation, have replicated, expanded, and reconfirmed the validity of the Eberhart-Inman work and have not found it in error.

TRANSTIBIAL PROSTHETIC GAIT

In 1957 the Berkeley project was specifically commissioned to reconsider transtibial prosthetic gait and biomechanics; with that goal, an advisory conference was held.[137] Basic transtibial prostheses at that time were attached to the limb with a thigh lacer that included articulated knee joints and a foot with an articulated ankle. Detailed review of the normal and transtibial amputee-gait data resulted in a totally new approach that led to two developments: the patellar tendon-bearing (PTB) prosthesis and the solid-ankle, cushion heel foot.[138–140] The improved transtibial socket was a PTB design that closely followed the contours of the proximal tibia.[141] The PTB prosthesis replaced the thigh lacer with supracondylar fixation, again with the advantage of anatomical contour and total contact.

Studies of Transtibial Prosthetic Gait

Most studies of individuals with transtibial amputation, instrumented and noninstrumented, have focused on foot design, with the general exclusion of alignment. In more recent years, an increase in studies focusing one prosthetic alignment, specifically the impact of the alignment of the socket to the foot and the associated energy cost, have evolved in number and depth of meaning and implication for the overall well-being of the client.

Prosthetic foot designers attempt to passively reproduce, by material quality and design, the normal dynamic functional balance between mobility and stability provided by the anatomical foot. The greatest difference is between the relatively rigid compressible heel–type feet and the mobile hinge of the single-axis foot.[142] Optimization of prosthetic foot stiffness has been studied in relation to the associated metabolic costs in

unilateral transtibial amputee walking. For people navigating the challenges of a unilateral amputation, the development of gait abnormalities and compensations, as well as elevated metabolic cost, is unavoidable. Therefore, studies modeling the variable impact of foot stiffness on metabolic cost is an integral part to optimization the prosthetic device. Modeling analyses showed optimization in foot stiffness through stiffening the toe and forefoot while making the heel and ankle less stiff. The optimization improved prosthetic foot performance by offloading the sound side knee during early to MSt decreasing the metabolic cost.[143] Motion analysis has shown that the articulated ankle improves weight acceptance stability by providing significant plantar flexion, allowing an earlier foot flat posture; however, the arc of knee flexion and the timing and intensity of the quadriceps do not differ from that of the compressible heel–type foot.[144,145]

Kendell and colleagues identified six factors that that can be related to dynamic stability in lower limb prosthesis users: shifts in anterior-posterior center of pressure, shifts in mediolateral center of pressure, cell triggering, maximum lateral force placement, stride time, and double support time. These parameters influenced the adoption of GPs which facilitated forward progression without compromising the location of the center of pressure in either direction.[146] Stance phase limb progression is enhanced by an articulating ankle in two ways. In footswitch analysis, the mobile ankle had a longer period of single limb stance time, whereas total stance time was shorter compared with solid-ankle designs.[145] In addition, there was more prolonged hamstring action with the compressible heel foot; this implies that a forward lean was used to improve progression over the less yielding foot. These functional advantages of a mobile prosthetic foot would be significant in a marginal walker, but the heaviness of a single-axis foot creates an energy-cost penalty that also must be considered. The relationship between the body, specifically the musculature of the limb involved with controlling a prosthetic device, and the device and its respective components work in synergy to provide body support, forward propulsion, limb-swing initiation, and mediolateral balance impacts the metabolic costs required.

Beginning in the 1980s, the use of elastic materials and designs has been increasingly applied to prosthetic feet. The initial objective was to facilitate running because the presence of normal knee control gives the individual with transtibial amputation considerable functional potential.[147] Foot designs all emphasize controlled dorsiflexion mobility for greater push-off. It has been assumed that these dynamic, elastic prosthetic feet would be advantageous for the average walker by reducing the greater-than-normal energy cost currently experienced by individuals with amputation.[148] The most mobile designs, in terms of dorsiflexion range, are those with a long-bladed shaft such as the Flexfoot and Springlite. These bladed shaft designs have not lessened the muscular demands of weight acceptance. Their simulated "ankle plantar flexion" during limb loading is no better than the solid-ankle, cushion-heel foot. Both result in a plantar flexion that is markedly less than the normal controlled, yet rapid, ankle plantar flexion of 12 degrees used to reduce the propulsive effect of the heel rocker by allowing early forefoot contact. Both prosthetic feet cause a significant delay in attaining the stability of foot flat.[149] One modeling study demonstrated that the prosthesis as a whole provided body support in the absence of ankle muscles, braking from early to late MSt, decreasing the body's need to provide compensation for missing anatomy, and propulsion in late stance decreasing the energy recruitment needed. GRF and the associated muscle recruitment and activation identified the ability of the prosthesis to transfer energy from the residual limb to the trunk implying greater overall propulsion of the trunk, furthering the idea more effectively with ESAR feet over solid ankle cushion heel feet. Relieving the body in part by decreasing the musculoskeletal deficit as well as lessening the metabolic burdens influences the perceived quality and the functional quality in the design of the prosthesis.[150] Finite element analysis (FEA) has been used most recently to investigate the implications of ESAR feet without the cofounding factors of gait deviations. FEA modeling standardized the mechanical characteristics of ESAR feet through simulation. The FEA demonstrations showed impressive consistencies with older data surrounding the relationship between stiffness and energy stored and returned to the user.[151]

The intact limb uses a modest arc (15–20 degrees) of knee flexion to absorb the shock of contact with the floor,[5] whereas prosthetic feet rely on a cushion heel. The time needed for adequate cushion compression delays the drop of the forefoot to the floor. This perpetuates an unsteady, heel-only source of support that requires increased active muscular control of the knee and hip to ensure weight-bearing stability. This subtle source of instability is obscured by two findings. The stiffness of the foot, in particular the heel, can contribute to increased prosthesis range of motion, increase energy storage in early-stance and energy return in late-stance; however, the decrease in propulsion and swing initiation as a result increases the net metabolic requirements for additional muscle activation and body support maintenance. In addition, the mechanical efficiency of the device is influenced by the adjustment of the stiffness of the device.[152] In addition, heel cushion compression delays the rate of initial tibial advancement, resulting in reduced weight acceptance knee flexion for the transtibial amputee compared to normal. This difference is reflected in calculations of subnormal moments and powers.[153,154] These findings have been interpreted as a sign of reduced muscle demand, and a corresponding conservation of energy has been attributed to the development and implementation of dynamic ESAR feet. Direct EMG recordings, however, showed significantly higher than normal muscle demand for five different feet tested.[155,156]

Transtibial Alignment

The positional relationship between the socket and prosthetic foot is critical to achieve optimal progression in stance, yet also highly subjective. The goal is to promote tibial progression in stance and place the knee in a stable (minimally flexed) weight-bearing posture without causing hyperextension in late stance and encourage the lower limb to follow a normal path of motion in swing.

Static or "bench" alignment uses the subcutaneous crest of tibia (tibial blade) to establish alignment of the residual limb within the prosthesis. In the sagittal plane, this landmark, at its origin at the tibial tubercle, is typically angled approximately 5 degrees forward of the perpendicular to the tibial plateau that serves as the supporting surface for the knee joint. Hence, if the socket is aligned by the tibial

blade, the socket is set so that the tibia is tilted slightly forward to avoid a backward thrust during stance. This angular posture of the prosthetic socket, in conjunction with a deliberate anterior displacement (translation) of the socket relative to the foot, generally succeeds in encouraging tibial progression.

Even with this alignment, the individual with dysvascular transtibial amputation who typically exhibits some degree of weakness will shift the weight line anterior to the knee by simply leaning forward during LR in a postural movement akin to a quad avoidance gait. This results in reduced knee flexion throughout stance phase and delayed flexion in swing (Fig. 5.16). A hesitation of stance progression (the MSt dead spot) is a common phenomenon. A delay in the rollover pattern, common to the dysvascular transtibial amputee, is reflected in the shear pattern (see Fig. 5.16B).

Final positioning of the socket-foot relation is determined by observational analysis of the subject's gait and feedback from the prosthesis user. This process, referred to as *dynamic alignment*, examines smoothness of the rollover pattern and medial-lateral verticality of the foot, avoiding both extremes of inversion or eversion during progression. The absence of abnormal motions in swing such as a whip, compensatory motions to avoid scuffing the foot in swing (e.g., degree of pelvic elevation or vaulting), and an erect trunk posture are additional observational criteria used for assessment. Comfort and ease of walking are criteria of the individual

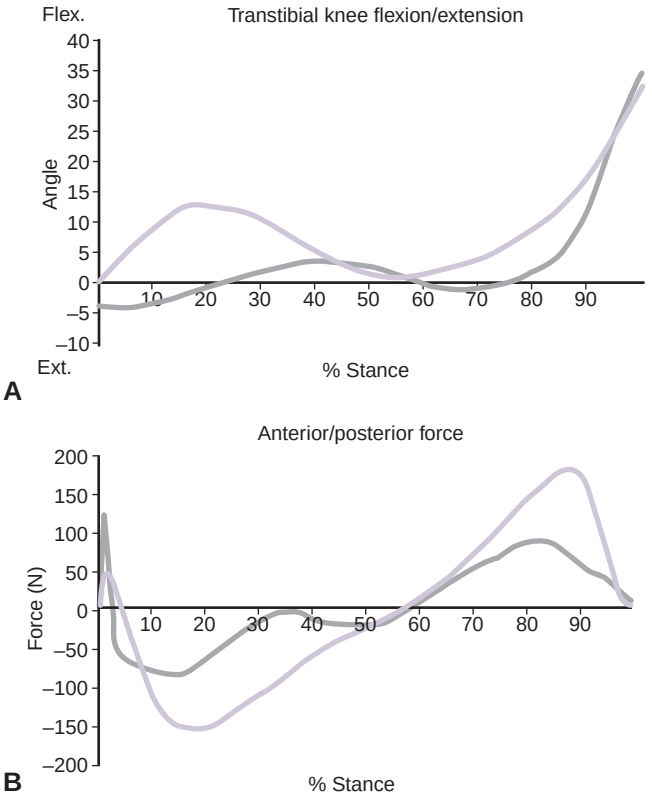

Fig. 5.16 (A) Patients with dysvascular transtibial amputation typically shift the weight line anterior to the knee early in stance, which results in reduced knee flexion throughout stance phase and delayed flexion in swing. (B) Patients with dysvascular transtibial amputation typically shift the weight line anterior to the knee early in stance, which results in typical midstance hesitation in the progression of rollover, reflected in the shear pattern. (Courtesy of VA Long Beach Gait Laboratory.)

with amputation. A study completed on individuals with transtibial amputation evaluated whether or not the client could perceive and effectively communicate feedback regarding induced perturbations to the prosthesis alignment. The data reported that subjects were able to communicate the extreme malalignments and demonstrated the ability to unknowingly shift loading and balance to compensate for smaller perturbations. Data analysis revealed that coronal adjustments were more noticeable to the subjects than sagittal or transverse adjustments and the data did not indicate whether or not the perception had anything to do with residual limb tissue volume or not. Overall, coronal translation and angulation alignment changes were perceived more often than sagittal alignment changes; however the subjects were not able to detect small changes in alignment that could be clinically significant.[157] Socket alignment changes and disruptions can be compensated for through balance and center of mass adjustments, as well as compensatory gait motions; however, the effects of malalignments on the kinetics and kinematics should not be ignored. Malalignments of the socket have been shown to propagate statistically significant changes in the socket reaction moments experienced in persons with transtibial amputations. Coronal perturbations caused significant changes in socket reaction moments at 30% and 75% of stance while sagittal perturbations triggered significant changes at 45% of stance phase.[158]

In optimizing the alignment in the coronal plane, there is an attempt to mimic the slight varus moment seen at the knee during MSt of normal human locomotion. This moment is usually achieved by a slight medial inset of the prosthetic foot relative to the socket, taking advantage of the tolerant weight-bearing areas in the proximal-medial and distal-distal regions of the residual limb where pressure is well tolerated. Inadequate inset of the foot, or worse, outset of the foot will generally result in excessive pressure on the very superficial cut end of the tibia (medial-distal) and the perineal nerve and bony prominence of the head of the fibula (lateral-proximal). Alignment affects the transmission of forces and moments from the limb through the prosthesis as well as from the ground up through prosthesis and ultimately to the limb; however, the relationship between alignment and the generation of reaction moments is not well established or implemented into the alignment process. The kinematic assessment is predominantly completed through observational gait analysis and client feedback. One study looked at the implications of a methodical alignment of the coronal plane first followed by the sagittal plane to study the associated socket reaction moments and observed gait deviations. The data revealed sagittal plane alignment (and malalignment) significantly affected coronal reaction moments in early stance while coronal plane alignments (and malalignments) did not produce significant sagittal reaction moments. This study concluded that implementing a systematic alignment approach would positively influence the reproducibility and consistency of the alignment process, with the recommendation to complete sagittal plane alignment first without concern that subsequent coronal plane alignment might alter or negate the prior adjustments.[159] Although observational analysis is appropriate for general clinical care, the alignment of individuals with amputation with complex fitting problems is best resolved through objective confirmation with force plate and motion data.

Initial Contact and Loading Response

Prosthetic control and success is achieved through several individual attributes as well as the interaction between them. The fit of the prosthetic socket, the alignment of the prosthesis, the prosthetic component choices utilized, and the contributions of the prosthetic user in the patterns of gait. Gait assessment for individuals with transtibial amputations must be critically assessed with these areas in mind, as well as the interdependent symbiotic relationships thereof.

Prior to early stance, the prosthetic foot swings through in anticipation of heel-first contact. As the prosthetic foot approaches contact with the floor the ball of the prosthetic foot is intended to be no more than an inch and a half above the ground's surface. Complications can arise if the prosthetic heel is not the primary aspect to come in contact with the ground; if the clients stride lengths are too long as a result of poor gait habit, if the suspension of the prosthesis is too tight not allowing full extension of the knee, or if the socket exhibits excess flexion restraining the knee from full extension, an inappropriately positioned foot at IC may result.[160] One case study found significant improvement in observed gait, mobility potential, and overall range of motion of the knee following multidisciplinary therapeutic approach. The Amputee Mobility Predictor increased from a score of 5 to 29, center of pressure data improved, passive range of motion steadily increased, activity level assessment revealed progression from K0 initially to K3 at the end of the study, and overall ambulation function improved.[161]

During IC, normal gait boasts 5 to 10 degrees of knee flexion on average.[162] Transtibial gait assessments strives to evaluate the achievement of similar metrics. Knee flexion in stance may be absent at times when full extension or excess flexion of the knee are observed. Full extension of the knee at IC can be a result of suspension issues, poor flexion alignment of the socket, or the relative alignment of the foot in relation to the socket may be inappropriate. Excess knee flexion at IC is measured as flexion greater than 10 degrees and can be produced by deficient suspension or a flexion contracture at the knee.[162] Kim and colleagues found that excess knee flexion negatively impacts gait ability, quality of life, and the potential eligibility for newer prosthetic technology.[161]

The spatial measurement of stride length in able-bodied gait reveals nearly equal lengths. In transtibial gait kinematics equal stride lengths are desired; however, unequal stride lengths can result from faulty defective suspension or poor gait habits.[160,162] One study by Sinitski and colleagues looked at the spatial characteristics of transtibial subjects in varied walking environments. The subjects adjusted their stride length and stride time to maintain stability in unfamiliar conditions; when walking on a self-paced treadmill, participants consequently adjusted their WS and walking strategy, in climbing a moderate slope compared with level walking. Stride length and stride time subsequently effect WS and ultimately metabolic cost, the spatial parameters of gait are important to monitor and control throughout the gait cycle.[163]

Viewed in the sagittal plane, the desired characteristics of LR include smooth controlled knee flexion and minimal vertical movement or piston action of the limb-socket relationship. Erratic, abrupt, uncontrolled, or delayed knee flexion can be detected when gait is viewed laterally. Erratic flexion of the knee may result from weak musculature.[160,162] Abrupt and uncontrolled knee flexion may arise from malalignment of anteroposterior positioning of the foot in relation to the socket, deficient alignment of the dorsi-plantarflexion positioning of the foot relative to the socket, if the heel of the prosthetic foot is excessively stiff or firm, or if the shoe does not house the prosthetic foot in a way that allows the needed movement and support.[160,162]

Occasionally, clients can display an extended knee with delayed progression through LR, sometimes described as "riding the heel" or continual pressure felt on the anterior distal aspect of the tibia. This presentation can be a product of malalignment of anteroposterior positioning of the prosthetic foot relative to the socket, inappropriate prosthetic foot selection, unsatisfactory socket flexion, or from a client who markedly utilizes the knee extensors.[160,162]

Knee control during gait is critical in the prevention of falls. Schafer and colleagues conducted a study of the impact of personalized training regimens on the rate of falls, as well as associated gait biomechanics.[164] This study concluded that subjects who received the personalized training plans had a significant reduction of falls over the 1-year study period compared with average annual fall rates. In addition, gait speeds increased from baseline, indicating potential impact of exercise interventions on gait kinematics.

Pistoning is described as the motion between the limb and the socket, which mimics the motion of a piston in the cylinder of an internal combustion engine. Piston action is produced in LR due to insufficient suspension, which allows the limb to slip vertically in relation to the socket as when weight is borne down through the limb. In addition, if the fit of the prosthesis does not maintain appropriate suspension, pistoning may also result.[160,162]

Midstance

At MSt, relative component alignment, alignment of the prosthesis relative to the body, and alignment of the body in space are observed to qualify gait parameters as well as the function of the device. Coronal plane observation yields superior views of MSt gait.

At MSt, the verticality of the pylon or shank of the prosthesis is evaluated. A pylon that leans medially can be produced by excess adduction in the alignment of the socket, or a prosthetic foot that is outset excessively. Alternatively, a pylon which leans laterally is produced by either a socket aligned in insufficient adduction, or a prosthetic foot that is unduly inset. Consequently, with a vertical pylon, the sole of the shoe (and the prosthetic foot) should be completely in contact with the ground at MSt. Commonly, a nonvertical pylon will be accompanied by a shoe that is not completely seated on the ground surface.[160,162] A device that is not optimally aligned, particularly at MSt when the maximum weight is born on the residual limb, implies the magnitude and means of weight transfer to the residual limb is directly impacted. One study looked at how the alignment of transtibial prosthetic devices influences the socket reaction moment impulse. Data showed alignment changes indicate significant alterations in the magnitude of the moment as well as the stance duration time, both of which may impact gait speed, metabolic cost, and long-term health of the residual and contralateral limbs.[165]

Width of the walking base is viewed in the coronal plane. The walking base is anticipated to be a minimum of 2 inches and a maximum of 4 inches when measured between the medial aspect of the heels as the foot passes the stance foot. A walking base that is less than the target minimum is said

to have a narrow walking base and is typically a result of the prosthetic foot being excessively inset relative to the socket alignment.[160] If the walking base exceeds the target maximum, it is described as a wide walking base and is commonly a result of the foot being too outset in relation to the socket. Additional causes may include poor gait habit, improper length of prosthesis, or an undetected hip pathology.[160,162] Aside from the biomechanical implications that a wide walking base can have there are additional interconnected costs that can be derived and from the width of a client's walking base. In a study conducted by Weinert-Aplin and colleagues, the relationship between center of mass motion in all three directions of motion, base of support and WS, and the metabolic cost of walking in both able-bodied individuals and different levels of lower limb amputee was considered. This investigation revealed that base of support and mediolateral center of mass displacement were the strongest correlates to metabolic cost and the positive correlations suggest increased mediolateral center of mass displacement or base of support will reduce walking efficiency.[37] Metabolic efficiency is a key consideration during all phases of gait, but is of particular interest during the stance phase of gait as the kinematics and kinetics directly contribute to the efficacy and acceptance of the device through associated quality-of-life implications.[166]

In normal human locomotion a varus moment at the knee is present at MSt as a result of the orientation of the GRF in relation to the knee. The GRF is present in nonabled bodied gait as well; however, the addition of the prothesis presents additional challenges and variables. At MSt, lateral displacement of the socket up to half an inch is an indication that the GRF is appropriately interacting with and influencing the body producing the desired varus moment at the knee. Lateral displacement exceeding half an inch indicates an excess varus moment at the knee. Excess lateral displacement can be produced by the prosthetic foot being disproportionately inset or the mediolateral dimension of the socket being too large.[160,162] Kobayashi and colleagues concluded that the varus moment impulse is a potential indicator of gait instability at MSt.[165] In contrast, if no displacement or medial displacement of the socket is observed at MSt, the desired varus moment at the knee is lacking and reveals the inappropriate or insufficient interaction between the GRF and the body. Medial displacement of the socket at MSt may result from a prosthetic foot that is extremely outset relative to the socket, pain on the residuum, a very short residuum, or an undetected knee pathology.[160] In addition, varus moment impulse is related the presence and magnitude of lateral trunk bending during stance on the prosthetic side.[165]

Lateral bending of the trunk toward the prosthetic side at MSt, displacing the head more than 1 inch, is an indication of the presence of complications with the alignment and fit of the prosthesis. A prosthesis that is of inappropriate length, a prosthetic foot that is disproportionately outset, or socket induced pain can result in compensatory trunk and head motion.[160,162]

Terminal Stance

TSt prepares the limb for initiation of swing phase. TSt is characterized by the completed progression over the prothesis accompanied by smooth flexion of the limb, with a flexion magnitude equal to the contralateral limb. As the heel of the prosthesis leaves the ground, the motion should be smooth and without any additional exertion; timing of this sequence is accomplished prior to IC of the contralateral limb.[160,162] Early or abrupt heel-off can be produced when the sagittal plane alignment of the foot in relation to the socket is incongruous, this compensation is commonly assessed by the perceived "drop-off" of the client at the end of stance. If heel-off is delayed, and the client experiences the feeling of "walking up a hill" or "being unable to get over the toe," the sagittal plane alignment of the foot in relation to the socket is most likely inappropriate.[160,162]

For new and seasoned clinicians alike understanding the influence of prosthetic socket fit, prosthetic alignment, prosthetic component selection, and the contributions of the prosthetic user in the success of the prosthesis and ambulatory function cannot be understated. Alignment and alignment changes effect socket moment impulse, impulse time intervals, and overall efficacy. When socket impulse exceeds the acceptable range, either defined by the wearer or physiological limits, compensations in GP or reduction of daily activity level result to decrease residual limb discomfort ultimately affecting overall function and quality of life.[165]

Preswing

As the limb continues to prepare for swing phase, body weight transfers smoothly to the contralateral limb without any perceptible rise or fall of the head and torso and the magnitude of flexion of the prosthetic knee is equal to that of the contralateral knee. Suspension of the socket retains the limb securely within the socket in preparation for the prosthesis to leave the ground. Sagittal plane assessment will reveal the rise or fall of the head and torso during PSw.

Inappropriate movement of the head and torso during PSw indicates that the alignment of the foot in relation to the socket may be misaligned or the provided socket flexion may be unwarranted; clients may describe this motion as falling too quickly to the contralateral side or "drop-off." Ineffective suspension or poor socket fit can result in the socket dropping away from the limb as body weight if off-loaded from the residual limb, described as pistoning, as swing phase is initiated.[160,162]

Swing Phase

Once the limb leaves the ground swing phase commences with the goals of heel rise equal to the contralateral limb, swinging the limb through on the line of progression free of any motion of the limb in the transverse plane (circumduction, medial, or lateral whips), with ample ground clearance of the prosthetic foot and adequate socket suspension. Swing phase assessment is best viewed in the sagittal plane and the coronal plane viewed posteriorly. Sagittal plane viewing provides feedback regarding heel rise, toe clearance as the prosthetic foot passes over the ground surface, and for assessing device suspension. ISw is characterized by heel rise of the prosthetic limb equal to that of the sound limb. Insufficient suspension or socket flexion can inhibit the appropriate heel rise during ISw.[160] At MSw, the limb passes over the ground without contact or additional force or energy to accomplish the task. Improper prosthesis length or device suspension can lead to the prosthetic foot not clearing the ground. In addition, limited knee flexion resulting from socket interference or physiological complications can also produce the same complication.[160,162] Socket suspension is imperative at all phases of the gait cycle; however, during the swing phase, should suspension be ineffective, the client will lose confidence in the device's safety and effectiveness, and may potentially

lead to significant harm. If pistoning is observed during swing phase, common causes may be socket fit or inadequate primary suspension.[160] Prosthetic toe clearance is imperative for protection from increased fall risk. Tripping is the predominant cause of falls and the rate of tripping increases with prosthetic use and even more so when adequate toe clearance or socket suspension is deficient.[167] Fifty-seven percent of older adults 65 years and older fell in a 2014 statistic, and of that 57% (nearly half of the falls) produced injuries that required medical care.[168] Toe clearance is a function of proximity of the prosthetic foot to the ground, swing limb velocity, and forward progression of the center of mass relative to the base of support. Research has eluded that the WS-related toe-ground clearance changes on the prosthetic side compared with the contralateral side may potentially increase the risk of tripping, further highlighting the need to adequately assess prosthetic fit and function as it relates to GPs.[169]

Coronal observations allow for assessment of the path of the limb relative to the line of progression, as well as detection of motion in the transverse plane as the limb travels through swing phase. Smooth acceleration and progression of the limb along the line of progression can be influenced negatively by a prosthesis that is too long, a prosthesis that is donned improperly and is internally or externally rotated, and if the suspension is not adequate or appropriate for the client.[160,162]

COMMON GAIT DEVIATIONS IN TRANSTIBIAL PROSTHETIC GAIT

Our understanding of prosthetic gait deviations and the dynamic alignment process has evolved over many decades. The important early work of Inman, described previously, served as a basis for subsequent development.[47] As the field of prosthetics has progressed the refinement of the various prosthetic gait deviations has continued to evolve. A brief description of the most common transtibial gait deviations is given in Table 5.1.[18]

Table 5.1 Common Gait Deviations in Transtibial Prosthetic Gait

Deviation	Description and Potential Causes
INITIAL CONTACT GAIT DEVIATIONS	
Excessive knee extension	Knee fully extended at IC. Typically, a result of incorrect suspension or socket fit.
Excessive knee flexion	Knee excessively flexed at IC. Often a result of poor socket suspension or a knee flexion contracture.
Excessive dorsiflexion	Seen when the ball of the foot is raised above the ground excessively. This can occur as a result of unequal stride lengths, suspension restricting knee motion, or poor socket alignment.
External rotation of foot	At the beginning of stance phase, the forefoot moves laterally. This movement may be a result of a prosthetic foot with a heel that is too firm, or external rotation of the limb due to poor gait habit or pain.
LOADING RESPONSE GAIT DEVIATIONS	
Irregular knee flexion	Knee flexion is uncontrolled, abrupt, excessive, or inadequate from IC to loading response. Potential causes include weak musculature, device malalignment, inappropriate component choice, or poor gait habits.
Foot slap	When the forefoot rapidly plantar flexes following heel contact. Commonly this is a result of insufficient plantar flexion resistance inherent to the prosthetic foot.
Excessive heel compression	The prosthetic heel compresses excessively, delaying tibial advancement and rollover. This is caused by improper heel stiffness of the prosthetic foot.
MIDSTANCE GAIT DEVIATIONS	
Hyperextension of knee	At MSt the knee progresses into a hyperextension moment. Hyperextension of the knee may be caused by weak musculature or ligamentous laxity of the knee, inappropriate prosthetic foot heel stiffness, or malalignment of the prosthetic foot in the sagittal plane.
Foot not flat on floor	At MSt the foot is not in complete contact with the floor. This can be caused by inappropriate socket alignment in the coronal plane or poor socket fit.
Excessive varus moment	At MSt the socket displaces laterally more than half an inch due to an excessive varus moment at the knee. This might be caused by inadequate alignment of the foot in relation to the socket, poor socket fit, or weak ligamentous structures of the knee.
Excessive valgus moment	At MSt the knee moves medially. This may be caused by inadequate alignment of the foot in relation to the socket, inversion of the prosthetic foot, or weak ligamentous structures of the knee.
Lateral trunk bending	At MSt the person leans laterally over the prosthetic side. This may be a result of inappropriate prosthesis height, residual limb pain, or poor device alignment.
Excessive abduction of prosthesis	Seen as excessive weight borne on the lateral aspect of the foot throughout stance. Common causes include excessive abduction of the socket (proximal socket-limb reference) relative to the individual's limb or excess eversion of the foot.
Excessive adduction of prosthesis	Seen as excessive weight borne on the medial aspect of the foot throughout stance. Common causes include excessive adduction of the socket (proximal socket-limb reference) relative to the individual's limb or excess inversion of the foot.
TERMINAL STANCE GAIT DEVIATIONS	
Excessive knee extension	The knee is fully extended at TSt. Common causes are malalignment of the prosthetic foot in the sagittal plane, inappropriate stiffness of the keel of the prosthetic foot, insufficient socket flexion, or poor gait habit.
Erratic knee flexion	The knee flexes erratically at TSt. Often a result of weak musculature of the knee or an undetected knee pathology.
Inappropriate heel rise timing	The prosthetic heel may rise too rapidly or too slowly during TSt. Rapid and delayed heel rise typically results from malalignment of the prosthetic foot.

Table 5.1 Common Gait Deviations in Transtibial Prosthetic Gait (Continued)

Deviation	Description and Potential Causes
Drop-off	During the transfer of body weight to the sound side, flexion occurs too quickly and may be abrupt. This is most commonly a result of malalignment of the foot in the sagittal plane, poor socket alignment, or the inappropriate prosthetic foot choice.
SWING PHASE GAIT DEVIATIONS	
Circumduction	A swinging of the affected limb laterally in a wide arc. Common causes include inappropriate length of prosthesis, undetected pathology of the hip or knee, or poor gait habit.
Insufficient heel rise	During swing phase the prosthetic heel rises less than the contralateral side. Often a result from insufficient suspension or improper socket alignment in the sagittal plane.
Vaulting	During swing phase on the affected side, the contralateral limb exhibits excessive plantar flexion or rising onto the toe of the unaffected foot. This may be caused by inappropriate length of prosthesis, inadequate suspension, poor gait habit, or residual limb pain.
Pistoning	A sense that the residual limb slips slightly out of the socket in swing and descends into the socket in stance. Causes may include loose socket fit, faulty suspension, or poor socket fit.
Lateral whip	During initial swing the foot "whips" laterally. A lateral whip may result from complications with the suspension system (particularly with cuff suspension) or the device may be donned with excess rotation.
Medial whip	During initial swing the foot "whips" medially. A medial whip may result from complications with the suspension system (particularly with cuff suspension) or the device may be donned with excess rotation.
Toe drag	During midswing the prosthetic foot touches the floor. This may be caused by the prosthesis length being too long, loose suspension, limited knee flexion from poor habits, or weak musculature.
ADDITIONAL GAIT DEVIATIONS	
Abducted gait	The person is observed to walk with a base of support that is excessively wide. This may result from malalignment of the foot, inappropriate prosthesis height, poor gait habit, or an undetected hip pathology.
Unequal stride length	Unequal stride lengths between affected side and sound side. This may result from poor device suspension or poor gait habit.
Excessive toe out	Observed when an individual progresses over the forefoot of the prosthetic foot too quickly from IC to preswing. The quick progression is a result of a shortened toe lever. This can be caused by a prosthetic foot being excessively externally rotated or external rotation of the limb due to poor gait habit or pain.

Case Example 5.5 **A Patient With a Unilateral Transtibial Amputation**

W.T. is a 59-year-old transtibial amputee secondary to peripheral vascular disease. He underwent the amputation in September 2009 and subsequently experienced a fall, causing secondary injuries to the residual limb. Previously, he underwent bilateral total knee arthroplasty, most recently on the right side in 2007. W.T. started physical therapy for gait training in March 2010 and completed it in July 2010. He has been referred for a gait evaluation due to complaints of right knee pain, as he has continued to become ambulatory with the prosthesis.

QUESTIONS TO CONSIDER

- Considering the gait deviations associated with transtibial amputees, how could this impact his affected side in conjunction with the total knee arthroplasty?
- What type of options could be considered to minimize the impact on his intact joints? With this, consider the role of client education and possible compliance issues.
- What type of qualitative and quantitative information would you use to support your decision(s)?

EXAMINATION AND EVALUATION

On the day of evaluation, W.T. presented using a single point cane and after discussion with the staff complained of intermittent pain at the distal end of his residual limb. A further chart review revealed that since the time that he completed physical therapy multiple prosthetic feet have been trialed, along with additional modifications to the prosthetic socket to help increase comfort. There were also documented issues of client noncompliance, particularly in terms of the prosthesis wear schedule. The individual had periodically developed areas of redness on his residual limb and was advised to pay particular attention to this area and to document it when it occurred.

An initial assessment with video-based data collection was determined to be an appropriate first step. During the evaluation, the client was asked to walk multiple times over level ground at his self-selected WS while being videotaped. The principal findings were as follows: (1) Periodic knee hyperextension during MSt on the involved side, (2) the involved side knee is often not fully extended at IC, and (3) for the times that the knee is flexed going into stance, there is a rapid extension during MSt.

Taking into consideration the individual's history and current complaints about exacerbated knee pain with ambulation, it was determined that a trial of a custom knee brace modified to fit in conjunction with his prosthesis would be the next alternative. He was subsequently casted over the prosthesis to help ensure that the device would contour appropriately and not interfere with its function. By doing this, the brace would provide additional support when combined with the single point cane.

QUESTIONS TO CONSIDER

- Given the situation with this client, would further, instrumented, kinetic, and kinematic testing be warranted?
- If so, how would you conduct the testing session, and in which specific variables would you look for changes?

TRANSFEMORAL PROSTHETIC GAIT

Initial research of transfemoral amputation by the Berkeley group focused upon unilateral amputation because the problems of this group appeared more critical at that time.[135]

Motion analysis showed a fully extended knee starting in TSw and continuing through stance. The inadequate ankle plantar flexion that followed heel strike and threatened knee stability was attributed to dependence on an ankle bumper in place of the lost pretibial muscle control. Active ipsilateral thigh control and postural adaptation by the sound limb and trunk were identified as the variable mechanisms used by the individual with transfemoral amputation to ensure knee extension stability. Rotation of the fully extended limb rolling over the ankle before heel rise causes a maximum rise of the hip (and thus center of gravity), which was interpreted as vaulting. Compensatory actions by the sound limb were identified.

In swing, the inability of the prosthetic foot to generate a propelling force to initiate limb advancement was interpreted as a need to restrict the weight of the prosthesis so that the work of hip flexors would not be excessive. The individual with transfemoral amputation also demonstrated rapid hip extension in TSw to use tibial inertia as a means of completing knee extension in preparation for stance. These findings of excessive knee extension in stance and excessive hip action in swing formed the basis for others to design more sophisticated knee joints to replace the then-dominant single-axis constant friction joint.

The biomechanical response to the problem of residual limb discomfort was twofold. Torque absorbers were designed, but the solution was the combination of improved socket design, in addition to more normal joint mechanics. The loss of knee control creates compensatory kinematic and kinetic changes that result in asymmetries reflected in a variety of gait parameters. As the individual wearing a transfemoral prosthesis with a compressible heel-type foot levers over the heel rocker during LR, the knee may be at an increased risk of destabilization. When challenged by the potential for knee instability, the prosthetic wearer will attempt to preposition the hip before LR, with a change in body mechanics to shift the GRF to a more anterior position. These typical compensatory patterns can be measured directly through EMG, kinematics, or kinetics, or inferred by measuring heel-only load-bearing time through a temporal analysis.

Temporal Values

There are a several temporal values for which individuals with transfemoral amputation differ compared with those without amputation. A retrospective footswitch gait study conducted at the National VA Prosthetics Gait Lab, Long Beach, California, measured the self-selected velocity in 10 individuals with traumatic transfemoral amputation and compared it with the self-selected velocity of individuals without amputation. The individuals with amputation demonstrated a mean stride length of 1.16 m compared with an average of 1.59 m for individuals without amputation.[170] Overall timing of the transfemoral prosthetic gait cycle was slower for the individuals with amputation, requiring a mean of 1.25 seconds from IC to subsequent IC compared with 1.08 seconds for individuals without amputation. The mean velocity of the individuals with amputation was 55.8 m/min versus 88.3 m/min for individuals without amputation. James and Oberg found that a longer, slower gait cycle on the prosthetic side combined with a reduced step length on the sound side resulted in a velocity that was only 38% of nonamputee velocity.[171] As profound as these differences are, they are probably still subtle enough to remain unremarkable in a typical clinical environment. Murray measured transfemoral gait with a younger group of individuals with amputation and found similar but slightly more subtle differences between individuals with amputation and those without amputation.[172]

Transfemoral Alignment

As previously mentioned, prosthetic control and success is achieved through several individual attributes as well as the interaction between them. The fit of the prosthetic socket, the alignment of the prosthesis, the prosthetic component choices utilized, and the contributions of the prosthetic user in the patterns of gait. For persons with transfemoral amputations not only must the clinician take into consideration the socket-foot relationship, but also the socket-knee relationship and the knee-foot relationship. Gait assessment for persons with transfemoral amputations must be critically assessed with the areas mentioned, as well as the interdependent symbiotic relationships thereof.

Initial Contact and Loading Response

Prosthetic alignment assessed during IC of the gait cycle yields optimum achievement of smooth controlled plantarflexion and knee extension as well as equal stride length to the contralateral limb. Knee instability may be observed as a result of inadequate positioning or mechanical adjustment of the prosthetic knee, deficient socket alignment decreasing the efficiency of the hip extensors, or prosthetic user error. Prosthetic user error or interference is common throughout the life of the prostheses effecting comfort, efficacy, and safety. User interference resulting in knee instability can include inappropriate shoe wear producing alignment changes or an undetected hip pathology or weakness. In addition to knee instability, plantarflexion that is uncontrolled or erratic may be detected. Erratic and uncontrolled plantarflexion can be produced by use of inappropriate distal components or component adjustment, as well as the client lacking trust in the safety and stability of the prosthetic device. At times unequal step length may be assessed. Step length is a function of alignment and trust. Inappropriate socket flexion alignment or prosthetic knee adjustment can lead to a shorter prosthetic step while residual limb pain and lack of trust can also produce asymmetric stride lengths.[173,174]

As the limb continues to progress from IC to LR a stable foot that remains on the line of progression during plantar flexion, an upright trunk with minimal lateral displacement of the head, and the presence of sufficient pelvic stabilization are anticipated. Commonly, the prosthetic foot may externally rotate and deviate from advancement along the line of progression. External rotation of the foot may be produced by ineffective socket contouring and fit, inappropriate prosthetic foot choice or alignment, or weak musculature may be present, preventing necessary control of the prosthesis.

Similar to lateral trunk bending observed in transtibial gait, lateral deviation of the trunk and consequent deviation of the head that exceeds 2 inches are undesired and must be addressed. Prosthetic device causes of excess lateral trunk bending during LR include inadequate socket or prosthetic foot alignment and incorrect prosthesis length. Additional client causes can include weak hip musculature, short residual limb length decreasing available strength necessary for hip stabilization, or a painful residuum with pain being located distally and laterally.[173,174]

The initiation of heel contact at the beginning of stance phase in transfemoral gait has been reported to be characteristically delayed on the prosthetic side, which typically demonstrates a longer swing phase.[172] Contemporary hydraulic knee units, particularly those that provide a programmable chip that can establish optimal swing phase timing characteristics, have the potential to overcome this limitation. However, probably because of cost, they do not represent a typical prosthesis. Early gait studies of single-axis prosthetic feet showed that as the prosthetic limb made contact with the ground and began to load, an exaggerated knee extension was seen in the prosthetic limb that continued throughout early stance.[172] This phenomenon depends somewhat on knee design. There is little evidence that polycentric knees, such as four- and six-bar linkage knee units, and others that have been designed to be stable with a few degrees of built-in flexion compliance during stance, provide normal kinematics of the knee in stance. Most individuals with transfemoral amputation who use the polycentric designs walk with a nearly extended knee.

The total vertical forces occurring on the prosthetic side are less during the initial double limb support period than on the contralateral side during the terminal double limb support period. It has been theorized that this loading restraint requires costly compensations of the sound limb.[175] Knee instability, which produces these costly compensations, generally results from inappropriate positioning of the knee joint relative to the socket and prosthetic foot. The individual with transfemoral amputation relies on hip extensor strength and the reduced lever arm of the transected femur to stabilize the prosthetic knee by restraining the limb during LR. Profound hip extensor weakness can be catastrophic and preclude functional ambulation. Anterior translation of the prosthetic socket relative to the knee and foot has the effect of shifting the GRF anterior to the knee joint axis, thereby increasing stability. Socket flexion affects knee stability as well. Because efficient use of the gluteus maximus as a hip extensor requires the muscle group to be on stretch, the prosthetist deliberately places the socket in a position of flexion. Five degrees of socket flexion are generally considered clinically optimal in an individual with no contracture at the hip. In cases of hip contracture, the amount of flexion is limited by the length of the femoral remnant.[135]

Stability of the knee joint is unquestionably the most important factor in considering a knee unit. Uncontrolled knee flexion renders an otherwise perfect prosthesis useless. Thiele and colleagues investigated possible neurophysiological reasons for weakness in individuals with transfemoral amputation by recording EMG activity of the quadriceps during gait. The team did not find abnormal recordings and concluded that muscle weakness is caused by biomechanical, rather than neurophysiological, factors. This supports the long-held clinical view that, apart from the individual's general muscle tone, residual limb length is a crucial factor because of its effect as a lever arm against the socket wall and as a result of intact or ablated insertions of the hamstring tendons and their obvious detrimental effect on extensor strength.[176] A slight degree of socket flexion is also a factor affecting stability because socket flexion slightly elongates hip extensors, rendering them more effective. The relative positions of the prosthetic foot, knee, and socket to this line significantly affect stability of the knee when the individual walks. When the ground reaction line passes posterior to the knee center, the knee will collapse unless resisted by another force, usually the hip extensors forcing the femur against the socket wall.

Another potential destabilizing factor is limitation of free plantar flexion at heel contact, which may produce a knee flexion moment in early stance. This is why an articulated prosthetic foot (as opposed to a prosthetic foot, which attains a plantar grade position by means of heel compression) provides increased stability for those with transfemoral amputation. A general clinical guideline on an individual who demonstrates minimal knee stability is that the prosthetic foot should reach foot-flat position (mimicking plantar flexion during LR) as quickly as possible, short of demonstrating a foot slap characteristic. As soon as the foot plantarflexes fully during stance phase, the ground reaction line moves anteriorly from the point of foot-floor contact at the heel to approximately midfoot, enhancing stability at the knee. Because of this, a single- or multiaxis foot with a soft plantar flexion bumper is preferred for those with a short transfemoral residual limb, who have limited muscular control for knee stability. At times, the single-axis function can be combined with that of dynamic ESAR foot.

Midstance

As the individual moves into MSt, sound side hip elevation and trunk lean toward the affected side provide balance, limit the force on the lateral aspect of the residual limb, and reduce the demands of the residual limb abductors. The transition from braking to propulsive shear on the ipsilateral limb is characteristically delayed and unsteady (Fig. 5.17A). It is necessary to maintain optimal alignment to reduce any further potential to negatively influence the MSt transitions. MSt gait is most effectively observed in two planes, the sagittal plane and coronal planes respectively; these two vantage points allow the clinician to observe the degree of presence of pylon verticality and prosthetic foot contact with the ground, appropriate width of walking base, and reasonable lateral trunk flexion. Pylon verticality is affected when socket discomfort exists, poor socket fit and alignment are not corrected, or when the individual has weak musculature and does not feel safe using the device. Typically, in addition to a nonvertical pylon, the prosthetic foot will not be flat on the floor. Inversion and eversion of the prosthetic foot can be produced by inappropriate socket alignment or socket fit. Transfemoral walking base is best viewed in the coronal plane. A width of 2 to 4 inches when measured between the medial aspect of the heels as the foot passes the stance foot is desired. Excess or insufficient walking base is both unaesthetic, inefficient, and unsafe; undesired widths are caused by inappropriate device alignment.[173,174]

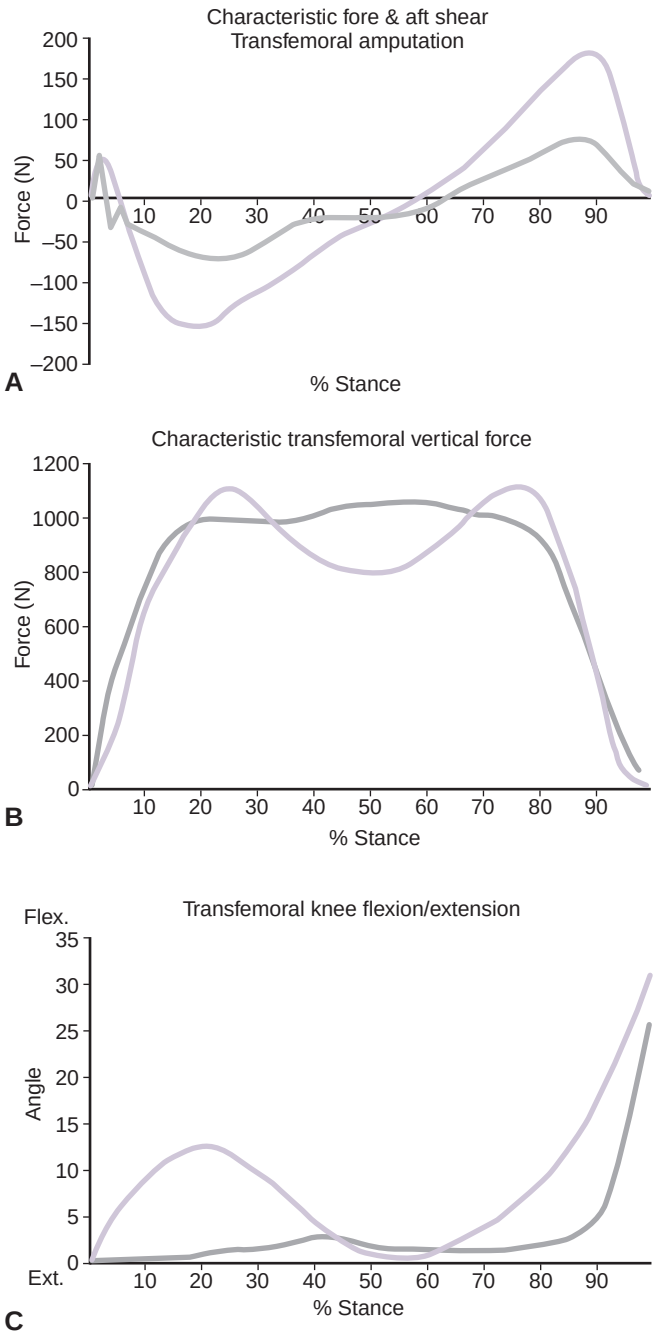

Fig. 5.17 (A) The transition from braking to propulsive shear on the ipsilateral limb during transfemoral prosthetic gait is characteristically delayed and unsteady. (B) Although there is a reduction in vertical force at midstance (Mst) of the sound limb as the prosthetic limb advances in swing, the prosthetic transfemoral limb demonstrates reduced upward velocity because the momentum of the contralateral swing limb lacks the vigor to lessen the vertical force of the affected stance limb during MSt. (C) Knee flexion of transfemoral prosthetic limb is reduced throughout stance. During preswing, delayed and reduced knee flexion, and consequent reduced heel rise on the ipsilateral limb is characteristic. (Courtesy of VA Long Beach Gait Laboratory.)

When both limbs are intact, the momentum of the contralateral swing limb results in a reduced vertical force at MSt of the stance limb. This is not so, however, for individuals with dysvascular transfemoral amputation, in which the reduced upward velocity and momentum of the contralateral swing limb does not have the vigor necessary to decrease vertical force of the prosthetic limb during MSt (see Fig. 5.17B). Maximum knee flexion and swing velocities of the sound side during swing phase, as well as the involved side during swing phase, can be positively improved through the use of microprocessor controlled knee units for some individuals.[177]

Stance phase knee flexion of the affected side is significantly reduced throughout stance (see Fig. 5.17C). During PSw, delayed and reduced knee flexion and consequent reduced heel rise on the ipsilateral limb are characteristic of the transfemoral amputee. Except in the case of those fitted with microprocessor stance control knees, it can be anticipated that many individuals with transfemoral amputation will progress through MSt with a nearly extended knee. Microprocessor-controlled hydraulic knees, particularly Otto Bock versions, have shown a trend toward improvements in stance knee flexion as well as increased velocity in stair descent.[178,179] This is an important development because it may provide increased energy efficiency in gait and avoid compensatory mechanisms, such as prepositioning of the femur before LR and MSt.

Terminal Stance

TSt is characterized by the smooth advancement of the center or mass without any observable rise or fall of the torso and head. In addition, step length of the uninvolved limb should be normal length and without excess lumbar lordosis. Pelvic rise or "hill climbing" and "drop off" are undesirable consequences observed in the sagittal plane. Pelvic rise is detected by noticeable elevation of the head and torso and is sometimes described by the individual as "difficult to ride over the foot." Pelvic rise is produced by inappropriate prosthetic foot alignment. Drop-off is evidenced when the torso and head drop markedly and is accompanied by a shorter rapid step on the uninvolved side. Drop-off is commonly a result of inadequate prosthetic foot alignment or compensatory gait habit. Increased lumbar lordosis is common in individuals with transfemoral amputation as a compensator strategy to overcome the constraints induced by traditional socket models.[180] During TSt the individual may exhibit additional lumbar lordosis in an effort to overcome insufficient socket alignment, improper socket fit, inherent hip musculature weakness or pathology, or a short residual limb which inadvertently decreases the function of the available lever arm.[173,174]

TSt on the prosthetic side is noted for its premature cessation. The prosthetic side generally shows a decrease in SLS time, whereas the sound side shows a concurrent increase in SLS time.[177] There is a persistence of knee extension on the prosthetic limb during contralateral sound side deceleration.[181,182] Delayed and reduced knee flexion, and consequent reduced heel rise on the ipsilateral limb, are characteristic of transfemoral prosthetic gait (see Fig. 5.17C). A failure to limit dorsiflexion in a single-axis foot at this juncture will have a destabilizing effect on the prosthetic knee joint during TSt. Without an appropriately placed dorsiflexion stop, nothing will dampen the forward progression of the tibia, and the tibial section may continue its anterior progression to the point of knee collapse.

Preswing

Characteristics of transfemoral gait in PSw include the hip, knee, and foot swinging through on the line of progression, heel rise of the prosthetic foot equal to the contralateral limb, and necessary suspension to maintain the socket securely on the limb. Typical causes for prosthesis progression that deviates from the line of progression are malalignment of the prosthetic knee, or socket alignment, and fit issues. A medial whip is observed when the prosthetic heel rises medially from the floor accompanied by lateral movement of the prosthetic knee. In contrast, a lateral whip is observed when the prosthetic heel rises laterally from the floor, accompanied by medial movement of the prosthetic knee. Excessive external and excessive internal rotations of the knee axis are to blame respectively. Socket rotations resulting in medial and lateral whips can result from inappropriate donning of the prosthesis or inadequate socket contouring and fit. Deviation from the line of progression can also be a result of weak musculature and inability to provide the necessary muscle control. Inadequate, delayed, or uneven heel rise is best observed in the sagittal plane. Heel rise deficiencies result from inappropriate prosthetic knee adjustment, a prosthesis that is aligned with too much inherent stability, or the individual may lack confidence to adequately operate the device. Lack of suspension can be detected in both the sagittal and coronal planes. As the body weight transfers to the contralateral limb and the prosthetic limb prepares to leave the ground the prosthesis must remain secure. Lack of adequate suspension may result in lack of toe clearance later in swing.[173,174]

During PSw in transfemoral gait, the vertical force of the sound side is abnormally high and greater than that of the prosthetic side.[175] Abrupt reversal from hip extension to hip flexion occurs because some hip extension is required for knee stability until the moment when the prosthetic knee has to flex to initiate swing. In normal gait, half the knee flexion required for swing phase is obtained passively during PSw.

During prosthetic PSw, inadequate forefoot support can lead to costly compensations in the double limb support period.[175] PSw is characterized by a rapid transfer of body weight to the contralateral limb. In normal gait, this transfer begins at 50% of the gait cycle and continues until the end of stance phase (approximately 62% of the gait cycle).

Individuals with transfemoral amputation often have a shortened sound side step length. This may be aggravated by insufficient socket flexion because the individual with transfemoral amputation uses any and all available lumbar lordosis to advance the sound limb. Failure to place the socket in flexion limits the availability of lumbar lordosis and prohibits a sound side step length that is at least somewhat close to normal. Even in an optimal prosthetic gait, typical sound side step length is reduced compared with the prosthetic side or that of normal gait.

Swing Phase

Similar to transtibial gait assessment, swing phase is observed through the lens of three smaller periods of time in the overall phase. ISw, MSw, and TSw compose the swing phase, and each subphase is categorized by unique attributes and expectations. Desired criteria of ISw includes smooth hip and knee flexion, while MSw criteria boasts a rhythmic progression over the prosthetic foot produced by the smooth peaking of the center of mass, as well as symmetric GPs for both limbs. Circumduction can be observed during swing phase resulting from inadequate knee unit adjustment, inappropriate prosthesis length or fit, insufficient suspension effectively lengthening the prosthesis, or lack of trust in the function of the device. Excessive elevation on the sound side limb during swing phase of the involved limb, also known as *vaulting*, may result from inadequate knee unit adjustment, inappropriate prosthesis length, insufficient suspension effectively lengthening the prosthesis, or poor gait habit. In conjunction with circumduction and vaulting occasionally, asymmetric gait is observed; the prosthetic foot may rise too high, and as a result additional time is spent on the sound side limb. Asymmetric gait during swing phase results from an adequate adjustment to the prosthetic knee.

Deceleration of the prosthetic limb is paramount in preparation of IC of the subsequent gait cycle. Deceleration should occur smoothly and without perceptible noise of knee extension or terminal impact, and equal step length is desired. Terminal impact is produced when the distal portion of the prosthetic limb travels with excess velocity as the knee reaches full extension. Terminal impact is a result of insufficient prosthetic knee adjustment, a knee unit that is in need of repair, or poor gait habit to ensure the knee is fully extended to prevent buckling. During TSt, unequal step length can result for many reasons. Component adjustment issues can produce knee hyperextension, elongating deceleration: a knee that does not reach full extension shortening deceleration and prematurely instigating IC, or a knee that bounces back after full extension allowing premature flexion prior to IC. Inappropriate socket alignment can produce a long sound side step or a short prosthetic step, or lack of accommodation for a hip pathology, whereas an individual who lacks confidence and trust may exhibit slow stride velocity, delayed contact with the floor to ensure full knee extension, or a short sound side step.[173,174]

Gait characteristics during swing phase when wearing a transfemoral prosthesis can be profoundly influenced by prosthetic alignment and design variations. The most challenging factor in achieving a functional swing phase is the lack of active dorsiflexion in most prosthetic designs. The Stewart-Vicars knee developed in 1947 and the more recent Hydracadence knee couple knee flexion with ankle dorsiflexion. However, this design concept has been largely ignored in recent years. With the prosthetic incorporation of active dorsiflexion in early swing, many costly postural substitutions, including vaulting and abducted or circumducted gait, could be minimized.

The swing velocity of the prosthetic limb is often slower than that of the sound limb.[171] The presence or lack of fluid control mechanisms variations in alignment stability, extension assist, and joint friction alignment mechanisms

can all influence swing phase timing. During MSw, the individual with transfemoral amputation demonstrates exaggerated hip elevation of the prosthetic side to enable swing clearance. In TSw, prosthetic swing time is much greater than sound limb swing time or normal gait swing time. Excessive prosthetic swing flexion is one of the commonly reported transfemoral prosthetic gait deviations. Contradiction in results of maximum knee flexion can easily be attributed to the wide variety of prosthetic dampening and extension assist designs, as well as other variations in prosthetic adjustment.[177]

COMMON GAIT DEVIATIONS IN TRANSFEMORAL PROSTHETIC GAIT

In 1951, New York University (NYU) published a method for observing amputee gait and described eight commonly seen gait deviations.[183] Years later, Hangar and associates at Northwestern University, under a grant from the Veterans Administration, developed an educational film that incorporated the eight deviations defined by NYU and expanded upon these.[19] A brief description of the most common transtibial gait deviations is given in Table 5.2.[18]

Table 5.2 Common Gait Deviations in Transfemoral Prosthetic Gait

Deviation	Description and Potential Causes
INITIAL CONTACT GAIT DEVIATIONS	
Knee instability	Uncontrollable knee flexion at from IC to LR. May be caused by anteriorly placed knee unit, excessive durometer of cushion heel or plantar flexion bumper, or weakness of hip extensors.
Foot slap	Rapid, uncosmetic plantar flexion movement at heel contact. Most commonly caused by insufficient plantar flexion resistance.
Unequal step length	Sound side step length is visibly shorter than the prosthetic step length. May be caused by inadequate preflexion of socket, hip flexion contracture. Associated with excessive lumbar lordosis and low back pain.
LOADING RESPONSE GAIT DEVIATIONS	
Excessive heel compression	The prosthetic heel compresses excessively, delaying rollover. This is caused by improper heel stiffness of the prosthetic foot or alignment of the foot in the sagittal plane.
External rotation	Foot externally rotates at heel contact. May be caused by excessively firm heel cushion or a tight prosthetic socket (especially on a residual limb with extra soft tissue), poor muscle control, or inappropriate rotation of the foot.
MIDSTANCE GAIT DEVIATIONS	
Lateral trunk bending	Significant leaning of the body over the hip during prosthetic MSt. Often caused by excessively outset prosthetic foot, distal lateral femoral discomfort, short prosthesis, excessively abducted socket, or gluteus medius weakness.
Foot flat is not accomplished	Inversion or eversion of the foot is present at MSt. Typically caused by inappropriate socket alignment in the coronal plane or poor socket fit.
Wide or narrow base of support	Base of support is either excessive or insufficient. Often caused by inappropriate coronal plane alignment of the foot.
Unequal toe out rotation	Toe out on the prosthetic side does not match that of the sound side. This is caused by improper rotation of the foot.
Knee hyperextension	Seen at MSt to compensate for perceived knee instability. Often caused by inadequate foot lever alignment, or improper alignment of the prosthetic foot in the sagittal plane.
TERMINAL STANCE GAIT DEVIATIONS	
Delayed progression	Hesitation or delay in rollover of prosthetic forefoot between MSt and TSt. May be the result of improper alignment of the foot levers, inadequate alignment of the prosthetic foot in the sagittal plane, or shoes with inadequate heel.
Drop-off	During TSt the transfer of body weight to the sound side occurs too quickly and causes the torso to lower excessively. This is most commonly a result of malalignment of the foot in the sagittal plane, improper alignment of the foot levers, or poor gait habit.
Excessive lumbar lordosis	Observed when the sound side step is shortened and lumbar lordosis exhibits excess posterior concavity. Common causes include insufficient socket flexion, improper socket fit, hip flexion contracture, weak hip extensor and/or abdominal musculature, or the client has a very short residual limb.
SWING PHASE GAIT DEVIATIONS	
Pelvic elevation	"Hip hiking" on prosthetic side from ISw to MSw, associated with increased energy cost of gait. Often caused by long prosthesis or inadequate knee flexion as swing begins.
Lateral whip	The heel of the prosthetic foot moves in a lateral arc as swing begins. Often caused by excessive internal rotation of the knee bolt, the socket is donned with excess internal rotation, poor socket fit, or weak musculature.
Medial whip	The heel of the prosthetic foot moves in a medial arch as swing begins. Often from excessive external rotation of the knee bolt the socket is donned with excess external rotation, poor socket fit, weak musculature, or interference from auxiliary suspension (Silesian belt or similar).

Table 5.2 Common Gait Deviations in Transfemoral Prosthetic Gait (Continued)

Deviation	Description and Potential Causes
Pistoning	A sense that residual limb slips slightly out of the socket in swing and descends into the socket in stance. Often the result of inadequate fit or suspension.
Inadequate heel rise	Heel rise is diminished in ISw, usually because of excessive mechanical resistance to knee flexion, prosthesis is aligned with too much stability, or inadequate pelvic rotation.
Excessive heel rise	Prosthetic foot rises abnormally upward during ISw, typically a result of inadequate resistance to knee flexion.
Circumduction	A wide lateral arch of the prosthetic limb during swing phase. Often the result of inadequate knee flexion, excessive medial brim pressure, inappropriate length of prosthesis, excessive mechanical resistance to flexion, prosthetic alignment too much stability, inadequate suspension, lack of confidence in prosthetic knee, or poor gait habit.
Vaulting	Rising up on the sound forefoot during MSt of the sound side in an effort to enhance prosthetic swing limb clearance. May result from a long prosthesis, excessive mechanical resistance to knee flexion, prosthesis aligned with too much stability, inadequate suspension, lack of confidence in prosthetic knee, or poor gait habit.
Terminal impact	An audible click at the end of TSw as knee unit fully extends with inappropriate mechanical resistance to flexion, or excessive assistance to extension, or by forceful knee extension by the prosthetic wearer.
Excessive knee extension	May be characterized by the heel not contacting the floor at the end of swing, the knee hyperextending. Often caused by insufficient trust in the prosthesis, or improperly adjusted knee extension resistance.
Knee flexion	Seen when the knee appears flexed or does not reach full extension, as well as when the knee bounces back after full extension prior to the end of swing phase.
Unequal step length	May be observed as a long or short sound side step. This may be caused by excessive or insufficient socket flexion respectively, or an undetected hip pathology.
ADDITIONAL GAIT DEVIATIONS	
Abducted gait	Wide walking base throughout the gait cycle. Often caused by pressure or discomfort on medial pubic ramus, small socket, or excessively long prosthesis.
Reduced velocity	An adaptation typically observed during initial training or with new components, often related to pain, fear, or insecurity.
TERMINAL STANCE GAIT DEVIATIONS	
Excessive knee extension	The knee is fully extended at TSt. Common causes are malalignment of the prosthetic foot in the sagittal plane, inappropriate stiffness of the keel of the prosthetic foot, insufficient socket flexion, or poor gait habit.
Erratic knee flexion	The knee flexes erratically at TSt. Often a result of weak musculature of the knee, or an undetected knee pathology.
Inappropriate heel rise timing	The prosthetic heel may rise too rapidly or too slowly during TSt. Rapid and delayed heel rise typically results from malalignment of the prosthetic foot.
Drop-off	During the transfer of body weight to the sound side, flexion occurs too quickly and may be abrupt. This is most commonly a result of malalignment of the foot in the sagittal plane, poor socket alignment, or the inappropriate prosthetic foot choice.
SWING PHASE GAIT DEVIATIONS	
Circumduction	A swinging of the affected limb laterally in a wide arc. Common causes include inappropriate length of prosthesis, undetected pathology of the hip or knee, or poor gait habit.
Insufficient heel rise	During swing phase the prosthetic heel rises less than the contralateral side. Often a result from insufficient suspension or improper socket alignment in the sagittal plane.
Vaulting	During swing phase on the affected side, the contralateral limb exhibits excessive plantarflexion or rising onto the toe of the unaffected foot. This may be caused by inappropriate length of prosthesis, inadequate suspension, poor gait habit, or residual limb pain.
Pistoning	A sense that the residual limb slips slightly out of the socket in swing and descends into the socket in stance. Causes may include loose socket fit, faulty suspension, or poor socket fit.
Lateral whip	During ISw the foot "whips" laterally. A lateral whip may result from complications with the suspension system (particularly with cuff suspension) or the device may be donned with excess rotation.
Medial whip	During ISw the foot "whips" medially. A medial whip may result from complications with the suspension system (particularly with cuff suspension) or the device may be donned with excess rotation.

Continued on following page

Table 5.2 Common Gait Deviations in Transfemoral Prosthetic Gait (Continued)

Deviation	Description and Potential Causes
Toe drag	During MSw, the prosthetic foot touches the floor. This may be caused by the prosthesis length being too long, loose suspension, limited knee flexion from poor habits, or weak musculature.
ADDITIONAL GAIT DEVIATIONS	
Abducted gait	The person is observed to walk with a base of support that is excessively wide. This may result from malalignment of the foot, inappropriate prosthesis height, poor gait habit, or an undetected hip pathology.
Unequal stride length	Unequal stride lengths between affected side and sound side. This may result from poor device suspension or poor gait habit.
Excessive toe out	Observed when an individual progresses over the forefoot of the prosthetic foot too quickly from initial contact to preswing. The quick progression is a result of a shortened toe lever. This can be caused by a prosthetic foot being excessively externally rotated or external rotation of the limb due to poor gait habit or pain.

Case Example 5.6 A Patient With a Hemipelvectomy Amputation

L. is a 38-year-old woman with a right hemipelvectomy amputation secondary to osteosarcoma. She has been referred to the gait laboratory for evaluation as a possible candidate for a microprocessor-controlled knee unit. For the past several years, she has been ambulatory without the use of assistive devices.

QUESTIONS TO CONSIDER

- Considering L.'s level of amputation, what types of difficulties or deviations might you expect during the course of level over ground ambulation?
- What quantitative measures would serve as indicators of the likely gait deviations?

EXAMINATION AND EVALUATION

L. was fitted with reflective markers and underwent three-dimensional kinetic and kinematic testing. This testing was performed at her self-selected WS, and she was given a suitable amount of time to become acclimated to the testing environment before data collection. Observational assessment indicates a significant amount of vaulting and excessive pelvic movement but no indication of circumduction.

The temporal data show that she walks at a rate of 92 steps per minute and a velocity of 0.96 m/s. Along with this, her step length on the left side is 0.58 m, and the right side is 0.70 m, even though the total stride length for both sides is 1.24 m. Similarly, the total stride time for both sides was 1.3 s; however, the single limb support time was 0.55 s on the left side and 0.41 s on the right. The step time for the left was 0.59 s, and the right was 0.71 s. Similarly, toe-off occurred at 68.8% of the gait cycle on the left side, and it occurred at 57.9% on the right.

Kinematic data at the ankle showed a consistent pattern of abnormal plantar flexion on the left side occurring from approximately 14% of the gait cycle through 60% of the gait cycle. Overall knee flexion on the left side was within the overall expected range, as was hip flexion in swing. The right side knee flexion showed approximately 5 degrees of knee flexion during LR and a peak average knee flexion of 53 degrees. Exaggerated anterior-posterior pelvic tilt was also documented (Fig. 5.18).

Kinetically, the left side consistently showed greater anterior/posterior shear forces compared to the contralateral side, usually twice as much force exerted on the left compared to the right. Along with this, there was no clear twin peak maximum in the vertical component of the ground reaction force. Instead, there were multiple maxima over the course of a single stance phase (Fig. 5.19).

QUESTIONS TO CONSIDER

- Based on what is presented here, what possible advantages could a microprocessor controlled knee unit have over a conventional mechanical unit? When considering this, bear in mind that the specific microprocessor knee unit she is being evaluated for is designed to allow for adjustments in both flexion and extension resistance based on the individual's walking velocity.
- What kinematic, kinetic, and temporal changes could you expect to see with a change in knee unit?
- Considering that the potential improvements are not absolute, do the potential benefits warrant the issuance of the device?

Summary

The examples of gait deficiencies typical of neuromuscular conditions and in prosthetic gait that we have considered demonstrate the complexity and variety that challenge orthotists, prosthetists, and physical therapists working with individuals with gait problems. Each individual presents unique combinations of pathological and compensatory deficits that require a combination of the essential tools of simple quantitative measure (cadence and velocity, step length, stride length and width, and double support time), systematic qualitative gait analysis (Rancho Los Amigos observational gait assessment protocol), measures of energy cost (PCI), LOA (FAC), and functional measures (the TUG or GARS-M). These tools help the clinician differentiate primary pathological conditions from secondary compensations, guide orthotic recommendation and therapeutic intervention, and assess efficacy of treatment. Instrumented gait assessment is an important part of preoperative assessment and research in orthotic and

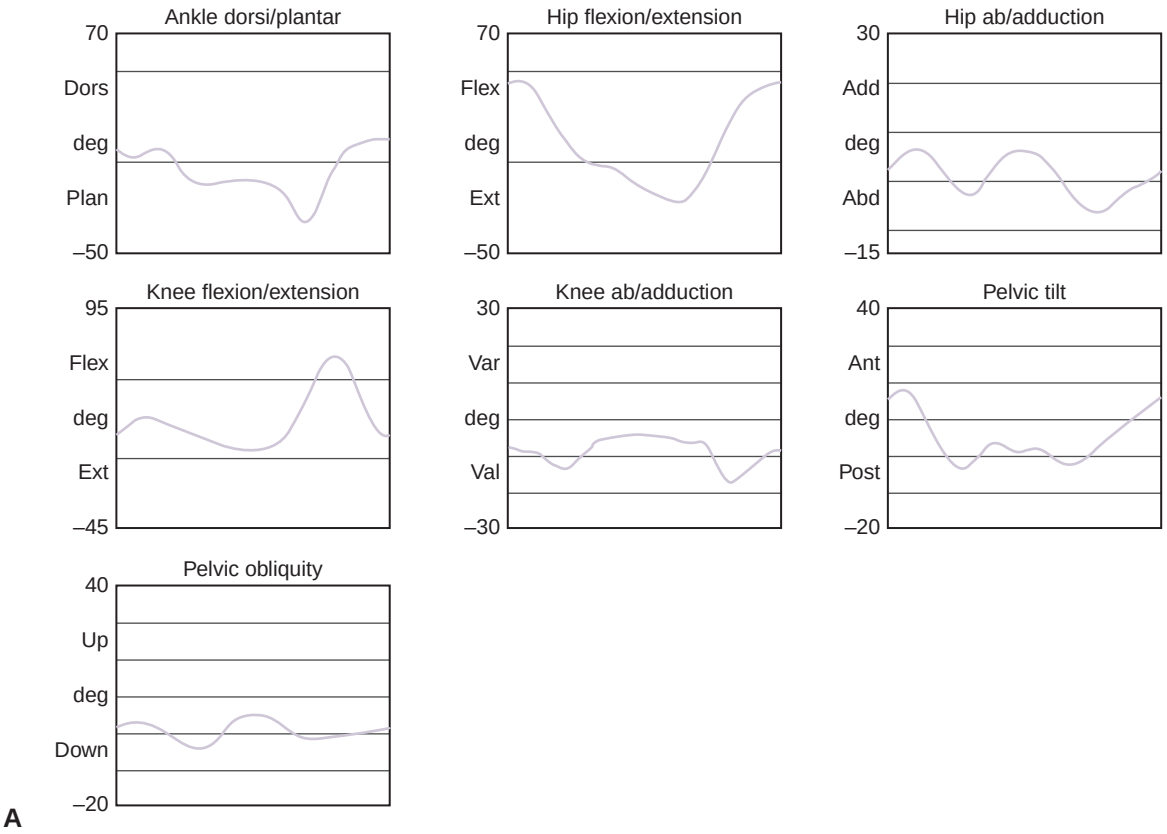

Fig. 5.18 A patient with right hemipelvectomy amputation: average motion data results for the left (A) and right side (B). Particularly note the ankle motion on the left side indicating the vaulting pattern.

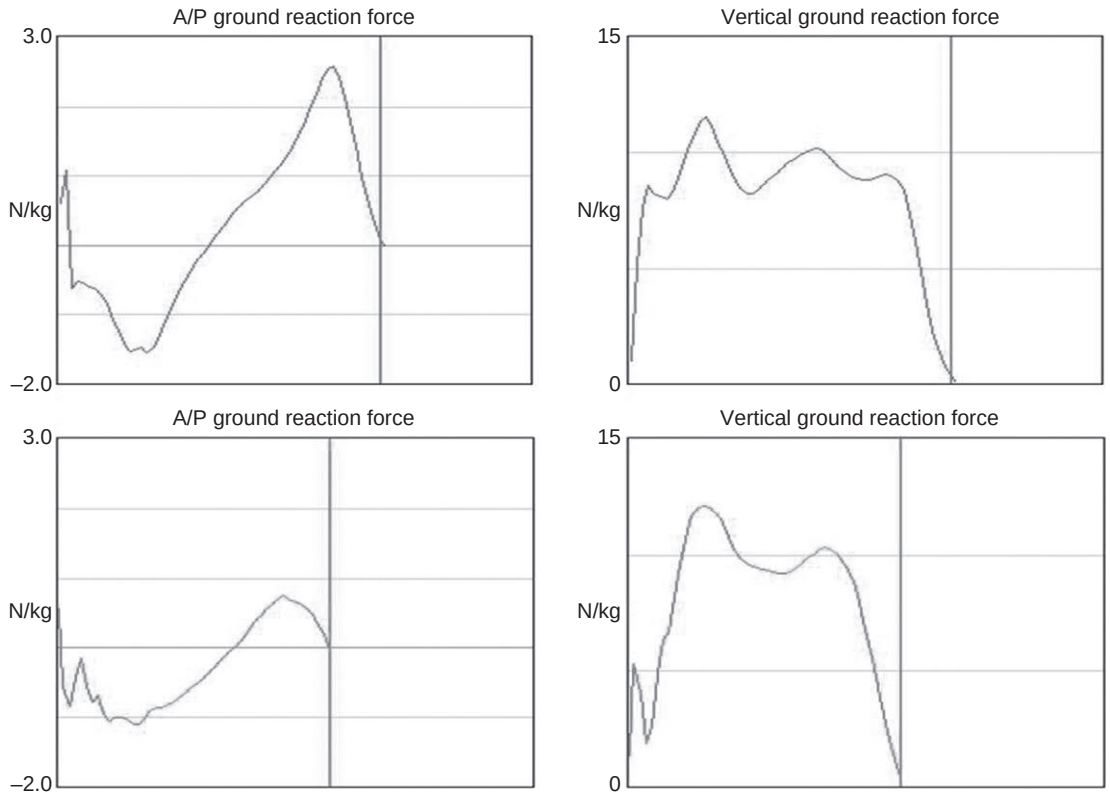

Fig. 5.19 A patient with right hemipelvectomy amputation: vertical and anterior-posterior (A/P) ground reaction force data for the left side (A) and right side (B). Note the difference in the vertical force patterns, especially the lack of two well-defined force peaks on the left side and the difference in magnitudes between the two peak force values on the left.

prosthetic design. In addition, the data collected in gait laboratories are accumulating into a database that can provide information necessary to build accurate outcome estimations for many groups of clients. The current challenge is for the clinic team to gain the broadest possible knowledge base in analytical gait assessment and to serve each individual as a team, considering each person as an individual.

6 Materials and Technology[☆]

GÉZA F. KOGLER, MICHAEL BRIDGES, JEREMY E. HILLIARD, and KEVIN K. CHUI

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Compare and contrast the materials most often used in current orthoses and prostheses.
2. Describe how the basic mechanical properties of commonly used materials determine how they will be used in orthotic and prosthetic devices.
3. Describe the process of, and measures used in, the formulation of a biomechanically appropriate orthotic or prosthetic prescription that will address a patient's functional deficits.
4. Describe how a prosthetist or orthotist determines the appropriate prosthetic or orthotic controls needed for the management of a patient's impairments or functional limitations.
5. Delineate the steps in the fabrication or production of a custom orthosis or prosthesis.
6. Discuss the use of computer-aided design/computer-aided manufacture (CAD/CAM) in the measurement for and fabrication of orthoses and prostheses.
7. Describe the factors influencing the development of central fabrication centers and the manufacture of prefabricated components, orthoses, and prostheses.

A fundamental concept and common goal within the professions of orthotics, prosthetics, and rehabilitation is the restoration of optimal form and function after injury or disease. In many cases, movement and mobility are compromised and the use of orthoses and prostheses can enable improved function. To accept this challenge, the fields of orthotics and prosthetics have evolved into uniquely specialized professions. In addition to training in the basic biologic and medical sciences, orthotists and prosthetists have an understanding of biomechanics, kinesiology, and the material sciences complemented by highly developed technical skills. Knowledge of the physical properties of materials and the techniques to manipulate and use them is essential to the design and fabrication of orthoses and prostheses. The topic is presented here as a general overview so that the rehabilitation clinician can develop a basic understanding of current design and fabrication processes used by orthotists and prosthetists.

Orthotics and Prosthetics in the 20th Century

Orthotics and prosthetics have a rich history of research and development. Many innovative devices have been designed to restore function and provide relief from various medical ailments. Although progress can be documented throughout human history, the most significant contributions to orthotics and prosthetics were made in the 20th century, stimulated by the aftermath of the world wars. Injured veterans who returned home from battle with musculoskeletal and neuromuscular impairments or traumatic amputation dramatically increased the demand for orthotic and prosthetic services. Although World War I stimulated some clinical progress in the two disciplines, notable scientific advancements did not occur until World War II. To improve the quality and performance of assistive devices at the end of World War II, particularly for veterans with amputation, the U.S. government sponsored a series of research and development projects under the auspices of the National Academy of Sciences (NAS) that would forever change the manner in which orthotics and prosthetics would be practiced.[1]

An extensive research effort was initiated by the NAS in late 1945, when a consensus conference revealed that few modern scientific principles or developments had been introduced in prosthetics.[2] Research and educational committees were formed between 1945 and 1976 to advise and work with the research groups. Universities, the Veterans Administration, private industry, and other military research units were subcontracted to conduct various prosthetic research projects. In summarizing the most notable achievements in prosthetics during this period, Wilson[3] cites the development of the total contact transfemoral socket; the quadrilateral socket design and hydraulic swing-phase knee-control units for the transfemoral prosthesis; the patellar tendon–bearing (PTB) transtibial prosthesis; the solid-ankle, cushioned-heel prosthetic foot; several new designs for the Syme prosthesis; and the Canadian hip-disarticulation prosthesis. He also notes the implementation of immediate postsurgical and early fitting as having a significant impact on the rehabilitation process for persons with lower extremity amputation. The most notable improvements in upper extremity prosthetics were the lyre-shaped three-jaw chuck terminal device and more efficient harnessing systems. In addition, modular components and advances in bioengineering have permitted increased use and availability of the myoelectric prosthesis since it was first proposed in 1950.[4]

[☆]The authors thank Mr. Kei Takamura, MSOP, Resident for his assistance with the pictures.

Of the wealth of scientific advances made during this intensive research period, the most important is the greater attention paid to the biomechanics of prosthetic alignment and socket design.[5] According to Wilson,[2] "The introduction of socket designs based on sound biomechanical analyses to take full advantage of the functions and properties of the stump in conjunction with the rationale for alignment undoubtedly represents the greatest achievement in prosthetics since World War II."

Although the focus of the NAS Artificial Limb Program was in prosthetics, it was anticipated that these efforts would also benefit orthotics. A formal research directive in orthotics did not begin until 1960. Biomechanical principles developed for the PTB prosthesis were immediately introduced in orthotics at the Veterans Administration Prosthetic Center, with the PTB orthosis to unload the foot-ankle complex axially.[6] The concept of fracture bracing or cast bracing began at approximately the same time and is now common practice for orthopedic management of fractures.[7,8] Clinical aspects of orthotic practice were also considered; a systematic approach to prescription formulation was established with the development of the technical analysis forms. Nomenclature to describe orthoses and their functions was standardized to identify the body segments they encompassed with the desired biomechanical control mechanisms.[9]

The introduction of new materials led to further advances in the field shortly after World War II. The use of thermosetting plastics in prosthetics permitted the development of the suction socket suspension system.[10] Transparent plastics offered a new approach to diagnostic and fitting evaluation techniques, such as the transparent prosthetic socket (test socket) and the transparent face mask for patients with thermal injuries. In orthotics, the addition of thermoplastics led to numerous innovative designs of ankle-foot orthoses (AFOs) in the 1960s and 1970s. The custom plastic AFO was an important technologic advance in lower extremity orthotics. The physical characteristics of thermoformable plastics allowed biomechanical controls to match the prescription for improved function. The mechanical properties of an orthosis could be controlled by the layout of the trimlines of a device or structural reinforcements through specially placed corrugations that could be incorporated into its surface geometry. Advances have been steady in the area of material engineering and continue to have an impact on orthotics and prosthetics. Numerous prosthetic feet have been introduced as elite athletes demand increased performance capabilities from their prosthetic components. Innovative designs for some prosthetic feet have been possible in part because of the diversity of carbon composite technology complemented by sound engineering design.

The development of computer-aided design/computer-aided manufacture (CAD/CAM) systems for orthotics and prosthetics, which began in the 1970s, was another major technologic advance, considering the long tradition of custom hand-crafted devices in the profession. In the late 1980s and early 1990s, as computers became more economical, facilities began to integrate CAD/CAM systems into their practices. CAD/CAM systems have now been designed for most orthotic and prosthetic applications, often with specialized digitizers, scanners, and milling equipment to accommodate the unique needs of a particular device. The current trend within the profession is that orthotists and prosthetists use the CAD portion to digitize and manipulate the data, then subcontract the production of a device from a central fabrication company for the CAM portion. The art and workmanship that have distinguished the orthotists and prosthetists from other health professionals for most of the 20th century continue to evolve as CAD/CAM technologies improve the design, manufacture, and diagnostic aspects of the field.

Orthotics and prosthetics have played an important historical role in the development of medical and surgical orthopedics and rehabilitation. Fundamental concepts that evolved from orthotic and prosthetic advancements are now basic principles in rehabilitation. Orthotics and prosthetics have evolved as sister professions because the technical skills and knowledge base to prescribe, fabricate, and fit the respective mechanical devices are similar. Because of this, material and technologic advancements have been shared between these two rehabilitation specialties.

Materials

In the first part of the 20th century, orthoses were constructed primarily of metal, leather, and fabric, and prostheses were manufactured from wood and leather. In the last 60 years, however, tremendous technologic advancements have been made in the material sciences. The demand for strong and lightweight components in the aerospace and marine industries has produced a variety of new materials that possess mechanical properties suitable for use in the construction of orthoses and prostheses. New plastics have led to revolutionary advancements in the profession, permitting increased durability and strength and significant cosmetic improvements. Although a multitude of materials are currently available, traditional ones are still in wide use; material selection depends in part on the individual needs of each patient. In a rehabilitation team setting, the orthotist and prosthetist are responsible for choosing the appropriate materials and components for fabrication because their experience and training are specialized in this area.

This chapter presents an overview of the general types of materials used in orthotics and prosthetics for rehabilitation professionals. Publications by the American Society for Testing and Materials contain specific technical information.[11] Industry standards established by the International Organization for Standardization for consumer and patient protection give the strength requirements for orthotic and prosthetic components.[12]

The types of materials used most commonly in current orthotic and prosthetic practice include leather, metal, wood, thermoplastic and thermosetting materials, foamed plastics, and viscoelastic polymers. In deciding which materials are most appropriate for a patient, the orthotist or prosthetist considers the five important characteristics of materials: strength, stiffness, durability, density, and corrosion resistance.

A material's strength is determined by the maximum external load that the material can support or sustain. Strength is especially important in lower limb devices, in which loading forces associated with gait can be very high, or when heavy use of the orthotic or prosthetic device is

anticipated. Materials may have higher strength in different loading scenarios. Some materials may be more effective under tensile load while others may be better under compressive loads.

Stiffness is a measure of the resistance of the material to relative atomic separation. This measurement, named the Young modulus, is larger when materials are stiffer and is related to the amount of force that is required to displace the atomic structure of the material.[13] The stiffer a material, the less flexible it is and the less likely that deformation will occur during wear. When significant external stability is desirable (e.g., in a fracture brace or a rigid prosthetic frame), a stiff material is often chosen. When conformation to body segments is necessary (e.g., in a posterior leaf-spring AFO or a flexible transfemoral prosthetic socket), a more flexible material is used.

Durability (fatigue resistance) of a material is determined by its ability to withstand repeated cycles of loading or unloading during functional activities. Repeated loading compromises the material's strength and increases risk of failure or fracture of the material. Fatigue resistance is especially problematic in the interface of materials with different characteristics.

Density is the material's weight per unit of volume, a prime determinant of energy cost during functional activities while a patient wears a prosthetic or orthotic device. Although the goal is to provide as lightweight a device as possible, strength, durability, and fatigue resistance needs may necessitate a denser material.

Corrosion resistance is the degree to which the material is susceptible to chemical degradation. Corrosion may occur in a number of ways when a liquid reacts with a solid. In general, the surrounding liquid interacts with the bonds of the solid which in turn weakens the solid.[13] Many of the materials used for orthoses or prostheses retain heat, making perspiration a problem. For some patients who require lower extremity devices, incontinence may also be a concern related to the urine interacting with the various materials of the prosthesis. Materials that are impervious to moisture are easier to clean than porous materials.

The ease of fabrication is another important consideration for materials. Certain materials can be easily molded or adjusted for a custom fit; others require special equipment or techniques to shape the material.

LEATHER

Leather is manufactured from the skin and hides of various animals. Tanning methods and the type of hide determine the final characteristics of the leather. As an interface material for an orthosis or a prosthesis, vegetable-tanned leather is used to protect the skin from irritation. Chrome-tanned leather is used for supportive purposes when strength and resiliency are needed. Additional chemical processes can be incorporated during manufacturing to produce leathers that are waterproof, porous, flexible, or stiff. Useful qualities of leather include its dimensional stability, porosity, and water vapor permeability.[14] These features have made leather a frequently used material within orthopedics, and it continues to be a material of choice in many current devices. Currently, leather is used for supportive components such as suspension straps, belts, and limb cuffs. Leather is also used to cover metallic structures such as pelvic, thigh, and calf bands. For foot orthoses and shoe modifications, leather is often preferred over synthetic substitutes because of its superior "breathability" characteristics.

Another important attribute of leather is its moldability. Although numerous techniques are available to mold leather, the most common one in orthotics and prosthetics is to stretch it over a plaster cast after it has been mulled (dampened or soaked) in water. When the water evaporates from the molded leather, its dried shape is maintained, and the leather can be trimmed to the desired dimensions. To increase strength and durability, leather can be reinforced by lamination with plastics or other leathers. Similarly, if padding is desired over bony regions of the body, foamed plastics or felt can be sandwiched between layers of leather for comfort or to distribute applied forces over a larger surface area. Three basic skills are required for crafting orthotic or prosthetic components of leather: cutting, sewing, and molding. A technique specific to leather work is that of skiving, or thinning the edge on the flesh side of the hide. Finishing methods such as these contribute to the final appearance of the leather work and the device.

METALS

The types of metal used in the fabrication of orthoses and prostheses can be categorized into three groups: steel and its alloys, aluminum, and titanium or magnesium alloys. These metals may or may not share similar characteristics. If metals are incorporated into an orthosis or prosthesis, the choice of metal is determined by the needs and preferences of the particular patient.

Steel

The general term *steel* refers to any iron-based alloy material. Carbon alloys have carbon added to the iron ore. The term *alloy steel* is used when other materials are included in the material manufacture. Alloy steels are further defined as low-alloy or high-alloy steels. Steels are strong, rigid, ductile, and durable, but their high density (weight) and susceptibility to corrosion are major disadvantages. Many different types of steel are available to meet various engineering needs. To assist in identifying the composition and type of material, the American Iron Steel Institute–Society of Automotive Engineers has established a four-digit numbering system. The first two digits in the number indicate the type of steel, and the last two digits identify the carbon content. For alloy steels, the first digit identifies the major alloy and the second digit indicates the percentage of the major alloying element.

The carbon content of steel is the major determinant of its ductility and yield strength characteristics. Yield strength is the point where the amount of stress applied to a material corresponds with that material's elastic limit, the point where any extra load plastically changes the material and it will not return to its original shape.[13] Ductility is the property of a material to deform in the inelastic or plastic range under load before failing. Low carbon content (0.05%–0.10%) produces high ductility and a low yield strength.[15] As the carbon concentration increases, yield strength increases and ductility is reduced. Heat treatments can alter the properties of carbon steel by increasing yield strength

and reducing ductility. The mechanical properties of low-alloy steels fall between those of carbon steels and high-alloy steels. High strength/weight ratios are possible with the high-alloy steels, an important characteristic for repetitive loading situations. These types of steels are used for some orthotic and prosthetic joint components. High-alloy steels are not very resistant to corrosion and are often more difficult to fabricate.

Stainless steel is a steel alloy that contains 12% or more of chromium, a material that increases resistance to corrosion and oxidation. Chromium produces a light oxide film on the surface that deters deterioration of the base metal. Because durability and protection from corrosion are highly desirable, stainless steels are used extensively within orthotics and prosthetics to enhance longevity of devices. Two types of stainless steel, martensitic steel and ferritic steel, have chromium as the predominant alloying element, but martensitic steel is the only one used in orthotics and prosthetics because it can be hardened by heat treatment. Stainless steel is used for orthotic and prosthetic joints, support uprights, and band material.

Aluminum

Aluminum alloys are well suited for orthotics and prosthetics because of their high strength/weight ratio and resistance to corrosion. As with steels, the properties of aluminum depend on alloying compositions, heat treatments, and cold working. *Wrought* and *cast* are terms used to describe the two ways to produce aluminum devices. Wrought metals are hot or cold worked, meaning they are formed using tools like a large roller, a stamp, or even a hammer around a mold.[13] The shape of the piece is mechanically formed from the outside force of the forming device. Casting is a process where liquid metal is poured into a mold, oftentimes made out of sand, and the final device takes the shape of the mold. Alloys are further subdivided into those that are heat treatable and those that are not. The low ductility and low strength of cast aluminum are ideal for prefabricated prosthetic components and in some assemblies for moving parts.

Wrought aluminum alloys are used in orthotics and prosthetics for structural purposes such as prosthetic pylons, orthotic uprights, and upper extremity devices. The high-compression bending stresses of lower extremity prosthetics are well suited to the use of wrought aluminum alloys.

Although aluminum alloys are very resistant to atmospheric and some chemical corrosion, the acids and alkalis in urine, perspiration, and other bodily fluids deteriorate the natural protective oxides on the material's surface, making the aluminum susceptible to corrosion. To deter corrosion in aluminum and to resist abrasive wear, various hard coatings, such as anodic or oxide finishes, can be applied. Mechanical finishes, such as polishing, buffing, and sandblasting, offer attractive cosmetic appearances for devices.

Titanium and Magnesium

Components made of titanium alloys have become more prevalent in prosthetics but are rarely used in orthotics. Although titanium alloys are stronger than those of aluminum and have comparable strength to some steels, their density is 60% that of steel.[16] Because prosthetic components made of titanium are lighter in weight than steel counterparts, they require less energy expenditure by the patient during use. Titanium alloys are also more resistant to corrosion than are aluminum and steel. However, it is important to note that titanium alloys are often more difficult to machine and fabricate. Consequently, titanium is most often used in prefabricated prosthetic components, when strength and light weight are of concern. Titanium is also more expensive than aluminum and steel, which has been a limiting factor for its use.

Magnesium alloys are lighter than those of aluminum and titanium, are corrosion resistant, and have a lower modulus of elasticity than does aluminum. The modulus of elasticity (Young modulus) is defined as the ratio of unit stress to unit strain in a stress-strain curve's elastic range; materials with low modulus values are associated with lower rates of fatigue under conditions of repeated stress. Although some of these features are promising, magnesium alloys have not yet been widely used in orthoses and prostheses.

WOOD

Wood possesses many desirable characteristics for use in prosthetics. Its wide availability, strength, light weight, and ability to be shaped easily have continued to be of benefit in prosthetic socket and component construction, even with the introduction of thermoplastics. The wood used in prosthetics must be properly cured, free of knots, and relatively strong. Yellow poplar, willow, basswood (linden), and balsa are most commonly used. Hardwoods have been reserved for prosthetic applications in which structural strength is essential, most often in certain types of prosthetic feet or as reinforcement for knee units. The keel prosthetic foot is fabricated of maple and hickory. The solid-ankle, cushioned-heel prosthetic foot has a hardwood keel that is bolted to the prosthetic shank, creating a solid structural unit for standing and ambulation.

PLASTICS AND COMPOSITES

One of the most important production-related characteristics of an orthotic or prosthetic material is its ability to be molded over a positive model. Because plastics can be readily formed, they are a very popular, widely used material for orthoses and prostheses. Plastics are grouped into two categories: thermoplastics and thermosetting materials.[17–19]

Thermoplastics

Thermoplastic materials are formable when they are heated but become rigid after they have cooled. Thermoplastics are classified as either low-temperature or high-temperature materials, depending on the temperature range at which they become malleable. Low-temperature thermoplastics become moldable at temperatures less than 149°C and can often be molded directly on the patient's limb, whereas high-temperature materials require heating to much higher temperatures and must be molded over a positive model of the patient's limb.[18] One advantage of thermoplastic materials is that they can be reheated and shaped multiple times, making possible minor adjustments of an orthosis or prosthesis during fittings. Thermoplastics are the material of choice for "shell" designs in which structural strength is

required. Some of the more popular materials used are acrylic, copolymer, polyethylene, polypropylene, polystyrene, and a variety of vinyls.

Certain low-temperature thermoplastics, those moldable at temperatures less than 80°C, can be applied and shaped directly to the body. Some of the most commonly available materials include Kydex (Kleerdex, Aiken, SC), Orthoplast (Johnson & Johnson, Raynham, MA), and Polysar (Bayer, Pittsburgh, PA). These materials are most often reserved for orthotic devices that are designed to provide temporary support and protection. Their susceptibility to repetitive stress, high loads, and temperature changes usually limits their use to spinal and upper extremity orthoses. Because these devices are molded directly on the patient, no casting is necessary, and the time required from measurement to finished product is greatly reduced. Another important convenience of low-temperature thermoplastic materials is that no special equipment is required; hot water heated in an electric frying pan, a heat gun, and sharp scissors are all that are necessary to produce a functional splint or orthosis.

High-temperature plastics are frequently used in the production of orthotics and prosthetics. The most commonly used materials include polyethylene, polypropylene, polycarbonate, acrylic, acrylonitrile butadiene styrene (ABS), acrylics, polyvinyl acetate, polyvinyl chloride, and polyvinyl alcohol.

Polypropylene is a rigid plastic material that is relatively inexpensive, lightweight, and easy to thermoform. Polypropylenes, which can be further characterized as homopolymers or copolymers, are one of the most widely used plastics in orthotics. The material has a white, opaque color and is available in sheets of various thicknesses, from 1 mm to 1 cm. Polypropylene is impact resistant and can endure several million cycles of repetitive flexes. This attribute has been extremely useful in orthotics for hinge joints and spring assists in AFOs. However, the material is susceptible to ultraviolet light and extreme cold and is sensitive to scratches and nicks. In prosthetics, the light weight of polypropylene makes it ideal for components such as sockets, pelvic bands, hip joints, or knee joints. Polypropylene is commonly used for prefabricated AFOs and preformed modular orthotic systems.

The long fatigue life of polyethylene during repeated loading situations makes this material suitable for a number of orthotic and prosthetic applications. Prosthetic sockets, orthotic hinge joint components, and compression shells for clamshell design orthoses are common uses of polyethylene plastics. Several densities of polyethylene are available from various manufacturers. Low-density polyethylene is used for upper extremity and spinal orthoses under the trade names Vitrathene (Stanley Smith & Co, Ltd, Isleworth, UK) and Streifen (FG Streifeneder KG, Munich, Germany). High-density polyethylene, Subortholen (Wilhelm Julius Teufel GmbH, Stuttgart, Germany), is used for spinal and lower extremity orthoses. The ultra-high-density polyethylenes such as Ortholen (Wilhelm Julius Teufel) are used principally for lower extremity orthoses.

Thermoforming. Thermoforming is one of the most common techniques used in orthotic and prosthetic laboratories to fabricate the "user" interface components of a device (e.g., prosthetic socket, AFO). The process of thermoforming entails heating a sheet of thermoplastic material in an oven until it has reached its "plastic" state (i.e., ability to distort) and then forcing the material over a prescribed shape (i.e., positive mold) under pressure until it has cooled. Negative air pressure or vacuum is the typical method used to apply pressure and form the plastic over the mold, hence the terms "vacuum-form" are also used to describe the process. Once the plastic has cooled and returned to its solid state, the perimeter of the formed components is determined and trimmed out. The edges of the plastic are then finished on specialized grinding machines that have a diverse set of abrasive sanding and buffing cone options that are used to achieve a high-polish smoothed edge.

Thermosetting Materials

Thermosets are plastics that are applied over a positive model in liquid form and then chemically "cured" to solidify and maintain a desired shape. To enhance their structural properties, thermosets are often impregnated into various fabrics by a process of lamination. Although this group of plastics has inherent structural stability, their rigidity precludes modification by heat molding; their shape can only be changed by grinding. Thermosetting plastics cannot be reheated without destroying their physical properties. Some of the most common thermoset resins used to produce rigid orthoses are acrylic, polyester, and epoxy. Because acrylic resins are strong, lightweight, and somewhat pliable, they offer a different set of characteristics than those of polyester resins. With lamination, acrylic resin can create a thin but strong structural wall for a prosthetic socket or component of an orthosis. However, if frequent adjustments are anticipated, thermoforming plastics are chosen instead because thermoset cannot be heated to make adjustments to their shape.

Composites. Composites are the combination of two or more materials with distinctly different physical or chemical properties that together produce a material with enhanced performance characteristics relative to their material properties as a single substance. Numerous types of composites exist under this broad descriptive term, ranging from natural materials such as wood to manmade materials such as concrete. This chapter focuses on the combination of fibers and matrices associated with thermosetting plastics.

Fiber-reinforced plastics (FRPs), also referred to as *composites*, have revolutionized orthotics and prosthetics, primarily because they can be engineered to have mechanical properties with strength characteristics optimized for specific types of loading situations, thereby greatly improving the functionality of many types of orthoses and prostheses. The mechanical properties of reinforcement fibers, for the most part, dictate the mechanical properties of a composite through the orientation and position of the fibers. In general, FRPs offer high strength and stiffness qualities yet are also capable of incurring compressive or flexural stresses. Plastics can also be reinforced with other fillers, particulates, and short or chopped fibers, but FRPs are most widely used. This section focuses on fiber reinforcement for thermosets.

Polymer composites are made of a binder material (i.e., resin), referred to as the *matrix*, which is reinforced with fibers to improve strength and stiffness. The matrix of a

composite encapsulates the fibers to maintain their desired orientation and position and ensure that load sharing of fibers is well distributed through the material. The volume fraction of resin to fiber is an important determinant of the mechanical properties of a composite and its performance. In general, the volume of fiber should be higher than the volume of resin matrix. A fiber volume fraction that approaches 90.7% with a matrix volume fraction of 9.3% is considered an ideal ratio.[20]

By comparison, the fibers in composite materials are stronger than the matrix material and can handle stresses applied to them better than the weaker matrix material. Typical fiber reinforcements used in polymer composites are fiberglass, carbon/graphite, and Kevlar aramid fibers (DuPont, Wilmington, DE). Grades of different fiberglass include E, C, and S glass, which stand for electrical (E), chemical (C), and strength (S), respectively. S glass has a higher tensile strength than E and C glass. Carbon fiber is widely used in orthoses and prostheses having strength properties greater than steel while also being lightweight and very stiff. Carbon fiber has superior stiffness properties in both compression and tension but, because it has relatively low impact strength, it is often combined with other reinforcement fibers like fiberglass or Kevlar to improve its performance. Aramid fibers (e.g., Kevlar) have tensile strength properties that are five times greater than steel for the same weight.

Laminar composites or laminates are fabricated out of "continuous fibers" that may extend the length of a given part and are one of the most common FRPs used in orthotics and prosthetics. Continuous fiber reinforcements can be woven into the form of a fabric in many different weave patterns. By combining different types of fiber fabrics (e.g., carbon graphite, Kevlar) and stacking these plies into layers, the resultant laminate can possess properties for particular modes of loading. When engineering laminates for orthoses and prostheses, the practitioner or technician must understand the manner in which loads will be transmitted through a device so that appropriate layering and orientation of plies will be incorporated into the composite to meet its functional performance duties. A laminate code system is used to describe the direction and ply layer with the longer dimension of the laminate serving as the x-axis and the width serving as the y-axis. A fiber orientation angle is used to describe the orientation of plies with respect to the x-axis, which is designated as 0 degree. A laminate code describes the sequencing of each layer from top to bottom. An example of a laminate code where the top ply is 0 degree followed by subsequent plies oriented respectively at 45, 90, 45 degrees, with the bottom ply at 0 degree would be written as follows: $[0/45/90]_2$. Brackets define the code's beginning and end, and the subscript indicates the adjacent plies are oriented the same, which is essentially one half of the ply description. The purpose of having a variety of different fiber orientation angles in composite laminates is that the load can be carried through the fibers in a number of different positions. For example, if the fibers were only oriented in one direction, then structural loading of the material at a different angle could result in a failure. Therefore multidirectional laminates have the capacity to endure loads in an orthotic and prosthetic device in variety of positions.

Processing Technologies and Composite Fabrication. Orthotic and prosthetic devices often are a compilation of custom-molded interface shell components combined with additional premanufactured parts (e.g., prosthetic foot, pylon). Practitioners and their technical staff have the capability to fabricate the human interface portions of a device within their laboratories, although the processes and equipment in their labs are limited to only a few techniques. Manufacturers on the other hand have the capacity to consider a much wider variety of processing techniques for mass producing composite parts and thus take advantage of processing technologies that can maximize the performance potential of the material.

The most common method for processing FPR composites in orthotic prosthetic laboratories is a contact molding technique called a "vacuum bag" lamination. The technique is relatively simple and does not require any specialized equipment. A flexible membrane bag of plastic is tightly stretched over the positive mold part and sealed; then negative air pressure (i.e., vacuum) is applied between the bag and the mold, drawing the bag tightly to the surface of the mold. A hand layup of fiber cloth is placed on the mold in a predetermined manner with regard to the orientation and position of the fibers with an understanding of how loads will be transmitted through the structure when it is incorporated into a device. After the desired layup of fiber and cloth is achieved, a second flexible membrane bag is pulled over the mold, creating an enclosure that can accommodate the wet liquid resin (matrix) part of the composite. After the resin is poured into an opening of the second bag and sealed, vacuum inside the enclosure draws the outer bag toward the mold, pressing the resin through the fiber in a uniform manner to create a thin-walled structure of composite that has a high fiber-to-resin ratio. If the atmospheric pressure that presses on the outside bag is not adequate to achieve the desired fiber-to-resin ratio, then the vacuum bag mold construct can be placed into an autoclave to create higher pressures on the external bag. Because most orthotic prosthetic laboratories do not have autoclaves for such procedures, central fabrication laboratories equipped with such equipment are being used to a greater extent to maximize the benefits of pressure processing in composites.

Foamed Plastics

Foamed plastics can be used as a protective interface between the orthotic or prosthetic and the skin, especially over areas that are vulnerable to pressure, such as bony prominences. Foamed plastics are grouped into two classes: open and closed cell. Cells are created in rubber or polymers in a high-pressure gassing process.[18] The microcell structure allows the foamed plastic material to be displaced in several planes, which is an ideal physical property for the reduction of shear forces. In an open-cell foam, the cells are interrelated (as in a kitchen sponge); in a closed-cell foam, the cells are separate from each other. Because closed-cell foams are impervious to liquids, they are less likely to absorb body fluids such as perspiration or urine; however, they do act as insulators and can be hot when worn for extended periods.

An orthopedic grade of polyethylene foam was introduced in the 1960s by a British subsidiary of the Union Carbide Company.[21] These closed-cell foams are available

in a wide array of durometer hardness. (*Durometer* refers to a spring indenture post instrument that is used to measure the resistance to the compression/hardness of a material.) Polyethylene foams are commercially available under trade names such as Plastazote (Hackettstown, NJ), Pe-Lite, Evazote (Bakelite Xylonite Ltd., Croydon, UK), and Aliplast (Alimed Inc., Dedham, MA). Various polyethylene foams are used in the manufacture of soft and rigid orthoses, depending on the density of the material. Plastazote is a low-temperature, heat-formable foam that has been used successfully in the treatment and prevention of neuropathic foot lesions.[22–25] Its light weight and forgiving quality to bony prominences make it a desirable interface for the insensate foot. See Hertzman[22] for a complete review of the use of Plastazote in lower limb orthotics and prosthetics.

Closed-cell foams are also made with synthetic rubber or polychloroprene. Neoprene is available in various densities, making the low-durometer versions suitable as liners for orthoses, whereas the firmer materials are used for posts or soling for shoes. Spenco (Spenco Medical Corp., Waco, TX) is a microcellular neoprene foam that reduces shear forces to the foot's plantar surface and the occurrence of foot blisters in athletes.[26] The nylon (polyamide)-covered neoprene acts as a shock absorber while also reducing friction on the foot's plantar surface.[21] Although few of these materials are heat moldable, most can be conformed without difficulty to the shallow contours of foot orthoses. Lynco (Apex Foot Health Industries, Teaneck, NJ) is an open-cell neoprene foam that dissipates heat more efficiently than its closed-cell cousin; however, it does not attenuate shock as well as Spenco.[21]

Polyurethane open-cell foams are alternatives for top covers for foot orthoses. They provide good shock absorption and dissipate heat well. Some of the commercially available open-cell polyurethane foams include Poron (Rogers Corporation, Rogers, CT), PPT (Professional Protective Technology, Deer Park, NY), and Vylite (Steins Foot Specialties, Newark, NJ).

Several studies that compare materials used to fabricate orthoses have been conducted.[27–33] In 1982, Campbell and colleagues[27] conducted compression tests on 31 materials to determine their suitability for insoles in shoes. Materials were classified according to stiffness into the categories "very stiff," "moderately deformable," and "highly deformable." The moderately deformable group of plastics, which included 19 of the tested foamed plastics, was deemed the most beneficial as an insole material. Campbell and colleagues[27] concluded that these materials could relieve stress from bony prominences and transfer the loads to the adjacent soft tissues more effectively than could the very stiff or highly deformable materials. Studies evaluating shoe insole materials also report them to be effective at attenuating shock during walking in various ways.[33]

Viscoelastic Polymers

A viscoelastic solid is a material that possesses the characteristics of stress relaxation and creep. Stress relaxation occurs when a material that is subjected to a constant deformation requires a decreasing load with time to maintain a steady state.[34] Creep refers to the increase in deformation with time to a steady state as a constant load is applied.[34] Sorbothane (Sorbothane, Inc., Kent, OH), widely used as an insole material, is made of a noncellular polyurethane derivative that possesses good shock-attenuating characteristics.[34] Viscolas (Viscolas Corp., Soddy Daisy, TN), another type of viscoelastic solid, has been found to attenuate skeletal shock at heel strike in the tibia to half the normal load.[15,35] Two other viscoelastic polymers used to fabricate orthotic prosthetic components are Viscolite (Polymer Dynamics, Inc., Allentown, PA) and PQ (Riecken's Orthotic Laboratories, Evansville, IN).

Prescription Guidelines

The formulation of a prescription for an orthosis or prosthesis greatly influences the potential functional outcome for the patient. It is critical that rehabilitation objectives and design criteria be carefully considered. Physicians, physical and occupational therapists, orthotists, and prosthetists who are involved in developing a prescription for an orthotic or prosthetic device must have a sound understanding of orthotics and prosthetics to be successful in effectively treating patients with these devices, although there is currently a degree of variability regarding best practice guidelines in the literature.[36]

Assessment of functional deficit includes a thorough evaluation of the patient's present physical status, including muscle strength testing, range of motion measures, and documentation of other physical impairments that would affect the fit or performance of the device. Equally important to the physical examination is the consideration of any individual needs of the patient and an understanding of how the treatment will affect daily activities and the patient's ability to navigate the home environment. Included in these considerations must be an individual's ability to don and doff an orthosis or prosthesis and any related components.[37,38] To increase the success of treatment, the patient and other rehabilitation team members must reach a consensus on the type of device and the associated training and education required for optimal functional outcome.

ORTHOTIC PRESCRIPTION

The Committee on Prosthetics and Orthotics of the American Academy of Orthopaedic Surgeons developed a technical analysis form to standardize the process of patient evaluation. This evaluation protocol documents the biomechanical deficits of the patient and provides the basic information needed for orthotic prescription formulation. This systematic approach has two major objectives: to define the anatomic segments that the orthosis will encompass and to accurately describe the biomechanical controls needed for treatment. The underlying principle of this assessment is that orthoses should be designed to control only those movements considered abnormal while permitting free motion in anatomic segments that are not impaired.

Technical analysis forms were developed for three general regions of the body: the upper limb, lower limb, and spine. The forms are four pages long with the same basic approach for formulating an orthotic prescription. The first page has sections for recording general patient information and noting major physical impairments (Fig. 6.1). The major

Fig. 6.1 The technical analysis form provides a systematic method of data collection for the development of prescriptions for lower extremity orthoses. The first page of the form is used to record the patient's history and current impairments. *AC,* Anterior cruciate ligament; *ASIS,* anterior superior iliac spine; *LC,* lateral collateral ligament; *MC,* medial collateral ligament; *MTP,* medial tibial plateau; *PC,* posterior cruciate ligament. (From Committee on Prosthetics Research and Development. *Report of the Seventh Workshop Panel on Lower Extremity Orthoses of the Subcommittee on Design and Development.* Washington, DC: National Research Council–National Academy of Sciences; 1970; and McCollough NC III. Biomechanical analysis systems for orthotic prescription. In: American Academy of Orthopaedic Surgeons, ed. *Atlas of Orthotics: Biomechanical Principles and Application.* 2nd ed. St. Louis: Mosby; 1985:35–75.)

impairment section characterizes any functional limitations, such as skeletal structure, sensation, or joint contracture. This information provides an overview of the patient's clinical presentation.

The second and third pages of the technical analysis form (Fig. 6.2) contain diagrams of the respective anatomic (limb or trunk) segments for which an orthotic prescription is being considered. Each skeletal region is represented in

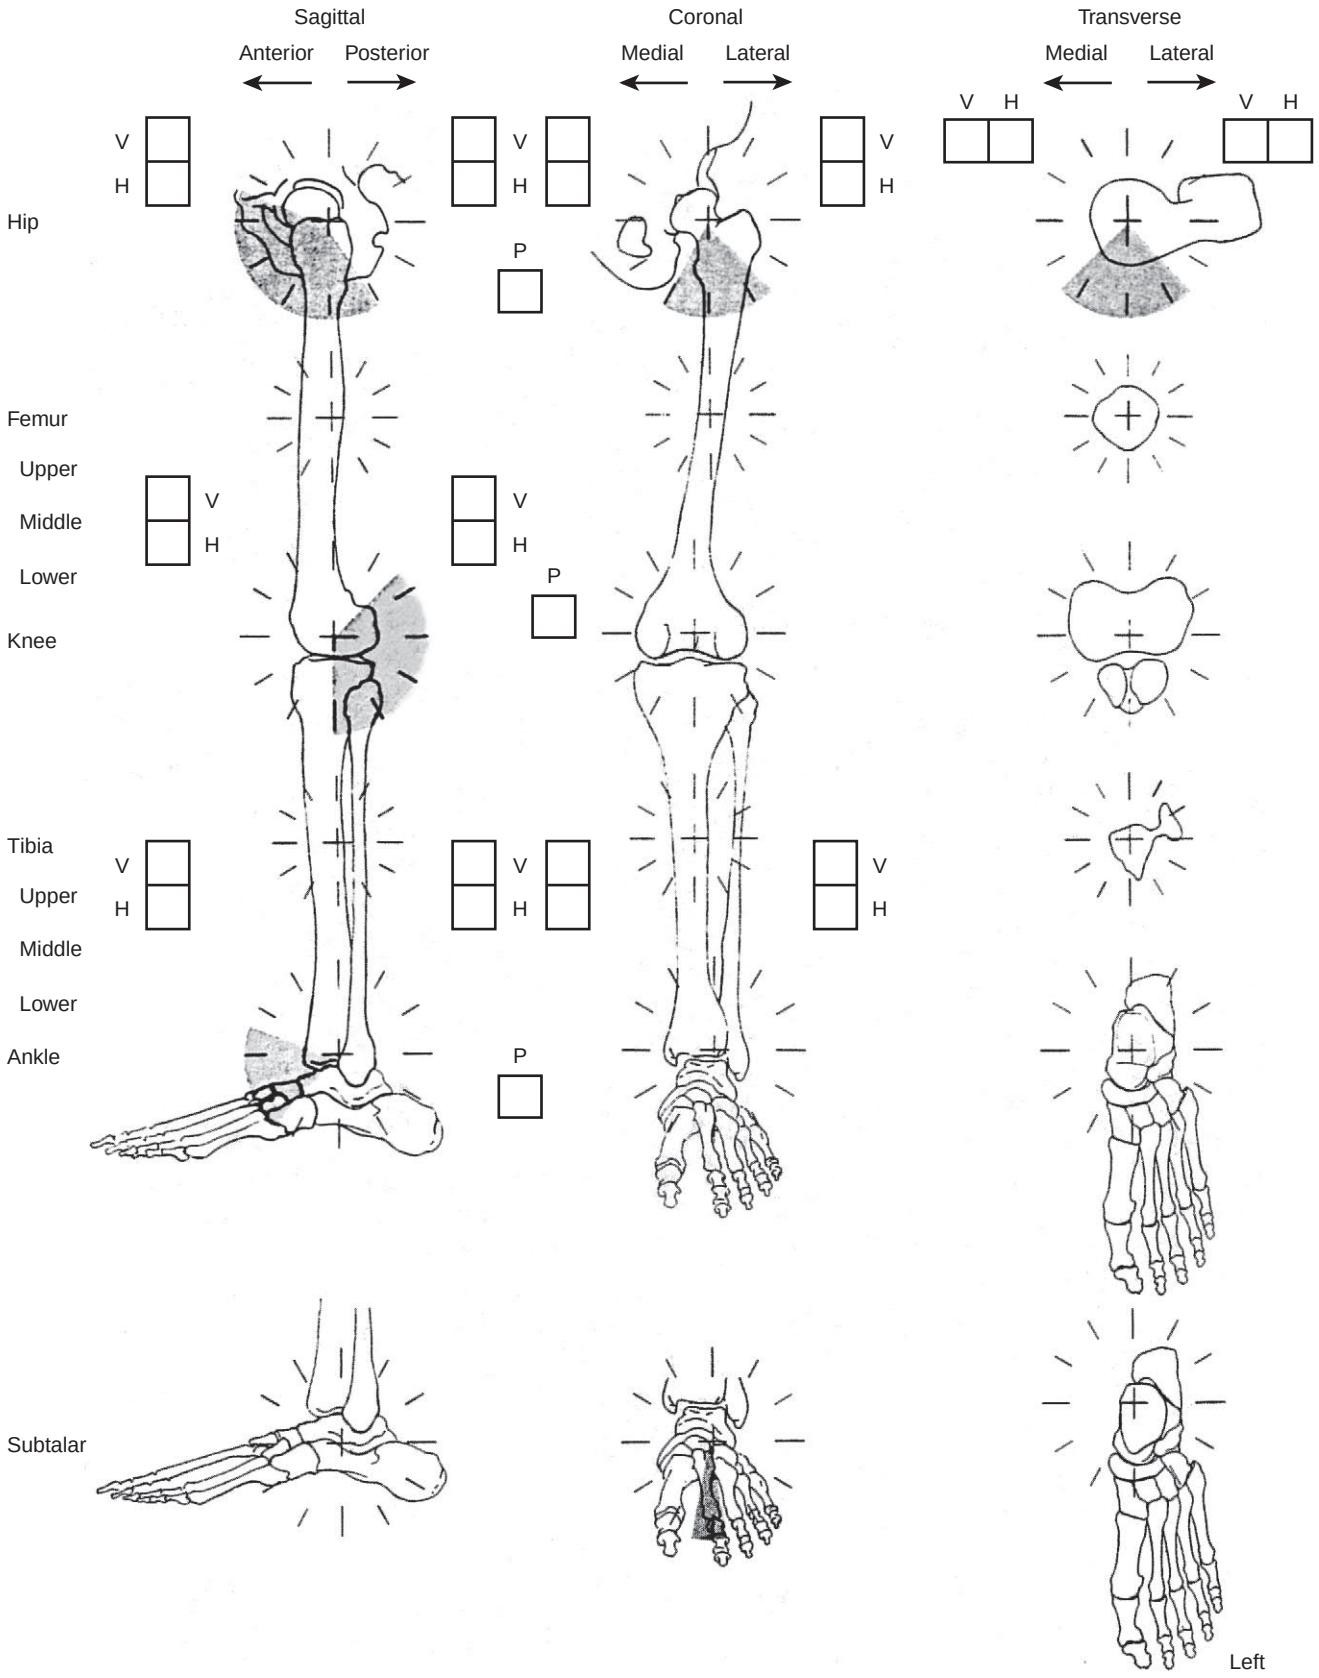

Fig. 6.2 Subsequent pages of the technical analysis form are used to detail characteristics of each limb or body segment for which the orthosis or prosthesis will be made. Information recorded on these pages includes existing deformity, proprioceptive capacity (P), restriction or hypermobility of joint rotary and translatory range of motion in all three planes of movement, volitional strength (V), and the level of hypertonicity (H). (From Committee on Prosthetics Research and Development. *Report of the Seventh Workshop Panel on Lower Extremity Orthoses of the Subcommittee on Design and Development*. Washington, DC: National Research Council–National Academy of Sciences; 1970; and McCollough NC III. Biomechanical analysis systems for orthotic prescription. three planes of motion: coronal, sagittal, and transverse. On either side of the figures, square boxes at the level of the joints are used to note volitional force, hypertonicity, proprioception, and range of motion. The fourth page consists of a summary of the functional disability, treatment objectives, orthotic recommendation, and a key for the biomechanical controls of function.

Voluntary movements of muscles are assessed by conventional muscle testing techniques. Muscle strength can be recorded with either the standard descriptive or numeric muscle grading systems, depending on regional preferences.

Two types of joint (limb) motion are recorded on the forms: rotary and translatory. According to McCollough,[39] all points of the distal segment move in the same direction, following the same path shape and distance during translatory motion. During rotary motion, one point of the distal segment (or its imaginary extension) remains fixed while other points move in an arc around it. Translatory motion is recorded with linear arrows in the direction of the distal segment's movement relative to its proximal counterpart. The linear arrows are placed below the circle (representing the joint axis) for translatory motion. If translatory force acts in the vertical axis, the linear arrow is placed to the side of the circle. Rotary motion and the related degree of range of motion are documented by an arrow within a protractor-type arrangement for each joint. The established normal range of motion for each joint is shaded on the form for comparative reference. If a fixed contracture or fusion of the joint is present, a double linear arrow is used.

Hypertonicity of muscle groups in each of the body segments is described by a functionally based letter scale.[39] A designation of mild tonicity is given when any hypertonus that is present is thought to be functionally insignificant. Moderate tonicity indicates that tone might have some functional value, such as assisting the patient in holding an item during minor tasks. A designation of severe tonicity indicates that normal function is not possible. The patient's proprioceptive ability is described in a similar way, as absent, impaired, or normal for each of the body segments of interest.

The final page of the technical analysis form (Fig. 6.3) contains space for an overview of functional impairments, a checklist of the orthotic treatment objectives, and a chart that details the orthotic recommendation. The desired orthotic control for each body segment is indicated by a specific letter; as many as seven types of orthotic controls can be incorporated into the design of an orthosis. The terms and descriptions of these controls are indicated in the key. If the orthotic recommendation section is completed correctly, the chart will indicate the body segments that the device will encompass and the desired biomechanical control of function needed. Any comments on the specific design requirements or materials, or both, can be detailed in the remarks section of the form.

For the orthotist, the prescription is the blueprint from which the design of a device is based. It specifies the force system requirements needed to achieve the treatment objectives independent of material selection or production processes. Although an in-depth biomechanical assessment may not always be necessary, a system based on these principles is a logical and objective method for formulating an orthotic prescription.

PROSTHETIC PRESCRIPTION

The formulation of a prosthetic prescription requires a different evaluative process. Prosthetic prescription depends on an in-depth understanding of components and materials as well as their indications and contraindications for use. Ideally, prosthetic prescription begins before amputation surgery, so the residual limb is of appropriate length and healing is adequate for optimal prosthetic use. Factors such as vascular supply, anticipated activity level, intelligence, vocation, social support, and age are also important to consider.[40] Range of motion, flexible and fixed contracture, functional strength, skin condition, girth measurements, pain, and sensation of the residual limb and the intact limb are evaluated.

An important part of prosthetic prescription is component selection.[41] The diversity of prosthetic foot-ankle units and knee mechanisms for lower extremity prosthetics, and the variety of terminal devices for the upper extremity, can present difficult decisions for those who are unfamiliar with their intended application. Therefore prosthetists are often relied on for recommendations on components because they are usually most familiar with the specifications and limitations. Many prosthetic teams have developed data collection forms to standardize the prosthetic prescription process. Redhead[42] suggests that the prescription for a prosthesis consider each of the major "prescription options." Examples of the specifications delineated by Redhead for a transfemoral prosthesis are type of limb, socket material and design, suspension, knee joints, knee controls, ankle joints, feet, and cosmesis.

Fabrication Process

Once a prescription for a custom orthosis or prosthesis has been created, the fabrication process begins. The traditional fabrication process is composed of six steps:

Step 1: Taking accurate measurements of the limb
Step 2: Making a negative impression (cast)
Step 3: Creating a three-dimensional (3D) positive model of the limb or body segment
Step 4: Modifying the positive model to incorporate the desired controls
Step 5: Fabricating the orthosis or prosthetic socket around the positive model
Step 6: Fitting of the device to the patient

In some instances, further modification or adjustment is necessary to achieve optimal fit and function of the device.

MEASUREMENT

Measurements are most often referenced from readily palpable bony landmarks. Important anthropometric measurements include the residual limb length, successive circumferences, and mediolateral and anteroposterior dimensions of the body segment for which the orthotic or prosthetic device is being created. Using this method, bony landmarks are identified as reference points and measurements are obtained at fixed distances from this reference. For instance, Boonhong performed this in subjects with transtibial amputation by identifying the tibial tubercle

and obtaining circumferential measurements in 4-cm increments down to the distal end of the residual limb[43]; others have elected to measure in 4-cm increments beginning at the distal end of the residual limb.[44] Measurements are recorded on forms that are specific to the body segment being treated, such as the technical analysis form previously described. These measurements are used in two ways: as a reference when modifications to the positive cast are needed and as the way to determine the placement of the perimeter trimlines of the device.

Although clinically practical and easily performed with simple tools such as a tape measure, caution needs to be exercised when using anthropometric measurement methods, because they have been shown to have poor intrarater and interrater reliability.[45] Water immersion has also been described to determine residual limb volume. To perform this in patients with a transtibial amputation, de Boer-Wilzing et al. used a 15-cm glass cylinder filled with water that was placed on a hand-operated elevator. The distal part of the residual limb was inserted into the water-filled cylinder and the elevator raised until specified reference points touched the water's surface, thus displacing an amount of water equal to the volume of the residual limb.[44] However, although results are less variable, this method cannot be used when open wounds are present or if a patient has bilateral leg amputations.[46] In addition, a recent systematic review indicated that there are inadequate data for drawing conclusions in patients with other types of limb amputations.[47]

New technologies, such as laser scanning methods (including CAD/CAM scanning), have helped to decrease fitting errors, manufacture time, and overall cost of prosthetic sockets.[48] One group of authors reported a mean percentage error of 1.4% using a 3D scanner and very low intrarater and interrater reliability coefficients (05.% and 0.7%, respectively).[48]

NEGATIVE MOLD

A negative impression is a mold taken of an actual body part that is used to create the 3D positive cast or model necessary for fabrication of the orthosis or prosthesis. This negative impression is most often taken with a plaster-of-Paris bandage or fiber resin tape, although in some instances direct impressions are used as an alternative. Creation of a negative impression has four steps. First, a layer of tubular stockinet or a stocking is placed over the skin to create a protective interface and control the position of soft tissue structures within the cast (Fig. 6.4). Tubular stockinettes are available in sizes that range from small diameter for the pediatric limb to large diameter for the adult torso. When a direct impression technique is being performed, a topical separator such as petroleum jelly can be used as an interface to minimize the risk of capturing cuticle hair in the impression. Second, bony prominences or other important guiding landmarks are marked on the body segment with indelible ink. These marks transfer to the inside of the negative mold and from there to the surface of the positive model.

Once the limb or body segment has been prepared, a thin layer of plaster of Paris or fiber resin tape is applied (see Fig. 6.4B). This procedure differs from that of fracture casts in one important way: the goal is to achieve an "intimate" fit that captures the actual contours of the limb or body segment so that no protective padding is required. Failure to achieve a successful interface between the wearer and the device may result in discomfort, excessive tissue stress, skin irritation and destruction, and potential amputation revision.[49] Rolls of elasticized plaster can be wrapped circumferentially in no more than two or three layers. Alternatively, strips of the material can be laid along the length of the limb or body segment. Most impression casting materials are readily available in roll form, although special versions have been produced for specific types of impression procedures, such as the fiber resin sock for an AFO. As the molding material is applied, the clinician smooths the surface, following the normal shape of the limb. While the mold hardens,

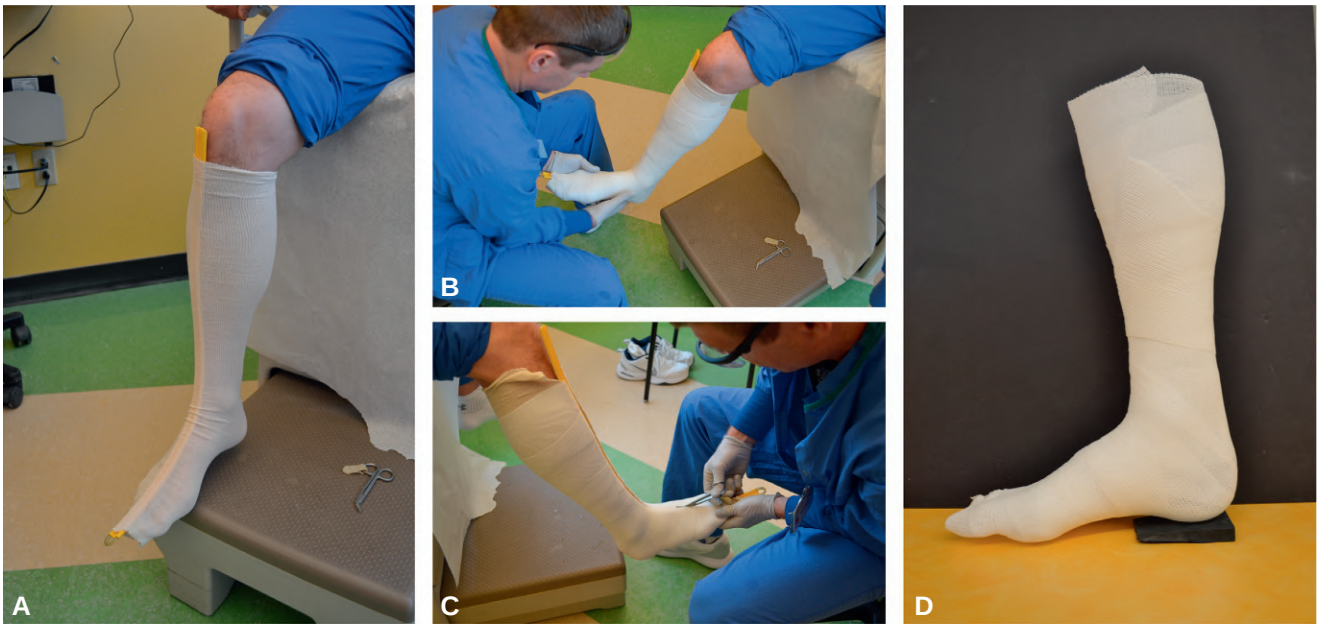

Fig. 6.4 The procedure for taking a conventional negative impression begins with placing a layer of cotton stockinette over the limb and marking bony prominences with an indelible water-soluble transfer pencil (A). Surgical tubing is positioned on the anterior aspect of the limb to serve as a guideline for cast removal and to protect the shin. The limb is positioned on a shoe "last" impression in preparation for circumferential application of a plaster-of-Paris bandage or fiber resin casting tape (B). The impression board allows the foot to assume the contours of a shoe during molding for an optimal foot/shoe/ankle-foot orthosis interface. Once the cast is "set," a cast saw is used to open the front of the cast (C), and the negative impression is carefully removed from the limb. The anterior edges are closed, and the ankle-foot alignment of the negative impression is verified with a plumb line (not shown in this picture) (D). (Courtesy Shriners Hospital for Children Portland.)

the clinician supports the limb or segment in the desired position, sometimes applying a light corrective force. As an example, the desired limb position of an orthosis incorporating the ankle joint might be in subtalar and talocrural neutral. If a PTB socket design is desired for a transtibial prosthesis, an extra force applied just distal to the patella marks its desired location on the resulting positive mold.

Once the cast is hardened sufficiently, it is carefully removed from the limb segment, preserving its shape and contours, and checked for alignment (see Fig. 6.4C and D). It is essential that the clinician who takes the negative impression has a thorough understanding of the forces that will be applied to the anatomic segments involved to ensure optimal fit and function of the orthosis or prosthesis. Estimates of soft tissue compression and skeletal alignment changes need to be carefully considered during the negative impression procedure. A skilled and experienced professional uses clinical judgment to create a negative impression, not only to capture the shape of the anatomic segment but also to apply an efficient force system to improve or maximize function. Basic design decisions must be made before the impression procedures so that any special accommodations required for the desired functional outcome can be incorporated.

Special negative impression techniques have been developed for specific purposes. Polystyrene foam impression blocks are one of the common methods of acquiring an impression of the plantar surface of the foot.[50] For patients who are recovering from facial burns, fabrication of a facial orthotic designed to deliver even, steady pressure during the period of scar maturation requires a highly detailed mold of the face. Alginate impressions, also referred to as *moulage techniques*, similar to those used in dentistry, are often used.

FABRICATING AND MODIFYING THE POSITIVE MODEL

Conventional methods for creating a positive cast are well established. The negative impression is prepared by sealing the mold so that it can accept liquid plaster of Paris. A separator material (e.g., silicone, soap) is added to the inner walls of the mold before the plaster of Paris is poured so that it can be removed more easily once the positive model has set. Once the cast has solidified, the negative impression is stripped away and discarded. The anatomic landmarks and reference points marked on the limb or body segment with indelible pencil and transferred from the patient to the negative impression are again transferred to the positive model. A mandrel (post) is embedded into the setting plaster of the positive model. This mandrel is used to hold the model for cast rectification and the rest of the production processes.

Model rectifications remove artifacts produced during the molding or impression process and bring the cast to specification of the measured values taken from the patient. Once the positive model has been rectified, further modifications can be made on the basis of the design of the orthosis or prosthesis being fabricated. During the negative impression procedure, soft tissue may have been manipulated for specific applications of force or pressure to be incorporated into the final orthosis or prosthesis. Although the positive model represents a 3D shape of a respective body segment, it cannot relay information about the density of the tissue that it will interface. In general, additional plaster is added where relief of pressure is desired (e.g., over bony prominences) (Fig. 6.5) or is removed where additional forces are to be applied. When the orthosis or prosthesis is formed over the model, an area of relief for a more intimate fit is achieved. Although some guidelines have been established regarding the amount of material to be removed or added to the positive model, the clinical experience of the prosthetist or orthotist is essential in this stage of the process. The positive model can also be modified to reconfigure surface geometry to improve the strength of the finished product.

Once design changes have been incorporated into the model, its surface is prepared for component production. This involves removing any surface imperfections with abrasive tools and abrasive sanding screen to ensure that the surface in contact with skin will be smooth. The positive cast is then ready to be used as a form from which different materials can be shaped to produce an interface component.

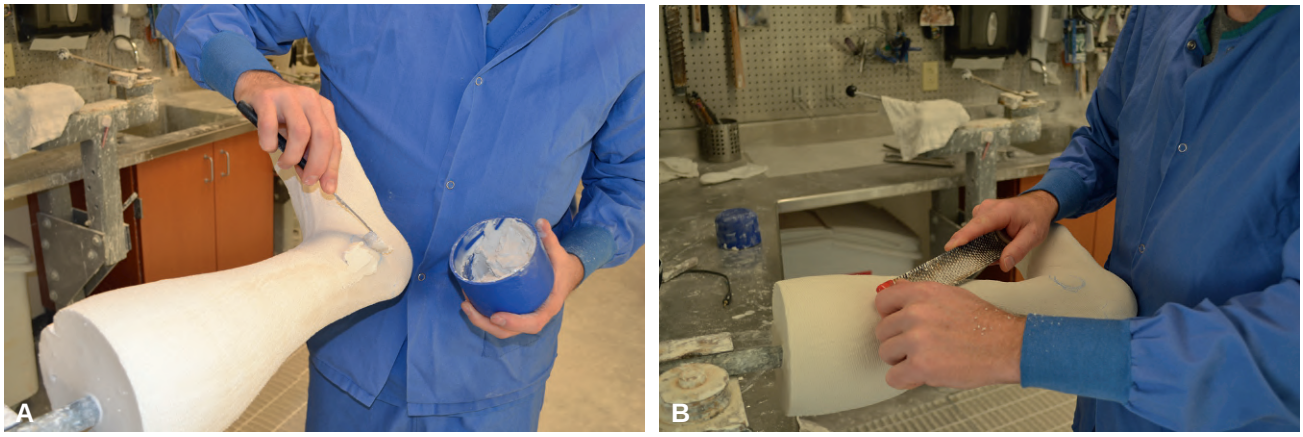

Fig. 6.5 In the rectification of a positive model, plaster of Paris added over pressure-sensitive areas, such as the lateral malleolus (A), results in a "relief" in the finished orthosis. Modification of the positive model by removal of material with a plaster rasp over pressure-tolerant areas (B) increases intimacy of fit for better loading or stabilizing of the limb. (Courtesy Shriners Hospital for Children Portland.)

FABRICATING THE ORTHOSIS OR PROSTHETIC SOCKET

The fabrication process used with the positive model depends on the material selected for the device. Thermoforming is a common production method used in orthotics and prosthetics. Thermoplastic sheet material is heated in an oven until it has reached its "plastic" state, then shaped over a positive model by changing the air pressure difference across its surface (vacuum forming) (Fig. 6.6). Once the plastic has cooled and returned to its solid state, trimlines are delineated on the formed plastic before the edges are finished and smoothed.

Computer-Aided Design/ Computer-Aided Manufacture

In the 1960s an alternative method of prosthetic fabrication that used computers was first introduced. Early CAD/CAM methods used stereophotography and digitization to create a numeric model, which guided a milling machine in the creation of a positive model of the residual limb.[2] A more complete concept of fabrication and manufacture of a prosthesis was developed at the University College London in the late 1970s and early 1980s.[51] After establishing a system for automated production of a prosthesis called Rapidform, the London research group conceived a completely automated fabrication process that used appropriate prosthetic alignment data.[52]

In the United States the Veterans Administration began funding research projects in the 1980s to investigate the potential of CAD/CAM in orthotics and prosthetics. Advances were also made in private industry as the availability of personal computers became widespread. Beginning in the late 1980s, manufacturers have designed a multitude of CAD/CAM systems for various applications in orthotics and prosthetics. Advances in computer hardware, processors, and software have made CAD/CAM systems fast and efficient, as well as an economical alternative for fabrication of devices for many orthotic and prosthetic practices.

Currently, most CAD systems use a scanning device to record digital information of a body segment for CAM. The primary components of a CAD/CAM system consist of a digitizing device, computer, and milling machine. Surface contours of the anatomic segment are recorded with various digitization devices: optical-laser scanners, surface-contacting stylus, and pneumatically operated mechanical posts. Digital information acquired from a scan of a body segment is processed by the computer and translated into a triordinate data point file. This file is used by the computer to create a graphic image in the form of a surface contour plot.[53] The data are then relayed to a milling unit to carve an orthosis or prosthesis for a positive model.

DATA ACQUISITION

Each of the many digitizers used for data acquisition is designed for a specific task or to handle certain anatomic regions. Noncontact laser digitizers capable of circumferential scanning are well suited for measurement of cylindrical shapes such as those found in limb prosthetics or spinal orthotics. An optical-laser camera mechanism images the surface topography of the body segment and records the measured data points in a computer. Special holding fixtures and bars to aid in patient comfort and safety are part of each system. An apparatus designed to scan the torso for a spinal orthosis usually requires a different setup than that of a limb prosthesis. Some scanners are capable of digitizing directly from the patient's body segment, whereas other systems take measurements from a negative impression or mold of the segment (Fig. 6.7). Compact, handheld contact digitizers have been introduced by several CAD/CAM manufacturers. These units allow the clinician to digitize a body segment by direct contact with the skin. Handheld contact digitizers are described as a wand, pen, stylus, or pointer. Contact digitizers often have special attachments to scan certain shapes or measurement tools, such as calipers, for acquiring anteroposterior or mediolateral dimensions. Their versatility permits data acquisition of complex shapes. In some systems, handheld digitizers can be used in conjunction with a laser scan.

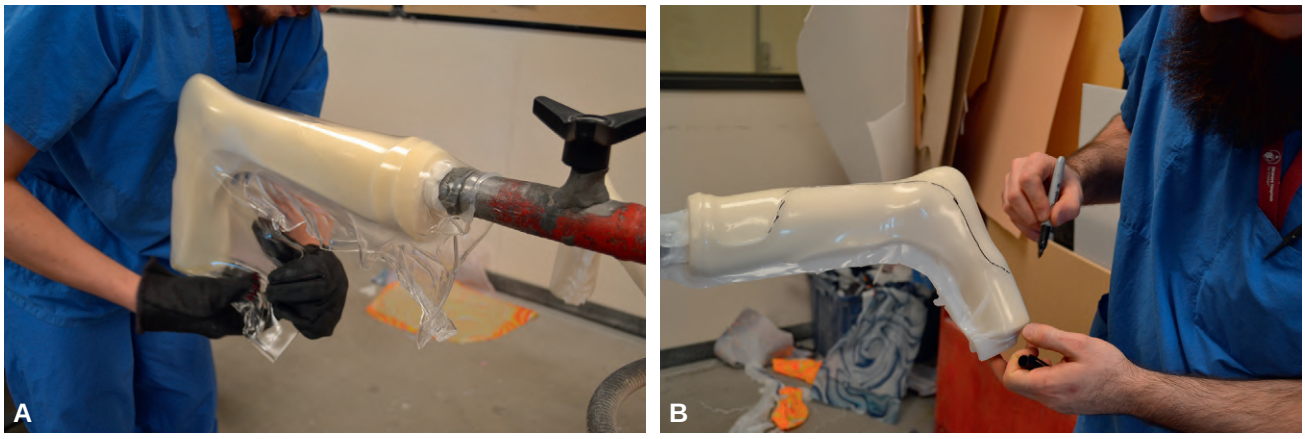

Fig. 6.6 Once a sheet of thermoplastic material has been heated, it is dropped over the rectified positive model (A) and the edges of the thermoplastic are sealed. Negative pressure created by a vacuum pump removes any trapped air and draws the polypropylene to the surface of the positive model. When the material has cooled, trimlines are drawn on the formed plastic (B) by using measurements taken during the initial evaluation and bony landmarks as guides. (Courtesy Shriners Hospital for Children Portland.)

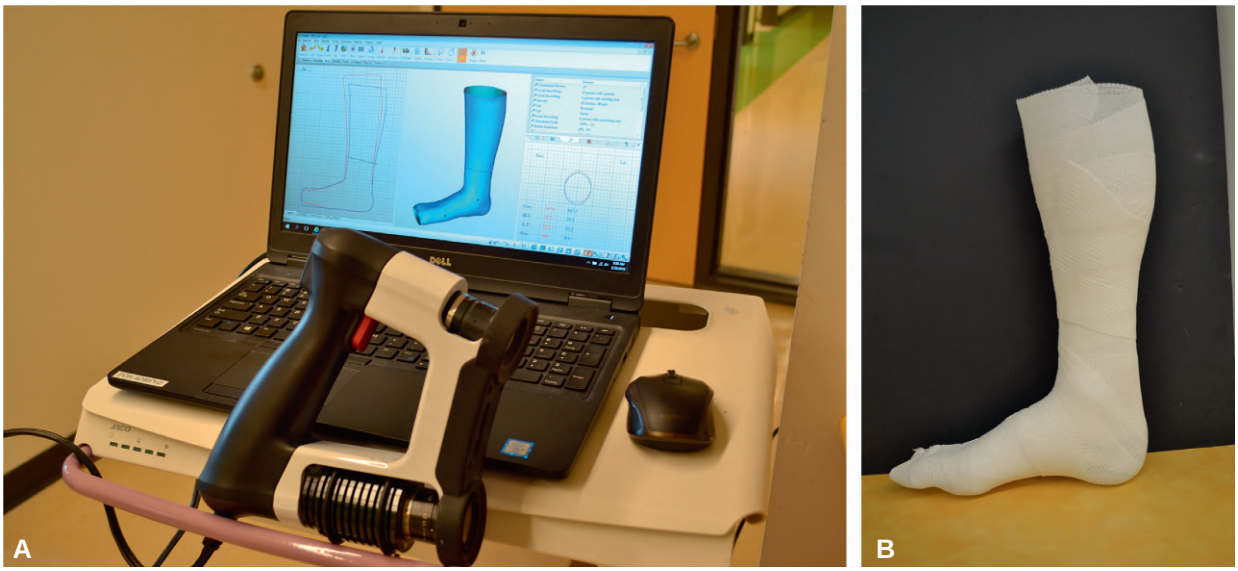

Fig. 6.7 Examples of computer-aided design/computer-aided manufacture data acquisition systems. A digital model of the residual limb (A) can be captured by a laptop computer, appropriate signal processor components, and a handheld digitizer (VORUM—Spectra 3D Prosthetics and Orthotics Scanner, Vancouver, BC). Laser digitization (B) can be used to capture accurately the contours of a conventional negative impression of a residual limb. (Courtesy Shriners Hospital for Children Portland.)

The use of digitizers in the production of foot orthoses is also becoming more common. Several systems based on differences in technique and philosophy in foot orthosis design have been developed for data acquisition of the foot. For full weight-bearing or partial weight-bearing techniques, pneumatically operated mechanical posts are used to digitize the foot's plantar surface (Amfit Corp, Vancouver, WA). Orthotic contoured shapes such as metatarsal domes can be evaluated during the digitization procedure to determine optimal position and comfort before fabrication. An optical-laser scanner situated under an acrylic platform has also been used for scanning the foot when a weight-bearing technique is desired (Bergmann Orthotics Lab, Northfield, IL). Because this system is also capable of scanning the foot with non–weight-bearing methods without the platform, it is quite versatile in clinical practice.

In many instances, orthotists and prosthetists are restricted to surface geometry and palpation of underlying anatomic structures to interpret the position of skeletal and soft tissue structures of the body segment. Magnetic resonance imaging and computed tomography have been used to create a 3D computer model and assist in making design decisions for a mechanical device. Data from these scans are converted to a working format for specific graphic and modeling programs. Although this capability may not be practical for all applications, it may offer insight into areas of further research and development in the field.

SHAPE-MANIPULATION SOFTWARE

The ability to modify the 3D model of a patient's body segment permits the clinician to incorporate the desired biomechanical controls into an orthosis or prosthesis. The amount of force applied to a specific area depends in part on manipulation of the digital 3D model. Software packages are currently available to assist orthotists and prosthetists in designing the most appropriate modifications for a given patient. Generic modification templates or custom-designed templates can be used to make a wide range of revisions to the data. The clinician can incorporate reliefs for bony prominences of the limb or trunk or can change the geometry of the shape to enhance structural strength characteristics in the final orthosis or prosthesis. Trimlines can be delineated so that technicians who are involved in the assembly of components can complete a device without further instruction.

MILLING AND PRODUCTION

Once the digital model is in place, the milling apparatus creates the actual orthotic or prosthetic device. Because each type of orthosis or prosthesis usually has specific milling parameters, a different setup may be required for each. For instance, the long, rounded shape of a transtibial or transfemoral socket is often manufactured with a lathe-type milling machine (Fig. 6.8). In contrast, foot orthoses are manufactured by an end mill setup because their plate-like structure and production processes create different finishing needs. The production laboratory needs to be large enough to have separate milling stations for each type of orthosis or prosthesis. This manufacturing limitation has led to the establishment of laboratory production companies that mill the positive models and manufacture the orthoses or prostheses from computer data transmitted by modem. Computer production networks can often reduce fabrication time and decrease production times, making the use of CAD/CAM economically feasible even for small orthotic/prosthetic facilities. Special production equipment is available that partially automates the thermoforming processes of some components. In the thermoforming machine for prosthetic sockets, a preformed polypropylene shell travels upward on a mechanical platform to an oven that heats the plastic to its formable temperature. The heated shell is

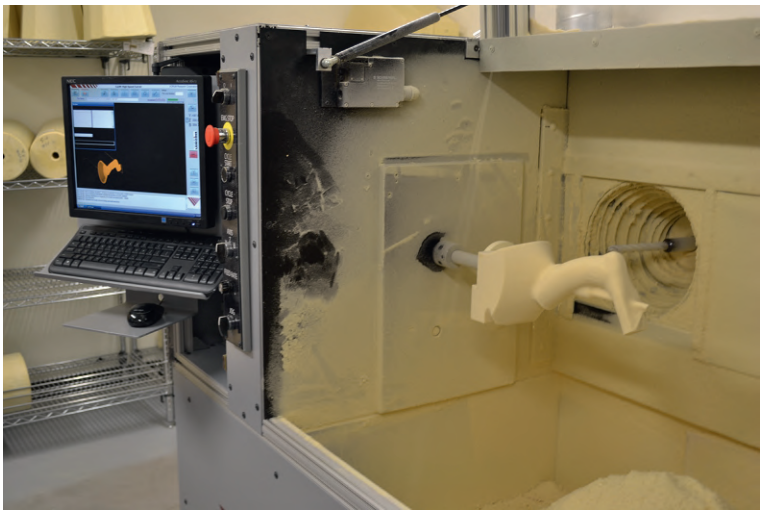

Fig. 6.8 A positive model for a transtibial prosthetic socket being carved on a computer-controlled milling/lathe machine (VORUM—3-Axis Carver, Vancouver, BC). (Courtesy Shriners Hospital for Children Portland.)

then lowered over the positive model of the residual limb and vacuum formed for an intimate fit.

CAD/CAM in orthotics and prosthetics will play an important role in clinical and research settings. Although the development of CAD/CAM in orthotics and prosthetics has a history that spans more than two decades, only since the 1990s has it become an integral part of some clinical practices. Systems that have been designed for virtually all prosthetic and orthotic applications can be integrated with computed tomography, magnetic resonance imaging, and other medical imaging technologies. The technological advancements of CAD/CAM offer orthotists and prosthetists an additional clinical fabrication and research tool. Although this sophisticated equipment can contribute greatly to certain clinical and manufacturing tasks, successful fitting of a device depends on proper data input and prescription formulation.

Central Fabrication and Mass Production

The techniques and processes associated with the fabrication of orthoses and prostheses described in this chapter can be relatively labor intensive and expensive. As managed care and insurance companies strive to reduce medical costs, the profession is under greater pressure to remain competitive by finding alternative production methods that are cost effective. One option is to maximize the clinical productivity of orthotists and prosthetists and limit their technical responsibilities. Central fabrication operations allow practitioners to develop clinical practices that do not require large technical facilities and space. Depending on the size of the practice, outsourcing the production portion of the business can be a more economical way to run an orthotic/prosthetic clinic. Some practitioners do not want to manage in-house technical operations that include additional technical staff, specialized equipment, and increased space requirements. Another advantage is that central fabrication may offer improvements in consistency and quality of devices.

CENTRAL FABRICATION FACILITIES FOR CUSTOM DEVICES

Central fabrication facilities typically specialize in the manufacture of custom orthoses and prostheses, often serving a large number of orthotic and prosthetic practices. These manufacturing services are available to produce almost every kind of orthosis and prosthesis, with many companies specializing in a specific area (e.g., spinal orthoses, knee orthoses, transtibial prosthetics). Some central fabrication operations offer the advantage of producing a device without the need for a negative impression, an additional cost savings in time and materials. A series of conventional measurements of patients combined with height and weight data is entered into a computer to generate a milled positive model for production. Orthotic systems in particular have been refined to produce excellent fitting devices that are comparable in function to custom-molded orthoses produced from a patient model. Although there will always be a need for custom-molded devices, technologic advancements in human factors, ergonomics, and computer modeling will improve generic sizing and contoured interface systems, permitting a larger portion of the population to be fit with prefabricated devices and components. Modular components of varying material properties are already a part of general practice in prosthetics.

MASS PRODUCTION

Mass-produced, prefabricated orthoses outnumber custom-molded orthoses fitted to patients for rehabilitative purposes. Orthopedic companies continue to develop orthotic and prosthetic products whose fit and performance approach that of custom-molded devices through diverse sizing systems and modular components. In the future, prefabricated modular component systems may bridge the gap between prefabricated and custom-molded devices by improving performance outcomes with custom-fitted systems and expanding their use in clinical practice. Although these advances in fit and function are possible for some problems, certain deformities and pathologic conditions will almost always require custom-molded or measured orthoses and

prostheses made by traditional or CAD/CAM methods of production.

Technologies Poised to Transform Prosthetics and Orthotics and Rehabilitation

Health care economics and reimbursement issues have impeded the pace of technologic advancements and patient access to new technologies in prosthetics and orthotics. The transfer of science and technology from other medical and engineering disciplines to prosthetics and orthotics will be important for continued innovation. Biosensor technologies, power actuation, and CAD/CAM are three areas primed to advance prosthetics, orthotics, and rehabilitation in the next decade. Orthotic and prosthetic practices are slowly transitioning from experiential practice-driven decision-making to one founded on biomedical sensor data from the user and their respective devices. Clinically relevant measures offer improved reliability to assess user performance and to determine treatment prognoses. Actuators can provide power assistance to augment movement and offer advantages that conventional passive prosthetic and orthotic systems cannot offer. Advances in 3D scanners and printers offer an alternative means for capturing the shape of a body segment for custom fitted interfaces, and 3D printers and computer numerically controlled milling machines and lathes could replace some of the traditional methods and processes (e.g., plaster-of-Paris molds) of fabrication. Although the application of newer technologies may be feasible, their adoption within the field will ultimately rest on treatment outcome results and monetary benefits to our health care delivery systems.

Biosensors. In comparison with other areas of medicine, prosthetics and orthotics have lagged behind in the use of biomedical instrumentation to assist in clinical decision-making, diagnostics, and monitoring user performance and outcomes. Considerable advances have been made in sensor technology, microprocessors, and data analyses that are applicable to orthotics and prosthetics. The reduction of sensor size and cost has permitted them to be embedded into orthoses and prostheses without compromising functionality for the user. Wireless systems (e.g., Bluetooth) that communicate through user-friendly interfaces (e.g., tablets) allow sensing systems to be used in the clinical setting, remotely in the home and community. Data on the actual use of an orthosis or prosthesis are important to monitor because compliance and dosage parameters (i.e., time of use) can help with treatment prognoses. In the orthotic management of scoliosis, temperature and force sensors embedded in thoracic lumbosacral orthoses provide clinicians with a relatively accurate account of patient use but can also reveal if the orthosis postural support is being optimized when in use.[54,55] The combined data of several sensors characterize the duration of use (i.e., time) and the manner in which the desired orthotic control is being achieved. As more sensor data are collected and studied in all domains of orthotics and prosthetics, the efficacy and efficiency of treatment interventions can be refined and improved on a foundation of clinically relevant measures.

Prostheses and orthoses interact with a respective body segment (e.g., leg, residuum) via a socket or shell-like interface, respectively. The specified geometry of the interface controls the manner in which loads are transmitted from the device to the human user. Therefore transducers that can quantify pressure and force data coupled with sensors that detect movement provide vital information for practitioners to optimize fit and function for the user.[56-58] In addition to gathering information from the human subject user, instrumented orthoses and prosthesis can collect data from the device itself for feedback and control systems to optimize function, user intent, and safety. Electromyography (EMG) sensors measure muscle activity, and if embedded into the interface, practitioners can consider a user's neuromotor response mechanism to the use of an orthosis or prosthesis. EMG data can also be used to determine control parameters for power actuation systems in devices.[59]

Power Assistance and Actuation. Traditionally, most orthoses and prostheses have designs that feature "passive" motion control mechanisms.[60] For instance, most ankle foot orthoses assist, resist, and/or limit ankle joint motion range mechanically with springs or elastic bands or through the controlled deflection of a strut element (e.g., posterior leaf spring AFO). Furthermore, passive resistance can be also be achieved via friction, pneumatics, hydraulics, and magnetorheologic dampening systems.[60] Although passive resistance has provided improvements in joint motion control in both orthotics and prosthetics, powered actuation can generate active joint movement. The use of different types of actuators to augment motion in orthoses and prosthesis is expanding at a rapid pace particularly with wearable exoskeletal robotic systems. Although technologic barriers still exist in creating systems for everyday use, there is promising applicability for powered assistance in the rehabilitation clinic/hospital setting for more controlled therapeutic interventions compared with traditional physical therapy techniques (e.g., care giver–assisted resistance training).[61,62]

Exoskeletal Robotics. Computer-controlled robotic systems have some distinct advantages over traditional rehabilitation therapies. Exoskeletal robots are often ideally suited for repetitive strength and/or stretching routines or when prescribed target dosages are needed. Although hands-on therapist-administered treatments have proven to be effective, robots have the potential to be more efficient due to their precision-controlled movement, and if instrumented with sensors they can provide valuable performance feedback data.

The biomechanical principles used to maximize fit, function, and comfort with orthoses are also applicable for exoskeletal robots. Actuators transmit power to mechanical armatures and levers linked to orthotic interface shells. Loads are transferred from external soft tissue structures (i.e., skin, muscle and fat) to the bone segments an anatomic joint (e.g., knee, ankle) to produce or limit motion. Exoskeletons can be equipped with sophisticated control systems that use various biomedical sensors for feedback to monitor motion.

Microprocessor-controlled prosthetic knees (MPKs) represent one of the most significant technologic advances made in prosthetics. In particular the Ottobock C-Leg (Ottobock, Duderstadt, Germany), introduced in 1997, was the first MPK that had microprocessor control stance

and swing phases. Compared with non–micro-controlled prosthetic knees, users of MPKs report an improved perception of balance confidence, and scientific studies are currently showing the incidence of falls can be reduced between 64% and 80%.[63] Imbedded sensors are critical to the control system of MPKs. Similar control systems for knee control in knee-ankle-foot orthoses have also been developed.[64]

3D Scanners and Shape Manipulation Software. Inherently, the portion of the orthosis and prosthesis that interfaces with the body is often custom-molded to achieve an exacting fit. Traditionally, a facsimile of a limb segment or body part is created by taking a mold or capturing the shape by tracing the contour combined with a series of relevant measurements to duplicate the geometry. Recent developments in laser-based scanners and structured light technology have offered more options for digital imaging of surfaces for prosthetics and orthotics.[65,66] Handheld portable scanners with both technologies allow more diverse applications to which 3D scanning can offer clinical advantages for custom-molded devices. Three-dimensional scanners are becoming more accessible for the clinical practice setting since the costs of scanners has significantly decreased for a number of applications. Some versions of structured light scanners can be attached to tablets or mobile phones. Both scanner technologies are portable, have fast scan times, and take highly accurate measurements. Although these new scanner technologies can help to streamline capturing the shape of body part, computer software to modify the topography of the interface is crucial to perfecting fit and function.

Numerous industry-specific CAD/CAM software programs are available for the design and manufacturing of prostheses and orthoses. Because orthotic and prosthetic applications are diverse, ranging from cranial helmets to spine and extremity orthoses and limb prosthetics, the software programs for each region of the body are often different. As such, a clinical practice has to have several distinct software programs to accommodate full range clinical services it may offer. Hence the costs associated with having multiple systems has contributed to a slow adoption of CAD/CAM in clinical practices and is why traditional processes and methods are still in wide use.

Multiple software programs, scanners, and printers may be needed for a prosthetic and orthotic service to have a fully integrated CAD/CAM operation in prosthetics and orthotics. Each region of body presents with a unique set of conditions in which a practitioner may need to capture the shape of an anatomic surface. For individuals with limb loss, a handheld scanner can be ideally suited to capture the shape of the residuum. For orthotic management of the foot, clinicians may prefer scanning the foot in partial weight bearing (e.g., seated) because the plantar soft tissues compress during loading and the shape of the foot changes dramatically compared with its shape in non–weight bearing. Practitioners may actually scan a negative impression (i.e., mold) or a positive model of a body part rather than the actual patient to acquire a digital image file. Thus traditional prosthetic and orthotic techniques are blended with CAD/CAM technologies as practitioners try to maximize the advantages of both approaches.

3D Printers and Additive Manufacturing. Additive manufacturing and 3D printing are quickly gaining traction within the profession as the technologies and materials improve and can better meet the demands for clinical use. The early plastics used in 3D printing lacked the strength and reliability of the conventional composites and thermoplastics used in the industry and slowed the application of 3D printing into clinical practice. However, advances such as carbon fiber–infused plastics and the ability to structurally engineer (e.g., vary thickness) a component have allowed some 3D-printed parts to be applicable for definitive use rather than for prototyping purposes. A diversity of materials is available with a wide variety of mechanical properties. Some of the most common filament materials used are: polycarbonate, nylon, ABS, polylactic acid (PLA), polypropylene, thermoplastic elastomers (TPEs), thermoplastic polyurethane (TPU), polyethylene terephthalate with glycol (PETG), polyvinyl alcohol (PVA), and acrylic styrene acrylonitrile (ASA). The addition of carbon and wood fibers or metal powders infused into the base materials can further enhance properties of materials.[67]

Maintenance of Orthoses and Prostheses

Routine care and maintenance of orthoses and prostheses are important for proper function and long-term use of a device. An orthotic or prosthetic maintenance program usually includes servicing by the orthotist or prosthetist and the patient. The service schedule depends on the specific orthosis or prosthesis, the materials from which it is made, the durability of the components, and the knowledge and ability of the patient and caregivers. Patient instructions for the daily care of an orthosis or prosthesis should include cleaning and inspection. Proper patient education of basic fitting criteria and instructions on donning and doffing a device allow the patient to evaluate the fit of a device during routine use. Professionals in orthotic and prosthetic work environments also need to adopt strategies to decrease the risk of cross-contamination from devices such as hand washing (frequency and time spent), cleaning devices and tools, and implementation of an infection control coordinator.[68]

Orthoses and prostheses should be inspected weekly for any defects, stress risers (nicks, scratches), loose screws, or weakened rivets. Any device that has mechanical components and moving parts and is subjected to repetitive loading requires periodic servicing; it is less expensive to recognize and fix early signs of a problem than it is to replace a device that has failed because of a lack of proper maintenance. Informing patients of potential problems associated with the use of their orthoses or prostheses and how to resolve these problems can prevent serious situations from arising.

Most plastic components should be cleaned with a mild antibacterial soap and rinsed thoroughly with cold water. Extra moisture should be absorbed with a towel and the orthosis or prosthesis air dried. Heat can distort some plastics; patients should be warned not to use electric hairdryers to dry their devices. Similarly, devices should not be left near direct heat sources, such as radiators, wood/pellet stoves, or

any appliance that generates heat when running. They must also be protected from intense direct sunlight.

Leather liners and covers are cleaned weekly with a leather "saddle" soap. Leather softeners should not be used unless directed by the orthotist, because they can compromise function of some straps and cuffs. Water-repellent treatments and protectants for leather often contain skin irritants and should not be used on leather components that have direct contact with the body.

Most orthoses and prostheses are designed to apply a corrective or stabilizing force to a body segment during wear. For some patients, especially those with fragile skin or scarring, this pressure may increase the risk of skin irritation or damage. The risk of skin problems differs from device to device and depends on the general health and skin condition of the individual who is wearing the orthosis or prosthesis. To minimize problems with skin intolerance of these extra forces, most new orthotic or prosthetic users begin with an intermittent wearing schedule. A treatment plan that incorporates a gradual buildup of orthotic or prosthetic use can avert complications such as excessive redness, chafing, and blisters. For a patient with a high risk for or a history of skin problems, a variety of preventive measures (e.g., foam or silicone interface liners) can be incorporated into the orthotic or prosthetic system.

Most custom orthoses or prostheses are designed to achieve a very intimate fit with the body segments that they encompass. Changes in the physical condition of a patient can significantly alter the fit and function of a device. Compromised fit occurs most often when the patient has had significant growth, weight gain or loss, muscle atrophy, edema, structural degeneration, or trauma. Periodic evaluations are necessary to ensure that fit and function are maintained in the months and years after the initial fitting. Semiannual or annual checkups should be part of the treatment plans for definitive orthotic and prosthetic devices.

To maintain proper function of a lower extremity prosthesis, special attention is needed in several areas. The alignment of a prosthesis is usually based on a specific heel height; variation from the prescribed heel height (when footwear is changed) often leads to functional problems during gait. In the same way, moderate to excessive wear of the shoe at the heel also compromises performance. The condition of footwear must be carefully and frequently monitored. The prosthesis should be free of dirt, sand, and other debris to ensure that joint mechanisms and their movements are not inhibited. Socket attachment and suspension systems need daily attention because they are usually prone to accumulation of lint, dirt, and other debris. If the prosthesis or any of its components are subjected to water, the device should be thoroughly dried to prevent permanent damage. Rubber bumpers in prosthetic feet deteriorate over time and with use and must be replaced regularly. The prosthetist can advise patients on specific parts that require regular maintenance.

The socket portion of a prosthesis should be faithfully cared for to avoid potential skin problems, especially infection, on the residual limb. When a special liner is used with a prosthesis, specific instructions for cleaning are necessary because materials used vary greatly. For patients who are fitted with suction sockets or special socket attachment mechanisms, the joining components or threads should be cleaned with a soft brush or rag to remove debris.

Summary

This chapter explores the materials and methods most commonly used in the prescription, measurement, and production of orthoses and prostheses. The type of design, materials, and components are selected to best facilitate the functional goals of the patient. The foundation for effectiveness of the orthosis or prosthesis is careful measurement of the body segment (by casting or by CAD/CAM) and careful modification of the resulting model for optimal fit. For an individual who is being fit for his or her initial orthosis or prosthesis, shared decision-making of the rehabilitation team, including the patient and caregivers, is essential. An orthosis or prosthesis that is difficult to don or is uncomfortable to wear is more likely to be found standing in a closet or pushed under a bed than on the patient for daily use.

7 Footwear: Foundation for Lower Extremity Orthoses☆

DANIEL A. RIDDICK, DANIEL H. RIDDICK, and MILAGROS JORGE

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Determine the proper fit of standard footwear for a patient's foot on the basis of necessary function of the foot during gait and the contour and alignment of the foot.
2. Recommend appropriate footwear styles and characteristics for patients with foot deformities and those who wear orthoses or prostheses.
3. Describe the shoe modifications and accommodative orthoses that can be used to address musculoskeletal problems affecting the foot and lower limb.
4. Describe the effect of selected problems and deformity of the forefoot, midfoot, or rearfoot on weight bearing and efficiency of the gait cycle and suggest appropriate footwear or orthotic interventions to reduce pain and improve function.
5. Identify special footwear needs for individuals with arthritis, gout, diabetes, peripheral vascular disease, hemiplegia, and amputation or congenital deformity of the foot and leg.

It can be said that the most essential element of clothing in any person's wardrobe is the shoe. No other article of clothing is designed to fit so precisely; moreover, continuous pressure from tight shoes can produce ulceration and deformities. Ill-fitting shoes can create shear forces that lead to skin breakdown, create and facilitate toe and foot deformities, and lead to falls.[1] Shoes perform the vital functions of transferring body weight to the floor during walking and of protecting the wearer from hazards in the environment. A well-designed shoe is the necessary foundation for many lower extremity orthotics and for prosthetic alignment and an energy-efficient gait. This chapter discusses the components and characteristics of shoes, ensuring proper fit, and choosing appropriate footwear for patients with foot dysfunction and deformity.

Components of a Good Shoe

A suitable pair of shoes minimizes stress on all portions of the feet, provides support, and acts as a shock absorber of ground reaction forces.[2] The basic parts of a shoe are the sole, upper, heel, and last. Each of these parts is further divided into component parts or areas that are required for proper shoe design (Fig. 7.1). Each component is crucial to the prescription of appropriate shoes for an individual's needs.

SOLE

The sole protects the plantar surface of the foot. The traditional sole consists of two pieces of leather sewn together with a layer of compressible cork in between. An additional layer, the insole, is situated next to the foot in most shoes. A heavy thick sole protects the foot against irregularities in the walking surface. The rigidity or stiffness of the sole is also important. Although it must be durable, the sole must not be so rigid as to interfere with the toe rocker of the metatarsophalangeal (MTP) hyperextension during terminal stance and preswing phases of gait.

Various areas of the sole are identified by location. The *welt* is the inside piece of the external sole; the *outsole* is the portion that is most external. The area that lies between the heel and the ball of the shoe, the *shank,* is commonly fabricated to provide reinforcement and shape using materials such as spring steel, steel and leatherboard, or wood strips between the welt and the outsole. The purpose of the shank is to prevent collapse of the material between the heel and the ball of the foot and to provide extra support. In most athletic shoes, the sole is rubber to provide maximal traction. Rubber soles absorb shock, thereby minimizing heel impact forces.

UPPER

The upper of the shoe—divided into the *vamp, tongue,* and *rear quarters*—covers the dorsum of the foot. The vamp extends from the insole forward. The tongue is an extension of the vamp in a blucher-style closure, but in the Balmoral or Bal-type Oxford, the tongue is separate (Fig. 7.2). The blucher-style closure can be opened slightly more than the Bal-Oxford closure to allow the foot into the shoe. The toe of the vamp is often covered with a separate piece of leather called the *tip.* The rearward line of the tip may be straight or winged. The vamp is joined to the quarters, which make up the sides and back of the upper. The two

☆The authors extend appreciation to Jennifer M. Bottomley, whose work in prior editions provided the foundation for this chapter.

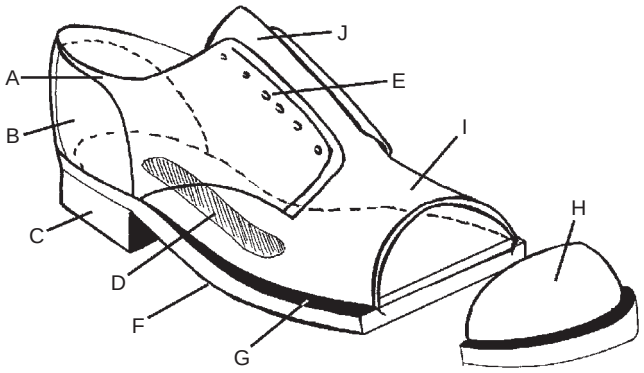

Fig. 7.1 Basic parts of a shoe. The upper is made up of the quarter *(A)* and its reinforcing counter *(B)*, which stabilize the rearfoot within the shoe; the closure *(E)* and the tongue *(J)* across the midfoot; and the shaft (vamp; *I*) and toe box *(H)*, which enclose the forefoot. The exterior outsole *(F)* is often reinforced with a steel shank *(D)* and is attached to the upper at the welt *(G)*. The standard heel *(C)* is ¾-inch high.

quarters are joined at a back seam. The design of the shoe dictates the shape and size of the quarters. For the Oxford shoe, the outside quarter is cut lower than the inside to avoid contact with the malleoli. In the Bal-type Oxford, the back edges of the vamp cover the forward edges of the quarter. The forward edges of the quarters are on the top of the vamp in the blucher style of shoe.

For individuals wearing orthoses and those with foot deformity, the blucher closure is preferable to the Bal-style closure because of its construction. The blucher closure has a separation between the distal margins of the lace stays, thus offering a wide inlet and making the shoes easier to put on and take off and having a readily adjustable circumference. High shoes, which encase the malleoli, provide additional mediolateral stability.

HEEL

The heel is located beneath the outer sole under the anatomic heel. The heel base is usually made of rigid rubber, plastic, or wood with a resilient plantar surface. As heel height increases, the ankle range of motion necessary to lower the forefoot to the floor increases. Weight-bearing pressures (vertical forces) on the forefoot and hallux also increase in midstance to late stance.[3] The individual with limited ankle motion may benefit from a compressible heel base to absorb shock and achieve plantarflexion during the early stance phase. A broad low heel maximizes stability and minimizes stress on the metatarsal heads. Most lower extremity orthoses and prosthetic feet are designed for a specific heel height. The efficacy of the orthosis or quality of the prosthetic gait can be significantly compromised if used with shoes that have higher or lower heels.

REINFORCEMENTS

Strategic shoe reinforcements contribute to foot protection. Toe boxing at the distal vamp shields the toes and prevents the anterior portion of the vamp from losing its shape. The toe box can also be increased in depth to protect and accommodate any toe deformities. The heel counter reinforces the quarters to help secure the shoe to the anatomic heel. The medial counter helps to support the medial arch of the shoe, and the heel counter aids in controlling the rearfoot. The convex shank piece stiffens the sole between the distal border of the shoe heel and the MTP joints and aids in supporting the longitudinal arch.

LASTS

Shoes are constructed over a model of the foot, called a *last*, which is styled from wood, plaster, or plastic. Manufacturers are now converting to computer-aided last designs. Regardless of the origin of the last, it determines the fit, walking ease, and appearance of the shoe. Commercial shoes are made over many different lasts in thousands of size combinations. Most shoes are made with a medial last, which means that the toe box is directed inward from the heel (Fig. 7.3). Shoes can also be made from conventional lasts, straight lasts, inflared or medial lasts, or outflared or lateral lasts.

ENHANCING FUNCTION

Shoes are an essential component of daily professional,[4] leisure, and recreational[5] life. Regardless of the reason for the use of a particular shoe, foot stability is critical to minimizing ankle injury, excessive pronation, and slippage of the heel during the gait cycle. A well-designed shoe provides a broad heel base, ankle collar, and close-fitting heel counter. A keystone of a good shoe is its ability to absorb shock. The construction of and materials used for the insole, midsole, and outer sole determine the amount of shock absorption that the shoe will provide.[6]

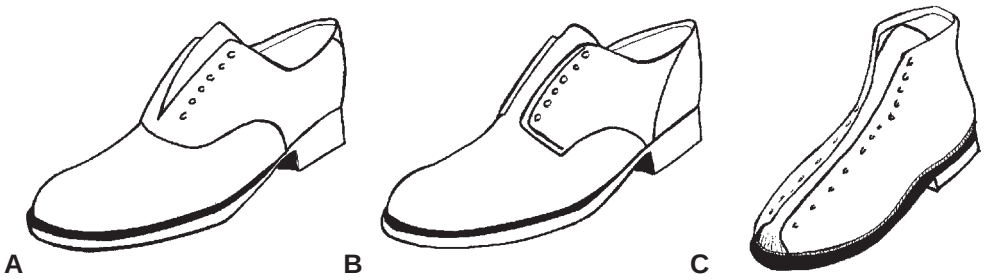

Fig. 7.2 Three types of shoe closures. (A) In the Bal Oxford, the tongue is a separate piece sewn to the vamp and anterior edges of the quarters. (B) In the blucher style, the tongue is an extension of the vamp and can be opened slightly wider. (C) For patients with rigid ankle orthoses, fixed deformity, or fragile neuropathic feet, the lace-to-toe (surgical) style may be necessary.

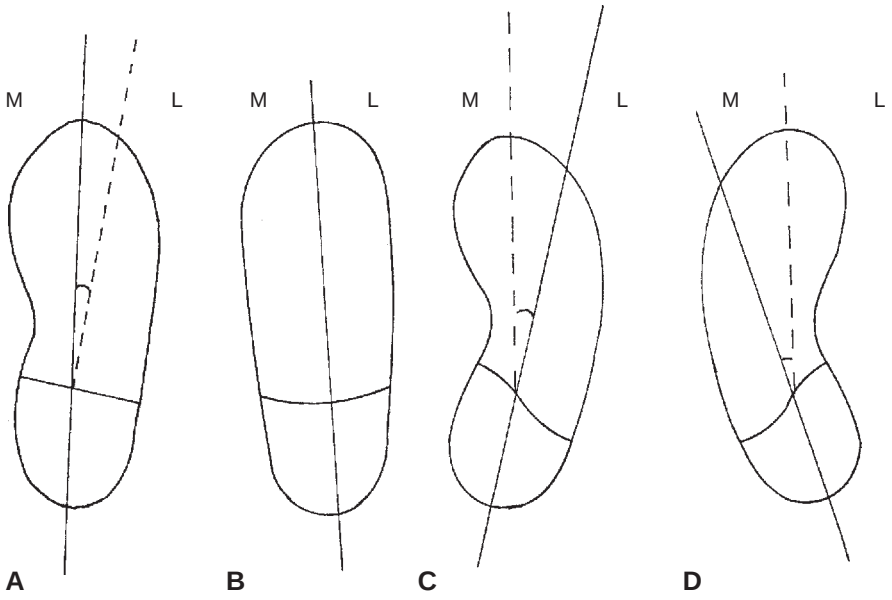

Fig. 7.3 The last determines the shape of the shoe. (A) In a conventional last, the forefoot is directly slightly lateral *(L)* to the midline. (B) A straight last is symmetric around the midline. (C) An inflared last directs the forefoot medially. (D) An outflared last directs the foot more laterally than a conventional last. *M*, Medial.

A good shoe must be flexible and provide stability with each step. Flexible construction is especially important in the sole to enhance the toe rocker in late stance phase. The sole should also provide adequate traction as it contacts the ground, especially in early stance as body weight is transferred onto the foot. A coefficient of friction that is sufficient to minimize slips and near slips is vital. Heel height can create stress on the forefoot during gait. Heels of more than 1½ inches exponentially increase weight-bearing forces on the metatarsal heads.[7]

The ability of a shoe to handle moisture is also an important consideration. For optimal foot health and comfort, perspiration must be wicked away and, at the same time, external moisture kept out.

The upper should be soft and pliable. Modern tanning techniques can create strong but supple uppers that surround the feet supportively and protectively without rubbing and chafing while also allowing the foot to breathe.

ORTHOTIC-RELATED FUNCTION

A molded insole contributes to foot stability, shock absorption, and a transfer of shear forces away from problem areas. Orthoses can enhance the function of the shoes. Chapter 8 presents the principles and practices of orthotic prescription in commonly occurring conditions of the foot.

Proper Fitting of a Shoe: "If the Shoe Fits"

The two primary determinants of proper shoe fit are the shoe's shape and size. *Shoe shape* refers to the shape of the sole and the upper. Proper fit is achieved when shoe shape is matched to foot shape. *Shoe size* is determined by arch length, not by overall foot length. The proper shoe size is the one that accommodates the first metatarsal joint in the widest part of the shoe. Properly fitting shoes are important in avoiding foot discomfort and deformity and are absolutely essential for individuals with arthritis, diabetes, and other foot disorders.[8]

Great variability is found in human foot size and shape. Mass-produced shoes, however, are formed over fairly standard lasts that give a shoe its special size and shape. In the well-fitting shoe, the shape determined by the last approximates the human foot. The design and construction of the shoe should allow for a roomy toe box; it should be wide enough for normal toe alignment and be ½ inch longer than the longest toe. Proper fit of the forefoot in the shoe can be a critical factor in reducing the incidence of bunions, hammertoes, and other forefoot deformities. In general, the shoe should be wide enough to accommodate the widest part of the forefoot. A tracing of the foot (standing) should fit within an outline of the shoe bottom.

Proper fit presupposes proper design, shape, and construction and is fundamentally wedded to availability in widths as well as lengths. It is important that the clinician cultivate a consumer mindset that realizes the medical importance of modifying the old cliché "if the shoe fits, wear it" to "if the shoe fits, wear it, and if it doesn't, order it in the correct size."

DETERMINING MEASUREMENTS

The average shoe salesperson does not offer to measure the foot, instead relying on the consumer to know his or her foot size. However, because foot size changes over time, periodic measurement of both feet for length and width is important. Many shoe styles that are available in retail shoe stores do not appropriately match the shape of an individual's foot. As a result, comfort and protection are compromised in the name of "style." This is especially problematic in the presence of foot deformity. Hallux valgus is a foot deformity that is aggravated by wearing shoes that are too narrow across

the metatarsal heads and triangularly shaped in the toe box. Shoes should be wide enough to allow the material of the upper that surrounds the widest region of the forefoot (i.e., the metatarsal heads) to be compressed at least 1/16 inch before bony contact is made. Likewise, there should be a space of at least ½ inch between the tip of the longest toe and the front of the toe box in weight bearing (generally the width of the thumb).

In the United States, 12 standard shoe widths are manufactured.[1] They range from the very narrow AAAAA to the very wide EEEE—that is, AAAAA, AAAA, AAA, AA, A, B, C, D, E, EE, EEE, EEEE. Because most retail stores stock shoes of midrange widths (A–E), patients with narrow or wide feet often have difficulty finding shoes of the optimal width.

Standard U.S. shoes are available in half-size increments, from an infant's size 0 to a man's size 16. The difference in length between half sizes is 1/16 inch. Standard shoe-sizing classifications are made by groups and lasts: infants' sizes 0 to 2; boys' sizes 2½ to 6; girls' sizes 2½ to 9; women's sizes 3 to 10; and men's sizes 6 to 12. Sizes larger than women's size 10 and men's size 12 must often be specially ordered. A U.S. women's shoe size is usually three half sizes smaller than the corresponding men's size (e.g., women's size 9 is the same as a men's size 7½).

European and U.K. manufacturers use a different numbering system. The comparison of European and U.K. women's to men's sizes is based on centimeters (e.g., women's size 38 EUR/5 UK is the same as men's size 40 EUR/5 UK). Table 7.1 compares the standard sizes for U.S., European, and U.K. shoe manufacturers and lists the measures for each size.

Table 7.1 Comparison of Standardized Shoe Sizes

United States	Europe	United Kingdom	Centimeters
WOMEN'S SIZES			
3	34	1	20
3½	34.5	1.5	20.5
4	35	2	21
4½	35.5	2.5	21.5

FOOT CONTOUR

Foot contour changes throughout the life cycle. Aging, pregnancy, obesity, and everyday stresses on the foot cause it to widen. Deformities such as bunions increase the width and shape of the foot, and splaying of the metatarsal heads creates a collapse of the transverse arch, further increasing the width of the forefoot.[9] Forefoot height may increase in the presence of toe deformities. Deformities such as pes planus[10] (foot flattening) or pes cavus[11] (high arches) change the contour of the midfoot. The shape of the foot must be considered and accommodated when an individual is measured for shoes. Often a "combined last" (where the last in the toe box is different from the rearfoot counter) is required to accommodate the contour of the foot. The relationship of the forefoot to the rearfoot is an important consideration in determining if the shoe shape, provided by the last, corresponds to the shape of the foot. Shoes with medial, straight, or lateral lasts can be ordered to best meet patient needs.

OBESITY AND EDEMA

Obesity in children[12] and adults[13] has been shown to affect the medial longitudinal, lateral longitudinal, and transverse arches of the foot as well as to increase the length and the width of the foot. The increased body weight puts even more strain on the plantar fascia and the ligaments of the plantar surface of the foot. Individuals exhibit overpronation with collapsing arches. With repetitive weight-bearing activities such as standing and walking, those structures begin to buckle under stress. The additional mechanical stress of carrying excess weight takes its toll on the feet, often resulting in problems such as plantar fasciitis, arthritis and bursitis, heel pain, neuroma, and gait changes.[14]

Proper shoe fitting is essential for preventing the secondary foot problems that stem from ill-fitting shoes. Overweight individuals should be encouraged to have their feet measured regularly, particularly if they have had a significant weight gain. It is often helpful to shop for shoes at the end of the day, when the feet are largest, and the shoe fitting should be done with the person standing to ensure that there is ½ inch between the end of the longest toe and the edge of the toe box. The shoes should be comfortable the moment they are worn.

Fluctuation in foot size in individuals with edema (e.g., those with kidney dysfunction or congestive heart failure or anyone who is taking diuretic medication) creates a challenge when shoes are being fitted. The contour of the foot is constantly changing. For someone with severe edema, a shoe/sandal with a Thermold Velcro closure (Fig. 7.4) is recommended to accommodate and support the foot and prevent the undue pressures imposed by a shoe that becomes too small during the course of the day. The consequences of ill-fitting shoes—especially shoes with a narrow tow box—are foot problems such as bunions, valgus deformity, and neuromas. Many of these problems can be prevented by the habitual use of properly fitting shoes.[1]

Fig. 7.4 Velcro closure shoe/sandal. Adjustable Velcro closures are recommended to accommodate edematous feet and prevent tissue damage due to high pressure. (Silvert's Stores, Concord, Ontario, Canada.)

Special Considerations

Feet come in many shapes, sizes, and conditions of health. The biomechanical and functional characteristics of feet change over an individual's lifetime and must also be reflected in shoe choice. An infant's foot must adapt to weight bearing, especially as walking becomes functional. The foot of a child continues to adapt as normal growth changes alignment of the pelvis, femur, and tibia. The influence of hormones during pregnancy also affects the structure and function of the foot. Finally, the combined influence of the aging process, obesity, and diseases that are common in later life can create special footwear needs for older adults.

PEDIATRIC FOOT

Many pediatric and lower extremity foot disorders are minimally symptomatic and do not require treatment, whereas others require more aggressive management. An understanding of the natural history of many of these disorders is important in establishing the appropriate footwear for toddlers and children as they begin to walk and run.[15–17]

In-toeing is a problem caused by positional factors in utero and during sleep, muscle imbalances due to paralytic disorders, and decreased range of motion in the lower kinetic chain. It may also be due to metatarsus adductus, internal tibia torsion, or internal femoral torsion.

Metatarsus adductus is characterized by a bean-shaped foot that results from adduction of the forefoot. In most children (approximately 90%), this disorder resolves spontaneously.[15] If it does not improve over the first 6 to 12 weeks of life, the treatment of choice is manual stretching and/or an outflared shoe. The bones of the foot are soft and can be corrected with positioning in the outflared shoe (reverse last) or Bebax shoe (Camp Healthcare, Jackson, MI).

Internal tibial torsion is a twist between the knee and the ankle. Generally this torsion disappears by 5 years of age. Torsion can be exacerbated by abnormal sitting and sleep postures with the foot turned inward. The Dennis Browne bar or the counterrotation splint is used in combination with a reverse last shoe to remodel the bones during growth. Persistent severe toeing created by internal tibial torsion requires a derotational osteotomy of the tibia/fibula in the supramalleolar region.

Internal femoral torsion can also be the cause of in-toeing with a twist between the knee and hip. Neither splints nor shoes are effective in treatment of torsion. Habitual sitting in the "W" position (e.g., when a child is watching television or playing games on the floor) can aggravate the problem. Children with internal femoral torsion should be encouraged to sit cross-legged as an alternative.

Out-toeing occurs in children who sleep in the frog position and have soft tissue contractures around the hip. This is usually a hip or a long bone torsion problem and is not affected by footwear.

Toe walking can be the result of an in utero shortening or a congenital shortening of the Achilles tendon but can also be an early sign of cerebral palsy, muscular dystrophy, or Charcot-Marie-Tooth disease.[18] Until 4 years of age, the ability to stretch the tendon is well preserved, and conservative treatment includes stretching, casting, ankle-foot orthoses, and/or a night splint. Z-plasty lengthening is performed if conservative interventions fail.[18] Shoe prescription objectives follow the same principles as those in the older adult with Achilles tendinitis.

Flexible and Rigid Flatfoot

Flatfoot or pes planus is defined at the loss of the medial longitudinal arch. Flatfoot is classified as either flexible or rigid. A flexible flatfoot has an arch that is present in open kinetic chain (non–weight bearing) and lost in closed kinetic chain (weight bearing). A rigid flatfoot has loss of the longitudinal arch height in open and closed kinetic chain.[19] Treatment of flatfoot disorders in children is approached through proper fitting shoes with good arch support and if necessary orthotic inserts in the shoes. Fitting children with standardized shoes that have good arches, be they dress shoes or athletic shoes, can support fallen arches and pronated feet. When additional support is necessary, insole orthotics can be added.[18,20] The shoe used to treat flatfoot is designed to correct heel valgus and supports the arch. Forefoot pronation is achieved by using a lateral shoe wedge combined with a medial heel wedge. A scaphoid pad supports the arch, and a strong medial counter prevents medial rollover. A Thomas heel is often used to provide additional support for the arch. In-shoe orthotics are prescribed to improve arch alignment, increase the duration of the stance phase of level walking, and reduce both the maximum foot pronation angle and tibial internal rotation.[18,19] Orthotics have been shown to reduce foot pain in children with flatfoot.[19]

The *calcaneovalgus* deformity is a congenital condition that is usually secondary to the individual's initial position in utero. The heel is in severe valgus and the foot is dorsiflexed so much that it rests against the anterolateral aspect of the tibia. Most cases correct spontaneously. Treatment of

the severe cases includes stretching and serial casting. Some rare severe cases, left untreated, persist into adolescence as pes planus.

An *accessory navicular bone* is a small ossicle at the medial tuberosity of the navicular. Individuals with an accessory navicular bone often complain of pressure and discomfort while wearing shoes. Often, placement of a prefabricated arch support in the shoe lifts the arch just enough to minimize rubbing on the shoe.

Hallux valgus (bunions) is most often the consequence of rearfoot valgus, leading to varus of the first metatarsal. The conservative approaches to treating this condition in children are orthoses and comfortable shoes, with a good heel counter to maintain the heel in subtalar neutral.

Curly toes involve the congenital shortening of the flexor tendons. Treated conservatively, flexors are stretched, and a rocker-like insole is used in the shoe to support the toes in extension. Shoes must have extra depth with plenty of room in the toe box.

Shoe prescription for these biomechanical problems of the foot and lower extremity in childhood is as valuable as a conservative corrective intervention. Overall, if a child's foot is developing normally and does not exhibit any signs of an abnormality, a soft-soled shoe is appropriate. If some degree of abnormality exists, a more supportive, rigid shoe is indicated for toddlers. In general, the stiffer the heel counter, the more effective the intervention.

The most common prescription shoe for young children is a straight-last shoe. This type of shoe is roomy enough to accommodate pads or wedges. In addition, a straight-last shoe does not generate any abnormal forces against the child's foot.

FOOT DURING PREGNANCY

During pregnancy, women may experience problems in their lower extremities, including edema, leg cramps, restless legs syndrome, joint laxity, and low back pain. As a result, foot pain is a common problem in pregnant women.[21,22] An important consideration is the provision of shoes with maximum shock absorption. Gel-cushioned running shoes are recommended, especially if women continue to jog or walk for exercise. Expectant mothers are also advised to exercise on soft surfaces to prevent problems caused by repetitive pounding on unforgiving surfaces.

High-heeled shoes exaggerate the lordotic curve and are inadvisable during pregnancy. As weight distribution shifts with advancing pregnancy, especially if edema occurs, many women choose to wear shoes with laces or a Velcro closure. Athletic and walking shoes provide good support, excellent cushioning, and a solid heel counter. If a heel is desired for special occasions, a 1-inch or lower-heeled shoe should be recommended. Even low but tiny tapered heels cause women to wobble as they walk.

Many women find that their feet have "grown" during pregnancy; after having returned to prepregnancy weight and clothing, their shoes no longer fit. Measurements often reflect an increase in shoe length of a half to a full size. The stress of extra body weight coupled with ligamentous laxity can reduce arch height, adding length to the feet. This process is a normal age-related change in foot structure, associated with wear and tear of the body over time, which is hastened during pregnancy. The hormonally induced tissue laxity of pregnancy leads to a broader forefoot as the metatarsal heads separate and the distal transverse arch flattens and to a longer foot as the longitudinal arch is less efficiently supported by soft tissue structures. For this reason, pregnant women are advised to wear a larger shoe size, with a square or deeper toe box or both, especially if edema is also a problem.

Gabriel et al., in a research study titled *Anthropometric Foot Changes During Pregnancy*, concluded that "the foot of the pregnant woman tends to flatten during gestational weeks 12 to 34, taking a more pronated posture, and the anthropometric changes in late pregnancy result in increases in foot length and forefoot width, changes that seem to be moderate."[23] The hormonal changes during pregnancy—which cause ligamentous laxity, flattening of the medial longitudinal arch, excessive pronation of the foot, and pregnancy-induced forward displacement of the center of gravity—cause foot pain, increased strain on the axial skeleton, and reduced efficiency of gait. Foot orthotics to support the metatarsal heads and medial longitudinal arch, placed in shoes with good shock-absorbing ability, can help decrease foot discomfort and prevent injury to the low back during pregnancy.[24]

FOOT IN LATER LIFE

Foot problems are among the most common complaints of older adults. Nearly one-third of community-dwelling adults 65 of age or older experience a fall.[25] Falls are the leading cause of both fatal and nonfatal injuries in older persons and often result in functional declines, institutionalization, and decreased quality of life. Researchers explain that the reasons for falls among the elderly are multifaceted and often the result of a combination of intrinsic (e.g., preexisting disease or chronic conditions, polypharmacy, muscle weakness, functional limitations, and vision impairment) and extrinsic risk factors such as hazards in the home and poor footwear. The increase risk of falls in the elderly has led to investigating factors that contribute to falls.[25] One of the factors associated with loss of balance and falls is the type of footwear worn.[26–28] Researchers investigated what elderly patients wear on their feet to help address the problem of frequent falls in the elderly population.[27] Elderly persons often wear poorly fitted shoes, slippers, and sandals that contribute to poor balance and increase the risk of falls. In the study, "Risk factors for falls in older citizens," the researchers identified bad footwear as an extrinsic factor that contributes to falls.[25] Persons in hospital settings wearing hospital slippers are at greater risk for falls.

Gait and foot problems in older adults are associated with diseases that are common in later life and with the aging process itself. Examples of conditions that can compromise gait and foot function include the residuals of congenital deformities, ventricular enlargement, spinal cord diseases, joint deformities, muscle contractures, peripheral nerve injuries, peripheral vascular disease, cerebrovascular accidents, trauma, ulcers, arthritis, diabetes, inactivity, and degenerative and chronic diseases. The anatomic and biomechanical considerations of podogeriatrics focus on the

interrelationships of the rearfoot, midfoot, and forefoot established by osseous, muscle, and connective tissue structures. The movement of one joint influences movement of other joints in the foot and ankle. Soft tissue structures establish an interdependency of the foot and ankle to the entire lower limb. As tissues age, they become stiffer, less compliant, weaker, and more vulnerable to breakdown.

Foot contour alters with aging; the foot gets wider, and bunions and splaying occur from collapse of the transverse arch. Forefoot height increases in the presence of toe deformities. Fat pads under the metatarsal joints atrophy and shift position distally, whereas the calcaneal fat pad atrophies and shifts laterally. These changes leave bony prominences that are vulnerable to breakdown.

In persons with type 2 diabetes, the development of Charcot joints (neuropathic arthropathy) is a relatively painless, degenerative, progressive neuropathic destruction of the bony architecture. The ankle mortis and the tarsal and metatarsal joints are most frequently affected.[29] a relatively painless, progressive, and degenerative destruction of the tarsometatarsal or MTP joints.

With the sensory losses that are common in type 2 diabetes, these joints are subjected to extreme stresses without the benefits of normal protective mechanisms. Capsular and ligamentous stretching, joint laxity, distention, subluxation, dislocation, cartilage fibrillation, osteochondral fragmentation, and fracture occur. Motor impairment contributes to wasting of muscles in the feet and permits digital contractures to compensate for dynamic muscular imbalances. Thus Charcot collapse may lead to the development of a rocker-bottom foot and increases the likelihood of developing hammertoe deformities.[29]

Many elderly persons with type 2 diabetes attribute their problem with walking to pain or a sense of unsteadiness, stiffness, dizziness, numbness, or impaired proprioception. Prevention of foot ulcers due to poor circulation, poor sensation, and ill-fitted footwear is critical for persons with diabetes. Persons with type 2 diabetes and dysvascular foot disease have greater need for specialized footwear such as custom-molded shoes.[30,31]

Physical therapists work with elderly individuals to reduce pain, improve circulation through exercise, increase muscle strength, improve balance and flexibility, and modify the reaction times of movements in order to maximize the individual's functional abilities and upright mobility. Assessing the elderly individual for appropriate footwear is a fundamental requirement for enabling him or her to become functional in ambulation.

The majority of foot problems in geriatric patients can be managed with proper shoe fitting and minimal shoe modifications. The most inexpensive footwear for this patient population comprises running or walking shoes. These are less expensive and fit within a fixed-income budget. They provide good foot support and can be purchased with Velcro straps for closure if hand function or foot edema is a problem. The Thermold shoe is also appropriate for many of the pathologic and structural deformities with which the older patient must deal that do not involve unhealed foot ulcers. When foot ulcers are present and prevention of limb loss is critical, more extensive therapeutic interventions are required, such as removable or nonremovable foot casts.[32]

Choosing Appropriate Footwear and Socks

A vast and somewhat bewildering variety of "off-the-shelf" footwear is available to consumers. Many shoes are designed with certain types of activities in mind. An understanding of their design and construction, as well as ensuring proper fit, can enhance foot health and minimizes the risk of foot dysfunction, injury, and pain.

ATHLETIC SHOE GEAR

Many people jump into fitness activities "feet first" and develop blisters, calluses, and other foot injuries because of inappropriate footwear. A well-fitting activity-appropriate athletic shoe enhances enjoyment of the activity by protecting and supporting the foot and minimizing injury. Athletic shoes are designed for specific activities. A running shoe is designed with a high-force heel impact and forward foot movement in mind; the various shoe models have specific features that are designed for different surface conditions and distances in running. Basketball shoes do not provide as much cushioning as do running shoes but instead focus on foot support during quick lateral movement. Aerobic shoes are also designed for lateral movement but provide more cushioning for the impact anticipated on the ball of the foot. Shoe soles are also designed for the surface on which the activity is performed. Some shoes are manufactured as cross-training shoes so that they can go from the workout in the gym to jogging, but they are not designed for high-mileage runners.

Determining the foot type is important in prescribing the best shoe. For individuals with a flat, low-arched foot, a shoe that provides maximum stability to prevent the foot from rolling in with each step is required. High-arched feet demand a shoe that is more flexible. "Normal" feet do best in a shoe that combines the last to accommodate the heel and the forefoot and that has forefoot flexibility. The size and shape of the toe box must also be considered. Enough room should be available in the toe box to prevent blisters, ulcers, and chafing of the toes. Shoes made from materials that "breathe," so that perspiration can escape, are desirable. Athletic shoes are best used only for their intended activity and should be replaced at regular intervals to maximize their effectiveness.

Most athletic footwear is available in medium widths, although a few manufacturers provide shoes in several widths. Children's athletic footwear is available in narrow, medium, and wide widths. Women's athletic footwear may be available in AA, B, and D widths. Men's athletic footwear may be available in B, D, EE, and EEE widths. The key element in proper fit of athletic shoes is comfort from the moment the shoe is put on, with no break-in period needed. The shoe should also provide adequate support and shock absorption for the sport or activity that is being pursued.

WALKING SHOES

A well-designed walking shoe provides stable rearfoot control, ample forefoot room, and a shock absorption heel and sole. This type of footwear may be specifically designed by an

athletic footwear manufacturer or even by an orthopedic footwear manufacturer. Walking shoes are available in various widths and in several different lasts. Long medial counters, Thomas heels, and crepe soles can be used to modify this type of shoe gear to meet specific needs.

DRESS SHOES

Despite the fashionable preference for shoes with narrow or pointed toes and slim high heels, the most foot-friendly dress shoe for women is a rounded-toe Mary Jane style with boxy heels. A good dress shoe approximates the shape of the individual's foot and provides flexibility and sufficient shock absorption. Prerequisites of a good dress shoe include a roomy toe box, low stable heel, proper width in the ball of the foot area, flexible outsole with skidproof bottoms, and arch support.

Triangular toe boxes and high heels, no matter how dainty, are best avoided because they can and do cause deformity. For a high-heeled shoe to stay on the foot, it must fit closely around the toes, resulting in no room for anything but the foot. The foot is virtually unsupported at the distal end of the shank, and extreme high pressure is present under the metatarsal heads. Heels higher than 2 inches make any kind of orthosis ineffectual. Because the angle of the foot causes the heel of the orthosis to lift up, high heels can transform an orthosis into a catapult. Although orthoses can help to relieve metatarsal and heel pain and provide arch support, they cannot offer any corrective features in a shoe that is designed so unnaturally for the human foot.

SOCKS

The sock is often overlooked when shoes of any kind are prescribed. Socks can aid in shock absorption, shield the skin from abrasion by the shoe stitching and lining, and prevent skin irritation from shoe dyes and synthetic leather materials. Additionally, clean, freshly laundered socks are integral to a sanitary foot environment. Unbleached white cotton socks are ideal because they lack dyes, are hypoallergenic, and absorb perspiration readily. Cotton socks also provide ample toe room, unlike socks that are made from stretchable fabric, which can crowd the toes.

The size and style of socks also influence foot health. Socks that are too short crowd the toes; those that are too long wrinkle within the shoe, creating potential shear pressure points. If knee-high socks are worn, the proximal band must not be unduly restrictive; similarly, the use of circumferential garters to hold socks can impede circulation to the foot. Any holes worn into a sock also potentially create shear pressures, and such a sock should be discarded. Mended holes in socks, because of the difference in thickness and materials, can irritate delicate or insensate soft tissue. An open hole at the toes pinches and constricts the digits, with excessive friction at the edges of the hole.

Specially designed socks that support and cushion the insensitive foot or athletic/military foot that is exposed to repetitive frictional forces are commercially available.[33] Use of these specially designed socks not only reduces the frictional shearing forces but also significantly decreases vertical ground reaction pressure forces, preventing blistering and ulceration.[30] Extra high-density padding functions as a natural fat pad, reducing the destructive effects of shearing forces and pressure and friction in the toe area. The concept of supportive socks is beneficial for patients with insensitive feet. It has also been used for individuals involved in aerobic exercise, baseball, basketball, cycling, golf, hiking, trekking and climbing, skiing, tennis, walking, and running.

Prescription Footwear, Custom-Molded Shoes, Accommodative Molded Orthoses, and Shoe Modifications

Alteration of foot function and alignment can be accomplished with one or more of the following strategies: use of foot orthoses[34] or prescription shoes[35] and modifications of shoes themselves.[36] These strategies are used to relieve pain and improve balance and function during standing and locomotion. Such alternatives are indicated when a transfer of forces from sensitive to pressure-tolerant areas is needed to reduce friction, shock, and shear forces; to modify weight transfer patterns; to correct flexible foot deformities; to accommodate for fixed foot deformities; and to limit motion in painful, inflamed, or unstable joints.

When special protective or prescription footwear is being considered, the functional objectives must be clearly stated so that the appropriate specific prescription can be developed. Careful examination of the foot helps the clinician identify pathologic conditions or mechanical factors, or both, that must be addressed and choose the appropriate materials and footwear styles to meet the patient's specific needs.

MOLDABLE LEATHERS

Thermold is an example of prescription footwear that can be used to protect feet that are vulnerable due to vascular insufficiency, neuropathy, or deformity. It is a cross-linked, closed-cell polyethylene foam laminated to the leather upper of the footwear that can be heat-molded directly to the foot. This makes modification for foot deformity easily managed and far less expensive than custom molding. Thermold shoes are also available in extra-depth styles, with a removable ¼-inch insole. Extra-depth shoes enable adequate room for custom-made insoles or orthoses to become an intricate adjunct to the footwear. In some instances, the Thermold can be used as an alternative to custom-molded footwear.

CUSTOM-MOLDED SHOES

Some foot problems cannot be accommodated in conventional footwear; the best solution then is custom-molded footwear. This footwear is molded directly over a plaster reproduction of the foot rather than a standard last. Special modifications—such as toe fillers, Plastazote, rocker bars, and elevations—can be added during manufacturing to meet the specific requirements of each foot. Because of this process, custom-molded shoes are made to conform to the foot shape in all respects (Fig. 7.5). Custom orthopedic shoes represent the ultimate combination of function and aesthetics. Incorporating biomechanics and craftsmanship,

Fig. 7.5 Examples of custom-molded shoes. These shoes are prescribed when foot deformities are too severe for accommodation in a conventional shoe. (Ottawa Foot Balance, Ottawa, Ontario, Canada.)

custom-molded shoes can redistribute weight, restrict joint motion, facilitate ambulation, and decrease the probability of neuropathic ulceration.[34,37,38]

PLASTAZOTE SHOE OR SANDAL

For patients with insensitive or ulcerated feet, a "healing sandal" or Plastazote shoe is often prescribed. This custom shoe is fabricated using a plaster cast of the individual's foot for construction.[39] Temporary protective footwear, such as a Plastazote boot or shoe or a healing sandal, is often used while a neuropathic ulcer heals so as to allow for ambulation without pressure on the healing area, especially for patients who are unable to walk or who are noncompliant with non–weight-bearing ambulation.

SHOE MODIFICATIONS

Various shoe modifications can be used to address functional and anatomic deformities of the foot and leg. Clearly stated objectives, based on careful evaluation, ensure that the appropriate shoe modifications are chosen.

Lifts for Leg-Length Discrepancy

For patients with leg-length discrepancy of ⅜ inch or more, a full-length external lift can be mounted to the sole of the shoe on the shorter limb to equalize leg length and reduce proximal stresses at the hips and spine. If the length difference is less than ⅜ inch, the discrepancy can usually be accommodated with an orthotic heel wedge worn inside the shoe. If the discrepancy is a result of a unilateral equinus deformity, a heel wedge can be attached to the external surface of the shoe. Leg-length discrepancy is a common result of a hip fracture, congenital anomaly, or biomechanical imbalance such as pelvic rotation, hip anteversion or retroversion, or unilateral foot pronation. The level of the pelvis and absolute and relative measures of leg length should be part of a comprehensive gait evaluation.[40]

Heel Wedging

Wedging is used to alter lines of stress to facilitate a more normal gait pattern. The most effective wedges range from ⅛ to ¼ inches in thickness at their apex. Larger wedges tend to cause the foot to slide away from the wedge toward the opposite side of the shoe, drastically reducing the effectiveness of the modification. Wedging is useful for children with a rotational problem, such as tibial torsion. In adults, wedges are used for accommodation in conditions such as a fixed valgus deformity of the calcaneus (Fig. 7.6).

A medial heel wedge is used when flexible valgus of the calcaneus is present (Fig. 7.7A). As the wedge elevates the medial heel, a resultant varus tilt acts on the calcaneus, preventing excessive pronation of the foot. A lateral heel wedge is used when flexible varus of the calcaneus is present (see Fig. 7.7B). Elevation of the lateral heel decreases the medial drive on floor contact at heel strike, tipping the calcaneus into valgus. A full heel wedge is sometimes used in the presence of fixed or functional equinus deformity. The goal of wedging is to obtain a subtalar neutral position during the stance phase of gait.[41]

Sole Wedging

Wedging can also be used to modify midfoot and forefoot positions. A medial sole wedge produces an inversion effect on the forefoot. This wedge is positioned along the medial aspect of the footwear, from a point just proximal of the first metatarsal head to the midline of the footwear (see Fig. 7.7C). Conversely, a lateral sole wedge creates an eversion effect at the forefoot. This wedge is placed proximal to the fifth metatarsal head to the midline of the footwear. The apex of this wedge is the fifth metatarsal head (see Fig. 7.7D).

A Barton wedge (see Fig. 7.7E) is used in the presence of severe flexible pronation deformities, such as those seen in pes planus, when control of the midfoot is the goal. The Barton wedge, usually made with 3/16-inch leather, extends along the medial side of the foot to the midtarsal joint and tapers laterally just anterior to the cuboid bone. It provides support to the navicular and helps invert the calcaneus. It is used when it is necessary to shift body weight laterally. When a Barton wedge is used, the shoe must have a firm medial counter. The Barton wedge can be incorporated in an internally placed lateral heel wedge for patients with fixed calcaneal varus or clubfoot deformity. Because an internal wedge is closer to the target deformity, it creates a positive force of greater magnitude than is possible with the external Barton wedge. Instead of tilting the footgear, the wedge tilts the calcaneus into the desired position.[42]

Fig. 7.6 A heel wedge provides elevation of the heel for equinus deformity. (Dr Richard Blake of San Francisco.)

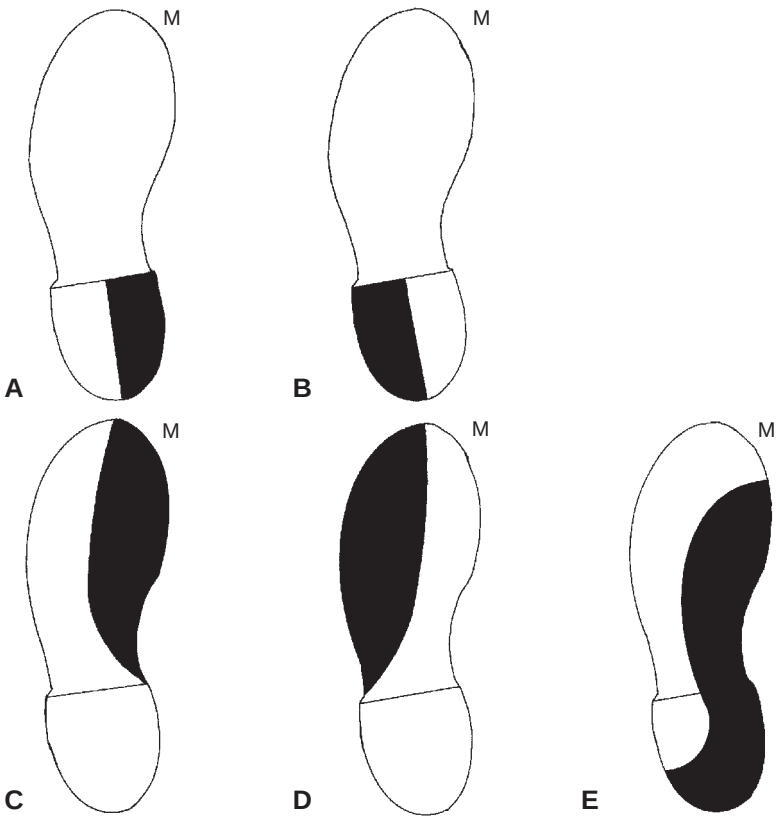

Fig. 7.7 Examples of heel and sole wedge modifications. A medial *(M)* heel wedge (A) is used when flexible valgus of the calcaneus is present; a lateral heel wedge (B) is used for flexible varus of the calcaneus. Medial sole wedges (C) create an inversion effect of the forefoot, whereas lateral sole wedges (D) create an eversion effect. A Barton wedge (E) supports the navicular bone and helps invert the calcaneus, shifting the body weight laterally.

Metatarsal Bars and Rocker Bottoms

A metatarsal bar is a block of material (usually stacked pieces of leather or rubber) attached to the sole of the shoe. Its placement proximal to the metatarsal heads significantly reduces pressure at the metatarsal heads during the push-off phase of the gait cycle.[43,44] The curved distal edge of the metatarsal bar is designed to follow the curve of the metatarsal heads. It is commonly used to adapt shoes worn by patients with transmetatarsal amputations, fixed arthritic deformities, diabetes, forefoot deformities such as hallux rigidus, and neuromas. The placement of a metatarsal bar or rocker facilitates push-off by simulating forward propulsion in the absence of metatarsal flexibility.

Rocker bottoms are made of either lightweight crepe or leather (Fig. 7.8). These modifications are flush with the heel and toe in an arch with an apex of ½ to ⅝ inch. The rocker bar redistributes body forces over the entire plantar surface of the foot while it is bearing weight. It facilitates a smooth roll during the stance phase of gait while reducing sheer stress and trauma to the midfoot and forefoot. It is often used to modify shoes worn by patients with partial foot amputations, arthritis, and diabetes. It is also used for patients who have any lower extremity orthosis that limits forward progression of the tibia over the foot and toes during the middle and late stance phases. For patients with diabetes, a rigid rocker sole (a steel-spring heel-to-toe with the toes extended and a rocking axis near the center of the foot) can be used to help distribute body weight and compel knee flexion at toe-off, thus reducing the length of stride and shear stress on the metatarsal heads.

Thomas Heels

"Thomas heel is a corrective shoe in which the heel is approximately 12 mm longer and 4 to 6 mm higher on the medial edge. This produces varus of the foot and prevents depression of the head of the talus."[45] The Thomas heel is designed to improve foot balance and relieve excessive pressure on the shank portion of the footwear. Applied as either a lateral or a medial flare of the heel, its goal is to increase stability during gait by assimilating subtalar neutral. A laterally flared heel is used with a rearfoot varus to decrease the incidence of inversion injuries. A medially

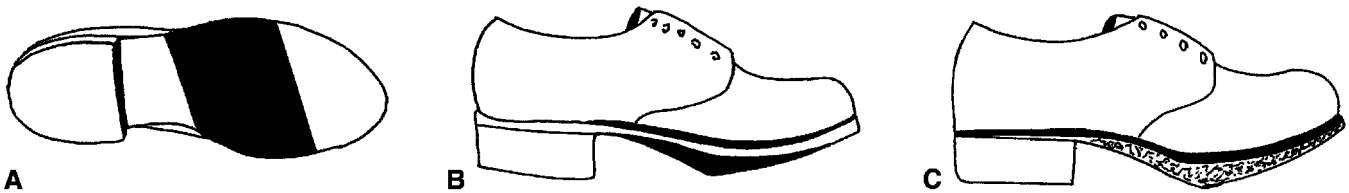

Fig. 7.8 Examples of rocker-bottom soles. A metatarsal bar (A) prevents undue pressure at the metatarsal heads during push-off in late stance. A rigid leather rocker sole (B) or an extended crepe rocker bar (C) redistributes body weight over the entire plantar surface, facilitating a smoother and more normal gait pattern while reducing stress and trauma in the forefoot.

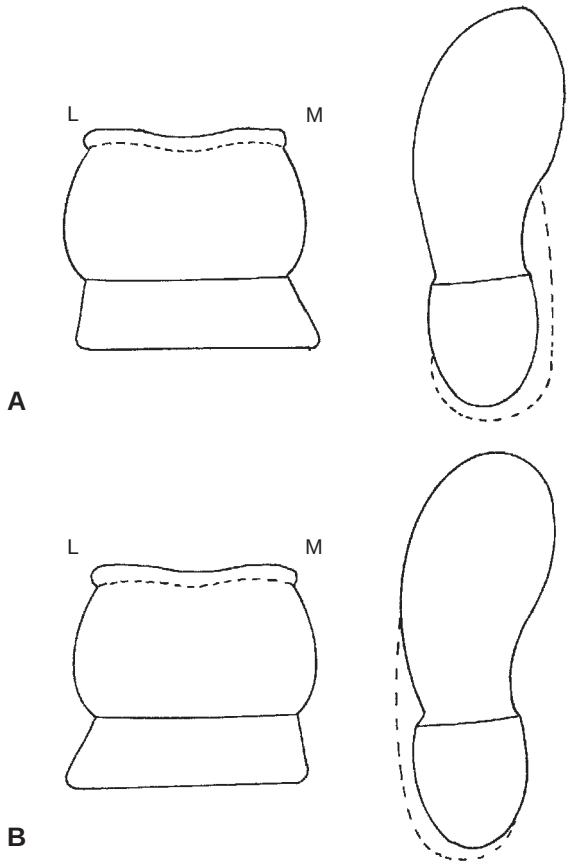

Fig. 7.9 Examples of Thomas heels. (A) A medial *(M)* flared heel provides a broader base of support and prevents eversion of the ankle. (B) A lateral *(L)* flared heel prevents inversion of the ankle.

flared heel is used with a rearfoot valgus to decrease the incidence of eversion injuries (Fig. 7.9). For instance, a medial flare from the heel to the sustentaculum tali prevents excessive pronation of the foot during gait.

Offset Heels and Shoe Counters

The offset heel is a modification used to help correct valgus or varus deformities. It offers a broad support base, especially at the superior surface of the heel, where the broad buildup against the shoe's counter provides reinforcement either medially or laterally. A heel counter is an extension along the medial or lateral borders of the shoe from the heel to the proximal border of the fifth or the first metatarsal head. This shoe modification strengthens the shank portion of the footwear for better control of the hind foot. The heel counter is often used in combination with the appropriate Thomas heel. A counter can also be placed medially or laterally in the midfoot region. A patient whose gait exhibits excessive pronation, as is common in rheumatoid arthritis (RA), may require a firm medial counter to prevent the shoe from collapsing medially and to assist in realigning the foot into a neutral position.

Attachments for Orthoses

For some patients with neuromuscular dysfunction (e.g., hemiplegia, paraplegia, multiple sclerosis), a traditional metal double-upright lower-extremity orthosis can be prescribed. If so, the shoe must be modified: a U-shaped orthotic bracket (stirrup) is attached to the shoe by means of three copper rivets, one on the heel and two in the shank. The metal is riveted through the outsole to the insole. To accomplish this, the heel is removed and the plate of the stirrup is attached. The groove is then cut through the heel, and the heel is reattached. The appropriate orthotic ankle joint is then attached to uprights of the stirrup.

Shoe Stretching

Shoes with leather uppers can be stretched almost one full width. Although a shoe cannot be truly lengthened, it can be made to feel longer with a toe box stretcher device that looks like the shape of the foot and is inserted into the shoe to expand it (Fig. 7.10). After the leather is moistened or softened, this device effectively raises and slightly rounds the toe box. Frequently the pressure of a flat toe box on the toes is more problematic than the length of the shoe. Specific points in the shoe can be softened and expanded by placing an "expansion knob" on the toe-box stretcher or using a ball-and-socket device. Site-specific stretching is particularly helpful for patients with toe deformities such as hallux valgus, hammertoe, mallet toe, claw toe, overlapping toes, and Taylor bunion deformity.[1]

Fig. 7.10 Tools used to stretch leather shoes. Stretching often provides adequate accommodation for deformities in conventional shoes. (Colonial Medical Assisted Devices, Nashua, NH.)

Blowout Patches and Gussets

Patients with foot deformities who prefer conventional shoes to Thermold shoes may find temporary pain relief if a blowout patch or gusset is applied to their shoe. The shoe leather around the area of deformity is cut away and replaced with a softer blowout patch or gusset of moleskin, soft leather, or suede.

Footwear for Common Foot Deformities and Problems

Conservative management of common forefoot, midfoot, and rearfoot deformities often involves modification of shoes, prescription footwear, or both. Specific footwear strategies for several common foot problems are described in the following section.

PROBLEMS IN THE FOREFOOT

The most common footwear variation used for abnormalities in the forefoot is a high toe box. High toe boxes are available in various types of footwear, including athletic sneakers, comfort shoes, Thermolds, and prescription footwear. To accommodate forefoot deformity optimally, the maximum height of the abnormal toes must be measured in a weight-bearing position. Tables of manufactured shoes by toe box space are available to guide the clinician in recommending shoes that most closely match a patient's needs.[46]

Metatarsalgia

Metatarsalgia is pain around the metatarsal heads that results from compression of the plantar digital nerve as it courses between the metatarsal heads. Excessive weight bearing with atrophy of the metatarsal fat pad can result in irritation of the nerves and potentially lead to the development of a neuroma. The three major objectives in shoe prescription for patients with metatarsalgia are to (1) transfer pressure from painful, sensitive areas to more pressure-tolerant areas, (2) reduce friction by stabilizing the MTP joint, and (3) stabilize the rearfoot and midfoot to reduce pressure on the metatarsal heads.[47] Characteristics of the shoe that will accomplish these goals include wide width to reduce pressure on the transverse metatarsal arch, long fitting to eliminate plantarflexed MTP joints, cushion soles to enhance shock absorption, and a high toe box to allow forefoot flexion and extension. Additionally, the shoe should include a long medial counter to stabilize the rearfoot, a lower heel to minimize pressure at the metatarsal heads, and preferably thermoldable leather to accommodate deformities. Shoe modifications often include a transverse metatarsal bar to redistribute pressure from metatarsal heads to metatarsal shafts and shorten stride and a rocker sole to reduce motion of painful joints.[48]

Sesamoiditis

Sesamoiditis is an inflammation around the sesamoid bones under the first metatarsal head. It often results from a loss of soft tissue padding under the first metatarsal head and from toe deformities such as hallux valgus and hallux rigidus. The objective of shoe prescription for patients with sesamoiditis is to redistribute weight-bearing forces from the first MTP joint and its sesamoids to the long medial arch and shafts of the lesser metatarsals. A transverse metatarsal bar is used to redistribute pressure from metatarsal heads to metatarsal shafts and to shorten stride. A rocker sole can be used to reduce motion of the painful hallux joint.

Morton Syndrome

The Morton toe/Morton foot syndrome was first described by Dudley J. Morton, an orthopedic surgeon, researcher, physician, and author.[49] Morton syndrome is the configuration of the foot in which the second toe is either the same size as the great toe or slightly longer than the great toe. The increase length of the second ray causes lateral instability. The three major objectives in shoe prescription for patients with Morton's syndrome are to (1) redistribute weight from the lesser metatarsals (especially the second and third) to the proximal phalanx of the hallux, (2) stabilize the rearfoot by maintaining subtalar joint neutral, and (3) accommodate forefoot varus as well as a possibly dorsiflexed first metatarsal. Shoe prescription includes a long medial counter for rearfoot support and stability, a straight or flared last to accommodate foot shape, a high wide toe box to reduce compression across the transverse metatarsal arch, a large enough shoe size to accommodate the long second toe, and a Thomas heel or wedge sole to support the medial longitudinal arch. A medial heel and medial sole wedge may be necessary when symptoms are severe.[49]

Morton (Interdigital) Neuroma

Morton neuroma is a painful condition of the foot characterized by neural degeneration and perineural fibrosis, most commonly seen between the third and fourth or the second and third metatarsals.[50] Overstretching of the digital nerves in extreme toe extension at the proximal phalanx can also result in the development of a neuroma. Two objectives should be considered for patients with Morton neuroma. First, the patient must obtain relief from the pain and burning, especially in the third interspace of the MTP joint. Second, compression of the digital nerve as it passes between the heads of the third and fourth metatarsals must be reduced. To achieve these goals, the shoe should be wide enough to eliminate transverse compression and have enough length to reduce plantarflexion of the MTP joints. A long medial counter can help to reduce pronation, a cushioned sole increases shock absorption, and a low heel unloads pressure on the metatarsals. Elastic laces may be helpful in allowing expansion of the forefoot. Shoe modifications for Morton neuroma might include a metatarsal bar to elevate the metatarsals and redistribute weight, a metatarsal rocker bar to immobilize the metatarsals, or a combination of both.[51,52]

Metatarsalgia of the Fifth Metatarsophalangeal Joint

Like the metatarsalgia described previously, metatarsalgia of the fifth MTP joint results in plantar digital nerve irritation at the interdigital space of the fourth and fifth metatarsal heads. When metatarsalgia of the fifth MTP joint is present, the goals of intervention are to redistribute weight

forces to the fifth metatarsal shaft and provide a broad base of support along the lateral border of the foot. The optimal shoe has a last with enough lateral flare to accommodate the lateral aspect of the foot and fifth metatarsal shaft, a firm lateral counter, and a firm leather or rubber sole. Possible shoe modifications include a lateral heel and sole flare ending proximal to the fifth metatarsal head to provide a broader base of support. Lateral heel and sole wedges may be useful for patients with flexible feet.

Hallux Rigidus (Limitus)

Degenerative joint disease of the first MTP joint causes pain, loss of mobility, and eventually fusion of the joint. Osteophyte formation on the dorsal aspects of the metatarsal head and base of the proximal phalanx can be quite painful and result in a loss of extension. For patients with hallux rigidus or limitus, the goals are to limit motion of the hallux and first MTP joint and to reduce pressure on the dorsal and plantar aspects of the hallux and first MTP joint.[53] To accomplish this, the shoe should have a high wide toe box and Thermold or soft leather uppers. When significant deformity is present, a steel shank from heel to phalanx of the hallux and a rigid rocker sole with compensating heel elevation may be necessary.

Hallux Valgus (Bunions)

Hallux valgus is characterized by a lateral deviation (abduction) of the hallux with a corresponding medial deviation (adduction) of the first metatarsal.[54] Deformity remains and worsens due to walking with a laterally rotated foot angle and walking in excess foot pronation, which are the common gait compensations.[46] Hallux valgus deformity is often associated with long-term wearing of shoes with a triangular toe box. Five objectives should be considered in the prescription of shoes for patients with hallux valgus: (1) to reduce friction and pressure to the first MTP joint, (2) to eliminate abnormal pressure from narrow-fitting shoes, (3) to reduce pronation of the foot from heel strike to midstance, (4) to correct eversion, and (5) to relieve strain on the posterior tibial tendon ligament. Patients with hallux valgus benefit from shoes with high wide toe boxes and Thermold or soft leather uppers. A combined last with increased last width in the toe box and a smaller heel for better control of the subtalar joint may also be indicated. Additionally, the choice of a shoe that is longer and wider helps to accommodate deformity; a lower heel to reduce forefoot pressure and a reinforced medial counter help prevent pronation.[46]

Hammertoes, Claw Toes, and Mallet Toes

Hammertoe deformity is characterized by hyperextension of the MTP joint, flexion of the proximal interphalangeal (PIP) joint, and extension of the distal interphalangeal (DIP) joint. This results in high load during weight bearing at the plantar metatarsal heads and at the plantar surface of the distal phalanx. Claw toe deformity features hyperflexion of the PIP and DIP joints, although the MTP joint can be hyperextended or hyperflexed.[55] Mallet toe deformity results from hyperextension of the MTP joint, flexion of the PIP, and a neutral position of the DIP so that weight bearing is on the tip of the distal phalanx. Deformities of the lesser toes can be problematic, especially for patients with compromised circulation and neuropathy. For these individuals, there are two major footwear goals: (1) to transfer pressure away from the metatarsal heads, the PIP joints, and the distal phalanx joints and (2) to encourage flexion of the MTP joints and extension of the PIP joints.[46] Patients with lesser toe deformities should wear shoes with a high wide toe box made of Thermold or soft leather to reduce the likelihood of microtrauma over the bony prominences. The shoe should also be long enough to allow flexion of MTP joints and extension of PIP joints rather than cramping the toes. Finally, a soft cushion outsole and low heel further reduce pressure on the metatarsal heads. Commonly used shoe modifications for lesser toe deformities include metatarsal bars to reduce pressure to metatarsal heads and shift weight bearing to metatarsal shafts as well as a rocker bar or rocker sole to accommodate rollover on fixed deformity.

PROBLEMS IN THE MIDFOOT

Shoe prescriptions, modifications, or both are also helpful in managing midfoot dysfunction and deformity. The most commonly encountered problems include pes planus, pes equinus, pes cavus, and plantar fasciitis.

Pes Planus

Pes planus is pronation of the midfoot that results in a failure of the foot to supinate during midstance. The longitudinal arch flattens, causing a splaying of the forefoot and lateral deviation of the metatarsals. This deformity can be either flexible or fixed (rigid).[10] For patients with a flexible pes planus, the goals of intervention are to reduce pronation from heel strike to midstance, correct eversion, relieve tension on the posterior tibial tendonitis, and relieve ligamentous strain. To do these things, the shoe should offer a long medial heel counter, a Thomas heel (medial extension) or a firm wedge sole, and a straight last. A custom shoe is recommended for severe cases. Shoe modifications may include a medial heel wedge to correct eversion and reduce pronation or a medial heel and sole flare in extreme cases.[46]

Because of the fixed nature of a rigid pes planus, the goals are somewhat different: to relieve ligamentous strain as well as arch pain and to correct eversion of the foot. The optimal shoe should offer a broad shank (extra wide midfoot), a straight last, and a long medial counter. Additionally, a wedge sole is applied to reduce the load on the metatarsal heads, stabilize the intertarsal joint, and provide a dorsiflexion assist.

Pes Equinus

In *pes equinus,* the plantarflexor muscles and Achilles tendon are tightened, which limits dorsiflexion of the ankle and results in a plantarflexion deformity.[56] For patients with a flexible pes equinus, the footwear prescribed attempts to reduce ankle plantarflexion, reduce the load on the metatarsal heads, and stabilize the subtalar joint. This can be accomplished in a shoe with a low heel. A rocker bottom can be applied to the sole to provide a dorsiflexion assist and further reduce load on the metatarsal heads.

When the pes equinus deformity is rigid or fixed, the goals of footwear intervention change. Instead of trying

to reduce plantarflexion, a posterior platform supports the rearfoot from heel strike to midstance and mimics the dorsiflexion needed at toe-off. It is important to contain the entire foot in the shoe, thus reducing the load on the metatarsal heads. For patients with unilateral deformity, it is also important to equalize the relative leg-length difference between the normal foot and the equinus foot through all phases of gait. The shoe prescription for patients with a fixed equinus deformity includes a Cuban (elevated) heel to provide a platform and deep quarter or high-top shoes. If modifications are necessary, they may include posterior heel elevation on the equinus side as well as on the contralateral limb to facilitate swing of the involved limb and reduce pelvic obliquity.

Pes Cavus

Pes cavus is an exaggerated longitudinal arch that can lead to a plantarflexed forefoot with retraction of the toes and severe weight-bearing stresses on the metatarsal heads and heel. Patients with pes cavus benefit from shoes that provide a broad platform for stability; reduce loading at the heels, lateral borders, and metatarsal heads; and accommodate the deformed foot within the shoe. The shoe should also have a firm heel counter to maintain rearfoot stability and a modified curved last to accommodate foot shape. Custom-molded shoes are recommended in severe cases. Possible shoe modifications for patients with pes cavus include a lateral flare to provide a platform for greater stability, a cushion sole to absorb shock on the heel and metatarsal heads, and a metatarsal bar to shift weight from the metatarsal heads.[57]

Plantar Fasciitis

Plantar fasciitis is inflammation of the plantar fascia at its insertion to the medial aspect of the calcaneus.[58] This inflammatory process can lead to the development of calcification at that insertion, commonly referred to as a *heel spur*. Plantar fasciitis is often a consequence of loss of the longitudinal arch in conditions such as pes planus or of undue stresses created in the forefoot with tightness of the gastrocnemius and soleus muscles or an elevated longitudinal arch. To reduce the painful signs and symptoms of plantar fasciitis, the goals of intervention are to transfer weight-bearing pressure from painful to more tolerant areas, reduce tension on the plantar fascia and Achilles tendon, control pronation from heel strike to midstance, and maintain the subtalar joint in a neutral position. The shoe prescribed for plantar fasciitis has a long medial heel counter to limit heel valgus, a high heel to reduce tension on the plantar fascia and Achilles tendon, and adequate length to minimize compression and promote supination from midstance to toe-off. The types of shoe modifications that may be useful include a posterior heel elevation to reduce tension on the plantar fascia and Achilles tendon.[59]

PROBLEMS IN THE REARFOOT

The most common dysfunctions and deformities of the rearfoot that can be addressed by footwear prescription or modification include arthrodesis, Achilles tendinitis or bursitis, and Haglund's deformity (pump bump).

Arthrodesis

Arthrodesis is a loss of mobility at the ankle mortise, the junction of the talus with the tibia and fibula. This deformity prevents motion at the ankle in all planes and alters progression through the stance phase of gait; it may also compromise limb clearance in swing phase. When arthrodesis of the ankle is present, the major objectives are to provide effective shock absorption and controlled lowering of the forefoot at loading response, improve comfort and efficiency of push-off, and accommodate any shortening or residual equinus. Shoes that address the problems of arthrodesis have a reinforced counter and may have a medial or a lateral flared heel (or a combination of both) to provide greater stability. Some patients benefit from a high-top shoe as well. Modifications that protect the foot and facilitate a more normal gait pattern include application of a cushioned heel to absorb shock and simulate plantarflexion after heel strike and a rocker sole to mimic the dorsiflexion needed in the late stance phase.

Achilles Tendinitis, Bursitis, and the Haglund Deformity

Undue stresses on the Achilles tendon, direct pressure of a too-short shoe, and/or tightness of the gastrocnemius and soleus muscles can result in tendinitis or bursitis. The *Haglund deformity* is an osseous formation at the insertion of the Achilles tendon at the calcaneus. The goals of shoe prescription for patients with Achilles tendinitis, bursitis, and/or Haglund deformity (pump bump) are similar: (1) to reduce tension on the Achilles tendon, (2) to provide dorsiflexion assist at heel strike and at toe-off, (3) to reduce abnormal pronation, and (4) to reduce pressure and friction (shear) at the insertion of the calcaneus. Patients with these problems require a slightly higher heel to reduce dorsiflexion, a long medial counter to limit subtalar motion, a longer shoe size to reduce compression pressure, and a backless shoe to prevent irritation of the pump bump. The types of shoe modifications that may be helpful include a posterior heel elevation to reduce tension on the Achilles tendon or a foam-filled posterior heel counter.

Diagnosis-Related Considerations in Shoe Prescription

Prescription footwear and shoe modifications are also extremely useful tools to protect joints, prevent skin problems, and enhance normal function of patients who are coping with arthritis, gout, diabetes, or peripheral vascular disease. Adaptations to footwear may also be helpful for patients with hemiplegia, partial foot amputations, or congenital deformities.

ARTHRITIS

Arthritis—whether degenerative, rheumatoid, or traumatic—leads to the destruction of joints. In working with patients with foot arthritis, the goals of intervention are to prevent or limit abnormal motion, accommodate for arthritic deformities, cushion impact loading, and reduce microtrauma within the joint.[60] A reinforced counter can help limit subtalar motion; a high-top shoe can also help

limit ankle motion. Extra-depth shoes may be needed to accommodate deformities of the midfoot and forefoot. Thermoldable leather is preferable if deformities need further accommodation. The application of a rocker bottom helps to improve push-off by shortening the distance between the heel and the MTP joint. It also reduces the total ankle motion required for push-off. Shock-absorbing accommodative orthoses can be placed inside the shoe, and a cushion heel can be added to absorb even more force at heel strike and limit ankle and subtalar motion. A flared heel can reduce medial and lateral movement at the subtalar joint. A Cochrane review, "Custom-made foot orthoses for the treatment of foot pain,"[34] found that custom foot orthoses compared with supportive shoes in persons with juvenile idiopathic arthritis (JIA) reduced foot pain after 3 months, but similar results were not achieved with the use of prefabricated neoprene shoe inserts. The review also found that in adults with RA, custom foot orthoses compared with no intervention reduced rearfoot pain after 3 months.

GOUT

For patients with gout, the treatment objectives are similar to those for patients with arthritis: preventing or limiting motion of painful or inflamed joints, accommodating foot deformities, and cushioning the impact of loading on the involved joints. A reinforced counter to limit subtalar motion or a high-top design to limit overall ankle motion should be considered. An extra-depth shoe of thermoldable leather is best able to accommodate deformities without creating pain and discomfort over sensitive joints. A rocker bottom can be applied to assist push-off, prevent pedal joint movement, and reduce ankle motion required for push-off. Shock-absorbing accommodative orthoses and cushion heels provide even more comfort and protection of inflamed joints during gait.

DIABETES

The loss of protective sensation in patients with diabetic neuropathy creates significant vulnerability to injury from repetitive microtrauma. Protection of the plantar surface of the diabetic foot from microtrauma is of paramount importance.[61] Patients with diabetic neuropathy often have significant weakness of intrinsic muscles. Forefoot deformities develop, including claw toes, which are susceptible to breakdown in areas of excessive shoe pressure. The risk of nonhealing, infection, and subsequent amputation is quite high; prevention is the most effective treatment strategy. Total-contact full-foot orthoses using soft, shock-absorbing materials helps distribute weight-bearing pressures over the entire plantar surface of the foot away from the vulnerable bony prominences. A Thermold leather shoe is recommended for the insensitive diabetic foot.[62]

PERIPHERAL VASCULAR DISEASE

Because the ability to heal is compromised in patients with peripheral vascular disease, any irritation or ulceration exponentially increases the risk of infection and subsequent amputation.[34] Here too, prevention of skin breakdown and protection of the vulnerable foot are the primary goals.[63] The ability to fit and protect the foot effectively is further challenged by fluctuating edema. A Thermold sandal with Velcro closure is often recommended for patients with peripheral vascular disease–related edema as a safe and effective alternative to standard shoes. If edema is not a problem, a soft Thermold shoe can protect the plantar surface of the foot from repetitive pressures and accommodate deformities that are at risk for shoe pressure–related trauma. Because hypersensitivity is often a problem with circulatory pathologic conditions in the lower extremities, a shoe that cushions the foot may be helpful. Elastic shoelaces allow expansion of the shoe for patients with minimal edema-related fluctuations in foot size.

HEMIPLEGIA

The patient with hemiplegia after a cerebrovascular accident (e.g., stroke) may have inadequate or excessive tone of the lower extremity. Many of these patients need orthotic intervention to control the foot and ankle in some or all phases of gait and to accommodate for any fixed deformities and to cushion impact loading at initial contact.[64,65] Footwear is selected to enhance orthotic function or, in some instances, to control mild dysfunction directly. A reinforced heel counter can help to limit subtalar motion and stabilize the foot on heel strike. A flared heel or high-top shoe may be recommended to enhance foot placement and stance stability. A rigid shoe shank may be required for some types of lower extremity orthoses. In the presence of an equinus deformity, a heel lift on the shoe provides total contact during weight bearing and facilitates stability. In severe deformities of the ankle, a custom-molded shoe may be the only option.

The most common ankle-foot orthoses used in hemiplegia tend to increase shoe length, width, and depth by a half to a whole size. Often the insole can be replaced with an insert foundation to garner a little more room for the orthosis within the shoe. Extra-depth shoes are particularly helpful for patients who are faced with difficulty in donning their orthoses and shoe because of upper extremity dysfunction in hemiplegia.

AMPUTATION AND CONGENITAL DEFORMITY

The foot that is shortened surgically or is congenitally deformed is a management challenge because the weight-bearing surface is reduced or altered, increasing the likelihood of tissue breakdown with repeated loading in gait. The type of protective footwear used can range from an over-the-counter extra-depth shoe for a mild deformity to a custom-molded shoe for a severe deformity. When the feet are of unequal size, it is more difficult to fit them without buying two pairs of shoes or having custom footwear made. If the difference between the feet is no more than one size in length, the larger size can be used with toe padding for the shorter deformed or amputated foot or with an orthosis to accommodate the deformity (Fig. 7.11). Frequently the shorter foot is also wider and must be accommodated by the appropriate orthosis custom-molded to the shoe. A toe filler will prevent the shortened foot from sliding within the shoe during gait but also increases the risk of skin breakdown. It is crucial that the first MTP joint be aligned with

Fig. 7.11 A toe filler can be used on a foot that has been shortened by amputation or congenital deformity. (Marathon Orthotics, Inc.)

the "toe break" point in the shoe. If the foot falls posterior to the toe break, stress is concentrated at the distal end of the foot, increasing the chance of pressure imposition by the "filler."

Reading the Wear on Shoes

For the clinician who is faced with decisions about modifying, repairing, or replacing footwear, examination of patterns of wear and erosion provides important information. Deterioration of the shoe itself impairs tactile sensibility and position sense judgment. Shoes that have outlasted their purpose often create abnormal forces and shearing that increase the risk of repetitive microtrauma to the skin and joints of the foot and ankle. Analysis of the wear and erosion of the shoe is a prescriptive tool in advising, prescribing, and modifying a shoe to fit individual needs.

Case Example 7.1 **A Patient With Diabetes Who Is Homeless and Has a Neuropathic Foot Ulcer**

J.H. is a 71-year-old homeless man living in a shelter with a 22-year history of type 2 diabetes mellitus treated with metformin. He presents with a large ulcer (6.552 cm^2) of the plantar surface of the midfoot with significant arch deformity of the right foot subsequent to an episode of Charcot arthropathy several years earlier. J.H. reports that the ulcer has been present for more than a year. He has complications resulting from diabetes, including retinopathy, peripheral neuropathy, and a history of numerous neuropathic ulcerations involving both feet. He also has a 24-year history of arterial hypertension and a documented myocardial infarction. He is currently managed with angiotensin-converting enzyme inhibitors and calcium antagonists. It is unclear how regularly he has taken his medications, although they are available at no cost through the shelter's clinic. J.H. has been homeless for 7 years.

J.H. is referred to the health clinic at the homeless shelter for diabetic and hypertensive assessment and conservative treatment of the foot ulceration.

QUESTIONS TO CONSIDER

- What tests and measures might the foot clinic team use to assess current status and changes in J.H.'s neuropathic wound, the deformity of his feet, the circulation and sensory status of his limbs, and his functional status and gait? What is the evidence of reliability and validity of these measures?
- What does the team need to understand about his current health status and diabetes control? How will they gather this information?
- What are J.H.'s immediate needs in terms of footwear? How might his needs change over time as his wound heals?
- Given his current health status and lifestyle, what factors will likely affect (both positively and negatively) clinical decision making about J.H.'s footwear, wound care, diabetes management, and follow-up care? How might the team prioritize goals and possible interventions?
- How would the team assess the efficacy of their interventions?

INITIAL RESULTS

Satisfactory metabolic control and blood pressure values were achieved during the initial week of medical management at the shelter clinic. J.H. was referred to Boston City Hospital (BCH) for a series of tests and measures on an outpatient basis. Although he was found to have bilateral diabetic retinopathy *(fundus oculi)*, there was no evidence of diabetic nephropathy. An echocardiogram pointed to left ventricular hypertrophy with a normal regional kinesis and an ejection fraction of 50%.

Electromyography showed normal conduction velocity and slight abnormalities of sensory action potentials in the nerves of both lower extremities. An elevated threshold of 40 V to biothesiometer and a partial loss of sensitivity (nine of nine areas tested were insensitive bilaterally) to a Semmes-Weinstein 5.07 monofilament are recorded. The transcutaneous oxygen tension was 30 mm Hg at the dorsum of the involved foot (right) and 15 mm Hg at the perilesional site. In the ulcerated limb, the ankle-brachial index measured with Doppler technique was 0.8. Duplex scanning showed widespread atheromasic lesions in the carotids and in the lower limb arteries without hemodynamically significant stenoses and no significant alterations in the venous distribution of the lower limbs.

J.H.'s ulcer on his right foot appeared superficial and was graded as a Wagner grade II ulcer. The ulcer was covered by a fibrinous exudate with keratotic margins. The microbiologic cultures were negative. A surgical debridement was performed at BCH and then J.H. was sent back to the shelter with instructions for local treatment before and after daily sharps debridement, consisting of the daily application of sterile paraffin gauze, as well as for "evaluation and conservative treatment" by a physical therapist.

QUESTIONS TO CONSIDER

- How might the team interpret the results of the tests performed at BCH? How will this information influence or inform wound care and recommendations for footwear for this patient?
- What additional information will the physical therapist and foot care clinic team have to gather?
- What are the primary goals of physical therapy/foot care intervention? What is the prognosis and anticipated outcome? What is the anticipated duration of this episode of care? How frequently might J. H. receive care?

Continued on following page

Case Example 7.1 A Patient With Diabetes Who Is Homeless and Has a Neuropathic Foot Ulcer (Continued)

- What interventions would be most appropriate to address the goals of wound healing and prevention of future recurrence of neuropathic ulcers?

PHYSICAL THERAPY EXAMINATION, EVALUATION, AND INTERVENTION

J.H. was examined at the shelter by a physical therapist on the Foot Clinic Team. He arrived at the clinic ambulating independently, without any assistive devices. The ulcer on the plantar surface of his midfoot measured 6.552 cm^2 in the Charcot joint deformity region of the right foot. The ulcer was determined to be secondary to repetitive trauma to this region due to shoes that had large holes in the midsections of the soles.

A total contact cast was applied. Selective padding of the cast included foam padding over the toes and an ulcerated area of the foot; felt pads over the malleoli and navicular prominence; and cotton cast padding around the proximal and anterior lower leg, heel, sides, and dorsum of the foot. A rubber heel mount was applied to the cast for ambulation. Fiberglass casting material was used to decrease the effects of the elements (weather) on a plaster cast for this homeless individual who spends much time outdoors. The cast is also bifurcated to allow high galvanic electrical stimulation to be used as a local treatment modality to the wound and to provide access for daily debridement, the application of dressings, and monitoring for secondary lesions. The cast was secured with Velcro straps. The patient was allowed to walk freely and was highly compliant, wearing the cast continuously.

The ulcer responded favorably to a combination of periodic surgical debridement, local wound care, and daily sharps debridement, a modified total contact casting protocol, and high galvanic electrical stimulation. After 6 weeks the ulcer had completely closed and J. H.'s condition remained stable. He was subsequently fitted with a total contact foot orthosis bilaterally and provided with a pair of Reebok walking sneakers with an extra width to accommodate the Charcot foot deformity bilaterally.

With proper intervention and attention to J.H.'s social situation, it is determined that the prognosis for preventing recurrence of his neuropathic foot ulcer wound is good and that he can be integrated into appropriate home, community, and work environments within the context of his disability. J.H. was placed in a permanent shelter/housing residence and obtained part-time employment as a guide at the Boston Museum of Science.

DISCUSSION

For individuals with neuropathic wounds, total-contact casting allows ambulation with protection from external stress and trauma. In addition, when such a cast is well molded and minimal padding is applied, the pressure is distributed evenly and maintained as long as the cast is worn. A total-contact cast also counteracts lymphatic congestion, which compromises the healing process. For J.H., the cast was bifurcated to allow for daily wound care while also providing consistent pressure relief and foot protection.

The major objectives of treatment after J.H.'s diabetic neuropathic wound healed were to protect the plantar surface from repetitive microtrauma and accommodate deformities that could be traumatized by excessive shoe pressures, which could result in ulceration and subsequent injury. A total-contact full-foot orthosis using soft shock-absorbing materials helped to distribute weight-bearing pressures over the entire plantar surface of the foot and away from the vulnerable bony prominences. A Thermold leather shoe or good walking sneaker is recommended for the insensitive diabetic foot.

Accommodative devices are insoles that are placed in shoes to balance the feet, allowing pressures to be evenly distributed and permitting support and shock absorption of the foot. An orthosis, in contrast, supports and also controls the foot by neutralizing pronatory forces. Following wound healing, a total-contact orthosis (Plastazote with a layer of ⅜-inch PPT) was fabricated for J.H. and placed in a pair of extra-depth Reebok walking shoes.

Accommodating shoe gear should be used by patients with diabetes, and walking barefoot should not be permitted. The shoe's upper should be soft, so as not to irritate any prominence or developing deformity. The accommodative insole used should be adaptable to changes as well. A combination of an expanded polyethylene, such as Plastazote, which can be heat-molded to provide total contact and then mounted on a shock-absorbing material such as PPT or covered with a neoprene, such as Spenco, which is soft and retains its shape, makes an excellent accommodative insole. This type of accommodative orthosis protects the foot from trauma to prominent areas and redistributes the forces to provide even weight bearing through total contact upon the plantar surface. When accommodative orthoses are used, the shoe must have adequate depth to accommodate it. Extra-depth shoes such as Thermold shoes or extra-depth sneakers allow not only the room needed for the accommodative insole but also modification of the upper through heat molding to accommodate lesser toe deformities. A rigid-sole rocker-bottom shoe might also be recommended to reduce pressures under the metatarsal heads during push-off. The apex of the rocker is positioned just proximal to the metatarsal heads, allowing for the shoe itself to provide forward propulsion of the foot.

Summary

The shoe is an essential interface between the foot and the ground. It protects the foot from trauma and supports the structures of the foot as an individual walks, runs, and changes direction. Fashionable footwear, especially for women, often compromises foot function rather than enhancing it. Foot function and footwear must have a developmental aspect as well—an understanding of how the foot changes over the life span and of the special needs of children, pregnant women, and older adults is essential. Knowledge about the components of shoes and their variations, the criteria for proper fitting, and the relationship between shoe design and activity-related demands is an important tool for clinical practice. Physical therapists are often called on to recommend footwear for patients with special needs. A baseline knowledge of shoe characteristics and modifications for certain types of deformities or diagnoses enhances this ability.

8 Foot Orthoses☆

ELICIA POLLARD

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Describe the major anatomical structures of the foot as well as the basic biomechanical principles associated with these structures.
2. Describe the effects of extrinsic and intrinsic deformities and of abnormal pronation on the function of the foot during the various phases of gait.
3. Explain the strategies used to examine and evaluate intrinsic foot deformities.
4. Describe abnormal pronation and the pathological conditions that contribute to abnormal pronation in gait.
5. Describe components of a foot orthosis, goals of orthotic intervention, and specific purposes of the most common orthotic interventions.
6. Discuss controversy related to traditional orthotic theory.
7. Review literature related to the efficacy of foot orthoses for the management of common disorders.

History of the Functional Foot Orthosis

The use of foot orthoses as an effective treatment tool for biomechanical dysfunction of the feet evolved during the twentieth century and continues to be the subject of research and technology. A growing body of literature has found foot orthoses to be an effective treatment for lower extremity pain, lower limb dysfunction, and overuse injuries.[1-4] Early on, foot orthoses were used to redistribute plantar surface foot forces to alleviate discomfort in pressure-sensitive areas of the foot. Little consideration was given to the specific foot abnormality that led to the pathological condition.[5] In the early 1900s metal foot braces began to be used to control motion at specific joints of the foot and to prevent pathological conditions.[6] These devices, although functional, were often not well tolerated because of the rigidity of the materials and the mismatch between brace design and foot pathokinesiology. In 1948, Schreber and Weineman first identified forefoot invertus (varus) and evertus (valgus) as primary foot deformities that required correction by an orthosis.[7] In the 1960s, Merton Root developed neutral impression casting techniques, positive cast modifications, and posting (mechanical correction) techniques.[8] The standards that Root established have enhanced orthotic comfort and function. Since then, functional foot orthosis use has increased considerably to address lower limb muscle activation pathology of the mechanics of the foot and ankle in musculoskeletal disorders and neurological disorders.[9-14]

☆The author extends appreciation to Roberta Nole, Donald S. Kowalsky, Juan C. Garbalosa, and John Thompson, whose work in prior editions provided the foundation for this chapter.

Triplanar Structure of the Foot

The foot is a complex of bones interconnected by a series of multiplanar articulations supported by soft tissue structures. It is subdivided into three functional components: the rearfoot, the midfoot, and the forefoot.

Several important articulations of the foot (talocrural, subtalar, midtarsal, first and fifth rays) are triplanar; the axis of rotation in these joints is not perpendicular to any of the cardinal planes (sagittal, horizontal, frontal) of the human body. As a result, motion about triplanar joints leads to simultaneous movement in all three of these cardinal planes.[8] The amount of motion evident in any single plane is related to the pitch (inclination) of the triplanar axis from the respective cardinal plane. Triplanar motion occurs in three-dimensional space; the breakdown of triplanar motion into its three constituent cardinal plane movements is artificial.

Because motion about a triplanar axis is three-dimensional, motion occurs simultaneously in the three cardinal planes. Blocking any one component of triplanar motion in a single cardinal plane prevents movement in the other two planes as well. This "all-or-nothing" rule is the premise for orthotic posting or wedging.[8] Theoretically, the addition of a post or wedge to an orthosis blocks the frontal plane component of triplanar motion, which, in turn, blocks or limits the triplanar motion of pronation. The design principles of foot orthoses are founded on knowledge of the functional anatomy of the foot.

TALOCRURAL JOINT

The talocrural joint (TCJ) (articulation between tibia, fibula, and talus, connecting the foot to the lower leg) has a triplanar axis of rotation. In neutral position, the TCJ axis passes through the tips of the medial and lateral malleoli, pitched

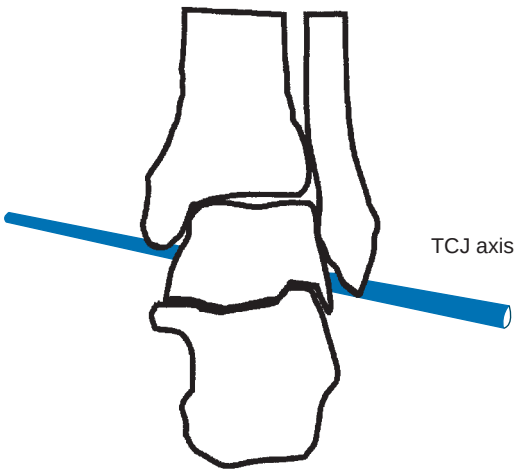

Fig. 8.1 Posterior view of the osseous components and axis of the talocrural joint *(TCJ)*. The osseous components of the TCJ are the tibia medially and superiorly, the fibula laterally, and the talus inferiorly. The axis of the joint passes in a posterolateral to anteromedial direction through the tips of the lateral and medial malleoli. (Courtesy Juan C. Garbalosa, University of Hartford, West Hartford, CT.)

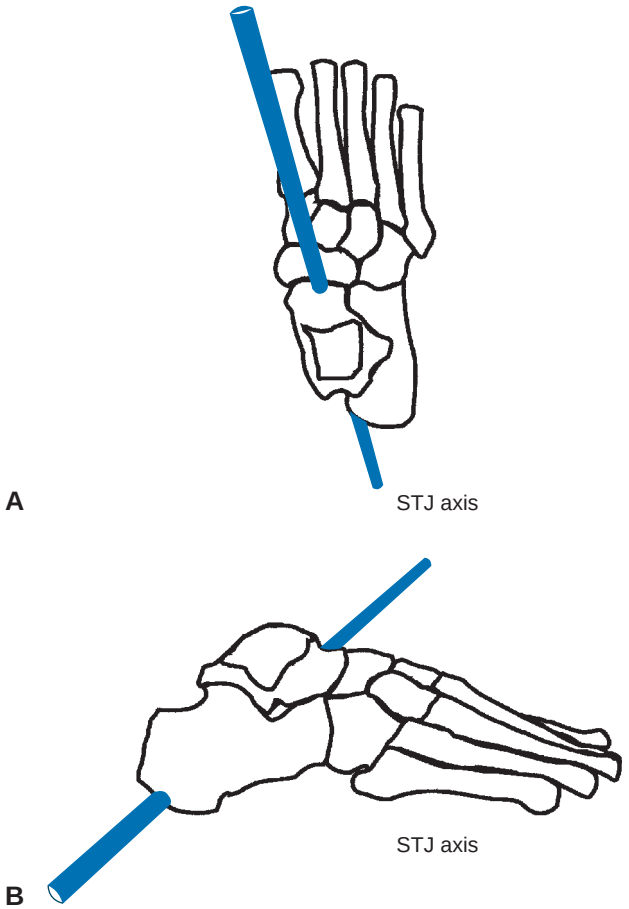

Fig. 8.2 Superior (A) and lateral (B) views of the osseous structures in the rearfoot: the superior talus and inferior calcaneus. Also pictured is the triplanar axis of the subtalar joint *(STJ)*. Note the inclination of the axis from all three cardinal planes of the body. (Courtesy Juan C. Garbalosa, University of Hartford, West Hartford, CT.)

10 degrees from the transverse plane and 20 to 30 degrees from the frontal plane (Fig. 8.1).[15-17] Although sagittal plane plantarflexion and dorsiflexion are primary motions at this joint, the slight inclination of the TCJ axis of rotation leads to concomitant transverse and frontal plane motion. During plantarflexion, the foot adducts and inverts; with dorsiflexion it abducts and everts. Normal range of motion (ROM) of the TCJ is between 12 and 20 degrees of dorsiflexion and 50 and 56 degrees of plantarflexion.[18] The medial (deltoid) and lateral collateral ligaments stabilize and limit motion that occurs at the TCJ.[19]

REARFOOT

The osseous structures of the rearfoot are the calcaneus (inferior) and the talus (superior) (Fig. 8.2). The articulation between the calcaneus and talus is the subtalar joint (STJ). Three joint surfaces are present in this articulation: posterior, anterior, and middle. The posterior joint surface has a concave talar and convex calcaneal portion, whereas the anterior and middle joint surfaces have convex talar and concave calcaneal arrangements.[20] This structurally based articular geometry, along with the interosseous talocalcaneal ligament, limits the amount and type of motion occurring at the STJ.[21,22] The medial and lateral collateral ligaments and the posterior and lateral talocalcaneal ligaments also offer support to the STJ.[23]

At the STJ, the triplanar axis of rotation is oriented in an anterosuperior to posteroinferior direction, pitched approximately 42 degrees from the transverse plane, 48 degrees from the frontal plane, and 16 degrees from the sagittal plane (see Fig. 8.2). The location of the STJ axis in the human foot varies greatly. Manter[24] reported that the inclination from the transverse and sagittal planes varies from 29 degrees to 47 degrees and from 8 degrees to 24 degrees, respectively.

The triplanar motions at the STJ are supination and pronation. Supination of the weight-bearing foot leads to dorsiflexion and abduction of the talus with simultaneous inversion of the calcaneus. Pronation of the weight-bearing foot results in plantarflexion and adduction of the talus and eversion of the calcaneus.[8] Because of the variability in location of the axis of rotation of the STJ, the component motions of supination and pronation vary as well. As the axis becomes more perpendicular to a particular cardinal plane, the motion occurring in that plane becomes more pronounced, whereas the other motions become less prominent.[25,26] This variability affects coupled motion between the joints of the foot and the lower leg. During pronation and supination of the rearfoot, the tibia and fibula rotate internally and externally in the transverse plane.[8,27,28] An increase in the frontal plane motion of the rearfoot could cause a simultaneous increase in the transverse plane motion of the lower leg.

MIDFOOT

The midfoot is composed of two bones: the cuboid and the navicular. The talonavicular and calcaneocuboid articulations between the midfoot and rearfoot form an important composite joint: the midtarsal joint (MTJ) or transverse tarsal joint. The articular surfaces of the talonavicular joint are convex–concave, whereas the surfaces of the calcaneocuboid joint are sellar shaped.[16,24] MTJ movement is supported and restricted by the bifurcate, short and

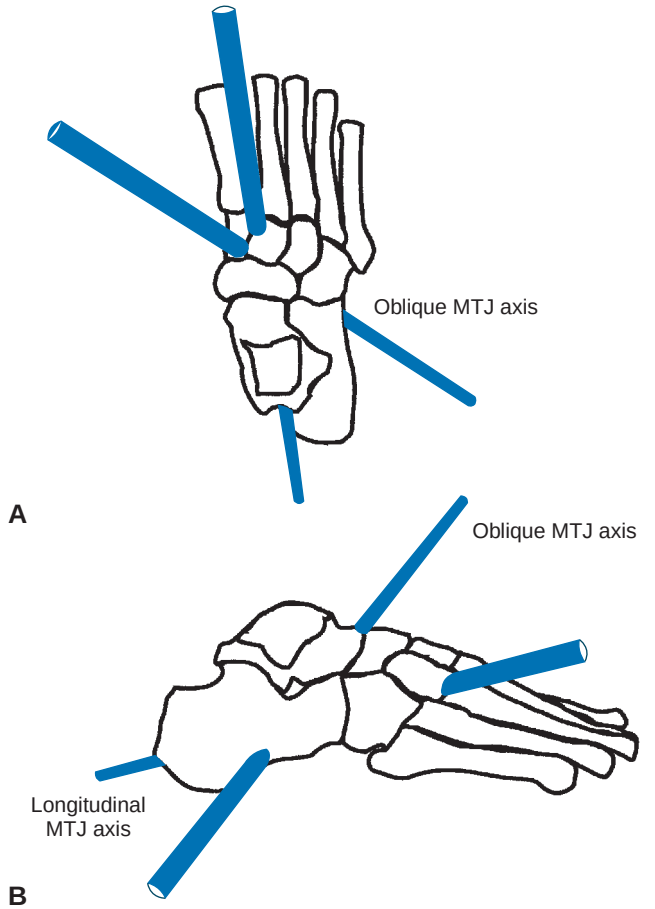

Fig. 8.3 A superior (A) and lateral (B) view of the osseous components of the midtarsal joint *(MTJ)*. The anterior portion of the MTJ is composed of the navicular and cuboid bones, whereas the posterior portion is composed of the calcaneus and talus. The two axes of the MTJ, the oblique and longitudinal axes, are also depicted. As in the subtalar joint, both axes of the MTJ are triplanar. (Courtesy Juan C. Garbalosa, University of Hartford, West Hartford, CT.)

long plantar, and plantar calcaneonavicular (spring) ligaments. The short and long plantar ligaments and the plantar calcaneonavicular ligaments also support the longitudinal and transverse plantar arches of the foot.[29]

Because the MTJ is a composite joint, motion occurs about two separate triplanar joint axes: a longitudinal and an oblique axis (Fig. 8.3). Movement of the forefoot about each joint axis can occur independently of the other. Manter[24] reported that the longitudinal axis is inclined superiorly 15 degrees from the transverse plane and medially 9 degrees from the sagittal plane, whereas the oblique axis is pitched superiorly 52 degrees from the transverse plane and medially 57 degrees from the sagittal plane. The predominant motion about the longitudinal axis is frontal plane inversion and eversion. Because of the slight deviation of the longitudinal axis from the three cardinal planes, small amounts of forefoot plantarflexion and dorsiflexion and adduction and abduction occur during inversion and eversion. Plantarflexion and dorsiflexion and abduction and adduction are the predominant movements around the oblique MTJ axis, with little concomitant inversion and eversion.[8,22]

These two joint axes produce the combined motion of supination and pronation of the MTJ. During supination and pronation, the forefoot inverts and everts about the longitudinal axis. The motion around the oblique axis is plantarflexion with adduction and dorsiflexion with abduction. The amount of motion possible at these MTJ axes is determined by the position of the STJ. In STJ supination, the two joint axes are nearly perpendicular so that MTJ mobility is restricted. This mechanism helps convert the forefoot into a rigid structure for propulsion during the push-off phase of gait (from heel rise through toe-off).[24,30] When the STJ is pronated, the joint axes are more parallel, allowing a greater degree of MTJ mobility.

FOREFOOT

The forefoot includes all structures distal to the navicular and cuboid bones; it is subdivided into five rays and toes. The first through third rays consist of a cuneiform and its associated metatarsal bone; the fourth and fifth rays consist only of a metatarsal. The tarsometatarsal joints—the primary joints of the ray complexes—have two opposing planar surfaces.[8,29] The hallux, or first toe, has two bones (a proximal and distal phalanx) and two corresponding joints (metatarsophalangeal [MTP] and interphalangeal [IP]). The lesser toes have three bones (proximal, middle, and distal phalanges) and three associated joints. The proximal articular surfaces of the MTP and IP joints are convex, and the distal articular surface is concave.[8] Numerous soft tissue structures support these joints.[29,31]

Although each ray has its own axis of motion, the first and fifth rays are of particular interest. The triplanar axes of rotation of these two joints are nearly perpendicular. The axis of the first ray is pitched at a 45-degree angle from the sagittal and frontal planes; the primary motions possible are plantarflexion with eversion and dorsiflexion with inversion. Because the axis of the first ray is minimally pitched from the transverse plane, insignificant transverse motion occurs.[8] In contrast, the axis of rotation of the fifth ray is oriented at a 20-degree angle from the transverse plane and a 35-degree angle from the sagittal plane. The resulting motions combine inversion with plantarflexion and eversion with dorsiflexion. Less motion is present about the axis of rotation of the fifth ray than of the first ray.[8] MTP joints have two separate axes of rotation: the vertical axis (abduction and adduction) and the transverse axis (plantarflexion and dorsiflexion).[8,16,29] Little frontal plane motion at MTP joints is normal; frontal plane motion leads to subluxation.[8]

PLANTAR FASCIA AND ARCHES OF THE FOOT

The plantar aponeurosis, one of the most functionally important soft tissue structures of the foot, is a sheath of fascia spanning most of the foot's plantar surface. Arising from the medial process of the calcanean tuberosity, it passes distally along the plantar aspect of the foot, then divides into five slips for its distal attachment at the base of the proximal phalanges by the plantar pads.[32] This fascial sheath plays an extremely important role in providing the stability needed by the foot during the toe-off phase of stance during gait and in supporting the longitudinal arch of the foot.

The medial longitudinal and transverse arches are formed by the ligamentous and osseous structures of a "normal" foot.[33] The medial longitudinal arch (MLA) extends from the calcaneus (posterior) to the first metatarsal head

(anterior) and is supported by the plantar aponeurosis, the short and long plantar ligaments, and the spring ligament. During weight bearing, the height of the arch is reduced as the supporting ligamentous structures are elongated. The transverse arch reaches across the foot from medial to lateral borders. The height of the arch varies along the length of the foot: its maximum height occurs at the cuboid-cuneiform bones of the midfoot, and its lowest point is at the metatarsal heads.

Function of the Foot in Gait

The foot and ankle complex has three major functions in the gait cycle: attenuating the impact forces, maintaining equilibrium, and transmitting propulsive forces. For optimal biomechanical and energy-efficient performance, the joints of the foot and ankle must work in harmony. In early stance, the foot-ankle complex absorbs energy generated at initial contact (IC) and decreases forces transmitted to proximal structures during loading. The foot and ankle must also adapt to surface conditions encountered by the foot as stance begins. In late stance, the foot and lower leg transmit propulsive forces generated by muscles of the lower extremity onto the ground. The ability of the foot and lower leg to accomplish these functions depends on the integrity of the various structures of the foot. Gait abnormalities occur when the foot and ankle complex is unable to compensate for deficits in motion or structure.

The kinematic, kinetic, and neuromuscular events of the normal human gait cycle have been described in many ways.[8,34,35] Most focus on five distinct events: IC or heel strike, loading response (LR) or foot flat, midstance (MSt), terminal stance (TSt) or heel-off, and preswing (PSw) or toe-off. See Chapter 5 for a more detailed description of the gait cycle.

SHOCK ABSORPTION

Musculoskeletal structures of the lower limb act from IC to MSt to attenuate impact forces.[8,34,36] Force plate recording of ground reaction forces (GRFs) estimates the foot's ability to absorb energy and decelerate the lower leg. The push of the foot against the floor creates a GRF with three components: vertical, medial, and lateral; and fore and aft forces. The vertical component of a typical GRF record has a bimodal shape (Fig. 8.4). The brief first peak results from the impact of the heel with the ground. Some of the vertical GRF is attributed to acceleration of the centers of mass of the foot and shank of the leg.

In early stance, from IC to LR, the STJ moves into pronation as the TCJ is plantarflexing.[8,34,37,38] The fibula and tibia internally rotate with respect to the foot.[26,27] Pronation of the STJ is controlled by eccentric contraction of the tibialis anterior, posterior tibialis, flexor hallucis longus, and flexor digitorum longus muscles.[8,34,39] Plantarflexion of the foot is controlled primarily by eccentric action of the tibialis anterior.[8,38] The combined muscle activity decelerates plantarflexion and pronation motion of the TCJ, STJ, and MTJ, slowing vertical and anterior movement of the center of mass of the foot and shank and decreasing impact forces encountered at IC.

The viscoelastic plantar fat pad absorbs some of the energy generated between IC and LR.[40] Pronation of the STJ flattens the arches of the foot, elongating plantar connective tissue structures. Because these tissues are viscoelastic, they also absorb some of the energy generated from IC to LR.

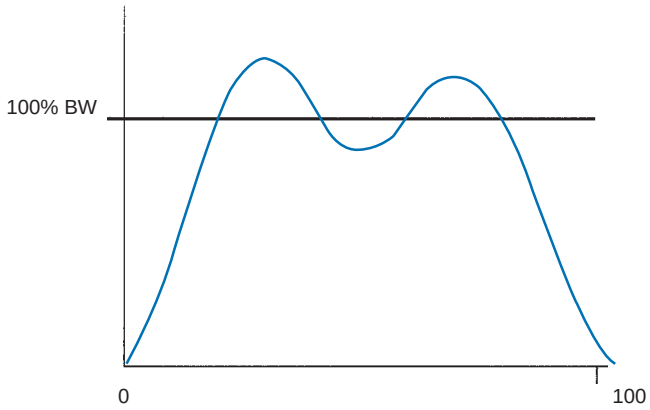

Fig. 8.4 Typical vertical ground reaction pattern during walking. Note the bimodal shape of the ground reaction force. The first peak occurs at initial contact, and the second peak occurs during the toe-off phase of gait. The recorded ground reaction force represents the whole-body center of mass acceleration. *BW*, Body weight. (From Valiant GA. Transmission and attenuation of heelstrike accelerations. In: Cavanagh PR, ed. *Biomechanics of Distance Running*. Champaign, IL: Human Kinetics; 1990:225–249.)

ADAPTATION TO SURFACES

In everyday walking, the foot must be able to adapt quickly to many types of terrains and uneven surfaces. The key contributor to surface adaptation is STJ pronation, which unlocks the MTJ, permitting the joints of the foot to function in loose-packed positions and enabling the osseous elements to shift their relative positions.

At IC, the forefoot is in a supinatory twist (inverted) about the longitudinal MTJ axis. Eccentric action of the anterior tibialis decelerates plantarflexion of the forefoot, lowering it to the ground. The MTJ becomes fully supinated at LR as a result of eversion of the STJ and GRFs acting upward on the foot's medial border. Contraction of the extensor digitorum longus and peroneus tertius abducts and dorsiflexes (pronates) the forefoot, locking it about the oblique MTJ axis and preparing the forefoot to receive the loading forces encountered at MSt.[8]

PROPULSION

During MSt (LR to PSw), the STJ is maximally pronated and begins to resupinate. At this time, the GRF maintains the MTJ in a pronated position about its oblique axis. At the same time, a pronatory twist is initiated at the longitudinal axis by concentric action of the peroneals. The MTJ locks in a fully pronated position around the longitudinal axis just before heel rise as the STJ reaches its neutral position. The MTJ must remain locked in this position throughout propulsion as the peroneals contract to lift the lateral side of the foot from the ground and transfer weight medially to the other foot. As the heel is raised from the ground, the rearfoot continues to supinate (talus abducts and dorsiflexes) as the lower limb rotates externally. This coupled motion necessitates supination of the MTJ about the oblique axis to maximize joint stability and to convert the foot into a rigid lever for propulsion.

Supination of the STJ occurs with concentric action of the tibialis posterior, flexor hallucis longus, and flexor digitorum longus and soleus, as well as the antagonistic functioning of the peroneus brevis.[8,34] The concentric activity of the gastrocnemius and soleus muscles causes vertical acceleration of the foot and lower leg. Propulsive forces generated by the foot and lower leg are transmitted to the floor.[8,34,38] The second peak of a GRF curve corresponds to propulsion in the late stance phase (see Fig. 8.4).

Supination of the STJ and locking of the MTJ about the longitudinal axis place the foot in a closed-packed position, transforming the foot into a rigid lever.[8,17,27,34,41] This transformation is aided by the action of the plantar aponeurosis as it wraps around the metatarsal heads. During TSt, the MTP joints extend (dorsiflex), creating a "windlass effect." This action compresses joints of the midfoot and forefoot, facilitating the transition from flexibility to rigidity required for effective push-off.

Biomechanical Examination

The biomechanical examination of the foot and ankle has three components: a non–weight-bearing assessment, a static weight-bearing assessment, and a dynamic gait analysis (Fig. 8.5). Five common intrinsic foot deformities are identified in the biomechanical examination: rearfoot varus, forefoot varus, forefoot valgus, equinus deformity, and plantarflexed first ray.

The theoretical model of biomechanical foot and ankle examination is based on the work of Root and colleagues.[8] Debate continues about the validity of Root's criteria for normalcy and the assumption that the STJ is in neutral position from MSt to TSt of the gait cycle. Reliability of the measurement techniques used to determine STJ neutral position has also been questioned.[42-45]Although controversial, Root's theory and his biomechanical evaluation and treatment techniques are used by many clinicians.

Root describes deviations from normal foot alignment as "intrinsic" foot deformities, which can lead to aberrant lower extremity function and musculoskeletal pathological conditions.[8,46] To prescribe an appropriate biomechanical foot orthosis, the source of the pathological condition or deformity must be determined by a detailed patient history and a comprehensive biomechanical examination.[47] This helps the clinician identify resultant pathomechanical abnormalities and determine the benefits of orthotic intervention.

Non–Weight-Bearing Open Chain Examination

During the non–weight-bearing open chain examination, the basic architecture of the foot and ankle is assessed. Any bony deformities or prominence of the joints or rays (toes) and any callosities are noted. The examiner uses a goniometer to locate the subtalar neutral (STN) position and identify any intrinsic foot deformities.

The non–weight-bearing goniometric examination is performed with the patient in the prone position, with the targeted lower extremity positioned with extended knee and the foot 6 to 8 inches off the treatment table. Placing the contralateral lower extremity in a figure-four position orients the ipsilateral lower extremity in the frontal plane, reducing the influence of proximal rotational limb disorders on measurement.[48]

EXAMINATION OF THE REARFOOT

Goniometric measurements of the non–weight-bearing examination assess the rearfoot with respect to STN position, as well as STJ mobility, based on calcaneal positioning in the frontal plane. Calcaneal frontal plane motion is the most readily examined component of triplanar STJ motion. To perform the examination, the stationary arm of a goniometer is aligned with an imagined bisection of the lower third of the limb (tibiofibular complex), the mobile arm is aligned with an imaginary bisection of the posterior surface of the calcaneus, and the axis of the goniometer is aligned at the STJ axis, just above the superior border of the calcaneus but beneath the level of the medial and lateral malleoli (Fig. 8.6).[48,49]

Subtalar Neutral Position

STN position can be manually estimated by palpation or by using a mathematical model developed by Root. If using palpation, the examiner identifies the anteromedial and anterolateral aspects of the talar head with the thumb and index fingers of the hand closest to the patient's midline, placing the thumb just proximal to the navicular tuberosity approximately 1 inch below and 1 inch distal to the medial malleolus (Fig. 8.7). In STJ pronation, the anteromedial talar head is most prominent beneath the thumb, and an anterolateral sulcus (the sinus tarsi) is apparent. The index finger is placed in this sulcus, where the talar head is found to protrude when the foot is fully supinated. The thumb and index finger of the other hand grasp the fourth and fifth metatarsal heads, moving the foot in an arc of adduction and inversion (supination) and abduction and eversion (pronation). STN is the point where the talar head is equally prominent anteromedially and anterolaterally.[46,48,49] The examiner then "loads" the foot by applying a dorsally directed pressure against the fourth and fifth metatarsal heads until slight resistance is felt. The loading procedure locks the MTJ against the rearfoot, mimicking GRFs of MSt.[8,50] The angular relation between the bisection of the calcaneus and the bisection of the lower third of the leg is measured with a goniometer (see Fig. 8.6), recorded on the evaluation form as rearfoot STN position.

Root's mathematical model for determining STN position uses a quantitative goniometric formula.[8,46] First, end ROM calcaneal inversion and eversion are determined by goniometric measurement. Total calcaneal ROM is the sum of the inversion and eversion values. The STN position is determined as the calcaneus is moved into inversion at one third of the total calcaneal ROM. If end-range calcaneal inversion is 25 degrees and end-range calcaneal eversion is +5 degrees, total calcaneal ROM would be 30 degrees. STN position is calculated to be at 5 degrees calcaneal inversion, one third of the distance from its fully everted position.

Reliability and clinical validity of both models have been debated.[44,46,48,51-53] Although acceptable reliability is possible, it is influenced by examiner experience. Palpation to determine STN position is efficient in terms of time but requires more advanced manual skills and experience than the mathematical model. The mathematical model may be more reliable for the entry-level practitioner.

Calcaneal Range of Motion

Calcaneal inversion and eversion occur primarily at the STJ, with lesser contributions from the TCJ. Calcaneal ROM is assessed with the patient in the prone position with the same anatomical landmarks and lines of bisection as for STN assessment. The examiner grasps the calcaneus in one hand, fully inverts it in the frontal plane until end ROM is achieved, and then takes a goniometric measurement.[53] The procedure is repeated for calcaneal eversion. The TCJ must be maintained in a neutral to slightly dorsiflexed position while measuring to lock it in a closed-packed position and better isolate STJ motion.[54] Normative values of 20 degrees for calcaneal inversion and 10 degrees beyond vertical for eversion have been reported.[8]

Because values of calcaneal eversion are larger when assessed in a full weight-bearing position, some clinicians suggest that this position is more clinically valid.[42,53] Assessment of calcaneal eversion in the weight-bearing

position represents a total "functional" pronation and eversion that is the summation of motion occurring at the STJ and compensatory motion occurring extrinsic to the STJ (e.g., TCJ, MTJ). Passive assessment of calcaneal eversion in a non–weight-bearing examination remains the most accurate method to determine the degree of composite pronation acquired from the STJ itself.

Talocrural Joint Range of Motion

In normal walking, the TCJ is maximally dorsiflexed just before heel rise when the knee is fully extended and the STJ is in a nearly neutral position.[8,55] When and whether an actual STN position ever occurs during gait is disputed.[42] However, the use of a standard position of knee extension and STN offers a consistent point of reference when assessing TCJ dorsiflexion. According to most sources, a minimum of 10 degrees TCJ dorsiflexion is required for normal gait; anything less is classified as an equinus deformity.[8,55-58] A minimum of 20 degrees of plantarflexion is also required for normal gait.[8]

Ankle dorsiflexion is measured in a non–weight-bearing position with the STJ held in the neutral position and the knee extended. The examiner forcefully dorsiflexes the ankle with active assistance from the patient. Active assistance

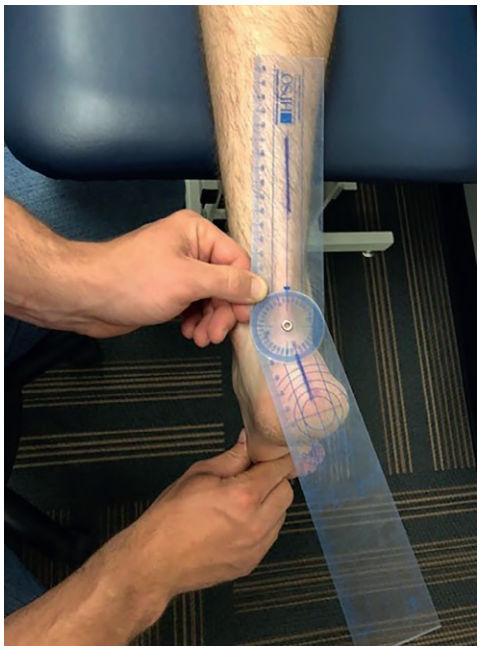

Fig. 8.6 Non–weight-bearing goniometric technique. A loading force applied by the examiner over the fourth and fifth metatarsal heads locks the forefoot on the rearfoot while the examiner's opposite hand operates the goniometer to measure subtalar neutral position and calcaneal range of motion. The examiner is seated at the distal end of the treatment table, with the chair height adjusted to position the patient's foot at chest level.

Fig. 8.7 To determine subtalar neutral position, the examiner moves the forefoot slowly between supination and pronation until the anteromedial and anterolateral surfaces of the head of the talus are equally prominent.

encourages reciprocal inhibition of the calf muscle group and is essential for accurate measurement.[55] The proximal arm of the goniometer is positioned along the lateral aspect of the fibula, the distal arm along the lateral border of the fifth metatarsal, and the axis distal to the lateral malleolus.[59] An alternative placement of the distal arm of the goniometer along the inferolateral border of the calcaneus may more effectively isolate true TCJ dorsiflexion (Fig. 8.8). This value is recorded as rearfoot dorsiflexion. Forefoot dorsiflexion is measured by repositioning the distal arm along the lateral aspect of the fifth metatarsal. This method allows the examiner to identify contributions or restrictions in sagittal plane motion from the oblique axis of the MTJ.

Fig. 8.8 Alignment of the distal arm of the goniometer along the inferior-lateral border of the calcaneus may provide a more accurate measure of talocrural joint dorsiflexion than the traditional alignment along the shaft of the fifth metatarsal used to measure overall ankle dorsiflexion.

If ankle dorsiflexion is less than 10 degrees when measured with the knee extended, remeasurement with the knee flexed may rule out soft tissue restriction of the gastrocnemius-soleus complex.[8,55] If dorsiflexion values are consistent in both positions, the limitation is likely a result of osseous equinus formation of the ankle.

During gait, ankle dorsiflexion occurs in a closed kinetic chain as the tibia and fibula rotate forward over a fixed foot. On the basis of this, some have suggested that assessing ankle dorsiflexion may be more accurate with the patient in a weight-bearing position.[42,57] The weight-bearing technique measures the angle between the tibia and the floor as the patient leans forward with the foot flat on the floor. Unwanted compensations are often difficult to control during weight bearing and may mask true TCJ limitations. The non–weight-bearing technique allows the examiner to assess end-feel and joint play, as well as mechanical blocks or joint laxity, providing additional information not accessible in the weight-bearing examination.

Rearfoot Deformities

Normal rearfoot position is one in which STN is 1 to 4 degrees of varus.[43,44,52,53] Values of more than 4 degrees are described as a rearfoot varus deformity. This deformity may be the result of ontogenetic failure of the calcaneus to derotate sufficiently during early childhood development.[8,50,60] Because this deformity is a torsional structural malalignment of the calcaneus, not a joint-related problem,

the TCJ and STJ lines remain congruent when observed in the non–weight-bearing STN position. As a structural deformity, it cannot be corrected or reduced by joint mobilization or a strengthening program. Instead, it is managed with a functional foot orthosis that partially supports the calcaneus in its inverted alignment while preventing excessive STJ pronation.

Assessment of calcaneal ROM predicts quality of motion and the integrity of the STJ. Measuring calcaneal motion into eversion allows the examiner to determine whether a rearfoot deformity is compensated or uncompensated (Fig. 8.9).

In a compensated rearfoot varus deformity, the calcaneus fully everts to vertical or beyond in weight bearing because the STJ possesses an adequate amount of pronatory motion to compensate for the deformity. A compensated rearfoot varus deformity of 10 degrees (STN position) requires that the STJ pronate or evert at least 10 degrees to enable the medial condyle of the calcaneus to achieve ground contact in weight bearing. Such excessive pronatory motion causes medial gapping and lateral constriction at the STJ line and a medial bulge of the talus as it moves into adduction and plantarflexion.

In an uncompensated rearfoot varus deformity, the calcaneus remains fixed in its inverted STN position with no eversion motion at the STJ. A partially compensated rearfoot varus deformity allows for partial STJ eversion so that the medial condyle of the calcaneus does not make complete contact with the ground on weight bearing. Alternative compensatory motion, extrinsic to the STJ, is necessary to achieve weight bearing on the medial aspect of the foot. One common compensation is an acquired soft tissue (valgus) deformity of the forefoot caused by a plantarflexed first ray. Other sources of compensatory motion can occur at the MTJ or proximally at the knee, hip, or sacroiliac joints.

An equinus deformity occurs when fewer than 10 degrees of ankle dorsiflexion are available as a result of osseous or muscular problems.[56,58,61,62] Clubfoot (talipe sequinovarus) is a congenital osseous deformity that includes varus deformity of both rearfoot and forefoot, rearfoot equinus, and an inverted and adducted forefoot.[63,64] The angular relation between the body and the head and neck of the talus is decreased, and the navicular is shifted medially. Muscular forms of equinus include congenital or acquired soft tissue shortening or muscle spasm.[58] Tissue contracture or shortening occurs in both contractile tissues (gastrocnemius, soleus, and plantaris) and noncontractile tissues (teno-Achilles and plantar fascia).[56,58]

Compensation for an equinus deformity occurs at the foot through pronation, perpetuating soft tissue contractures. The STJ is forced to pronate maximally to gain as much sagittal plane dorsiflexion as possible. Although foot pronation allows some dorsiflexion from the STJ, the amount is often inadequate. Pronation of the STJ unlocks the MTJ, creating an unstable midfoot while allowing further dorsiflexion and forefoot abduction from the oblique axis of the MTJ.[58] Other compensatory strategies for equinus deformity include knee flexion (especially in individuals with cerebral palsy), early heel rise, toe walking, shortened stride length of the contralateral lower limb, and toe-out walking.[34,46,58] Clinical consequences of long-term ankle equinus include many conditions normally associated with the excessively pronated foot: plantar fasciitis, heel spurs, bunions, and capsulitis.[58]

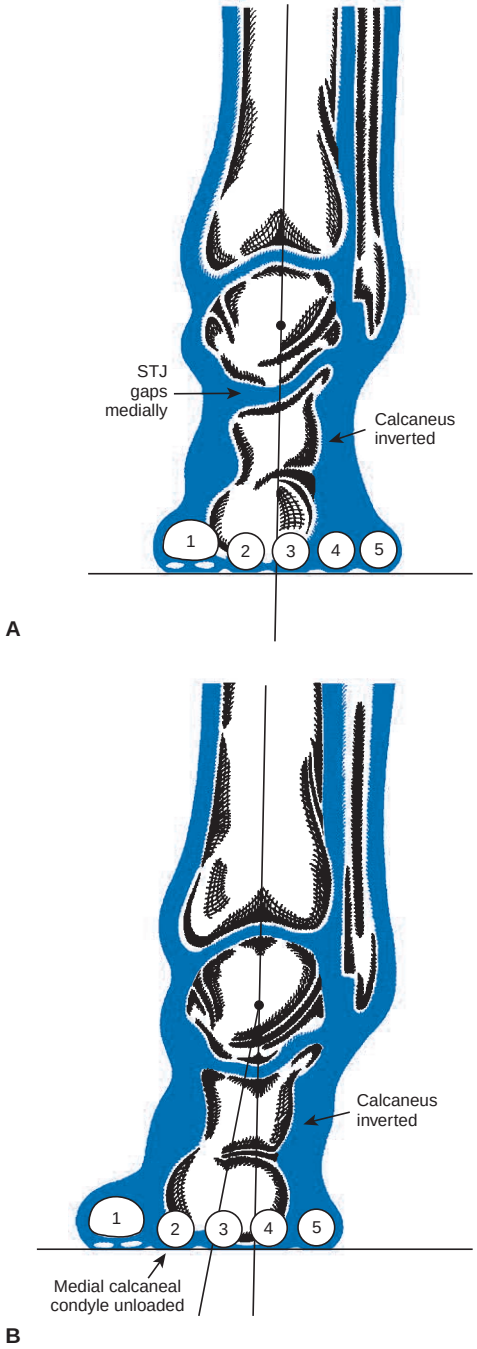

Fig. 8.9 (A) In relaxed calcaneal stance, compensation for a rearfoot varus is normally subtalar joint (STJ) pronation. (B) In an uncompensated rearfoot varus, the STJ cannot pronate and instead may develop compensatory midtarsal joint pronation about the longitudinal joint axis. (Courtesy Stride, Inc., Middlebury, CT.)

EXAMINATION OF THE FOREFOOT

Forefoot position is assessed with the STJ in neutral position. Because the first and fifth rays have independent axes of motion, forefoot orientation is defined by the planar relation of the second, third, and fourth rays to the bisection line of the calcaneus.

NEUTRAL FOREFOOT POSITION

If the forefoot is properly balanced, the plane of the three central metatarsals is perpendicular to the bisection of the calcaneus when in STN (Fig. 8.10). In a forefoot varus deformity, the forefoot is excessively supinated or inverted, whereas in a forefoot valgus the forefoot is excessively pronated or everted.

Mobility Testing: Locking Mechanism

To isolate the STN position in the non–weight-bearing examination, the examiner attempts to lock the MTJ by applying a dorsally directed loading pressure with the thumb and index fingers over the fourth and fifth metatarsal heads of the patient's foot (see Figs. 8.6 and 8.7). Loading force must be gently applied over the fourth and fifth metatarsal heads until tissue slack is taken up from the normally plantarflexed resting position of the ankle.[8,60] Overload of the forefoot leads to dorsiflexion and abduction of the foot, placing the forefoot in an excessively pronated position and giving a false valgus orientation.

Although many forefoot measurement devices are available, forefoot orientation can be accurately assessed with a standard goniometer.[65] To assess the forefoot to rearfoot relation, the proximal arm of the goniometer is aligned along the bisection of the calcaneus, with the axis just below its distal border. The distal arm is positioned in the plane of the three central metatarsal heads (Fig. 8.11). The angular displacement is recorded on the evaluation form under STN position for the forefoot assessment (see Fig. 8.5).

In normal walking, the MTJ locks as heel rise begins so that the foot is converted into a rigid lever for propulsion. This lock requires that the STJ be in the neutral position. Clinical assessment of MTJ mobility and the locking mechanism is an advanced manual skill. Observations made during weight-bearing assessment (e.g., toe sign, navicular drop test, talar bulge) provide an elementary method to identify an MTJ unable to lock.

An ineffective locking mechanism at the MTJ is often more clinically significant than the absolute degree of forefoot deformity. For example, a forefoot varus deformity of 3 degrees with a poor MTJ locking mechanism may be symptomatic, whereas an 8-degree forefoot varus deformity with a normal MTJ locking mechanism may not be.

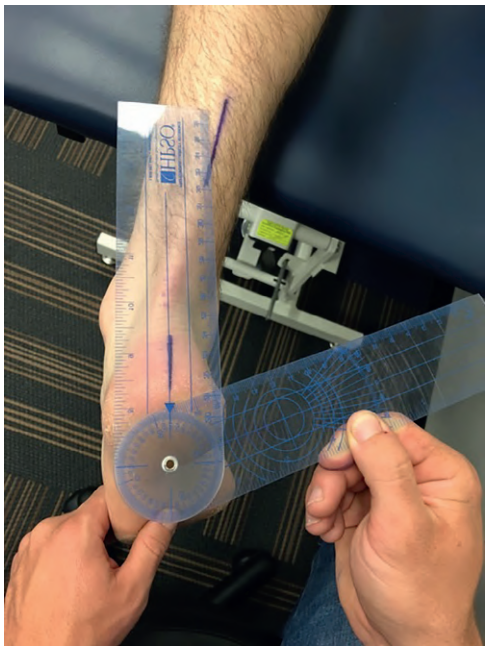

Fig. 8.11 Measurement of forefoot orientation in subtalar neutral position with a standard goniometer. The proximal arm of the goniometer is aligned with the bisection of the posterior surface of the calcaneus, and the distal arm parallels the plane of the metatarsal heads. The axis lies beneath the distal aspect of the calcaneus.

Identifying Forefoot Deformities

Although the prevalence of forefoot deformity, with or without symptoms, is well documented, less agreement exists regarding which types of deformity are most common.[52,66] If an individual has bilateral forefoot deformity, the deformities may not be of the same severity or type. MTJ deformities

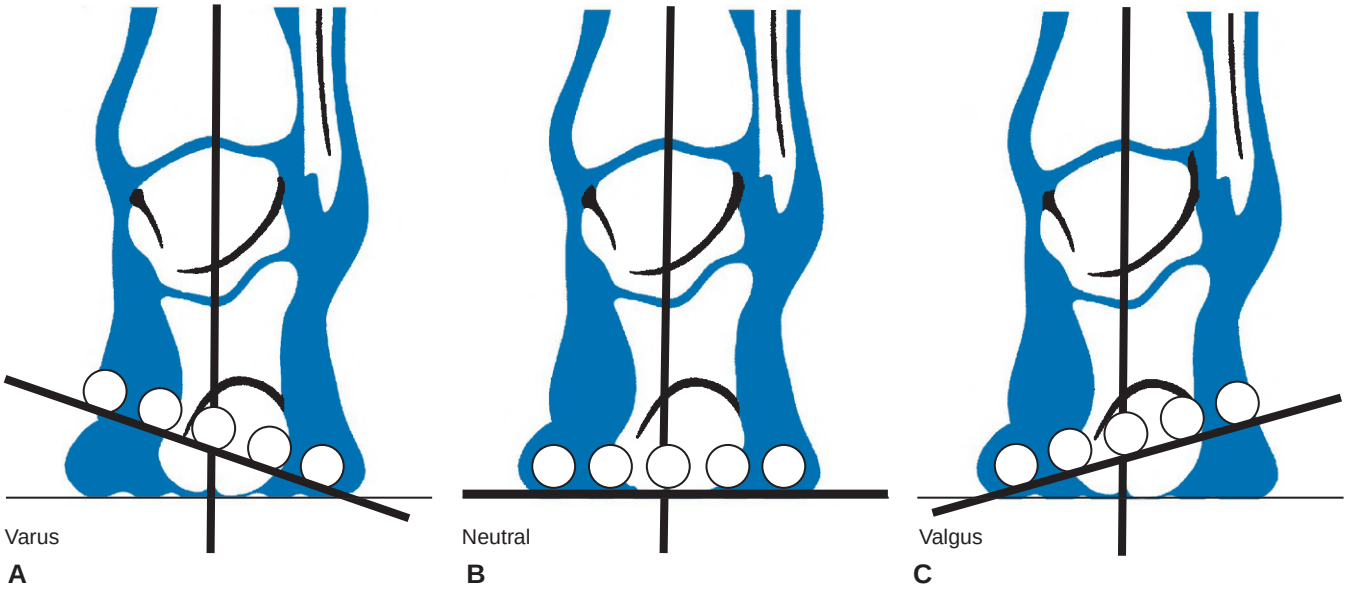

Fig. 8.10 In subtalar neutral position, the normal orientation of the forefoot to the calcaneus (B) is perpendicular. Excessive supination and inversion of the forefoot in subtalar neutral position indicates a forefoot varus (A), whereas excessive pronation and eversion of the forefoot indicates a forefoot valgus (C). (Courtesy Stride, Inc., Middlebury, CT.)

change the location of the lock of the forefoot against the rearfoot.[8] Although these osseous frontal plane deformities alter the direction of motion, they do not limit the total ROM of the MTJ.[8] In forefoot varus, locking of the forefoot occurs in an inverted position relative to the rearfoot.[8] Forefoot varus results from ontogenetic failure of the normal valgus rotation of the head and neck of the talus in relation to its body during early childhood development.[8,50,60]

Compensations for foot deformities are viewed in a relaxed weight-bearing position, which is referred to as relaxed calcaneal stance (RCS). When excessive pronation of the STJ compensates for the deformity on weight bearing, the condition is called a compensated forefoot varus (Fig. 8.12A). When the STJ cannot adequately pronate to accommodate an inverted forefoot, an uncompensated forefoot varus is present. The medial forefoot does not make contact with the ground, and the lateral forefoot is subjected to excessive pressure. A thick callus develops beneath the head of the fifth metatarsal, and the risk of stress fracture is increased. Plantarflexion of the first ray and pronation at the MTJ are common compensations that allow the medial forefoot to make contact with the ground (see Fig. 8.12B). Persistent MTJ stress may lead to joint damage and excessive forefoot abduction and eversion.

Forefoot valgus occurs in the frontal plane deformity, locking the forefoot in eversion relative to the rearfoot.[8] Root suggests that this deformity results from ontogenetic overrotation of the talar head and neck in relation to its body during early childhood development.[8,50,60] Forefoot valgus can be a rigid or flexible deformity. In rigid forefoot valgus, the compensatory weight-bearing mechanism occurs at the STJ as excessive supination or calcaneal inversion. It is a result of excessive premature GRFs at the first metatarsal head, causing rapid STJ inversion and increasing loading forces beneath the fifth metatarsal head. Thick callosities are often present beneath the first and fifth metatarsal heads. In contrast, flexible forefoot valgus is usually an acquired soft tissue condition. It most often occurs as a consequence of uncompensated rearfoot varus as an attempt to increase weight bearing along the medial foot. Because this deformity is flexible, no compensatory mechanism is necessary. Contact force beneath the first metatarsal head simply pushes it up out of the way, and the foot functions as if this condition were not present.

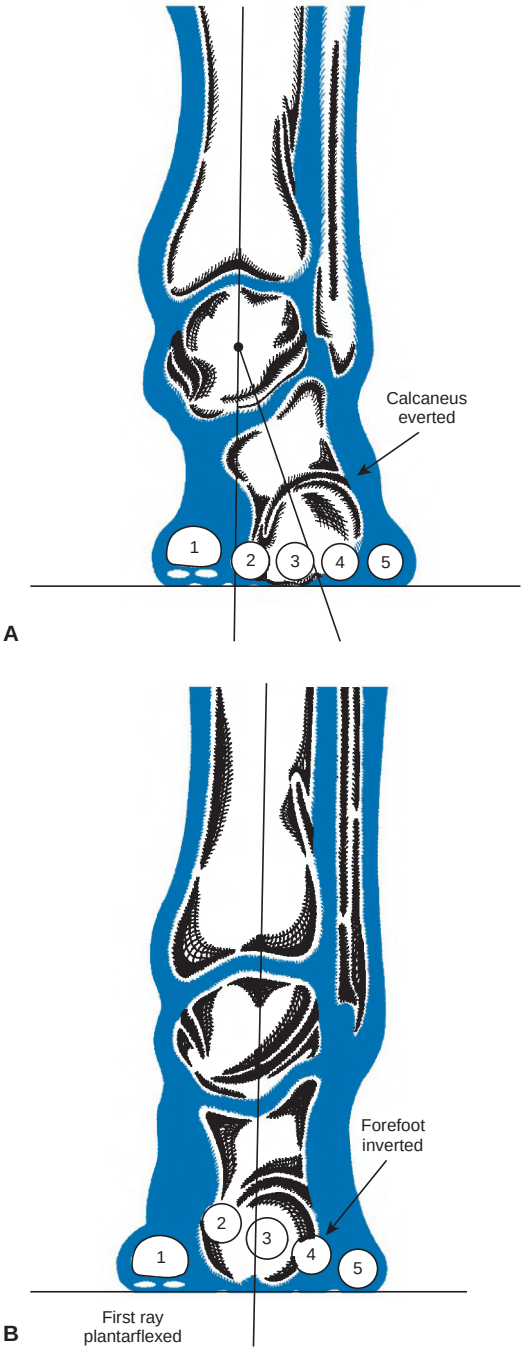

Fig. 8.12 (A) In relaxed calcaneal stance, compensation for a forefoot varus deformity is normally subtalar joint pronation, resulting in an everted calcaneus. (B) In an uncompensated forefoot varus, the subtalar joint is unable to compensate. Instead, the first ray plantarflexes to achieve weight bearing medially on the foot. (Courtesy Stride, Inc., Middlebury, CT.)

The First Ray

Assessment of first ray position is also carried out in the STN position. Ideally, the first ray lies within the common transverse plane of the lesser metatarsal heads. To examine the mobility of the first ray, the examiner holds the first metatarsal head between the thumb and index finger and performs a dorsal and plantar glide while stabilizing the lesser metatarsal heads with the other hand. Normally, first ray movement is at least one thumb width above and below the plane of the other metatarsal heads.[8]

As the stance phase is completed, activity of the peroneus longus creates a pronatory twist of the forefoot, stabilizing the medial column of the foot on the ground, locking the MTJ about its longitudinal axis, and converting the foot to a rigid lever for propulsion. Adequate plantarflexion of the first ray must be present for conversion from flexible forefoot to a rigid lever. Three factors determine how much first ray plantarflexion must occur: the amount of inversion of the foot at propulsion, the width of the foot, and the length of the second metatarsal.[8] The more the foot inverts during propulsion, the further the first ray must plantarflex to make ground contact. Elevation of the medial forefoot is related to foot width; wide feet require more first ray plantarflexion. An excessively long second metatarsal also increases the distance that the first ray must plantarflex to make ground contact.

In some instances, the first ray is inappropriately dorsiflexed above the plane of the other metatarsals, resulting

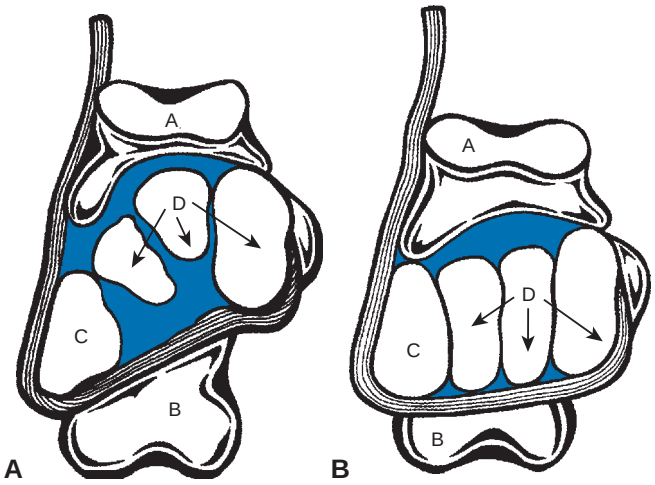

Fig. 8.13 (A) Cuboid pulley mechanism in a normal foot. (B) In an abnormally pronated foot, the mechanical advantage of the peroneals is impaired. *A,* Talus; *B,* calcaneus; *C,* cuboid; *D,* the cuneiforms. (Courtesy Stride, Inc., Middlebury, CT.)

in restriction of plantarflexion and impeding normal propulsion. The first ray may also be plantarflexed below the plane of the other metatarsals. In uncompensated rearfoot varus, for example, the eversion motion of the calcaneus is insufficient, the medial condyle fails to make contact with the ground, and excessive weight bearing is present on the lateral border of the foot. The peroneus longus contracts to pull the first metatarsal head toward the ground in an attempt to load the medial side of the foot. This action is possible because of the cuboid pulley system (Fig. 8.13).[8] When the STJ remains abnormally pronated in late stance phase, orientation of the cuboid tunnel is altered and the mechanical advantage of the peroneus longus is lost. The MTJ cannot lock, and the foot is unstable throughout propulsion.

The presence of a rigid plantarflexed first ray sometimes results in a functional forefoot valgus (Fig. 8.14). The compensatory mechanism for this condition is similar to that for rigid forefoot valgus: STJ supination or calcaneal inversion on weight bearing to lower the lateral aspect of the foot to the ground.

The Hallux

In normal gait, dorsiflexion of the hallux occurs during the late propulsive phase as the body moves forward over the foot. Sagittal plane motion of the hallux is assessed as passive ROM. The stationary arm of the goniometer is positioned along the medial first metatarsal and the mobile arm along the medial proximal phalanx of the hallux. The axis is medial to the first MTP joint.[54] Sufficient force is applied to bring the hallux to its end ROM. Normal range of hallux dorsiflexion is between 70 and 90 degrees.[8,59]

In hallux limitus deformity, pathomechanical functioning of the first MTP joint prevents the hallux from moving through its full range of dorsiflexion during propulsion. Repetitive trauma to the first MTP joint can lead to ankylosis, or hallux rigidus. Functional hallux limitus is a condition in which full first MTP ROM is present when non–weight-bearing, but a functional restriction of hallux dorsiflexion occurs during gait. Functional hallux limitus disrupts the normal windlass mechanism previously described.[67,68]

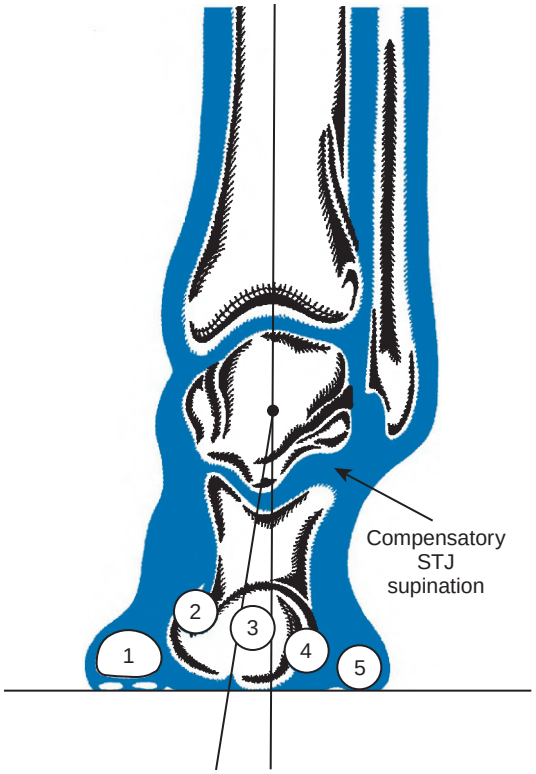

Fig. 8.14 Plantarflexed first ray deformity in relaxed calcaneal stance. Compensation occurs at the subtalar joint (STJ), with lateral gapping and medial compression. (Courtesy Stride, Inc., Middlebury, CT.)

Limitation of hallux dorsiflexion prohibits the normal progression of the foot and interferes with propulsion of the body over the hallux. Several gait compensations can overcome this limitation.[67,68] An abducted or toe-out gait pattern shifts propulsion to the medial border of the hallux. A pinched callus then develops from friction between the hallux and shoe during propulsion. Alternatively, the IP joint of the hallux may hyperextend, causing a callus in the sulcus of the IP joint.

Hallux abductovalgus (HAV) is a progressive, acquired deformity of the first MTP joint that eventually results in a valgus subluxation of the hallux.[8,50] This deformity is caused by abnormal STJ pronation with hypermobility of the first ray.[4] A common misconception is that HAV is hereditary. Although the congenital osseous abnormalities that lead to aberrant STJ pronation are hereditary, HAV occurs to compensate for these other deformities. Another misconception is that HAV is caused by restrictive footwear. Although inappropriate or restrictive footwear can accentuate or speed the progression of HAV deformity when present, the deformity is frequently observed in populations that do not typically wear shoes.[8,50]

ADDITIONAL OBSERVATIONS

Several other important observations are made as the non–weight-bearing examination is completed. Non–weight-bearing arch height is observed for later comparison to weight-bearing arch height as a composite estimate of foot pronation. Toes are inspected for positional deformities such as hammertoe, claw toe, crossover deformity, and the presence

of bunions or bunionettes. The plantar foot is checked for callus, plantar warts, or other signs of excessive pressure. The shoes are inspected for excessive or uneven wear patterns.

Static Weight-Bearing Closed Kinetic Chain Examination

The open chain kinetic motion evaluated in the non–weight-bearing examination is dramatically different from the functional sequence of events in the closed kinetic chain of standing and walking. Open kinetic chain pronation (calcaneal dorsiflexion, eversion, and abduction) and supination (calcaneal plantarflex, inversion, and adduction) are triplanar motions around the STJ.[8,16,32] During closed kinetic chain pronation, internal rotation of the leg is coupled with talar adduction and calcaneal plantarflexion and eversion. Closed kinetic chain supination couples external rotation of the leg with talar abduction and calcaneal dorsiflexion and inversion. In the open kinetic chain, movement is initiated in the distal segment (the foot). In the closed kinetic chain, motion is initiated proximally (at the tibia and talus). A thorough closed kinetic chain examination includes static postural observations, dynamic motion testing, and gait assessment.

Compensatory mechanisms that result from intrinsic deformities are assessed as the foot is subjected to GRFs during the static weight-bearing examination. This provides valuable insight regarding how the body compensates for the intrinsic foot deformities or impairments of normal foot joint function identified in the non–weight-bearing examination. Improper foot functioning can lead to a complex series of compensations that influence the mobility patterns of the foot and lower leg, as well as the knee, hip, pelvis, and spine.

The patient stands in a relaxed, weight-bearing posture (RCS). The examiner observes the patient's preferred stance, noting postural alignment and foot placement angle. The patient then adjusts the stance position, if necessary, to assume equal weight-bearing double-limb support, with feet 5 to 10 cm apart and oriented in neutral toe-in and toe-out foot placement angle. This adjusted posture, with neutral foot placement angle, offers a better frame of reference for assessing planar alignment and enhances the reliability and consistency of the measurement.[46] Postural alignment or body symmetry of the patient is evaluated in the frontal, sagittal, and transverse planes.

FRONTAL PLANE

Static weight-bearing examination in the frontal plane focuses on the angular relation of the calcaneus and the tibia and fibula with respect to the floor and the relation between the pelvis and the lower leg.

Calcaneal Alignment to the Floor

With the patient in double-limb stance posture, a line bisecting the posterior surface of the calcaneus is visualized and the angular relation between the line and the floor is taken. Because the infracalcaneal fat pad often migrates (related to prolonged weight bearing), care must be taken to avoid errors in visual assessment (Fig. 8.15). Palpation of the osseous medial, lateral, and inferior borders of the calcaneus helps to factor out fat pad migration and to improve measurement accuracy. Calcaneal alignment also can be quantified with a protractor to measure the degree of calcaneal tilt relative to vertical.[69]

The key question to answer is whether the calcaneus is inverted, vertical, or everted relative to the floor during stance; the actual angular degree is not as important as the relative orientation of the calcaneus. This component of the examination assesses the ability of the STJ to provide enough pronation to compensate for its neutral position. In the normal closed chain STN position, the calcaneus is in 1 to 4 degrees of varus (inversion). The STJ must have an equal amount of compensatory pronation to lower the medial condyle to the ground for a vertical calcaneus. If a

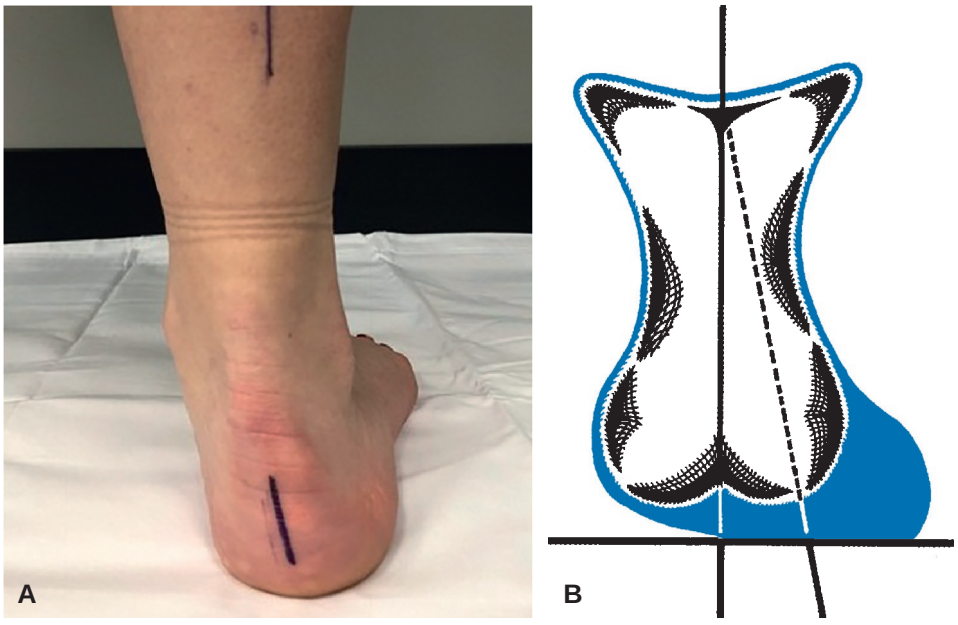

Fig. 8.15 (A) Calcaneal alignment to floor. (B) Lateral migration of the infracalcaneal fat pad can give the illusion of an everted calcaneal to floor alignment. (Courtesy Stride, Inc., Middlebury, CT.)

patient has uncompensated rearfoot varus of 10 degrees in STN as well as restricted calcaneal motion (-4 degrees) eversion, the STJ would not be able to achieve sufficient pronation or eversion in stance for normal calcaneal alignment. Instead, the calcaneus would be in an inverted alignment relative to the floor. Inverted calcaneal position also occurs when a rigid forefoot valgus or rigid plantarflexed first ray deformity is present. STJ supination is a compensatory mechanism for both deformities.

In contrast, forefoot varus deformity requires excessive compensatory STJ pronation; calcaneal eversion occurs in weight bearing. The position of the calcaneus with respect to the floor provides insight into the type of STJ compensation present and can be correlated with the biomechanical findings of the non–weight-bearing examination. If the STJ is unable to pronate enough to completely compensate for a deformity, additional pronatory motion occurs at the MTJ or by eversion tilting of the talus within the ankle mortise.[8,46,53] The functional rearfoot unit (calcaneus and talus) may assume a valgus (everted) position relative to the floor, even if calcaneal eversion is restricted.

Tibiofibular Alignment

Proximal structural malalignments, such as tibialvarum or valgum, contribute to abnormal foot pronation and overuse injuries. In osseous congenital tibialvarum, the distal third of the tibia is angled medially in the frontal plane, whereas in tibialvalgum, the distal tibia inclines away from the midline.[46]

Tibial alignment can be measured with either a standard goniometer (Fig. 8.16) or a bubble inclinometer; both assess the angular relation between the bisection of the distal third of the lower leg relative to the supporting surface.[46,70] Radiographic measurement of lower leg position is better correlated with clinically assessed tibiofibular position values than with isolated tibial position. Radiographic measurement may be the most accurate method to isolate true tibial varum.[71]

The test position is critical because variation in STJ alignment greatly influences tibiofibular varum measurement values. Tibiofibular varum values are larger in RCS than in the STN position because of the combined effects of osseous malalignment and varus leg alignment associated with compensatory STJ pronation in stance.[70-72] The incidence of tibiofibular varum appears to be high, although no clear normative values have been established.

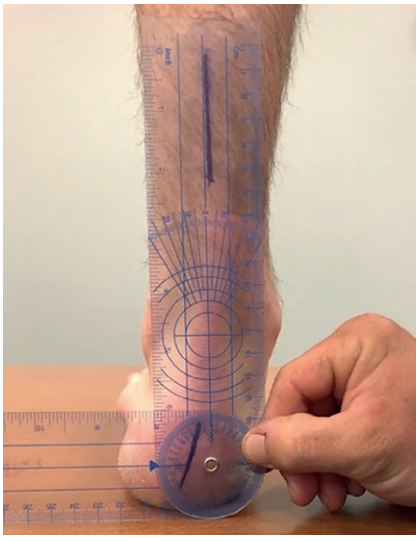

Fig. 8.16 Goniometric assessment of tibiofibular varum. The proximal arm of the goniometer is aligned with the bisection of the distal third of the tibiofibular complex, and the distal arm is level with the floor. The axis of measurement shifts with the degree of varum or valgum deformity and may not always fall directly behind the calcaneus.

The alignment of the distal third of the leg relative to the floor more accurately represents tibiofibular position than tibial position. Values assessed in STN reflect neutral tibiofibular alignment, whereas values assessed in RCS represent compensatory tibiofibular repositioning in response to STJ and MTJ pronation. High tibiofibular varum values measured in STN elevate the medial foot from the supporting surface, requiring excessive compensatory foot pronation during gait. High tibiofibular varum values in RCS suggest excessive foot pronation, although the source of that pronation cannot be isolated.

Alignment of the Pelvis and Lower Leg

The final component of the frontal plane assessment evaluates symmetry of the anterosuperior iliac spines, iliac crests, greater trochanters, gluteal folds, popliteal creases, genu varum or valgum deformities, fibular heads, patellae, and malleolar levels. Asymmetry often indicates sacroiliac joint dysfunction or leg length discrepancy, influencing foot position and function in the closed kinetic chain.

SAGITTAL PLANE

The second component of the weight-bearing examination considers function in the sagittal plane. The examiner looks for evidence of genu recurvatum or excessive knee flexion, navicular drop, talar bulge, and inadequate or excessive height of the longitudinal arch.

Knee Position

Viewing the patient's stance from the side, the examiner observes the verticality of the tibia. In genu recurvatum, the proximal tibia is aligned behind the axis of the TCJ, resulting in hyperextension of the knee and plantarflexion of the TCJ with relative shortening of the limb. Genu recurvatum also occurs as a compensation for equinus deformity at the ankle. When true leg-length discrepancy is present, two types of compensation are possible. If limb length difference is small, genu recurvatum may adequately shorten the longer limb. For larger limb length differences, knee flexion of the longer limb is often used to minimize asymmetry.

Navicular Drop

The position of the navicular is examined by using the navicular drop test, a composite measure of foot pronation focusing on displacement of the navicular tuberosity as a patient moves from closed kinetic chain STN to the RCS position.[73] Excessive navicular displacement is associated with the collapse of the MLA and may be correlated with midfoot pain or other symptoms of excessive foot pronation.[46] Subotnick[74] established an interdependency between MTJ and STJ function based on articulation of the navicular and cuboid with the talus and calcaneus. Brody[73] suggested that the navicular drop test is a valid assessment of STJ function in the closed kinetic chain. Although navicular drop occurs with STJ pronation that stems from intrinsic foot deformity, it can also be the result of muscle insufficiency or ligamentous laxity.[46]

To measure navicular drop, an index card is held perpendicular to the medial foot, the level of the navicular tuberosity is marked in STN position and in RCS, and the distance between the marks is calculated.[42] Normative studies report a mean navicular drop of between 7.3 and 9 mm.[43,75] A navicular drop of more than 10 mm is considered abnormal.[75]

Talar Bulge and Arch Height

When excessive STJ pronation is present in stance, the talus moves into adduction and plantarflexion. Displacement of the talar head causes an observable medial bulge in the region of the talonavicular joint.[76] The height of the MLA normally decreases moderately in weight bearing as a result of normal STJ pronation. Pes planus deformity (flatfootedness) is characterized by excessive collapse of the MLA. In hereditary rigid flatfoot, the MLA is low or absent in non–weight-bearing and weight-bearing positions. In flexible flatfoot, the height of the MLA is normal in non–weight bearing but drops excessively in weight bearing because of abnormal STJ pronation. In normal foot alignment, the medial malleolus, navicular tuberosity, and first metatarsal head fall along the Feiss line.[76] In a severely pronated foot, the navicular tuberosity lies below the Feiss line. In extreme cases the tuberosity may even rest on the floor.[76,77]

TRANSVERSE PLANE

The final component of the static weight-bearing examination considers foot function in the transverse plane. The examiner looks for signs of excessive pronation or forefoot adduction and torsional deformities of the lower extremities.

Toe Sign

A positive toe sign indicates excessive pronation or abduction of the foot in the transverse plane (Fig. 8.17). The sign is determined by the number of toes that can be seen in a posterior view when the patient is standing in RCS with a neutral foot placement angle.[68] Normally no more than 1.5 toes are visible beyond the lateral border of the foot. If more toes can be seen, abnormal pronation may be present, causing excessive transverse plane motion or abduction of the foot. A false-positive toe sign can occur in the presence of a relative toe-out foot placement angle associated with lateral rotational deformities (e.g., femoral retroversion) or muscle imbalances that limit internal rotation of the hip (e.g., tight piriformis). Ensuring that the patient's patellae are oriented in the frontal plane before assessing toe sign reduces the risk of false-positive findings.

Fig. 8.17 Toe sign, demonstrating excessive transverse plane motion as evidenced by the abducted position of the forefoot.

Torsional Deformities

Transverse plane abnormalities of the femur and tibia also adversely affect normal foot functioning. The femoral shaft normally has 12 degrees of medial rotation relative to the femoral head and neck (Fig. 8.18). In femoral anteversion more than 12 degrees of rotation are present, whereas in retroversion, fewer than the expected 12 degrees of medial rotation are present.[76] In normal transverse plane tibial alignment, the fibular malleolus is situated posterior to the tibial malleolus, for 20 to 30 degrees of lateral rotation.[76] Internal tibial torsion or femoral anteversion increase medial rotational forces, leading to abnormal foot pronation. Excessive external tibial rotation or femoral retroversion increases lateral rotational forces, leading to abnormal foot supination.

To assess femoral torsion, the patient lies in the prone position with the knee in 90 degrees of flexion.[46] The examiner palpates the greater trochanter as the lower limb is passively moved laterally (representing hip internal rotation) and medially (representing hip external rotation). Femoral torsion is measured at the point where the greater trochanter is most prominent (Fig. 8.19). When there is "normal" anteversion of 12 degrees, tibial position will indicate slight internal rotation of the hip. A vertical tibia indicates femoral retroversion.

Tibial torsion is assessed with the patient in the supine position, with 90 degrees of ankle dorsiflexion and the leg placed neutrally in the frontal plane (Fig. 8.20). The examiner holds the stationary arm of the goniometer parallel to the table surface while the mobile arm is aligned with the TCJ axis as it passes through the medial and lateral malleoli. This angular displacement represents tibial torsion. Normally, 20 degrees of external tibial torsion are present.

Dynamic Gait Assessment

The final component of the clinical evaluation is the observation of foot function during walking. During the dynamic gait assessment, extrinsic factors that affect foot function (e.g., muscle imbalances or weaknesses, proximal structural deformities, kinesthetic or proprioceptive losses) are observed. Videotaping the individual while he or she is walking on a runway or treadmill may enhance the accuracy of the assessment. The function of the rearfoot, midfoot, and forefoot is examined at each of the subphases of the gait cycle, with special attention to compensatory gait mechanisms.

Functional Foot Orthoses

Although 4 to 6 degrees of triplanar STJ pronation are necessary to provide adequate shock absorption and accommodation to uneven ground terrain, persistent or recurrent abnormal pronation disrupts normal temporal sequencing of the gait cycle. This disruption creates an unstable osseous and arthrokinematic situation that contributes to pathological musculoskeletal conditions.[8,49]

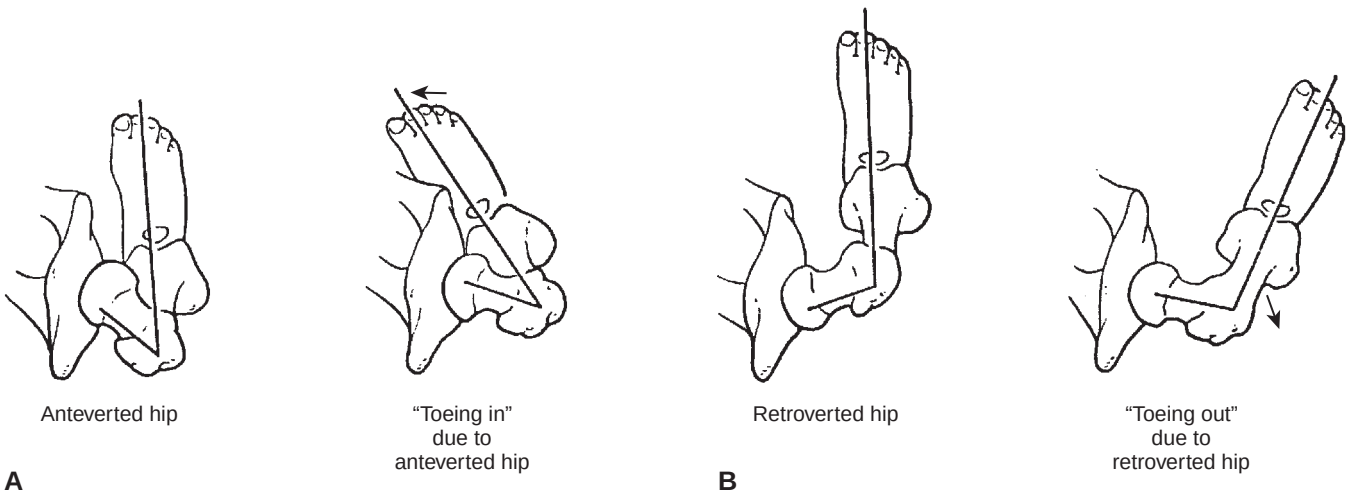

Fig. 8.18 (A) With excessive femoral anteversion, the limb appears to be internally rotated when the head of the femur is well seated in the acetabulum. (B) With femoral retroversion, the limb appears to be externally rotated when the femur is well seated in the acetabulum. (From Magee DJ. *Orthopedic Physical Assessment*. 3rd ed. Philadelphia: Saunders; 1997: 475.)

Fig. 8.19 Assessment of femoral torsion in prone position with a standard goniometer. The examiner palpates the greater trochanter and rotates the lower leg. Femoral torsion is measured at the point of greatest prominence of the greater trochanter.

Fig. 8.20 Tibial torsion is measured as the angle between horizontal and the plane of the axis of the talocrural joint.

Compensatory motion occurs in the primary plane of a given deformity. In frontal plane deformities (e.g., rearfoot varus or forefoot varus), the typical compensatory motion is eversion at the STJ. In transverse plane deformities (e.g., torsional deformities of the hip, femur, or tibia), the typical compensatory motion is adduction at the STJ. In sagittal plane deformities (e.g., ankle equinus), the typical compensatory motion is dorsiflexion at the STJ. Root's model suggests that single-plane compensatory motion is beneficial, allowing adequate accommodation for a deformity.[4] However, because the STJ is a triplanar structure, movement in one plane leads to movement in the others as well. The associated motion of the other planes has the potential to become dysfunctional and destructive.[8]

A functional foot orthosis is an orthopedic device designed to promote structural integrity of the joints of the foot and lower limb by resisting the GRFs that cause abnormal skeletal motion during the stance phase of gait.[49] A functional foot orthosis attempts to control abnormal foot functioning during stance by controlling excessive STJ and MTJ motion, decelerating pronation, and allowing the STJ to function closer to its neutral position at MSt.[78-81] In contrast, an accommodative foot orthosis is used to distribute pressures over the plantar surface for individuals with fixed deformity or vulnerable neuropathic feet.

CRITERIA FOR ABNORMAL PRONATION

Five criteria are used to determine whether pronation is abnormal. Pronation is considered an abnormal mechanical condition when the following conditions are present:

1. STJ pronation is more than the normal 4 to 6 degrees.[8,39,80]
2. The foot pronates at the wrong time, disrupting the normal sequencing of events during closed kinetic chain motion.
3. Pronation is recurrent, with each step contributing to repetitive microtrauma to musculoskeletal structures.
4. Pronation happens at a location other than the STJ (e.g., when MTJ pronation compensates for limited STJ motion).
5. Unnecessary destructive compensatory motion occurs in the other planes of motion of the STJ.[8]

CAUSES OF ABNORMAL FOOT MECHANICS

Three pathological situations contribute to abnormal foot mechanics: structural malalignment, muscle weakness or imbalance, and loss of structural integrity.

Structural Malalignment

Structural malalignment can be intrinsic or extrinsic to the foot or caused by abnormal mechanical forces.[8] Rearfoot and forefoot varus and valgus, ankle equinus, and deformities of the rays are examples of intrinsic deformities. Congenital and developmental conditions, such as tibial varum or valgum, torsional deformities of the tibia or femur, and other conditions that occur above the foot and ankle are extrinsic deformities. The types of abnormal mechanical forces that might contribute to pathomechanical foot function include obesity, leg length discrepancies, and genu valgum or varum. Orthotic management for structural malalignment is preventive; control of aberrant or excessive STJ and MTJ motion forestalls the sequence of mechanical events associated with abnormal pronation or supination, minimizing the consequences of painful foot conditions.

Muscle Weakness or Imbalance

A variety of upper and lower motor neuron diseases result in muscular weakness, abnormal muscle tone, or paralysis of the foot, with resultant instability of foot structure and reduced mechanical efficiency during gait.[47] In Charcot-Marie-Tooth disease (hereditary sensory motor neuropathy), for example, weakness of intrinsic, peroneal, and anterior tibial muscles contributes to development of a "cavus" foot, with claw toes, metatarsus adductus, or other deformities of the rays.[47] When muscle weakness or imbalance is present, the examiner must identify its origin and extent, the specific soft tissue structures involved, the resultant mechanical foot deformities, and the potential to reduce them. An effective foot orthosis for a patient with muscular weakness deters the pathomechanical sequelae that result from such induced structural foot deformities.

Compromised Joint Integrity

Compromised joint integrity and mechanical instability also can be caused by pathological musculoskeletal conditions of the foot or ankle, including arthritis, acute trauma, or chronic repetitive injury. For example, in rheumatoid arthritis, joint deformity results from synovitis and pannus formation. Autodestruction of connective tissue weakens tendons, contributes to muscle spasm and shortening, and erodes cartilaginous surfaces. Eventually, joint dislocations occur.[82]

The loss of protective sensation associated with peripheral neuropathy also contributes to compromised joint integrity. Patients with diabetes mellitus, chronic alcoholism, or Hansen disease (leprosy) are particularly vulnerable. The inability to perceive microtrauma because of sensory compromise, weakness of intrinsic muscles of the foot, compromised autonomic control of the distal blood flow, and the poor nutritional and metabolic state of soft tissues combine to increase the risk of plantar foot ulceration. If neuropathic osteoarthropathy (Charcot-Marie-Tooth disease) occurs, significant bone and joint destruction, collapse of the midfoot, and a fixed rocker bottom deformity can result.[83] Plantar ulceration at the apex of the collapsed cuneiforms or cuboid is common.[84] Whenever mechanical instability is present, normal joint orientation is altered, and gait compensation shifts weight-bearing forces. A foot orthosis can be used to reduce pain, reduce weight-bearing stresses, control abnormal or excessive joint motion, or compensate for restricted motion.

Goals of Orthotic Intervention

A functional foot orthosis attempts to improve foot mechanics during walking, regardless of the cause of foot dysfunction, by the following actions:

- Controlling velocity of pronation
- Redistributing plantar pressures
- Supporting abnormal structural forefoot positions that lead to abnormal rearfoot function in stance
- Supporting abnormal rearfoot deformities that lead to excessive STJ pronation
- Resisting extrinsic forces of the leg that lead to aberrant pronation and supination of the foot
- Improving calcaneal positioning at IC
- Repositioning the STJ in the neutral position just before heel rise
- Fully pronating the MTJ, when the STJ is in the neutral position, to lock and stabilize the foot, converting it into a rigid lever for propulsion
- Allowing normal plantarflexion of the first ray and stabilizing the forefoot in response to the retrograde GRFs sustained during propulsion
- Providing a normal degree of shock absorption during LR

A functional foot orthosis does not support the MLA of the foot; STJ pronation is controlled by the pressure of the rearfoot post on the calcaneus at the sustentaculumt ali. The ultimate goal is to stop, reduce, or slow abnormal compensatory motion of the joints of the foot as the foot and leg interact with the GRFs.

Measurement and Fabrication

The information gathered in the non–weight-bearing and static weight-bearing examinations and in gait analysis provides direction for orthotic prescription. A simple plaster cast is used to make an accurate negative impression of the patient's foot in the STN position. A positive model based on this impression is then prepared. Thermoplastic materials are heat molded over the model to form an orthotic shell. Accommodative padding, soft tissue supplements, and covering materials are added to address the patient's functional foot problem. The orthosis is fitted to the patient, and its effect on foot function during gait is evaluated. An early wearing schedule is devised, and an appointment for a recheck visit is scheduled.

NEGATIVE IMPRESSION

If a foot orthosis is to control abnormal pronation and supination effectively and to minimize painful symptoms in gait, the negative foot impression must precisely duplicate the existing foot structure, including any intrinsic deformities. The goal of the foot impression is to capture the patient's STN position during the MSt phase of the gait cycle.

Comparison of Negative Casting Techniques Used for Fabrication of Foot Orthotics

Multiple strategies can be used to take negative impressions, including suspension techniques, modified suspension techniques, direct pressure techniques, foam impression systems, digital casting, and in-shoe vacuum casts. The negative impression techniques may be applied with the patient in semi–weight-bearing, weight-bearing, or non–weight-bearing positions. Foot measurements are greatly influenced by the technique used to obtain the impression.[85]

The foam box technique (Fig. 8.21) captures a negative impression of the foot with the patient in semi–weight-bearing. Typically, the patient is seated on a firm surface and the practitioner directs the foot to the foam box. After the foot makes contact with the foam and the desired position is established, the practitioner applies a downward pressure along the tibial axis moving the heel into the foam followed by the forefoot. The foot is then removed from the box leaving a negative impression in the foam. The foam box technique requires less technical skills and is more time efficient than plaster negative casting. It might be used when the goal is to fabricate an accommodative (soft) foot orthosis.[86,87]

Fig. 8.21 Negative cast impression using the foam box technique. (Courtesy Amfit, Inc., Vancouver, WA.)

The digital casting technique produces a digital foot impression and allows for a variety of positions depending on the scanning device, which might include an optic laser, digitizer, pressure mat system, or digital photography.[88,89] Computerized images of the foot can be viewed by the practitioner from multiple angles, and some software allows the practitioner to modify the images (Fig. 8.22). The CAD/CAM system uses a milling apparatus to create the actual orthosis.

Plaster casting has traditionally been the gold standard for obtaining negative cast impressions. Foot alignment during plaster casting is a critical factor for the effectiveness and quality of the foot orthoses. It is common practice to align the STJ in a "neutral" position.[90] Because maintenance of the STN position and correct loading of the forefoot are difficult to control in weight-bearing impression techniques, suspension and direct pressure non–weight-bearing techniques appear to be the most reliable methods for making accurate negative impressions. The direct pressure technique, one of the easiest procedures to learn, captures the STN position by loading the fourth and fifth metatarsal heads to mimic GRFs during MSt (Fig. 8.23). Alternative casting procedures are also available.[91,92]

Direct Pressure Impression Technique

The patient is placed in the prone position, in the figure-of-four position used for goniometric measurement. Two double-layer thickness wraps of 5-inch plaster bandage are used to make the negative cast. The first wrap is cut to surround the foot from just distal to the fifth metatarsal head, around the posterior heel, to just beyond the first metatarsal head. The second wrap is cut so that, when draped over the plantar surface of the forefoot, it overlaps the first wrap at the metatarsals.

The first wrap is thoroughly moistened with tepid water and any wrinkles in the mesh are smoothed. The top edge of the plaster splint is folded 0.5 inch, providing reinforcement to prevent distortion when the cast is later removed. The first wrap is draped over the heel, just below the malleoli, and along the borders of the foot to just beyond the first and fifth metatarsal heads. Because total contact with the sole of the foot is essential, the plaster is carefully smoothed along the sides of the foot, across its plantar surface, and around the curves of the malleoli. The second wrap is moistened and draped around the forefoot, overlapping the distal edges of the first layer. Any excess bandage is folded into the sulcus of the toes. This layer should also have a wrinkle-free total contact with the foot and toes.

Once both wraps are in place, the foot is positioned in the STN position by maintaining appropriate forefoot loading pressure at the fourth and fifth metatarsal heads. The plaster splint is sufficiently hardened when an audible click is produced when it is tapped. The negative cast is then

Fig. 8.23 Negative cast impression by the direct pressure technique. The foot is maintained in subtalar neutral position while the plaster hardens.

carefully removed. The skin is gently pulled around the reinforced top edge to loosen contact from the cast. A downward force over the superior border of the heel cup is exerted to free the heel from the cast. A gentle forward force is then provided to free the forefoot and to remove the cast from the foot.

Errors in Negative Casting

Accuracy in the negative impression is the key to an effective orthotic. Although the casting procedure is simple, three types of errors during the process can compromise the efficacy of orthotic design.

First, the foot may be inadvertently supinated at the longitudinal MTJ axis as a result of contraction of the anterior tibialis while the patient "helps" hold the foot still. Alternatively, the loading force may be applied too far medially at the forefoot, creating a false forefoot varus. An orthosis manufactured from such a cast can cause excessive pressure plantar to the distal aspect of the first metatarsal shaft. It can also lead to lateral ankle instability or the development of a functional hallux limitus or HAV deformities.[93]

The second common casting error occurs when the foot is excessively supinated at the oblique MTJ axis. Improper loading at the fourth and fifth metatarsal heads results in insufficient dorsiflexion of the forefoot. When this happens, transverse skin folds can be seen inside the negative cast at the MTJ. An orthosis manufactured from this cast creates an excessive sagittal plane angulation plantar to the calcaneocuboid joint (lateral longitudinal arch), with pain and irritation on weight bearing.[93]

The third error occurs when the STJ is excessively pronated during casting, placing the foot in a false forefoot valgus position. An orthosis manufactured from this cast does not capture the STN position and is ineffective in controlling the symptoms of abnormal pronation.[93]

POSITIVE CAST MODIFICATIONS

Once a satisfactory negative impression of the patient's foot has been obtained, a positive cast is made and then modified. The hardened negative impression is filled with liquid plaster and allowed to dry. The negative cast is peeled away, leaving a positive mold of the foot (Fig. 8.24). Modifications to the positive cast ensure an effective correction in foot alignment and function by redirecting forces through the foot. Those made to enhance comfort include plaster additions to relieve pressure-sensitive regions of the forefoot and MLA. Because the negative cast is taken in a non–weight-bearing position, it is also modified to allow for the elongation of the foot and expansion of the soft tissues in weight bearing. The cast is also modified to allow for normal plantarflexion of the first metatarsal during propulsion.[50,94] Intrinsic or extrinsic posts can be added for further correction of forefoot or rearfoot deformities.

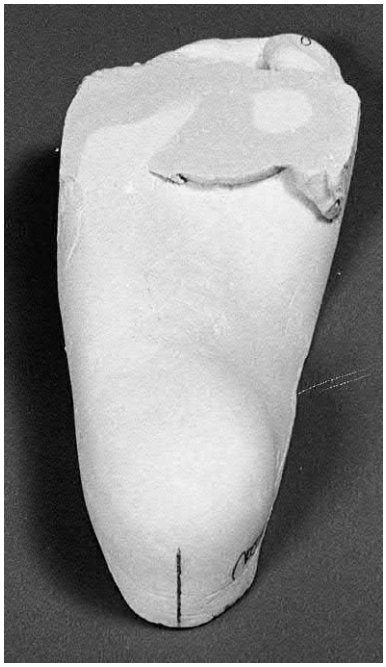

Fig. 8.24 The modification process of forefront position on a positive cast.

Forefoot Posting

Two techniques can be used to provide orthotic correction for forefoot deformity. Both are based on modification of the positive cast impression. The first, a traditional Root functional orthosis, uses an intrinsic correction. A plaster platform is applied to the positive cast at the level of the MTP joints to balance the abnormal forefoot to rearfoot relation (Fig. 8.25). A lateral platform corrects forefoot valgus, and a medial platform corrects forefoot varus.[50] When the shell is pressed over the modified positive mold, it creates a convexity at the distal anterior border of the orthosis. This posting technique achieves correction by effectively realigning the skeletal structure of the foot.[94] The intrinsic posting technique is often selected when shoe volume is limited, as in some women's footwear.

A second forefoot posting technique involves a variation of Root's original design, referred to as a standard biomechanical orthosis. In this technique, a neutral platform is formed on the positive mold, but the existing valgus or varus position of the forefoot is maintained. An extrinsic forefoot post or wedge is attached to the bottom of the orthotic shell to support the forefoot in its position of deformity. Unwanted compensatory motion is prevented by stabilizing the distal border of the orthosis (Fig. 8.26). Although an orthosis with an extrinsic correction takes up more space inside the shoe than an intrinsically corrected orthosis, it can be modified more easily if the individual has difficulty tolerating the original posting prescription.

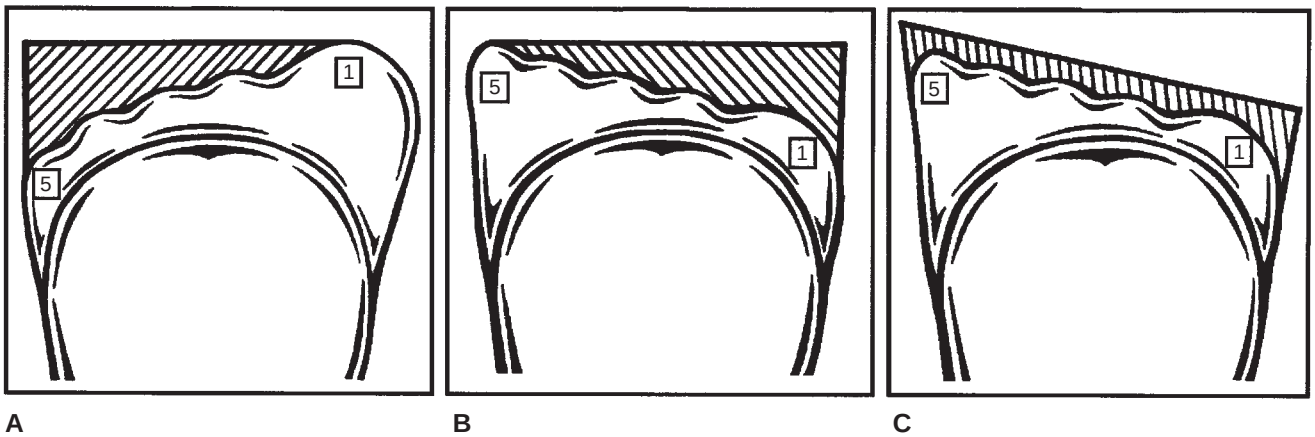

Fig. 8.25 Cross section at the level of the metatarsophalangeal joints, with first and fifth metatarsals labeled, demonstrating intrinsic modifications to the positive mold. (A) A lateral platform corrects forefoot valgus. (B) A medial platform corrects forefoot varus. (C) A neutral balancing platform maintains forefoot alignment and serves as a base for extrinsic posts. (Courtesy Stride, Inc., Middlebury, CT.)

Rearfoot Posting

As the foot makes contact with the ground and moves through stance during gait, GRFs act on the joints of the foot. An orthosis acts as an interface between the ground and the foot, creating its own orthosis reactive force. In a foot that pronates excessively, the foot orthosis is designed to decrease STJ pronation during weight bearing by creating a supination moment acting medial to the STJ axis.[6] This can be accomplished by adding an extrinsic rearfoot post or wedge to the inferior surface of the heel cup or by modifying the plaster mold to incorporate an intrinsic rearfoot post to the heel cup of the orthosis. A rearfoot post effectively reduces rearfoot pronation (eversion) during the contact phase of gait as well as the angular velocity of eversion.[6,95,96]

Extrinsic rearfoot posts are attached to the bottom of the orthosis shell beneath the heel (see Fig. 8.26B). A medial wedge or rearfoot post increases orthosis reactive forces at the sustentaculum tali (medial to the STJ axis) to reduce abnormal STJ pronation. It also promotes stability of the heel by increasing the contact surface of the orthosis beneath the heel.[94,95] An intrinsic rearfoot post can be made with a medial heel skive technique. A plaster modification is performed on the medial aspect of the heel of the positive mold to increase the amount of varus (medial) sloping within the heel cup of the orthosis in an effort to control pronation.[6] An intrinsic rearfoot post reduces overall bulk of the orthosis for optimal fit within a shoe. A combination of intrinsic and extrinsic rearfoot posting permits more correction than possible with either method independently.

THE ORTHOTIC SHELL

To be effective, a functional orthosis must be made on the basis of a neutral position model of the patient's foot. Prefabricated foot supports do not offer adequate control of foot motion or resistance to GRFs and cannot fulfill all criteria of functional foot orthoses. A custom orthosis, made of rigid or semirigid materials, can offer maximal resistance to weight-bearing forces and optimal realignment of foot structure. Accommodative orthoses, made of softer materials, support the arches of the foot and provide relief to pressure-sensitive areas while offering minimal control of STJ motion.[97,98] A semifunctional orthosis is a hybrid of functional and accommodative orthoses that combines the motion effectiveness of a semirigid shell with soft posting and accommodative material to cushion the foot.

Many studies have evaluated the effectiveness of the different types of orthotic materials in controlling rearfoot mechanics and clinical symptoms.[97-101] Some suggest that orthotic materials be classified by degree of rigidity (soft, semirigid, rigid), but standards for the classification of materials are not well established.[5]

A rigid orthosis achieves maximal motion control and biomechanical correction of a foot deformity; it is lightweight, and takes up the least space within the shoe. Some clinicians are concerned that orthoses made of rigid materials are uncomfortable to the wearer. However, Anthony[50] suggested that those "who propose rigid devices to be patient intolerant are generally less acquainted with the theory of podiatric biomechanics and the correct diagnostics and prescription formularies that are critical for the provision of a truly functional foot orthosis."

Semirigid materials, such as polypropylene and TL-2100 (Performance Materials Corp., Camarillo, CA), are attractive alternatives to rigid orthotic shells. Polypropylene is a flexible olefin polymer that resists breakage. TL-2100 is a thermoplastic composite of resin and fiber that is harder and more rigid than polypropylene.[5]

Soft orthoses are often made of closed-cell foams manufactured from heat-expanded polyethylene. Examples of such foams include Aliplast and Nickleplast (Alimed, Inc., Dedham, MA) and Plastazote (Bakelite Xylonite Ltd, Croydon, UK), cross-linked polyethylene expanded foams available in many densities. Pelite (Fillauer, Inc., Chattanooga, TN) is a cross-linked, closed-cell foam that can be heat molded in the fabrication of semiflexible foot orthoses. Various rubberized or thermoplastic cork materials are also used.[1] Lightweight and available in different densities, these materials are effective in orthotics for which accommodation and shock absorption are desirable. However, these same features limit the durability and the useful life of the orthosis because these materials are prone to rapid and permanent shape deformation.[5]

For some individuals, extrinsic accommodative modifications are necessary to address a particular deformity. Examples of accommodative supplements are listed in Table 8.1.

Covering Materials

Once appropriate posts and supportive materials are attached to the shell of the orthosis, a covering material is applied to provide an interface with the skin of the foot. Vinyl is a commonly used orthosis-covering material. Spenco (Spenco Medical Corporation, Waco, TX) and various other fabric-covered neoprene materials are resistant to shearing and enhance shock absorption. They are often chosen as covering materials for certain sport orthoses when shear forces are expected to be high or for occupational situations that demand prolonged standing on hard surfaces.

Table 8.1 Accommodative Padding and Soft Tissue Supplements for Functional Foot Orthotics

Supplement	Description
Metatarsal mound	This is a dome-shaped addition in the form of a teardrop positioned with the apex just proximal to the metatarsal heads to support a collapsed transverse metatarsal arch. Often used to control symptoms of neuroma by reducing shearing of the metatarsals during the contact phase. Reduction of the shearing eliminates irritation to the interdigital nerves of the forefoot.
2–5 bar	A pad of uniform thickness placed beneath the second through fifth metatarsal heads relieves pressure beneath the first metatarsal head during propulsion. It is used when a rigid plantarflexed first ray is present.
Metatarsal head cutout	This is a U-shaped pad positioned beneath a rigid plantarflexed metatarsal head to relieve pressure from a painful callosity. It is often used for hammertoe deformity.
Morton extension	This is an extension of the plastic shell, or the addition of an inlay made of dense material, beneath the shaft of the first metatarsal to the sulcus of the hallux. It is often used for a dorsiflexed first ray or Morton toe.
Heel cushion	This is placed in the heel cup of the orthosis to enhance heel cushioning and shock absorption. It is often made of the soft tissue–supplementing material Poron (Rodgers Co., Rogers, CT.) or a viscoelastic polymer. It is used when irritation or atrophy of the infracalcaneal fat pad is present or for a calcaneal stress fracture.
Forefoot extension	A soft tissue–supplementing material, such as Poron, is added to the distal end of the orthotic shell to cushion the metatarsal heads or as a base for other forefoot inlays.
Scaphoid pad	This is a material of soft to medium density placed beneath the medial longitudinal arch to decelerate pronatory forces.

Managing Rearfoot Deformity

In a well-aligned foot, 4 to 6 degrees of STJ pronation occur during the stance phase of gait. In rearfoot varus, more than 6 degrees of STJ pronation are present. A fully compensated rearfoot varus deformity of 10 degrees pronates at the STJ 10 degrees during gait to lower the medial condyle of the calcaneus to the ground, but only 6 degrees of this pronation are considered excessive.

The appropriate orthotic design for rearfoot varus is a medial post or medial wedge. Complete orthotic correction is difficult to achieve and quite uncomfortable for the individual wearing the orthosis. Because of this, the initial goal is often to create an orthosis that provides 50% correction of a rearfoot deformity. For example, to correct the excessive 6 degrees of pronation, a medial rearfoot post or wedge of 3 degrees would be applied to the orthosis.

If an individual with a rearfoot varus deformity of 10 degrees is uncompensated to −5 degrees of calcaneal eversion, a medial or varus wedge of 3 degrees is not effective because the STJ would reach its end-range eversion motion (−5 degrees) before the orthosis provided support. To manage uncompensated rearfoot deformity effectively, the varus wedge must be large enough to prevent the STJ from reaching its end ROM. In this example, a larger medial rearfoot varus post or wedge of at least 5 degrees is necessary. When the rearfoot is aggressively posted (more than 3 or 4 degrees of varus posting), the distal medial aspect of the orthosis shell loses contact with the ground, as if a forefoot varus deformity were present. In these circumstances, a medial forefoot post is used to counteract the induced apparent forefoot varus.

Managing Forefoot Deformity

For forefoot varus deformities, a medial (varus) wedge or post is indicated. For forefoot valgus deformities, lateral (valgus) posts or wedges are used. Forefoot deformities can be corrected through intrinsic plaster modifications or extrinsic posting. For an orthosis to be accurately balanced so that it does not wobble, a forefoot deformity must be corrected to its fullest extent (e.g., an 8-degree forefoot varus deformity requires an 8-degree medial wedge or post).

The addition of a large extrinsic post to the distal end of the orthotic shell often creates problems with shoe fit. One possible solution is to correct large forefoot deformities with a combination of intrinsic and extrinsic techniques. In this example, a 4-degree medial intrinsic plaster platform and a 4-degree extrinsic medial forefoot post or wedge would provide the desired correction without bulkiness. For individuals with a forefoot varus deformity of 10 degrees or more, a semipronated or pronated negative cast can reduce the forefoot deformity to a more manageable degree.[91]

Plantarflexion of the first ray is managed according to the level of flexibility of the deformity. A fully flexible plantarflexed first ray deformity does not require orthotic intervention. A semirigid or rigid plantarflexed first ray deformity requires the addition of a metatarsal (second through fifth) bar inlay. The thickness of the inlay is determined by how far below the first metatarsal head lies relative to the plane of the remaining metatarsal heads. The orthotic intervention for patients with a rigid plantarflexed first ray and forefoot varus is an extended medial forefoot wedge. The forefoot post is modified with a cutout to accommodate the dropped first metatarsal head position. In some cases, a small forefoot varus deformity combined with a large, rigidly plantarflexed first ray deformity results in a functional forefoot valgus (see Fig. 8.14).

Orthotic Checkout and Troubleshooting

Delivery of an orthosis includes evaluation of its fit, comfort, and mechanical alignment. The orthotic shell should end just proximal to the metatarsal heads. The width is evaluated to ensure that normal first ray plantarflexion and propulsion are not compromised. The position of the orthosis within the shoe is also evaluated; its volume, impact on heel height, points of excessive pressure, and tendency to cause pistoning during gait are considered. On initial fitting, many individuals report that the orthosis feels slightly strange or unusual. However, the orthosis should not cause undue

discomfort. Fit and mechanical functioning of the orthosis are evaluated in standing and walking.

Patient education in appropriate break-in protocols and wearing schedules is an important component of orthotic delivery. A new orthosis is usually worn for 2 hours on day 1, 4 hours on day 2, 6 hours on day 3, and so forth, until the individual is able to wear the orthosis comfortably all day. A follow-up visit is scheduled after the orthosis has been worn for at least 2 weeks. By this time, the patient should feel comfortable with the orthosis for normal activities of daily living. Thereafter, progressively increased use of the orthosis for all activities, including sport and occupational use, should be well tolerated. Adjustments are occasionally necessary to optimize patient comfort and mechanical alignment.

Controversy With Root's Paradigm

Much discussion on the basic components of Root's theory has occurred in the past decade.[55,102-109] Root's theory is founded on "normal" foot structure and the concept of the STN position: the point of maximal congruence in the articulation of the talus and navicular.[8,16,32,65] STN position supposedly (1) minimizes stress to the surrounding joints and ligaments, (2) is the most efficient position regarding muscle function and attenuation of the impact forces at IC, and (3) represents the point at which the foot converts from a mobile adapter to a rigid lever.[8,46,65] According to Root's traditional theory, normal foot alignment occurs just before TSt during gait, when the STJ is in the neutral position and the MTJ is fully locked.[8]

The major criticisms of Root's paradigm raise concerns about the reliability of measurement of the STN position, the STN position during the gait cycle, and criteria for "normal" foot alignment.[42,45,66,104,108,110]

RELIABILITY OF MEASUREMENT

When considering available evidence about the reliability of foot measurements and the STN position, although acceptable levels of intrarater reliability exist,[43,44,51,53,110,111] interrater reliability of foot measurements and the STN position is low.[42,102,104,108] Diamond and colleagues[112] and Cook and colleagues[111] found that interrater reliability can be improved with training. McPoil and Hunt[42] noted that considerable confusion exists regarding the definition and measurement of STN position. They suggested that Root's STN position may misinterpret the work by Wright and colleagues,[113] who referenced relaxed standing position, not STN neutral, as the basis of their work. To further add to the confusion, the definition of STN position used in some reliability studies was not identical to Root's methods.[108] Based on the review of reliability studies, McPoil and Hunt[42] suggested that physical therapists are not able to agree on the position and motion of the STJ.

SUBTALAR POSITION IN STANCE

According to Root, ideal foot alignment occurs just before TSt during gait, when the STJ is in the neutral position and the MTJ is fully locked.[8,114] In a study of rearfoot motion of 51 healthy adults, McPoil and Cornwall[115] marked patients' lower leg and calcaneus with bisection lines and then filmed relative calcaneal and lower leg position while walking, while standing in a double-support relaxed standing, and while in the STN position. Their findings did not support Root's paradigm. They found that (1) the rearfoot is slightly inverted before IC, (2) the maximal rearfoot pronation was reached at the 37.9% point of stance phase, and (3) the neutral position of the rearfoot for the typical pattern of rearfoot motion should be the resting standing foot posture rather than STN position.[113] As a result, they suggested that the relaxed standing foot position rather than the STN position should be used during casting.[113]

Pierrynowski and Smith[116] used three-dimensional analysis and six experienced raters to study the pattern of rearfoot motion throughout the gait cycle relative to the STN position. The right lower extremities of nine patients were evaluated by each rater six to seven times, and the STN position was recorded. Patients then walked on a treadmill and were recorded for 30 seconds to allow the capture of approximately 25 walking cycles. For most patients, the rearfoot was everted throughout stance, with maximal eversion occurring at 44% of the gait cycle.[111] They found that the STN position occurs at 64% and 74% of the gait cycle, with the rearfoot inverted between these points. The rearfoot was everting from 0% to 44%, inverting from 44% to 70%, everting from 70% to 90%, and inverting from 90% to 100% of the gait cycle.[114] The authors concluded that the manufacture of foot orthoses should not be associated with the STN position.[116]

CRITERIA FOR NORMAL ALIGNMENT

Root described deviations from normal foot alignment as intrinsic foot deformities, which can lead to aberrant lower extremity function and musculoskeletal pathological conditions.[8,65] Root and colleagues[114] defined three criteria for normal foot and ankle alignment in the loaded STN position: (1) a bisection of the lower leg being in parallel to the bisection of the calcaneus, (2) the plane of the metatarsal heads being perpendicular to the bisection of the calcaneus, and (3) the distal third of the lower leg being perpendicular to the floor. McPoil and colleagues[42,102] examined 116 feet in 58 asymptomatic individuals, finding 8.6% with forefoot varus, 44.8% with forefoot valgus, 14.7% with a plantarflexed first ray, 83.6% with subtalar varus, and 98.3% with tibiofibular varum. Only 17% (116 feet) of the 58 individuals evaluated demonstrated normal criteria.[42] In an examination of forefoot to rearfoot relations of 120 healthy asymptomatic individuals, Garbalosa and colleagues[52] found that only 4.58% of the 234 feet studied exhibited normal criteria, 86.67% had forefoot varus, and 7.75% had forefoot valgus. Astrom and Arvidson[117] performed standardized clinical assessments on 121 healthy individuals, finding that none demonstrated an ideal foot position; most had a valgus position in the STN position (mean, 2 degrees), forefoot in varus (mean, 6 degrees), calcaneal valgus in stance valgus (mean, 7 degrees), and 6 degrees of tibial varus with respect to vertical. The evidence from these studies suggests that an "ideal" foot may be based on a questionable theoretical concept.

Foot Type and Lower Extremity Biomechanics

A question that has been the focus of recent research focuses on the relation between various foot types and the amount of pronation during gait. Recent reviews of the literature suggest this question might not have a simple answer. Dicharry and colleagues[118] compared static and dynamic measures of navicular drop in 72 healthy adults. Although the participants had significantly different static measures of various foot types, they only displayed small or no differences during running and walking. The findings suggest that features other than foot type affect dynamic joint function. According to Razeghi and Batt,[119] foot type alone cannot explain ankle and foot kinematics because of the interrelated function of the subtalar, talocrural, and knee joints. Goffar and colleagues[120] examined the relation between foot type and pressure distribution during loaded gait. Although specific foot types had characteristic force distribution patterns, an increase in load resulted in a consistent increase in force distribution over the entire foot during gait regardless of foot type. Ball and Afheldt[108] suggested that attempts to justify static classification of foot type schemes as a means of predicting dynamic joint function have had mixed results.

Foot Type and Lower Extremity Overuse Injuries

A number of published studies have provided conflicting evidence on the relation between foot type and lower extremity injuries.[121] Many researchers have reported an association between abnormal alignment of the foot and lower extremity and occurrence of lower extremity injuries. Dahle and colleagues[122] studied the relation between foot type (classified in standing as supinated, pronated, or neutral) and occurrence of ankle sprain and knee pain in 55 athletes during the football and cross-country seasons. Although the relation between foot type and subsequent ankle sprain was not supported, foot type was strongly related to knee pain; 48% of those with pronated feet and 50% of those with supinated feet had significant knee pain compared with 21% of those classified with neutral alignment. Gross and colleagues[123] examined the relationship between forefoot and rearfoot varus alignment to hip conditions in 385 older adults. Older adults with more forefoot varus were 1.8 times more likely to have ipsilateral hip pain, 1.9 times more likely to have hip pain or tenderness, and 5.1 times more likely to have undergone total hip replacement when compared with older adults with less forefoot varus. There was not a significant relationship between older adults with rearfoot varus and hip conditions. Powers and colleagues[124] compared the prone STN rearfoot position of 15 patients diagnosed with patellofemoral pain with 15 control subjects, reporting a statistically significant difference in rearfoot varus found in the patellofemoral group (8.9%) compared with control subjects (6.8%). In a retrospective study of the relation between foot posture and incidence of medial tibial stress syndrome (MTSS), Sommer and Vallentyne[125] measured the foot angle in 14 standing limbs with MTSS and 36 control limbs. They reported a mean foot angle of 137 degrees in symptomatic limbs compared with 145 degrees in asymptomatic limbs. They also reported that a standing foot angle of less than 140 degrees and a varus alignment of the rearfoot or forefoot, measured qualitatively in the STN position, were predictive of a previous history of MTSS.

Some reports do not support the relation between foot type and lower extremity injury. Donatelli and colleagues[126] reported no statistically significant relations among static or dynamic foot posture and injury status in professional baseball players. Razeghi and Batt[119] suggested that arch height may not influence injury occurrence. Similarly, Cowan and colleagues[127,128] found that individuals in the US Army with low arches might be less likely to have lower extremity injury. Considering the variety of reports in the literature, Razeghi and Batt[119] surmised that "the effect of foot type on the occurrence of lower extremity injuries has not been the subject of well-controlled studies and few, if any, causal correlations have been demonstrated."

FOOT STRIKE PATTERN DURING RUNNING AND LOWER EXTREMITY BIOMECHANICS

The current literature describes three foot-strike patterns that are predominant when running: rearfoot, midfoot, and forefoot. Rearfoot striking occurs when the heel contacts the surface first. During midfoot striking simultaneously the heel and ball of the foot contact the ground first, and forefoot striking happens when runners land on the ball of their foot first.[129-131]

How the foot contacts the ground affects lower extremity joint moments and causes different kinematics of the lower extremity and contrasting kinetics.[131] Goss and Gross[132] suggested that runners with initial foot strike anterior to the heel may reduce knee joint loading and vertical GRFs but upsurge ankle joint loading. Kulmala and colleagues[133] examined the biomechanical differences in forefoot strike patterns and rearfoot strike patterns. Runners with a forefoot strike pattern had lower peak hip and knee frontal plane moments, lower patellofemoral loading, and higher ankle plantarflexor and Achilles tendon loading than runners with rearfoot strikes. According to Williams and colleagues,[134] forefoot strike, with or without shoes, produced a significant shift from loading at the knee to the ankle when compared with rearfoot strike.

FOOT STRIKE PATTERN DURING RUNNING AND LOWER EXTREMITY INJURIES

Habitual foot strike pattern may affect common lower extremity injuries during running. Daoud and colleagues[131] studied the relation between foot strike patterns and injury rates among 52 runners on the Harvard University Cross Country team. Significantly higher rates of repetitive stress injury were found in runners on the college team with rearfoot strikes than those with forefoot strikes. Diebal and colleagues[135] examined whether adopting a forefoot running strike pattern would decrease pain and disability associated with chronic exertional compartment syndrome (CECS). Following a 6-week forefoot strike training program, 10

participants with CECS who habitually ran with a rearfoot strike pattern experienced significant decrease with pain and disability associated with the condition. Their running distance increased over 300%. One year after the program, participants' running speed and distance were greater than that observed at the conclusion of the 6-week intervention. Although participants were candidates for surgery before the training program, they all avoided surgery.

Orthoses and Lower Extremity Function

Overpronation has been implicated as a cause of many overuse injuries. Traditionally, a foot orthosis is used to help control abnormal foot functioning during the stance phase by controlling excessive STJ motion, decelerating pronation, and allowing the STJ to function closer to its neutral position during stance.[79-81] Literature regarding the efficacy of foot orthoses in controlling lower extremity and foot biomechanics is growing.[4,136,137] A systematic review and meta-analysis conducted by Richter and colleagues[138] reported that there is evidence for the use of foot orthoses to prevent lower limb overuse conditions.

EFFECT ON REARFOOT BIOMECHANICS

The use of foot orthoses is based on the premise that control of frontal plane rearfoot motion in stance provides a means of controlling pronation of the foot. Novick and Kelley[139] investigated the effects of medially posted rigid orthoses in 20 asymptomatic individuals during the LR phase of the gait cycle. They report a significant decrease in calcaneal angle (angle between the sagittal plane and bisected posterior tubercle of the calcaneus), calcaneal eversion angle (mathematical sum of the tibia vara angle plus the calcaneal angle), angular velocities and angular accelerations, as well as a shift medially in the center of pressure relative to the ankle joint. These findings that an orthosis is able to reposition the rearfoot concur with earlier studies examining the effects of orthoses on rearfoot mechanics.[98,101,140,141] MacLean and colleagues[142] examined the impact of custom foot orthoses on lower extremity mechanics of 15 female runners. The runners performed five running trials with and without the orthoses. The runners displayed a significant reduction in maximum rearfoot eversion angle (2 degrees) and rearfoot eversion velocity while wearing the orthoses.

Johanson and colleagues[143] examined the effects of three different orthotic posting methods on subtalar pronation during ambulation in 22 individuals with a forefoot varus deformity of at least 8 degrees. Individuals ambulated in running shoes with (1) unposted prefabricated shells with a polyurethane arch support and individualized shells posted (2) at the rearfoot, (3) at the forefoot, and (4) at both the rearfoot and forefoot. Forefoot posts were approximately 50% of the measured forefoot varus deformity, and the rearfoot posts were 80% of the forefoot post. Running shoes without shells were used as the control. Measurements of calf to calcaneus and calcaneus to vertical were recorded for each situation. Shells with and without posting decreased calcaneal angles compared with running shoes alone. Concurrent posts of rearfoot and forefoot decreased calcaneal angles similar to rearfoot posting alone; both decreased the angle more than forefoot posting alone. Similarly, Genova and Gross[144] found significant reduction in calcaneal eversion during static stance with shoes alone and shoes with orthoses, compared with the barefoot condition, in 13 individuals with barefoot standing calcaneal eversion angles of at least 10 degrees. The condition of the shoes and the orthoses was not statistically different in controlling eversion in static standing. Individuals demonstrated lower angles for maximal calcaneal eversion during stance and for calcaneal eversion at heel rise for the shoe with an orthosis compared with the shoe alone during fast walking on a treadmill. Branthwaite and colleagues[145] investigated the biomechanical effects of simple orthotic designs at rearfoot in nine individuals with varus deformities of the feet by using biplanar orthoses (medial wedging at the heel) or cobra pads (medial wedging and an arch support). A decrease in calcaneal eversion occurred with the biplanar orthosis compared with no insole, but no difference occurred with cobra insoles. Neither condition produced significant changes in the maximal eversion velocity.

The difficulty in predicting the biomechanical effects of orthoses on the rearfoot was demonstrated by Brown and colleagues,[146] who compared shoes only, over-the-counter arch supports, and custom-made semirigid orthoses to control rearfoot pronation in 24 patients with a forefoot varus deformity. Custom-made orthoses were posted at both the rearfoot and forefoot, with forefoot posts at 60% of the forefoot deformity and rearfoot posts at 50% of the forefoot deformity. Although a difference was found in the total pronation among the three groups, the authors suggest additional research is warranted to identify orthotic factors responsible for the biomechanical effects associated with the clinical successes of foot orthotics. Butler and colleagues[147] found that rigid or soft orthoses posted 6 degrees at rearfoot were unable to control calcaneal eversion excursion, peak eversion, and eversion velocity during running in individuals with normal foot alignment.

Miller and colleagues[148] suggested that mechanisms by which orthoses control rearfoot motions are not as clear as might be expected. The examination of GRFs during ambulation of 25 individuals with pes planus with or without a rearfoot device found no significant change in the mediolateral GRFs during the stance phase of gait. However, significant differences were found in the vertical and anterior posterior GRFs during various percentages of the stance phase.

Several variables that must be considered in interpreting these disparate findings, including the materials used, whether individuals are running or walking, foot alignment and biomechanics, and posting methods. Although rearfoot mechanics appear to be altered by foot orthoses, further investigation into the mechanisms responsible for these effects is needed.

EFFECT ON LOWER LIMB BIOMECHANICS

Foot orthoses influence lower extremity kinematics and kinetics as well as rearfoot mechanics. Eng and

Pierrynowski[100] examined the three-dimensional effects of soft foot orthoses during the contact, MSt, and propulsion phases of walking and running on the TCJs, STJs, and knee joints in 10 women with a history of patellofemoral joint pain and forefoot varus or calcaneal valgus greater than 6 degrees. Soft orthoses produced a modest decrease in frontal and transverse plane motion in the TCJs, STJs, and knee joints during walking and running. Knee joint motion in the frontal plane decreased during the early and MSt phases of walking but increased during the contact and MSt phases of running. This work demonstrates the complex coupling of lower extremity kinematics with motions of the STJ; reductions in subtalar motion in the frontal plane have an impact on knee function in both the frontal and transverse planes during walking.

McPoil and Cornwall[149] also studied the effects of soft and rigid orthoses on tibial rotation. Ten individuals with documented rearfoot or forefoot deformity ambulated with unposted, premolded, soft orthoses and rigid polyethylene orthoses posted according to the individual's deformity. Both orthoses decreased the rate and amount of tibial internal rotation during walking. Stacoff and colleagues[150] observed the effects of medially posted cork orthoses on calcaneal and tibial motions in five runners. Three-dimensional tibiocalcaneal rotations were assessed after inserting intracortical bone pins into the calcaneus and tibia. Although the effects on eversion and tibial rotation were small and variable, a statistically significant orthotic effect was present for total tibial rotation. The authors, noting that the differences were unsystematic across conditions and were specific to each individual, speculated that the effects of orthoses might be proprioceptive as well as mechanical.

Joseph and colleagues[151] studied the relationship between ankle pronation/eversion with excessive knee valgus and risk of anterior cruciate ligament injury in female athletes during drop jumps. Ten female athletes performed drop jump landings with and without a medially posted orthosis. A three-dimensional kinematics of the knee and ankle were measured during the jump. The authors reported a significant decrease in ankle pronation/eversion and knee valgus at IC when the athletes had a medial post in their shoes. Their findings support medial orthotic posts for potentially decreasing the risk of anterior cruciate ligament injury. Tillman and colleagues[152] evaluated the impact of orthotic posting on the tibial rotation induced by jumping from a 43-cm-high platform in seven women without foot malalignments by using three conditions (shoes only, shoes with orthoses posted 8 degrees medially, and shoes with orthoses posted 8 degrees laterally). Tibial internal rotation increased by 2.6 degrees with laterally posted inserts and decreased by 3.1 degrees with medially posted inserts. Nester and colleagues[153] examined the effects of medially and laterally wedged orthoses on the kinematics of the rearfoot, knee, hip, and pelvis during walking, reporting main effects on the rearfoot, with minimal effects at knee, hip, or pelvis. Laterally wedged orthoses increased pronation and decreased laterally directed ground forces, whereas medially wedged orthoses decreased pronation and increased the laterally directed ground forces.

Williams and colleagues[154] examined the effects of graphite "inverted" orthoses (orthoses used to provide more aggressive control of pronation by using an inverted position as opposed to a more vertical orientation), standard graphite orthoses posted with a 4-degree medial wedge, or shoes alone in 11 runners who had been initially fitted with the standard orthoses for various lower extremity injuries. Surprisingly, the three conditions produced no significant differences in the peak rearfoot eversion or rearfoot eversion excursion.

A significant decrease in the rearfoot inversion moment and work with the inverted orthosis suggests this orthotic design might decrease demand on the structures controlling eversion. However, increased internal tibial rotation and an adduction moment at the knee occurred with the inverted orthosis, raising concern that potential for lateral stress increases with this aggressive orthotic approach.

Kuhn and colleagues[155] examined quadriceps femoris Q-angle in 40 men with bilateral pes planus or hyperpronation syndrome before and after the insertion of foot orthotics. Of the 40 men, 39 had a significant decrease in bilateral Q-angle in the direction of correction after insertion of full-length flexible orthotics. Men with asymmetrical Q-angle measurements showed significantly greater symmetry of Q-angle measures after orthotic placement. Kuhn and colleagues[155] noted that hyperpronation can cause the tibia to internally rotate, leading to femur internal rotation and resulting in lateral tracking of the patella. They concluded that insertion of full-length flexible orthotics in men with hyperpronation significantly improves quadriceps femoris Q-angle.

Stackhouse and colleagues[156] studied biomechanics during running in 15 individuals with normal alignment. Individuals ran with both rearfoot and forefoot strike patterns and with and without semirigid orthoses with 6 degrees of rearfoot posting. The orthoses did not change rearfoot motion in either strike pattern but did reduce internal rotation and genu valgum by approximately 2 degrees through most of the stance phase. Although no statistically significant reduction occurred in the inversion moment and inversion work, the authors believed that the reductions they found were clinically relevant and might explain the reduction of injuries seen when orthoses are used.

Although evidence supports the fact that foot orthoses can and do influence lower extremity kinematics and kinetics, the variability of individual responses makes it difficult to determine exactly which biomechanical effects will occur. This variability also makes it difficult to forecast who is likely to benefit from orthotic intervention. Efficacy of foot orthoses is not solely the result of altered rearfoot kinematics, as proposed by Root. The contribution of the neuromuscular system to the effect of orthotic intervention is now being considered.

EFFECT OF THE NEUROMUSCULAR SYSTEM

Nigg and colleagues,[157] citing problems in previous studies (e.g., small skeletal changes produced by orthotic use, minimal decrease in impact forces, and nonsystematic effects caused by individual variability), proposed that mechanisms involving the neuromuscular system contribute to the way that foot orthoses alter lower extremity function. They were especially interested in sensitivity of the foot and pressure distribution on the foot surface, noting that (1) the foot

has many sensory receptors to detect forces and deformations acting on it, (2) the sensors detected input signals into the foot with patient-specific thresholds, and (3) individuals with similar sensitivity thresholds seem to respond to their movement patterns in a similar way. They suggested that force signals from the floor were filtered by the shoe, the orthosis, and finally by the plantar surface of the foot, which then transferred the filtered information to the central nervous system. The central nervous system, in turn, prompted dynamic responses in the lower extremity on the basis of patient-specific conditions. Comfort of the orthosis is an important consideration; a comfortable orthosis is likely to minimize muscular work during walking. According to Nigg and colleagues,[157] an optimal orthosis would reduce muscle activity, feel comfortable, and improve musculoskeletal and neuromuscular performance in walking.

Based on his analysis of the role of impact forces on foot function in gait, Nigg[158] proposed a new paradigm focusing on locomotor systems and strategies for impact and movement control. The dynamic systems model of motor control suggests that locomotor systems keep general kinematic and kinetic situations similar for any given task. Nigg suggests that a muscle tuning reaction occurs to cause forces that affect muscle activation before ground contact, and that muscle adaptation (to ensure a constant joint movement pattern) affects muscle activation during ground contact. The interplay of the realignment of the skeleton and locomotor system muscle tuning affects joint and tendon loading and, in turn, fatigue, comfort, work, and performance.

Electromyographic and Imaging Evidence

Mundermann and colleagues[159] studied 21 recreational runners who used a flat shoe insert, posting alone, custom-molded orthoses, and custom-molded orthoses and posting. They analyzed the effects of each condition on lower extremity kinematics, kinetics, and electromyographic data as well as comfort during use. Thirty-five percent of differences in comfort were explained by changes in 15 kinematic, kinetic, and electromyographic variables; these 15 variables correctly classified the corresponding orthotic condition in 75% of cases. Mundermann and colleagues[160] suggested that comfort not only reflected subjective perceptions but also was related to biomechanical variables. In an extension of their work, Mundermann and colleagues[160] observed that the effects of molding were more important than posting on change in kinematic and kinetic variables.

Hertel and colleagues[161] examined electromyographic activity of the vastus medialis, vastus lateralis, and gluteus medius during functional activities in 30 individuals with different foot types, comparing electromyographic activity in four conditions: no orthotic, 7 degrees medial rearfoot post, 4 degrees lateral rearfoot post, and neutral rearfoot post. Surface electromyographic activity data of the muscles was collected while the individuals performed single-leg squatting, lateral stepdown, and maximum vertical jump. During single-leg squat and lateral stepdown, higher vastus medialis and gluteus medius activity was noted with all orthotic conditions. During the vertical jump, less vastus lateralis was noted with all orthotic conditions. Foot type did not influence the outcome in any of the activities.

Kulig and colleagues[162] studied the influence of foot orthoses on tibialis posterior activation in six adults with pes planus. Exercises consisting of resisted foot adduction and plantarflexion were performed barefoot and then with foot orthoses and shoes a week later. Magnetic resonance images of tibialis posterior, tibialis anterior, peroneus longus, medial gastrocnemius, and soleus were obtained pre- and postexercise. When wearing foot orthoses and shoes, only the tibialis posterior was activated. When barefoot, the magnetic resonance image signal intensity of the tibialis posterior was lower, and five of the six participants activated the tibialis posterior and additional muscles. The researchers concluded that selective activation of the tibialis posterior can be improved in people with pes planus by wearing foot orthoses with shoes.[159]

Lack and colleagues[163] examined the effects of prefabricated foot orthoses on the muscle activity of the vastus medialis oblique, vastus lateralis, and gluteus medius while performing a step-up task in 20 participants with patellofemoral pain. Wireless surface electromyography recorded the muscle activity of the participant's affected leg, and no significant changes in muscle onset time were noted. Vastus lateralis and vastus medialis oblique peak amplitudes did not have a significant change, but gluteus medius peak amplitude was reduced.

Bird and colleagues[164] considered electromyographic activity of lumbar erector spinae and gluteus medius muscles with prefabricated foot wedges (a 5-degree lateral wedge, a 5-degree medial wedge, or a 2-cm heel wedge). Although no change in amplitude of electromyographic signal occurred, wedging at the heel and lateral forefoot led to earlier electromyographic activity of the erector spinae. Gluteus muscle activity was delayed with bilateral heel wedges, as was ipsilateral gluteus activity when a unilateral heel wedge was used. Although changes of onset for the erector spinae and gluteus medius averaged only 4% and 2% of the gait cycle, respectively, the researchers suggested that these changes are likely to be clinically significant over the course of a day.

Dedieu and colleagues[165] investigated the muscular activity pattern of 12 adults with calcaneal valgus and increased eversion at the midfoot. They analyzed the effect of custom-made insoles and a rearfoot post on the muscle activity of the tibialis anterior, soleus, gastrocnemius medialis, gastrocnemius lateralis, and peroneus longus. During walking with insoles, the duration of muscle activity was shorter and the start time was delayed.

Vanicek and colleagues[166] considered how foot orthoses affected the ability of six healthy alpine skiers to hold a skier's squat position and on the duration of fatigue of the vastus lateralis. Individuals were examined under three conditions: no orthoses, high-volume orthoses, and low-volume orthoses (based on the amount of foam incorporated into the orthosis). A decrease in median firing frequencies toward the end of contraction suggested that high-volume orthoses reduced myoelectric fatigue. However, no significant differences in the ability to sustain a squat occurred under the three conditions.

Balance and Postural Control

If neuromuscular systems play a role in the effectiveness of orthoses, changes in balance and posture control would be anticipated with their use. Guskiewicz and Perrin[167] examined the effects of custom orthoses in 13 patients with acute

ankle inversion sprains and in 12 noninjured patients. As anticipated, orthoses reduced postural sway in the medial and lateral and inversion and eversion directions, with a larger effect in patients who had the injury. The researchers propose that, by restricting undesirable motions, the orthoses enhanced the ability of joint mechanoreceptors to detect movement. In contrast, Hertel and colleagues[168] found that six different orthotic interventions (shoe only; molded Aquaplast orthoses [Aquaplast Thermoplastics, Wyckoff, NJ]; orthoses in the neutral, medially posted, and laterally posted positions; and a prefabricated, rigid, laterally posted heel wedge) did not influence postural sway in 15 patients with unilateral ankle sprains while they performed unilateral standing. None of the orthotic conditions decreased frontal or sagittal postural sway compared with shoes alone. Hertel and colleagues[169] also studied 15 healthy patients with normally aligned feet under the same six conditions, focusing on center of pressure length and velocity in both the frontal and sagittal planes during unilateral stance. In this study, sagittal plane motion was not different among the various conditions; however, medially posted orthoses reduced frontal plane motion more than the other conditions. Frontal plane center of pressure excursion increased with a prefabricated, rigid, laterally posted heel wedge compared with medially and neutrally posted conditions. Frontal plane velocity was lower with medial posting compared with a prefabricated, rigid, laterally posted heel wedge and neutral orthoses. However, the prefabricated, rigid, laterally posted heel wedge produced significantly greater frontal plane velocities than the medially or laterally posted conditions.

Gross and colleagues[170] have documented that placement of foot orthoses in the shoes of older adults can affect improvement in static and dynamic balance. Thirteen older adults over the age of 65 who reported at least one inexplicable fall during the past year participated in the study. Participants were tested for tandem stance, one-leg stance, tandem gait, and alternating step tests during preintervention and postintervention sessions. Improvements in balance performance were seen immediately after foot orthoses were placed in the older adults' shoes in all tests except tandem gait. Although participants reported tandem gait as being the most challenging task, their balance also improved with this performance measure. They took more than three times the number of steps in the postintervention session when compared with their baseline performance.

Percy and Menz[171] found that orthoses did not affect postural stability in 30 professional soccer players in bipedal, dominant leg, and tandem stance. Sway was assessed under four conditions: barefoot, soccer shoes only, soccer shoes with soft insoles, and soccer shoes with rigid orthoses. The researchers concluded that orthoses had no beneficial or detrimental effects in the elite athletes studied. In contrast, Olmsted and Hertel[172] found that foot orthoses differentially benefit those with various foot types. They assessed static and dynamic postural control in 30 patients grouped by rectus, planus, or cavus foot type. Patients wore custom-molded, semirigid foot orthoses for 2 weeks between baseline and posttest measurement. Improvement in reach occurred in three of eight directions on the Star Excursion Balance Test in those with cavus foot type. Patients with cavus foot type also demonstrated a decreased center of pressure velocity in static stance.

Rome and Brown[173] examined postural sway in 50 patients identified as pronators (per the Foot Posture Index) in a randomized clinical trial. Patients were assigned either to a control or an orthotic group. The orthotic group wore prefabricated, high-density ethyl vinyl acetate orthoses with low-density ethyl vinyl acetate rearfoot wedging for 4 weeks. At 4 weeks, medial-lateral sway decreased in the orthotic group; however, no differences in anterior-posterior sway or mean balance occurred between the groups. Collectively, these studies suggest that orthoses do affect electromyographic activity, balance, and postural control. Health professionals may be better able to identify those most likely to benefit from orthotic intervention if measures of postural control and neuromuscular function are incorporated along with the assessment of lower extremity and foot skeletal alignment.

Management of Overuse Injuries

Although the specific biomechanical and neurological effects of foot orthoses on walking and running are not completely understood, orthoses can and do reduce symptoms and improve function. Although current evidence does not include many randomized, controlled clinical trials, the available evidence does support efficacy of orthotic intervention in the management of lower extremity injuries.

PAIN ASSOCIATED WITH FOOT DEFORMITY

Burns and colleagues[174] examined the effect of custom foot orthoses on foot pain (and other factors) in individuals with cavus foot type. The study consisted of 154 individuals with 75 randomly selected to the custom foot orthoses group and 79 to the control group. At 3 months' follow-up,[172] individuals reported data with mean foot pain improvement of 31.2 points with custom foot orthoses and 20.3 points with the control. Individuals with the custom foot orthoses improved pain scores by 74% compared with 43% with the control group. D'Ambrosia[175] reported on 200 individuals who had used orthoses to manage a variety of running injuries, including posterior tibial syndrome, pes planovalgum, metatarsalgia, plantar fasciitis, and iliotibial band tendonitis. Almost all had severe pronation with forefoot varus before prescription of an orthosis. Rates of reported improvement were quite high: 73% in posterior tibial syndrome, 90% in pes planovalgum, 86% in metatarsalgia, 82% in plantar fasciitis, and 66% in iliotibial band syndrome. Of those with cavus foot type, only 25% showed improvement with orthotic use.

Donatelli and colleagues[176] received follow-up surveys from 53 (65%) of 81 individuals who had previously been fitted with custom-molded, semirigid orthoses for pes planus and chondromalacia, with 95% having a forefoot varus deformity. All respondents had a 6- to 8-week trial of temporary orthoses modified according to alterations in pain before receiving custom-molded, semirigid orthoses. Respondents were asked to describe or rate pain relief with orthoses, orthotic satisfaction, continued use of orthoses, and ability to return to previous level of activity. Pain relief was reported by 96% of respondents, 91% were satisfied with their orthoses, 94% were still wearing their orthoses (length of time with orthoses varied from 3 months to 2 years from time

surveyed), and 70% were able to return to their previous level of activity.

Moraros and Hodge[177] surveyed 525 individuals who used custom-fitted orthoses provided by podiatric physicians to determine effectiveness and patient satisfaction. Of the 453 records completed in useable form (89% response rate), the chief symptom was fully resolved in 62.5%, partially resolved in 32.8%, and unresolved in 4.7%. Overall satisfaction for fit and quality was 83.1%. Although limitations are inherent in survey research, the relatively high response rate and sample support the usefulness of orthoses in relieving painful foot symptoms.

PATELLOFEMORAL PAIN SYNDROME

The role of foot orthoses on patellofemoral pain has been the subject of several studies that have provided research data for a systematic review on the efficacy of foot orthoses in the treatment of patellofemoral pain.[178] Almonroeder and colleagues[179] reported mixed results of the effectiveness of foot orthoses in the treatment of patellofemoral pain. They found that the peak patellofemoral joint stress significantly increased, but the timing of the peak was delayed during running with a foot orthosis. According to Boldt and colleagues,[180] adding medial wedge foot orthoses in the shoes of female runners with patellofemoral pain syndrome (PFPS) had minimal effect on hip and knee joint mechanics.

Johnston and Gross[181] assessed the effect of foot orthoses on pain, stiffness, and function in 16 individuals with patellofemoral pain and excessive foot pronation. Following baseline assessments, the individuals were fitted with custom foot orthoses. Statistically significant improvements in pain and stiffness were found 2 weeks following the foot orthotic intervention, and improvements in physical function were noted at the 3-month follow-up.

Barton and colleagues[182] used a variety of weight-bearing measurements to compare foot and ankle characteristics of individuals with PFPS to those without the syndrome. In relaxed stance, individuals with PFPS had significantly greater pronated foot posture than the control group when determined by longitudinal arch angle and posture index measurements. The PFPS group also demonstrated greater ranges of motion when STJ neutral was used as a reference posture.

In a single subject design, Way[183] investigated the use of a custom-molded thermoplastic foot orthosis on PFPS in a 19-year-old collegiate softball player with a mild forefoot varus bilaterally and increased midfoot pronation during MSt and TSt. Intervention included pain-free stretching and strengthening exercises, modalities, and nonsteroidal antiinflammatory medication. The study design involved a 13-day baseline phase, a 17-day intervention phase (after which the patient removed orthoses for an 11-day withdrawal phase), and a second intervention phase in which orthoses were reintroduced for the last 32 days of the study. Pain was rated by a visual analog scale, and function was evaluated with the Functional Index Questionnaire. Pain decreased in each consecutive phase; function improved between phases for seven of the nine functional activities assessed in the Functional Index Questionnaire. On the basis of these findings, Way[183] suggested that orthotic intervention is appropriate for PFPS.

Saxena and Haddad[184] retrospectively reviewed 102 outcomes of interventions in individuals with chondromalacia patella, retropatellar dysplasia, or PFPS. Multiple interventions were noted, including semiflexible orthotics. Overall, 76.5% of patients demonstrated a reduction in pain and improved function, and 2% were asymptomatic after a 2- to 4-week intervention period.

Sutlive and colleagues[185] sought to identify characteristics of patients with PFPS likely to improve with a combination of orthoses and modified activity. They examined 50 patients in active military duty who had symptoms of PFPS during a partial squat or when ascending stairs. Measures included (1) rearfoot alignment in STN, (2) forefoot to rearfoot alignment, (3) navicular drop, (4) RCS, (5) Q angle, (6) tibial varum or valgum, (7) tibial torsion, (8) leg length, and (9) standard goniometric and postural test positions to determine ROM and tissue tightness. Patients wore unposted, premolded, full-length insoles with full arch support and heel cushioning for 21 days while concurrently limiting various activities. All completed a visual analog scale and a Global Rating of Change Questionnaire at baseline and at the end of the intervention period. Of 50 patients, 33 completed the study, with a total of 78 knees with PFPS (many had bilateral symptoms). Data from 27 patients who demonstrated 50% or more improvement in visual analog scale scores were examined to determine which patient characteristics could predict orthotic success. Likelihood ratios identified several predictors of successful outcome: forefoot valgus of 2 degrees or more, great toe extension of 78 degrees or less, and navicular drop of 3 mm or less. Of those with PFPS, the patients with these three characteristics were more likely to respond to orthotic intervention.

PLANTAR FASCIITIS

The use of foot orthoses in the management of plantar fasciitis also has been examined. A 12-month study by Landorf and colleagues[186] compared the effectiveness of sham, prefabricated, and custom orthoses on pain and function in 136 individuals with plantar fasciitis. Participants were allocated to one of the three groups (sham, prefabricated, or custom) by a computer-generated random assignment, and no other treatments were allowed during the 12-month trial. At 3 months, the prefabricated and customized groups experienced greater improvements in function and pain compared to the sham group, but only the orthotic effects on function were statistically significant. Compared to the sham, the mean pain score for the prefabricated and custom orthosis was 8.7 and 7.4 points better, and the mean function score was 8.4 and 7.5 points better, respectively. All three groups improved with function and pain compared with baseline status at 3 months and 12 months, and there were only slight differences between the groups at 12 months.

Gross and colleagues[187] studied 15 individuals with plantar fasciitis for at least 1 month. Eight patients had excessively pronated feet, and seven had a cavus foot type. Eleven of 15 had unsuccessfully used noncustom arch supports before enrollment in the study. At baseline, patients completed the pain and disability index of the Foot Function Index, were timed during a 100-m walk, and rated pain experienced during the walk with the visual analog scale. They received custom-fabricated, posted, multilayer

orthoses with a thermoplastic core and were reevaluated after 12 to 17 days of orthotic use. Although no differences in preintervention and postintervention walk times occurred, visual analog scale pain ratings after the walk were lower than baseline, with only one patient demonstrating increased pain after the walk test. The scores on the subsections of the Foot Function Index also improved after orthotic use, with improvement of 66% in the pain subscale and 75% in the disability subscale. All patients continued to wear their orthoses at a follow-up phone call made 2 to 6 months after testing.

McClinton and colleagues[188] examined ankle plantar flexor and toe flexor muscle performance in 27 individuals with plantar faciitis using the rocker-board plantarflexion test and modified paper grip test. They also assessed the association between muscle performance and duration of foot orthoses use. Participants demonstrated decreased muscle performance when compared with a control group of 27 individuals without plantar faciitis. Self-reported duration of foot orthosis use was inversely related to muscle performance. Participants who reported using foot orthoses longer, regardless if they used it consistently or sporadically, presented with greater impairments in plantar flexor muscle performance.

Seligman and Dawson[189] retrospectively evaluated 10 older individuals (mean age, 71 years) with heel pain from plantar fasciitis who used a heel pad made of Sorbothane (Sorbothane, Inc., Kent, OH) attached to a custom-molded, medium-density Plastazote insert reinforced with cork in the MLA. Duration of pain ranged from 6 months to several years; 5 of 10 patients previously tried other interventions. Pain was rated by a 10-point Likert pain rating scale. A significant difference occurred between baseline pain ratings (5.7/10) and postintervention pain ratings (1.85/10).

MORTON NEUROMA

Kilmartin and Wallace[190] found that orthotic intervention did not improve symptoms of Morton neuroma. A total of 23 individuals with pain of the third and fourth intermetatarsal space, aggravated by exercise and relieved by rest, were randomly assigned to two groups, with no consideration of foot type. Those in the supination group wore a Cobra orthosis with a thicker medial heel and arch filler. Those in the pronation group wore a reverse Cobra orthosis with a thicker lateral heel. Pain was measured by a visual analog scale. Sensory impairment and pain were objectively measured by tests that elicit neuroma pain. Function was assessed with the McMaster-Toronto Arthritis Patient Function Preference Questionnaire patient-specific measure of maximal function. No differences in pain or function occurred between the supination and pronation groups. Neither orthosis produced additional symptoms in the lower extremity.

The authors suggested that prescribing a custom orthosis based on foot type would have provided greater relief of symptoms.

LOW BACK PAIN

Dananberg and Guiliano[191] examined the effects of orthotic intervention in 32 patients with chronic low back pain. Patients completed the Quebec Back Pain Disability Scale at baseline after wearing foot orthoses for 1 month and after wearing orthoses for at least 6 months. The Quebec Scale provided a back pain score and a disability score. Permanent orthoses were fabricated on the basis of the results of temporary orthoses with modifications specific to each patient, in-shoe pressure analysis, gait video analysis, and clinical examination. At 1 month, significant reduction was observed in the mean pain and disability scores. Of the original 32 patients, 23 were contacted at the 6-month follow-up and reported significant improvement in function and reduction in pain. In comparing their outcomes with previous work by Kopec and colleagues,[192] who used the Quebec Back Pain Disability Scale to evaluate improvement in 178 patients undergoing standard back care interventions, the authors suggested that the use of foot orthoses enhanced outcomes over traditional back care. Of note, the protocol for evaluating patients for permanent orthoses was extensive.[192]

Although few randomized, controlled clinical studies have been undertaken, and most have been done with a small sample size in specific patient populations, current evidence supports that foot orthoses reduce symptoms of pain and improve function in individuals with overuse injury. In contrast, a current systemic review and meta-analysis of randomized control trials conducted by Chuter and colleagues[193] reported that there is insufficient evidence to support foot orthoses as a treatment or prevention for low back pain. Some evidence existed that control trials that concentrated on variables such as patient history and physical examination to identify patients with low back pain most suited for orthoses treatment had a greater effect on mitigating the pain.[193] Foot structure and type, orthotic materials, posting methods, and fabrication methods must be considered in determining who is likely to respond to orthotic intervention and in comparing the effectiveness of various orthotic interventions.

Summary

Although many components of Root's theory have been questioned, there is little doubt concerning the importance of his work in the field of foot biomechanics and orthotic intervention. Root's work provides a foundation for most of the research performed to gain a better understanding of the influence of the foot on lower extremity biomechanics and overuse injuries. Although research has provided some answers about mechanisms underlying the efficacy of orthotic intervention, many more questions also have been raised. Additional research is necessary before clinicians will be able to prescribe orthoses confidently based on likely outcomes.

Case Example 8.1 **Individual With Rearfoot and Forefoot Dysfunction**

M.L. is an active 50-year-old woman who recently began to train for a local 10-km race. She is referred by her family physician for evaluation and intervention because of thickened and painful plantar callus under the second and fourth metatarsal heads and on the lateral surface of the hallux in both feet. The discomfort has increased to a point that she is unable to complete the distances she needs to run to prepare for the upcoming race.

M.L. is 5 feet, 5 inches tall and weighs 132 lb. In relaxed standing, no leg-length discrepancy is apparent, although both patellae are rotated inward, slight hyperextension and recurvatum at the knee is present (left more than right), and both feet are markedly pronated.

The following values are recorded in the non–weight-bearing and weight-bearing examinations:

Non–Weight-Bearing Examination Component	Left	Right
Rearfoot STN position	6 degrees varus	7 degrees varus
Calcaneus inversion	18 degrees	22 degrees
Calcaneus eversion	12 degrees	14 degrees
Ankle dorsiflexion	9 degrees	7 degrees
Rearfoot dorsiflexion	2 degrees	0 degrees
Forefoot STN position	Mild valgus	Moderate valgus
Locking mechanism	Fair	Poor
First ray	Slightly plantarflexed	Slightly plantarflexed
Hallux dorsiflexion	75 degrees	80 degrees
Medial longitudinal arch	Medium height	Medium height

STN, Subtalar neutral.

Weight-Bearing Examination Component	Left	Right
Calcaneal/floor alignment	Eversion	Eversion
Tibiofibular position	40 degrees	37 degrees
Navicular drop (STN to relaxed calcaneal stance)	10 mm	12 mm
Navicular position (Feiss)	Slightly below	Moderately below
Toe sign	2.5 toes visible	3 toes visible
Femoral torsion	14 degrees	16 degrees
Tibial torsion	25 degrees	27 degrees

STN, Subtalar neutral.

QUESTIONS TO CONSIDER

- What are the normative values for non–weight-bearing range of motion in the rearfoot (STN position, calcaneal inversion and eversion, dorsiflexion) and forefoot (STN position, midtarsal joint dorsiflexion, first ray position, and mobility)?
- What rearfoot and forefoot deformities do M.L.'s examination findings suggest?
- What are normal findings for the closed chain static weight-bearing examination?
- How should the findings for M.L.'s weight-bearing examination be interpreted?
- How do the findings of M.L.'s non–weighting-bearing and weight-bearing examinations relate to each other? What deformities are compensated versus uncompensated?

Case Example 8.2 **Individual With Rearfoot and Forefoot Dysfunction**

M.L. wants to continue training for her upcoming race without increasing her pain and further damaging soft tissue in her feet. An appropriate prescription is being created for her on the basis of the findings of her examination and the principles of orthotic design.

EXAMINATION FINDINGS

Relaxed standing: no apparent leg-length discrepancy, both patella rotated inward, slight hype knee (left more than right), marked pronation of both feet.

Non–Weight-Bearing Examination Component	Left	Right
Rearfoot STN position	6 degrees varus	7 degrees varus
Calcaneus inversion	18 degrees	22 degrees
Calcaneus eversion	12 degrees	14 degrees
Ankle dorsiflexion	9 degrees	7 degrees
Rearfoot dorsiflexion	2 degrees	0 degrees
Forefoot STN position	Mild valgus	Moderate valgus
Locking mechanism	Fair	Poor
First ray	Slightly plantarflexed	Slightly plantarflexed
Hallux dorsiflexion	75 degrees	80 degrees
Medial longitudinal arch	Medium height	Medium height

STN, Subtalar neutral.

Weight-Bearing Examination Component	Left	Right
Calcaneal/floor alignment	Eversion	Eversion
Tibiofibular position	40 degrees	37 degrees
Navicular drop (STN to relaxed calcaneal stance)	10 mm	12 mm
Navicular position (Feiss)	Slightly below	Moderately below
Toe sign	2.5 toes visible	3 toes visible
Femoral torsion	14 degrees	16 degrees
Tibial torsion	25 degrees	27 degrees

STN, Subtalar neutral.

QUESTIONS TO CONSIDER

- What are the primary short-term and long-term goals of orthotic intervention for M.L.? Are the therapeutic goals for orthotic intervention similar to or different from M.L.'s goals? How quickly will the orthosis have an impact on the level of pain and function?
- What options should be considered in addressing her forefoot deformity in each foot? What type of posting (intrinsic vs. extrinsic, medial vs. lateral) is most appropriate? How much of a wedge or post should be recommended? Why? How might the recommendations for each foot be similar or different?
- What options should be considered in addressing the rearfoot deformity in each foot? What type of posting (intrinsic vs. extrinsic, medial vs. lateral) would be most appropriate? How much of a wedge or post should be recommended?Why? How might the recommendations for each foot be similar or different?
- What type of materials would be most appropriate to use in her orthosis? Why?
- Are fabricating orthoses for both her running shoes and her usual daily footwear advisable? Why or why not?
- What type of wearing schedule should be recommended? Should she alter her training schedule or expectations about participating in the upcoming race? Why or why not?
- How frequently should M.L. be followed up during this episode of care? How should the outcomes of orthotic intervention be assessed?

The effectiveness of biomechanical foot orthoses depends on a number of factors. An understanding of causes and effects of aberrant foot motion on pathological conditions of the foot is essential in determining the appropriate orthosis prescription and plan of care. Clinicians who do not carefully consider biomechanical principles and other factors that contribute to clinical signs and symptoms are likely to prescribe an ineffective or inappropriate orthosis. Information gathered from all three components of the biomechanical examination (non–weight-bearing, static weight-bearing, and dynamic gait assessment) is critical for orthotic design and prescription.

Historically, the principles and design of the Root functional orthosis and the biomechanical foot orthosis have had consistently effective clinical results. Root's model demands a keen understanding of foot biomechanics, careful prescription, and advanced fabrication skills. With this understanding and attention to detail, the end result may be a lightweight, durable, cost-effective foot orthosis that substantially reduces the detrimental effects of aberrant foot motion.

9 Principles of Lower Extremity Orthoses

ERIC FOLMAR, HEATHER JENNINGS, and MICHELLE M. LUSARDI

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Define the functional objectives (reasons) that an ankle-foot orthosis (AFO), knee-ankle-foot orthosis (KAFO), or hip-knee-ankle-foot orthosis (HKAFO) would be prescribed for persons with mobility dysfunction.
2. Explain the evaluative process used to determine appropriate prescription for individuals requiring a lower extremity orthosis.
3. Describe the biomechanical control systems for foot, ankle, knee, and/or hip designed into an AFO, a KAFO, or an HKAFO.
4. Describe how each type of lower extremity orthosis is designed to enhance achievement of stance phase stability, swing limb clearance, limb prepositioning, adequate step length, and efficiency of gait.
5. Describe how each of the most commonly prescribed AFO, KAFO, and HKAFO designs affect transition through the rockers of stance and swing phase of gait.
6. Compare and contrast the indications and limitations of prefabricated, custom-fit, and custom-molded lower extremity orthoses.
7. Apply knowledge of normal and pathologic gait, assessment of impairment, and functional potential in the selection of an appropriate lower extremity orthosis for patients with neuromuscular impairments.
8. Identify effective strategies for donning/doffing the orthosis, gait and mobility training, and orthotic maintenance for children and adults using lower extremity orthoses.
9. Select appropriate outcome measures to evaluate effectiveness of orthotic intervention and gait training for persons using lower extremity orthoses.

There are many factors to consider when selecting a lower extremity orthosis for individuals with musculoskeletal or neuromuscular dysfunction who have difficulty with mobility and walking. An orthosis may be designed to substitute for impaired muscle performance in the presence of weakness to improve foot clearance in the swing phase of gait.[1] An orthosis may be used to provide stance phase stability and support to enhance alignment of limb segments when there is structural instability of one or more lower extremity joints.[2] An orthosis may be designed to limit joint motion or unload forces during weight bearing to allow healing after surgery or prevent injury to vulnerable joints.[3] For persons with impaired motor control and abnormal tone, orthoses may enhance mobility by minimizing the impact of abnormal movement associated with hypertonicity by positioning limb segments for optimal function.[4,5] Alternatively, an orthosis may be used to minimize the risk of development of bony deformity and contracture associated with long-standing hypertonicity, especially in growing children.[6] Given the many different reasons that an orthosis might be prescribed, there is no "one size fits all" option: Health professionals must clearly define what they want an orthosis to accomplish, consider its practicality and cost, and sort through the many options available to select the design and components that will best meet the patient's needs and goals.

This chapter systematically reviews the design and the pros and cons of AFOs, KAFOs, and HKAFOs as a means to improve mobility and function for children and adults with neuromuscular dysfunction. We will start with a quick review of the gait cycle and its "rockers" as a foundation for understanding how an orthosis can provide stance-phase stability or enhance swing phase mobility. Then we will compare and contrast the various AFO designs, discuss contemporary KAFO components and design, explore traditional HKAFOs and their uses, and finally consider orthotic options for reciprocal gait for patients with significant neuromuscular disease or disability. We will apply our growing understanding of lower extremity orthoses in problem-based cases for children and adults with cerebral palsy, and weakness due to spinal cord compression, multiple sclerosis, diabetic amyotrophy, and Guillain-Barré syndrome.

What Type of Orthosis is Best?

When an individual with neuromuscular or musculoskeletal dysfunction has difficulty with mobility and walking, decisions about orthotic options are best made by collaborative interaction within the framework of an interdisciplinary team.[7] Members of this team include the person who will be using the orthosis, his or her family members or caregivers, any physicians involved in his or her care (e.g., a neurologist, orthopedist, or physiatrist), the physical and occupational therapists who are likely to be involved in functional training, and the orthotist who will design, fabricate, deliver, and maintain the orthosis. The combined knowledge and skills of all members of the team ensures that the prescription will best match orthotic design to the patient's functional needs (Table 9.1).[8] If the team is not able to gather in one place as decisions are being made, there must be effective strategies for communication in place so that each team member can contribute his or her unique perspective about why an orthosis is indicated and how the orthosis will facilitate the individual's functional ability.

Physical therapists examine the patient to provide information about muscle performance and motor control, range of motion, alignment of the limbs, and the gait cycle, with attention to both primary impairments and the compensation strategies the individual uses while walking, as well as how the orthosis might impact biomechanically on other daily motor tasks (e.g., a child's ability to get up and down from the floor).[9] Physicians bring to the team an understanding of the specific disease or disorder that the patient is dealing with, including the condition's natural history and likely prognosis, types of secondary musculoskeletal problems that are commonly encountered, and any cognitive, developmental, or multisystem involvement that may be associated with the disease.[10] Family members and the individual needing the orthosis are concerned with practical issues, such as who will be responsible for applying (donning) or removing (doffing) the device and the ease with which this can be accomplished, as well as information about the types of activities that the individual wants to be involved in while using the orthosis (lifestyle and leisure activities).[11] The orthotist uses knowledge of materials and biomechanics, information provided by team and family members, and results of the individual's physical examination to design and fabricate the orthosis that will best address the mobility problem that needs to be solved.[9]

The team must not overlook the significant contribution of the individual and caregiver in the prescription process.

Table 9.1 Components of the Preorthotic Prescription Examination Organized by ICF Categories

ICF Category	Domain		Concerns
Body structure and function	Joint integrity and stability		Ligamentous instability, joint deformity
	Range of motion		Soft tissue contracture, joint deformity
	Limb length and alignment		Rotational deformity, unequal limb length
	Muscle length		Fixed versus modifiable contracture
	Overall flexibility		Ability to don/doff; impact of orthosis on trunk, back
	Motor control		Quality of voluntary motion
	Muscle tone		Flaccidity, hypotonicity, hypertonicity, fluctuating tone
	Muscle performance		Strength, power, endurance
	Involuntary movement		Impact on tolerance of orthosis
	Coordination		Ability to don/doff
	Somatosensory function		Ability to detect skin irritation/damage
	Perceptual function		Ability to don/doff
	Upper extremity function		Ability to don/doff
	Postural control, balance		Ability to don/doff
	Visual function		Ability to perform skin checks, don/doff
	Cognitive function		Understanding of how to use orthosis
	Cardiovascular endurance		Ability to functionally use orthosis
Activity level	Gait analysis	Observational	Primary gait problems and compensations
		Kinematic	Primary gait problems and compensations
		Kinetic	Impact of orthosis on moment throughout gait cycle
		Energetics	Impact of orthosis on physical work of walking
		Assistive device	Safe function with orthosis and assistive device
		Various surfaces	Impact of resistance, unstable surface on gait
	Transitions	Sit to/from stand	Preparing to walk and returning to seated position
		To/from floor	Activities on the floor (especially for children/play)
		Managing falls	How to protect self and recover from fall
		Inclines/stairs	Degree of mobility in home and public environment
	Activities of daily living	Donning/doffing	Will assistance be necessary? Who will provide help?
		Self-care	How will orthosis impact on self-care ability?
		Toileting	Will orthosis need to be removed to use the bathroom?
		Dressing	Ability to manage clothes and shoes
Participation level	Home		Ability to take part in family activities, roles
	School		Mobility in classroom, hallways, outside play areas
	Work		Mobility in entrance, workspace, common areas
	Leisure		Mobility over surfaces, use of tools/devices
	Transportation		Ability to drive, use public transportation

ICF, The World Health Organization's International Classification of Functioning, Disability and Health.

The use of an orthosis enhances, as well as constrains, lower limb function; for example, it requires considerable adjustment on the part of the person who will be wearing the orthosis. An understanding of the individual's or the caregiver's expectations about what the orthosis will accomplish is a key component of orthotic prescription and training. Discussion and education about what an orthosis will and will not do for the wearer can minimize potential mismatch of expectation versus actual outcome. Acceptance and functional use of the orthosis depend on just how well it meets identified needs and goals, as well as the cost of its use in terms of inconvenience and disruption of lifestyle.[12]

Careful consideration of the individual's diagnosis is also critical when selecting materials and designing the orthosis. Questions that the team should consider during the decision-making process include: Can we reasonably expect that an individual's musculoskeletal or neuromuscular status is stable and likely to remain the same over time? Does the disease typically have a progressive course, such that decline in function is anticipated over time? Or, as in the case of traumatic injury, will the person's condition and functional ability improve with time as healing occurs? What can be expected in terms of muscle function and strength, range of motion and joint function, and functional mobility and gait over time? How might growth and developmental status influence future orthotic needs? All of these must be accounted for in the design of the orthosis.

The selection of any orthotic device must include careful consideration of four factors:

1. The *advantages* or positive outcomes expected when using the orthosis (i.e., how it will improve mobility and gait, influence tone, or protect a limb or body segment).
2. Any disadvantages or *concessions* that may be associated with its use (i.e., the ways in which it may complicate daily activity, mobility, or preferred activities; the energy cost associated with its use; the relative expense of the device).
3. The *indications* that the orthosis may be useful to the individual (i.e., the match between the person's characteristics and needs and what the orthosis will provide).
4. The circumstances or characteristics of the individual that make use of the device detrimental or *contraindicated*.

Consideration of these four factors guides clinical decision-making when comparing and contrasting the various options for lower extremity orthoses. Characteristics of an ideal orthosis are summarized in Box 9.1.

To help an individual use the orthosis most effectively, the physical therapist must understand how the orthosis should fit with respect to its design (i.e., what are the optimal trim lines?) and force control systems (how does it act on the limb segments?) (Box 9.2). Every orthosis uses force applied to the limb to accomplish the goals of its design. An orthosis is most comfortable and effective when (Fig. 9.1):

1. The forces are distributed over large surface areas to minimize pressure on skin and soft tissue.
2. The forces are applied in such a way that a large moment arm reduces the amount of force needed to control the joint.
3. The sum of the primary force and opposing counterforces of each control system equals zero.

Box 9.1 Characteristics of an Ideal Orthosis

Function

- Meets the individual's mobility needs and goals
- Maximizes stance phase stability
- Minimizes abnormal alignment
- Minimally compromises swing clearance
- Effectively prepositions the limb for initial contact
- Is energy efficient with the individual's preferred assistive device

Comfort

- Can be worn for long periods without damaging skin or causing pain
- Can be easily donned and doffed (e.g., considering clothing, footwear, toileting)

Cosmesis

- Meets the individual's need to fit in with peers

Fabrication

- Can be made in the shortest period of time
- Uses a minimally complex design
- Has some degree of adjustability to enhance initial fitting
- For children, responds to growth or change over time
- Is durable: stands up to stresses/strains of daily activity

Cost

- Can be made with minimal initial cost and minimal cost for maintenance

Box 9.2 Principles Underlying Control Systems in Orthotic Design

1. Pressure = Force/Area
2. Torque = Force × Distance
3. Control direction of primary force and direction of counterforces
4. Equilibrium Σforces = 0

Determinants of Functional Gait

There are five factors that influence how well an individual is able to walk.[13] The first is *stance-phase stability*: The limb in contact with the ground must be stable enough to support body weight and respond to the ground reaction forces (GRFs) as the individual moves through stance phase. The second is *clearance in swing*: The advancing limb must clear the ground adequately during swing phase to minimize risk of stumbling and trips. Swing limb clearance is influenced by the ability to maintain a level pelvis by stance limb abductor muscles, as well as by action of the hip, knee flexors, and dorsiflexors of the swing limb as they relatively shorten the length of the swinging limb. The third is *swing phase prepositioning*: By the end of swing, the foot about to contact the ground must be positioned for an effective initial contact and loading response as stance begins. The fourth is *adequate step length*: There must be adequate motor control and range of motion at the hip, knee, ankle, and forefoot of both limbs so that optimal step length can occur. The fifth is *energy conservation*: If there are problems with timing, muscle performance, coordination, or postural control during the gait

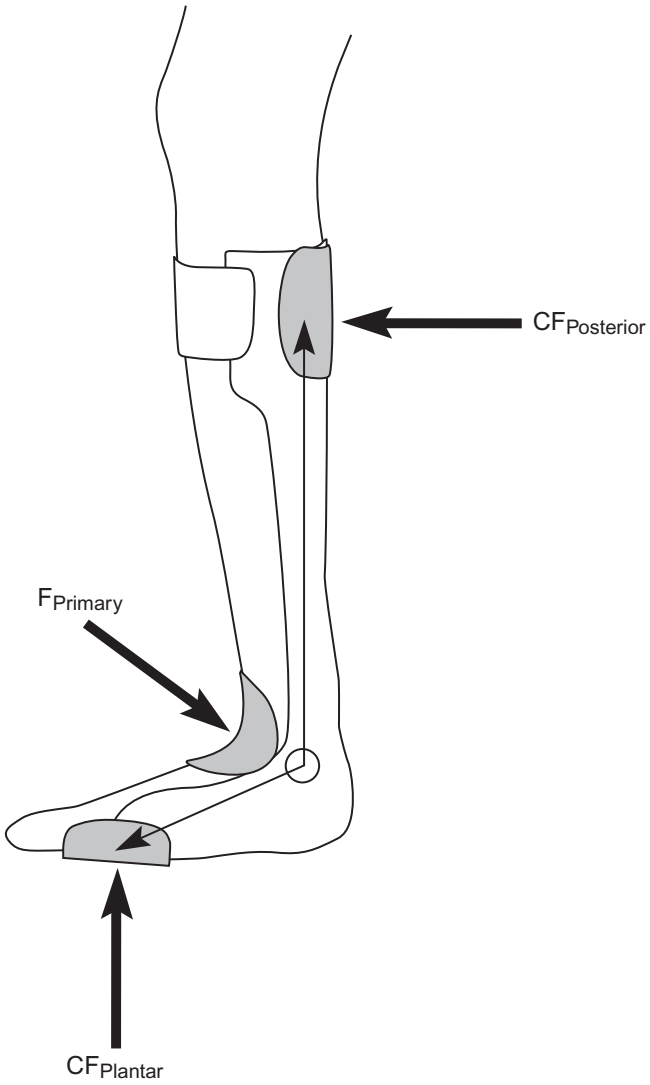

Fig. 9.1 Principles underlying the plantarflexion control system acting during swing phase in a rigid/solid ankle-foot orthosis. The large primary force *($F_{Primary}$)* is applied in a posterior-inferior direction over a large surface area (stippled area) anterior to the axis of the ankle joint, usually by the shoe's closure or reinforced by webbing across the anterior ankle. The two counterforces, applied in an upward *($CF_{Plantar}$)* and anterior *($CF_{Posterior}$)* direction, also over a large surface area, far from the axis of the ankle joint, create an effective moment arm so that less force is required to achieve the desired stabilization. The sum of the primary *(large arrow)* and two opposing counterforces *(small arrows)* is zero in a well-balanced orthosis.

cycle, the energy cost of walking rises substantially, and efficiency of ambulation is compromised.

If neuromuscular or musculoskeletal dysfunction substantially interferes with these determinants, functional ambulation may be an unrealistic goal without an appropriate orthosis. Refer to Chapter 5 for greater detail about characteristics of the normal and pathologic gait cycle.

Rockers of Stance Phase

Orthotists describe three transitional periods, or rockers, during stance phase of walking as the body progresses forward over the foot (Fig. 9.2).[14] During the *first (heel) rocker*, there is a controlled lowering of the foot from neutral ankle position at initial contact to a plantarflexed flat foot, as well as acceptance of body weight on the limb during loading response. When motor control and muscle performance is efficient, eccentric contraction of the quadriceps and anterior tibialis prevents "foot slap" and protects the knee as GRF is translated upward toward the knee. In the *second (ankle) rocker*, the tibia begins to rotate over the weight-bearing foot, from its initial 10 degrees of plantarflexion at the end of loading response, then through vertical into dorsiflexion as midstance is completed. Eccentric contraction of the gastrocnemius and soleus muscles "puts on the brakes" to control the speed of the forward progression of the tibia over the fixed foot throughout midstance. At the start of the *third (toe) rocker*, the forefoot has converted from its mobile adaptor function of early stance to a rigid lever for an effective late stance, and the heel rises off the ground so that body weight has to roll over the first metatarsophalangeal joint through push-off in terminal stance. During fast walking and running, acceleration occurs as active contraction of the gastrocnemius-soleus complex propels the foot and leg into swing phase.

All lower extremity orthoses provide some degree of external stability to foot and ankle joints; as a result, the smooth transition through the rockers of stance phase is often compromised.[15] Disruption of forward progression during stance negatively impacts step length, cadence, and single limb support time.[14] The optimal orthotic prescription must balance the need to provide external support with the possible compromise on forward progression and mobility: The orthotist strives to select an orthotic design that provides minimum necessary stability so that mobility will be the least compromised.[15] In many instances, modifications of footwear, such as the addition of a cushion heel (which simulates controlled lowering of the foot in loading response) or a rocker bottom sole (which simulates forward progression of the tibia over the foot throughout midstance), can substitute to some degree for the mobility lost when external control is necessary.[16] The rehabilitation team must weigh the impact of stability provided by an orthosis on progression through stance and its impact on a patient's functional status: At times, compromise is unavoidable if the patient's functional deficits are to be addressed effectively.

Prefabricated, Custom Fit, or Custom Molded?

How does the team determine whether an individual would benefit from a relatively less expensive prefabricated orthosis versus a more costly (in both time and money) custom-molded orthosis designed specifically for the person? There are a number of factors to consider in making this decision.

The effectiveness of an AFO is determined by to the intimacy and consistency of its fit. Intimacy of contact between limb and orthosis is best achieved in custom-molded designs.

Mass-manufactured, prefabricated orthoses are available in a wide spectrum of orthotic designs, by shoe size, and made of a number of different materials. The degree to which they can be modified or adjusted to fit an individual varies; this may be problematic for persons with foot deformity, extremely wide or narrow feet, large calf muscles, sensory impairments, or variable limb volume. They are

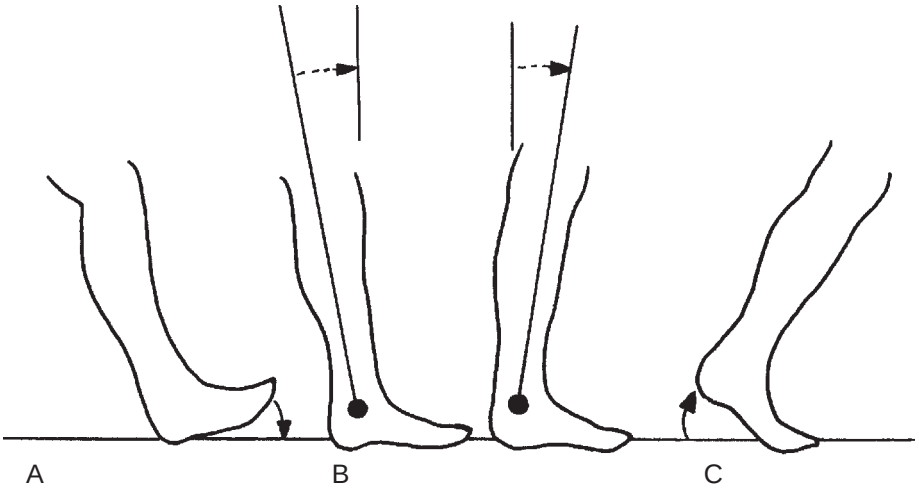

Fig. 9.2 Three transitional rocker periods occur as the body moves forward over the foot during stance. (A) During first rocker, the transition from swing into early stance, controlled lowering of the forefoot occurs, with a fulcrum at the heel. (B) During second rocker, controlled forward progression of the tibia over the foot occurs, with motion of the talocrural joint of the ankle. (C) In the third rocker, transition from stance toward swing occurs as the heel rises, with dorsiflexion of the metatarsophalangeal joints.

attractive to payers because they are significantly less expensive than custom-fit or custom-molded orthoses. However, many rehabilitation professionals are not satisfied with the ability of a prefabricated orthosis to provide optimal external support and control of motion over time: Durability is directly related to the quality of material used and by the lack of intimate fit to an individual's limb. Even a minimal amount of pistoning or heel elevation within the orthosis during walking can lead to skin irritation or breakdown and, in the presence of hypertonicity, an increase of underlying abnormal extensor tone. Therapists may opt to use a trial run with prefabricated orthoses as an evaluative tool to determine which orthotic design might best meet the patient's needs during the time that a custom orthotic is being prepared or when the patient's condition requires use of an orthosis for only a short time period[17] or when the patient condition is unstable. Because prefabricated orthoses do not fit the foot intimately, they should be used with extreme caution in persons with neuropathic foot conditions whose ability to perceive soft tissue irritation and damage is compromised.[18]

Another alternative is a manufactured orthosis that is then custom fit using heating or relieving techniques or the application of additional materials to obtain as close a fit to the individual's foot and limb as possible. Although custom-fit orthoses provide better control than similar prefabricated versions, they are not as effective in terms of fit and function as a custom-molded orthosis.[19] Custom-fit orthoses may be appropriate when change in functional status (either improvement or deterioration) is anticipated, such that the orthosis will need to be replaced or adjusted frequently.

Custom-molded orthoses provide the optimal control of the limb and, because of their intimate fit, are especially important for patients with impaired sensation, significant hypertonicity, or risk of progressive deformity associated with their condition. The orthotist constructs the orthosis around a rectified model of the person's limb, ensuring adequate pressure relief over vulnerable areas (i.e., bony prominences) and building in the desired stabilizing forces based on the orthotic prescription.[20] Refer to Chapter 6 for more details about the process of fabrication.

The only true contraindication of a custom-molded thermoplastic design is significantly fluctuating limb size associated with conditions that lead to edema of the braced extremity.[21] When limb size fluctuates, intimacy of custom-molded fit is lost: When the limb is at its lowest volume, excessive movement of the limb within the orthosis occurs, compromising orthotic control and increasing risk of skin irritation and damage. When the limb is significantly edematous, the AFO may become constricting, leading to pressure-related problems. For persons with congestive heart failure, advanced kidney disease on dialysis, or other conditions associated with unpredictable fluctuation in limb volume, the total contact of a custom-molded orthosis may be inappropriate and a conventional double upright orthotic design should be considered.

Appropriate Footwear

Whether the decision is to use a prefabricated, custom-fit, or custom-molded orthosis, the ultimate ability of the AFO to meet its therapeutic goals depends on the type and condition of the individual's footwear.[16] Refer to Chapter 7 for more information about key characteristics of shoes worn with an orthosis. Recognition of the need to consider footwear is not always intuitive to the individual, caregivers, or health professionals working on improving the ability to ambulate. It may be necessary for the individual to wear a shoe that is one-half to a whole size larger to accommodate an orthosis; a shoe that is too short or too tight can interfere with the biomechanical function of the orthosis. Shoe closure of an Oxford-style or athletic shoe (whether tied with laces or closed with Velcro) often provides the diagonally directed force that stabilizes the calcaneus in the heel cup of the orthosis; if the calcaneus moves out of position during walking, the effectiveness of orthotic control is compromised. Loafer-type shoes and most sandals do not provide adequate stabilizing forces during the stance phase of gait.

Although most thermoplastic AFO designs allow individuals to alternate among several pairs of shoes, changing heel heights dramatically alters the biomechanical function of the orthosis. The orthotist and therapist share responsibility for patient and family education about appropriate footwear, monitoring shoe condition to assess impact of wear and tear on its construction and stability, as well as ongoing evaluation of the effectiveness of the orthosis in meeting the individual's functional needs over time.

Ankle-Foot Orthoses

AFOs are, by far, the most frequently prescribed device used to control the lower extremity during each phase of the gait cycle for individuals with neuromuscular or musculoskeletal impairments that make walking difficult. It is important to note that the acronyms used to name lower extremity orthoses describe joints that are positioned within the orthosis. In reality, AFOs also effectively address stability of the knee joint (proximal to the orthosis) during stance.[22]

AFOs fall into two categories: *static orthoses* that prohibit motion in any plane at the ankle (e.g., solid AFO [SAFO], anterior floor reaction AFO, patellar tendon–bearing [PTB]/weight-relieving AFO). In contrast, *dynamic orthoses* allow some degree of sagittal plane motion at the ankle (e.g., posterior leaf spring [PLS] or spiral AFOs, articulating SAFOs). Whether static or dynamic, the primary goal of an AFO is to provide just enough external support for stability in stance and clearance in swing with minimal compromise of forward progression through the heel, ankle, and toe rockers of gait.[15] The actions, indications, and contraindications for the various AFO designs are summarized in Table 9.2.

Table 9.2 Summary of Indications for, Impact on Gait of, and Contraindications for Commonly Prescribed Lower Extremity Orthoses

Type of Orthosis	Category	Actions	Indications	Contraindications	Options
UCBL orthosis	Static	Stabilize subtalar and tarsal joints in stance	Rearfoot valgus/varus Flexible pes planus	Rigid foot deformity	Thermoplastic Gillette modification
DAFO	Dynamic	Stabilize subtalar and tarsal joints in stance	Flexible pes planus Mild to moderate spastic diplegic or hemiplegic CP Hypotonic CP	Rigid foot deformity	Thermoplastic
Supramalleolar	Dynamic	Stabilize subtalar and tarsal joints in stance Preposition foot for IC by heel	Flexible pes planus Mild to moderate spastic diplegic or hemiplegic CP Hypotonic CP	Significant equinovarus hypertonicity	Thermoplastic
Posterior Leaf Spring	Dynamic	Assist limb clearance in swing Preposition foot for IC by heel	Dorsiflexion weakness, impaired motor control, LMN flaccid paralysis of dorsiflexors	Moderate to severe hypertonicity	Thermoplastic
Carbon Graphite AFO	Dynamic	Assist limb clearance in swing preposition foot for IC by heel	Paralysis or impaired muscle performance of dorsiflexors	Moderate to severe hypertonicity	Custom or prefabricated
Neuro-orthoses	Dynamic	Assist limb clearance in swing Preposition foot for IC by heel	Dorsiflexion weakness or low tone	Flaccid paralysis Patient intolerance of electrical stimulation	Functional electrical stimulation
Articulating ankle	Dynamic	Assist limb clearance in swing Preposition foot for IC by heel Permit advancement of tibia (2nd rocker) in stance	Impaired motor control of ankle musculature Potential for recovery of neuromotor function	LMN paralysis (flaccidity) or hypotonicity as primary problem	Thermoplastic or metal double upright Dorsiflexion assist Plantarflexion stop Adjustable range into dorsiflexion can be incorporated Often requires shoe with cushion heel
SAFO	Static	Control ankle position throughout stance Provide stance phase stability via ankle-knee coupling Assist limb clearance in swing Preposition foot for IC by heel Distal trim line behind metatarsal heads or extended toeplate	Significant hypertonicity with seriously impaired motor control at ankle and knee	LMN paralysis (flaccidity) or hypotonicity as primary problem	Thermoplastic Basis for KAFO and HKAFO Requires cushion heel and rocker bottom shoe
Tone-inhibiting AFO	Static	Control ankle position throughout stance Provide stance phase stability via ankle-knee coupling Typically extended toeplate	Significant hypertonicity with seriously impaired motor control	LMN paralysis (flaccidity) or hypotonicity as primary problem	Thermoplastic, Basis for KAFO and HKAFO Requires cushion heel and rocker bottom shoe

BIOMECHANICAL PRINCIPLES

The biomechanical principles of AFOs are founded on the functional anatomy of the ankle-foot complex. Dorsiflexion and plantarflexion of the ankle are multiplanar (i.e., movement occurs in all three planes of motion) as the talus rotates through the mortise of the ankle in both open chain movement and when the mortise moves over a relatively fixed (weight-bearing) talus in a closed chain movement.[23] The proximal surface of the mortise is shaped by the syndesmosis (fibrous articulation) between the distal tibia and fibula. The medial wall of the talocrural joint is formed by the medial malleolus, a downward extension of the tibia. The lateral wall, formed by the lateral malleolus of the fibula, is both longer and shifted posteriorly. Because of the shape of the articular surfaces of the talus in its mortise and the offset position of the malleoli, the axis of the ankle joint is slightly oblique, running in an anteromedial to posterolateral direction. As a result, dorsiflexion is accompanied by some degree of forefoot pronation and abduction along with hind foot valgus. Plantarflexion is accompanied by forefoot supination with adduction and hind foot varus. Note that during stance, movement occurs in a closed chain situation because the foot is fixed on the ground by weight-bearing forces, so that the mortise rolls over the head of the talus.

If an AFO has mechanical ankle joints, the axis of the mechanical joints should be aligned as closely as possible to the obliquely oriented anatomic axis of motion (Fig. 9.3). The mechanical joint heads are placed at approximately midline of the malleoli in the sagittal plane. This strategy reduces the likelihood of abnormal torque and shearing between the orthosis and limb as the individual wearing the orthosis walks. When there is incongruence between the anatomic and mechanical axes, excessive motion of the limb within the orthoses is likely, and action of the mechanical ankle joint is compromised.

Fig. 9.3 Alignment of the mechanical ankle joint axes must reflect the degree of external rotation/tibial torsion that is present in the transverse plane.

Static Ankle-Foot Orthoses

Static AFOs are the most aggressive of the AFO designs in providing external support. They restrict ankle and foot motion in all three planes to provide significant stance-phase stability and swing limb clearance. However, because of their rigidity, these orthoses greatly compromise transitions through the first (heel), second (ankle), and, to less degree, third (toe) rockers of stance phase. Individuals using static AFOs do better functionally wearing a shoe with a cushion heel and rocker bottom to simulate these key transitions. The decision to recommend a static AFO should be made carefully, weighing the benefit of greater stability against the cost of lost mobility.

SOLID ANKLE-FOOT ORTHOSES

The SAFO, also known as a rigid AFO, is typically fabricated from relatively thick thermoplastic and aims to hold the ankle and foot in as close to biomechanically neutral position (zero degrees of ankle dorsiflexion, subtalar and calcaneal neutral, with a balanced forefoot) as possible given the individual's functional anatomy.[24] The anteroposterior trim line of the SAFO falls at or near the midline of the medial and

Fig. 9.4 Custom-molded, solid ankle-foot orthosis holds the ankle in as close to optimal static alignment as possible for a given patient. Mediolateral ankle stability is a result of trim lines at the midline of the malleoli. The crossed Velcro strap anterior to the ankle helps to position the rear foot appropriately within the heel section of the orthosis.

lateral malleolus (Fig. 9.4). Medial and lateral corrugations may be incorporated into the shell of the orthosis to provide additional strength when hypertonicity or excessive weight creates loading forces that require a stronger orthosis. The proximal border is typically trimmed to fall 1½ inches below the apex of the head of the fibula for protection of the common peroneal nerve. The footplate is either trimmed just short of the plantar metatarsal heads or can be lengthened beyond the metatarsal distally into a toeplate if greater stability is required or hypertonicity is a concern.[4] Some orthotists recommend the addition of a tone-inhibiting bar if hypertonicity is severe.[25] There is a tradeoff to consider if the footplate is lengthened: It is much easier to fit into and put on shoes with a shorter footplate; assistance may be necessary to don shoes when the SAFO has a full toeplate.

SOLID ANKLE-FOOT ORTHOSES CONTROL SYSTEMS

There are four distinct control systems incorporated into the SAFO design (Fig. 9.5). To resist plantarflexion during swing phase, there is a fulcrum force applied at the anterior ankle (by strapping or by the shoe's laces or Velcro closure) opposed by a distal counterforce upward under the metatarsal heads and a proximal counterforce at the posterior proximal surface of the AFO. To resist dorsiflexion during stance phase, there is an upward and inward compressive force at the posterior heel, opposed by a distal downward counterforce delivered by the shoe, and a proximal force applied by the anterior closure straps just below the knee. It is important to note that the locked ankle created by an AFO generates an extensor moment at the knee during stance. In this way, an SAFO can substitute for impaired motor control or muscle performance of knee extensors for persons with stroke, cerebral palsy, or other neuromotor dysfunction.

To resist varus and inversion of the foot, a medially directed force is applied just above and below the lateral malleolus, with laterally directed counterforces at the proximal medial tibia and the medial foot. To resist valgus and eversion of the foot, there is a laterally directed force applied above and below the medial malleolus, with medially directed counterforces just below the fibular head proximally and at the lateral foot distally.

The degree of control for the foot is also influenced by the position of the trim lines of the foot section. When there is midtarsal joint deformity with forefoot abduction or adduction to contend with, trim lines are adjusted to capture the shafts of the first and fifth metatarsals. If there is too much subtalar valgus, the height of the medial wall is increased, and a flange might be placed proximal to the medial malleolus. These strategies provide greater surface area for distribution of corrective forces applied by the orthosis so that the patient is more comfortable with the external stability it provides. If knee hyperextension at midstance is a problem for individuals with impaired motor control, the orthotist might fabricate the SAFO set in just a couple of degrees of ankle dorsiflexion, rather than neutral, to minimize excessive extension moment and preserve knee joint health over time. A Gillette modification can be added to the outer medial or lateral surface of the heel cup to influence excessive valgus or varus moment at the knee joint during stance. A medial or lateral post (similar to those used in a biomechanical foot orthosis) can be incorporated into the foot section to equalize forefoot to rearfoot relationships or to enhance biomechanical effects on the knee.

Progression Through Stance Phase

The SAFO biomechanically interferes with transitions through all three rockers of gait in stance phase because of the fixed ankle position inherent in the design.

The orthosis prevents the controlled lowering of the foot that usually occurs in the ankle/first rocker during loading response. If the shoe does not have a compressive cushion heel to mimic controlled lowering, the orthosis propels the tibia rapidly to achieve foot-flat position. The individual wearing the orthosis needs some eccentric ability of the quadriceps to counteract the rapid knee flexion moment that accompanies the SAFOs propulsive force acting on the tibia. This is especially true if the SAFO has been set in a few degrees of dorsiflexion to minimize risk of knee hyperextension in early stance.

The proximal anterior strapping used to hold the limb in the upper part of the SAFO acts with the fixed ankle position to prevent forward progression of the tibia over the weight-bearing foot during the second/ankle rocker that typically occurs during midstance. If the individual's shoe does not have rocker bottom characteristics, this check of forward momentum compromises effective preparation for push-off and transition from stance into swing phase and necessarily shortens stride length achieved by the swinging limb.

In nonpathologic gait, there are 60 degrees of extension at the hallux during the third, or toe, rocker of gait. For

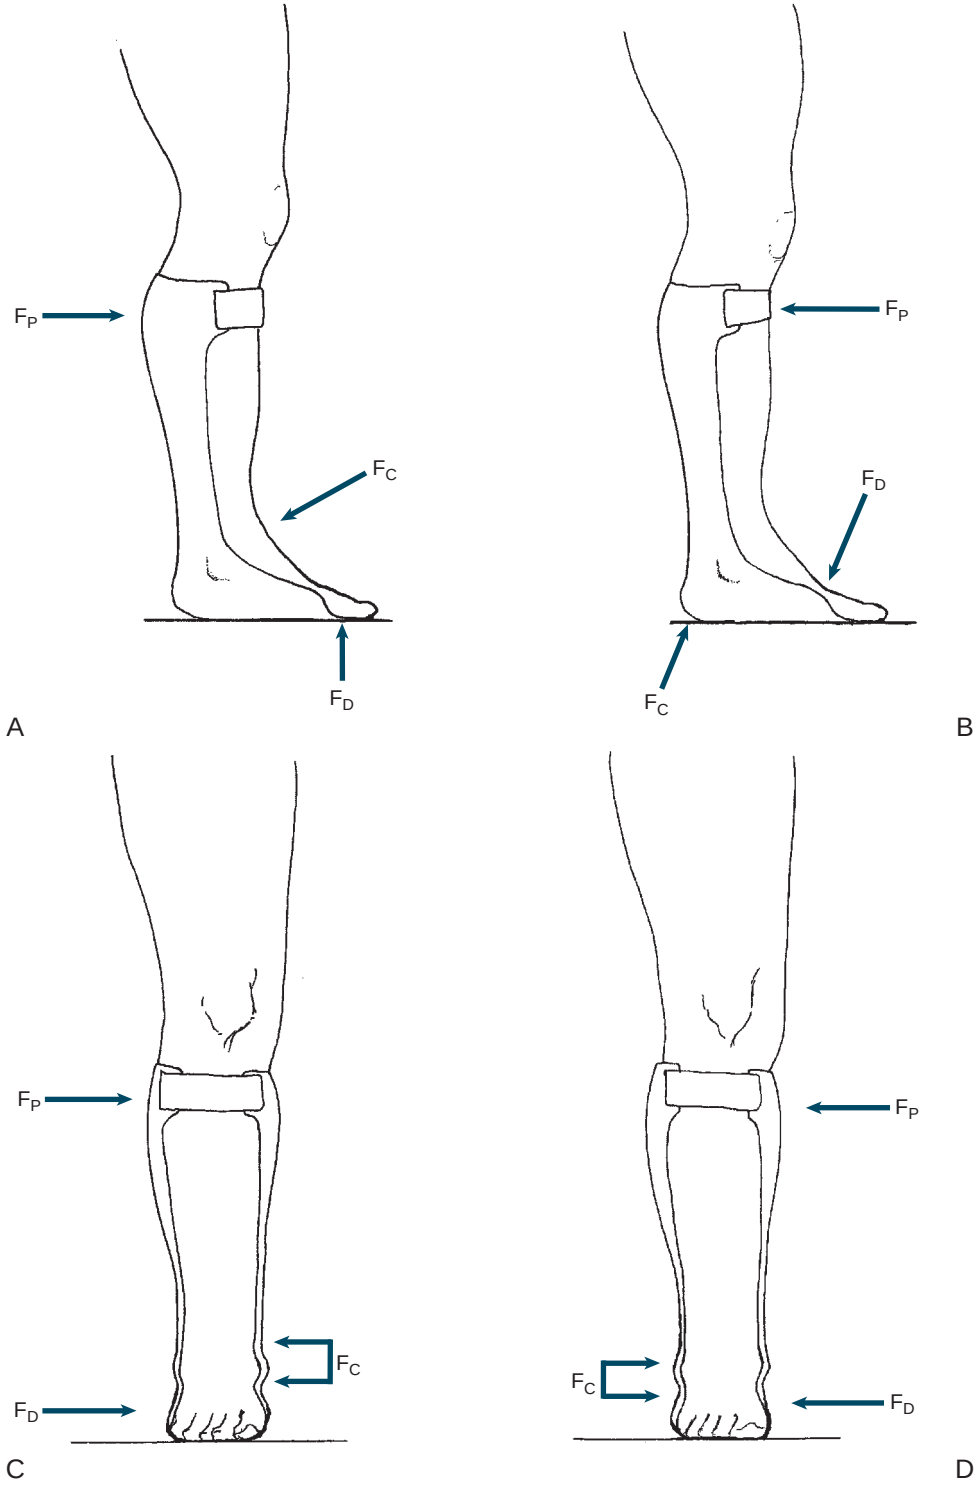

Fig. 9.5 The four force systems in a molded thermoplastic solid ankle-foot orthosis design. (A) Plantarflexion is controlled during swing phase by a proximal force *(F_P)* at the posterior calf band and a distal force at the metatarsal heads *(F_D)* that counter a centrally located stabilizing force *(F_C)* applied at the ankle by shoe closure. (B) For control of dorsiflexion during stance phase (i.e., forward progression of the tibia over the foot), F_P is applied at the proximal tibia by the anterior closure, F_D at the ventral metatarsal heads by the toe box of the shoe, and counterforce F_C at the heel, snugly fit in the orthosis. (C) The force system for eversion (valgus) locates F_D along the fifth metatarsal, F_P at the proximal lateral calf band, and F_C on either side of the malleolus. (D) To control inversion (varus) of the foot and ankle, F_D is applied by the distal medial wall of the orthosis against the first metatarsal, F_P at the proximal medial calf band, and F_C at the distal lateral tibia and calcaneus/talus on either side of the lateral malleolus.

persons wearing a SAFO with a footplate that extends into a stiff toeplate, the third/toe rocker of the foot will certainly be limited. A shoe with rocker bottom characteristics can assist a smoother rollover when extension of the hallux is limited.

INDICATIONS FOR SOLID ANKLE-FOOT ORTHOSES

The SAFO design is often selected for individuals with moderate to severe hypertonicity where equinovarus

significantly impairs the ability to walk.[4,26-28] It may also be used for persons with unpredictable fluctuating muscle tone (athetosis) to provide external stability that makes ambulation possible in the presence of unpredictable variation in antigravity tone.[28] It may be recommended for persons with significant generalized lower extremity weakness or significant hypotonicity, providing external support as a substitute for impaired muscle performance that would otherwise prevent ambulation.[29,30] In both of these circumstances the SAFO is a substitute for severely impaired muscle activity. A custom-molded SAFO has also been used to protect the foot and ankle in the management of orthopedic conditions.[31]

ANTERIOR FLOOR REACTION ANKLE-FOOT ORTHOSIS

All static AFO designs use moments that result from the GRF to provide stability during stance. An orthosis that has evolved from the basic SAFO design to better address impaired motor control of the knee and weakness of the quadriceps is the anterior floor reaction orthosis (FRO)[32,33] (Fig. 9.6A to D). The FRO is fabricated to hold the ankle in a few degrees of plantarflexion. This restricts the ability of the tibia to roll forward over the foot in the second/ankle rocker of gait, creating an extensor moment that stabilizes the knee during stance (Fig. 9.7A to C). If stability is also needed in late stance phase, a stiff toeplate can be added to reinforce the extension moment at the knee. The FRO and SAFO use the same force systems to control foot and ankle position. Whether the FRO is fabricated in a single piece (see Fig. 9.7A) or as a SAFO with the addition of a thermoplastic anterior shell (see Fig. 9.7B), padding is added where the FRO contacts the proximal surfaces of the tibia to make the extra extension force delivered by the orthosis more tolerable to the wearer.

The FRO is often used for children with neurologic conditions who demonstrate "crouch gait," who have paralysis, or who have weakness at the knee and ankle.[32-34] The FRO relies on a GRF vector that passes anterior to the anatomic knee joint. As knee and hip flexion contractures approach or exceed 10 degrees, the GRF vector nears or passes posterior to the anatomic knee joint and the FRO is less effective in stabilizing the knee during stance.[32] The FRO is contraindicated for persons with notable recurvatum during stance and those with cruciate ligament insufficiency; in these circumstances, the extra knee extension moment can further damage joint structure. Although the rigid control of ankle and knee enhances mechanical stability in stance, these external restrictions imposed by the FRO may compromise efficacy of postural responses. In those with balance impairment, an ambulatory assistive device (e.g., a cane, Lofstrand crutches, or rolling walker) may be needed for safety, especially if FROs are worn on both limbs.

WEIGHT-RELIEVING ANKLE-FOOT ORTHOSES

The weight-relieving AFO, also known as a PTB-AFO, incorporates the intimate fit and load-bearing characteristics of a PTB prosthetic socket into a SAFO or traditional metal double upright AFO (discussed later) as a means of offloading or unloading weight-bearing forces during stance phase for individuals with a painful, unstable, or recently repaired ankle or foot.[35-37] The anterior shell of the AFO is modified to accept weight-bearing forces via the medial tibial flare and patellar tendon bar, along with total contact around the upper calf.

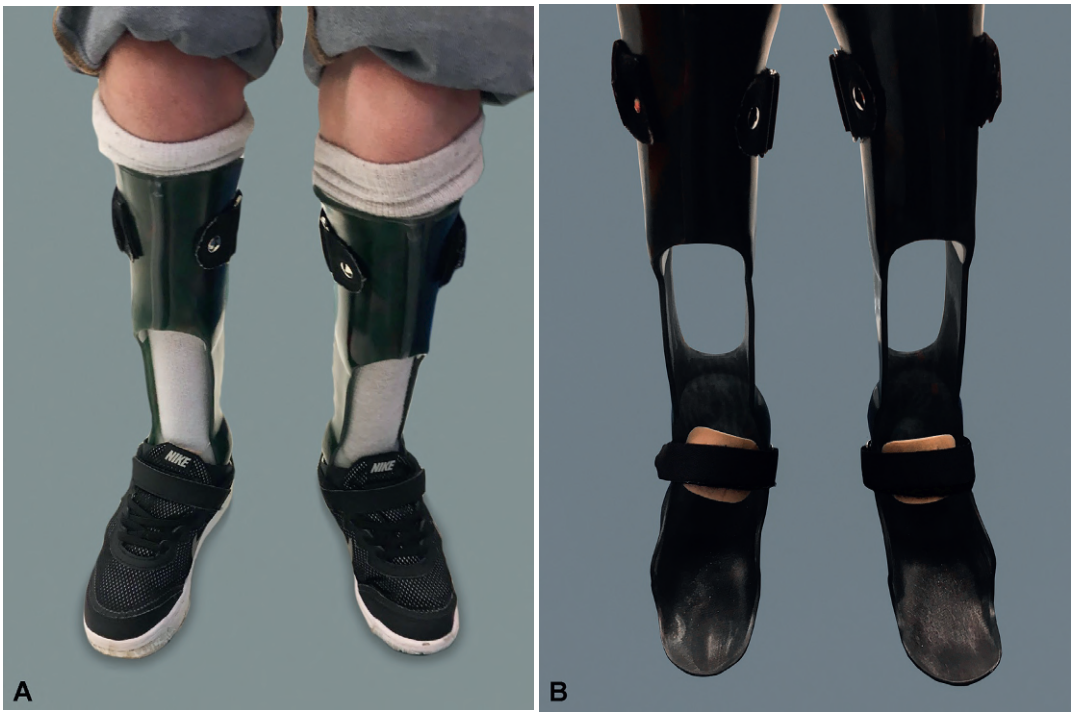

Fig. 9.6 (A and B) This floor reaction orthosis (FRO) was fabricated using carbon graphite and fiberglass in a thermosetting process because of the desire to provide maximum stiffness. The combination of a solid-ankle design and an anterior wall produces a knee extension moment at midstance and enhances stance phase stability.

Continued

Fig. 9.6, cont'd (C and D) This FRO has a solid supramalleolar orthosis that provides medial lateral joint stability to the ankle through the rigid design and custom fit.

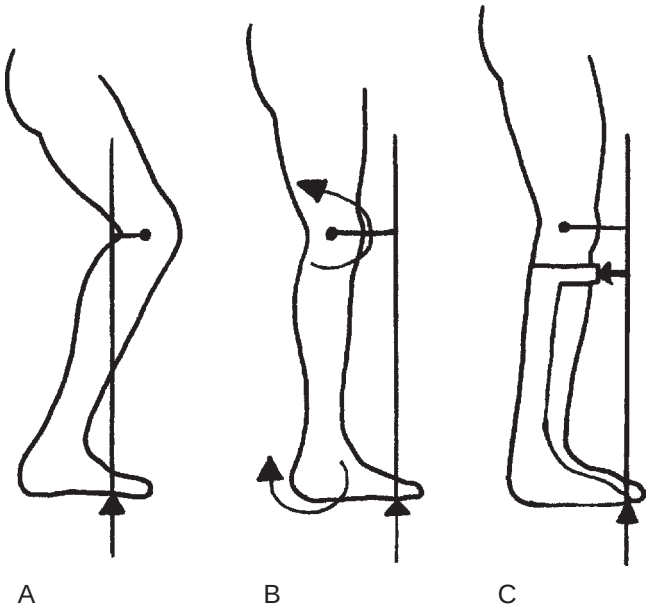

Fig. 9.7 (A) When a patient walks in a "crouch gait" pattern, the ground reaction force (GRF) vector passes behind the knee at midstance, creating a flexion moment at the knee, which must be counteracted to maintain upright position. (B) In normal gait, knee stability at midstance is assisted by a ground reaction moment as the body moves over the foot, and the GRF vector passes anterior to the knee. (C) The solid ankle-foot orthosis and the floor reaction orthotic designs use a fixed ankle position to harness the GRF, creating a large extension moment at the knee.

As with a PTB prosthetic socket, the proximal portion of the PTB-AFO is set in approximately 10 degrees of knee flexion (with respect to vertical) to load some of the body weight onto the anterior shell at the medial tibial flare and patellar tendon bar during stance. This axial force is then transmitted to the ground through the medial and lateral walls of the thermoplastic orthosis, which may be reinforced with metal uprights or through the medial and lateral uprights of a traditional double upright AFO. This strategy effectively reduces axial loading of the ankle and foot during gait.

Individuals wearing a weight-relieving AFO must have normal anatomic structure of the knee, adequate muscle performance and motor control of the quadriceps muscles for stability in early stance, and sufficient skin integrity to tolerate the loading forces applied by this orthotic design.

Dynamic Ankle-Foot Orthoses

Dynamic orthoses allow some degree of sagittal plane motion at the ankle; many permit dorsiflexion during stance phase to facilitate the ankle rocker of gait but restrict plantarflexion during swing phase to facilitate swing limb clearance, incorporating some type of orthotic ankle joint. These dynamic orthoses are available in both thermoplastic and more traditional metal double upright designs. These are reviewed in order from least restrictive to most supportive designs.

UNIVERSITY OF CALIFORNIA BIOMECHANICS LABORATORY ORTHOSIS

In the 1970s, researchers at the University of California Biomechanics Laboratory (UCBL) developed a custom-molded shoe insert, currently known as the *UCBL orthosis*, as an orthotic intervention for subtalar joint instability.[38] The UCBL controls flexible calcaneal deformities (rearfoot valgus or varus) and transverse plane deformities of the midtarsal joints (forefoot abduction or adduction) by "grabbing" the

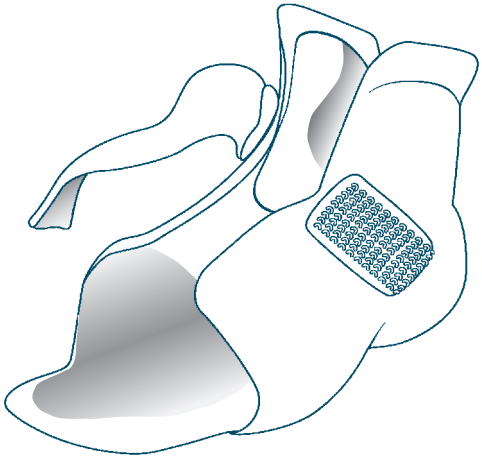

Fig. 9.8 The dynamic ankle-foot orthosis is a flexible polypropylene brace designed to optimize subtalar joint alignment through its supramalleolar design. (Reprinted with permission from Zablotny CM. Use of orthoses for the adult with neurological involvement. In Nawoczenski DA, Epler ME [eds], *Orthotics in Functional Rehabilitation of the Lower Limb*. Philadelphia: WB Saunders; 1997:229.)

calcaneus and supporting the midfoot with high medial and lateral trim lines; it realigns the calcaneus, providing a more stable foundation for the articular surfaces of the talus, navicular, and cuboid bones in cases of instability.[39] The *Gillette modification*, an external post positioned either on the medial or lateral border of the heel cup, can be used to apply additional rotatory moments to the calcaneus during weight bearing. It is important to recognize that the UCBL orthosis acts primarily at subtalar and midfoot tarsal joints during weight bearing; it would not be appropriate for persons with swing phase clearance issues, which require the trim line of the orthosis be placed above the ankle joint.

DYNAMIC ANKLE-FOOT ORTHOSIS

The dynamic ankle-foot orthosis (DAFO), also known as a flexible supramalleolar orthosis (SMO), is a custom-molded orthosis that has evolved from the UCBL shoe insert to better address sagittal plane control of the ankle and foot during stance and to facilitate foot clearance in swing.[40] Custom-molded from relatively thin thermoplastic, its proximal trim lines are just superior to the ankle joint, and its distal trim lines encase more of the forefoot than the UCBL (Fig. 9.8). By limiting movement of the midfoot and forefoot and by holding the foot in functional position, the DAFO provides a stable base for more effective motor performance and postural control during standing and ambulation.[41,42]

POSTERIOR LEAF SPRING ANKLE-FOOT ORTHOSIS

The PLS AFO is a dynamic thermoplastic AFO designed to accomplish two things[43]:

- Support the weight of the foot during swing phase as a means of enhancing swing limb clearance
- Assist with controlled lowering of the foot during loading response in stance as part of the first/heel rocker

The PLS is one of the groups of AFOs that provide dorsiflexion assistance. In contrast to the SAFO, medial and

Fig. 9.9 The posterior position and arc of the trim lines at the ankle and the thickness of thermoplastic material used determine the degree of flexibility of the posterior leaf spring ankle-foot orthosis. This design assists with foot clearance by limiting plantarflexion during swing phase.

lateral trim lines are located well posterior to the midline of both malleoli so that the orthosis is flexible at the anatomic ankle joint (Fig. 9.9).[44] The degree of flexibility is determined by the thickness of the thermoplastic material used to construct the orthosis and width of the posterior upright in the distal third of the orthosis.[44] In custom-molded PLS orthoses, the orthotist tailors the stiffness of the orthosis using the trim line pattern that will best support the weight of the foot during swing, as well as the individual's needs for stability in stance.[44]

Once the heel contacts the ground at initial contact and the loading response begins, the flexible plastic of the PLS serves as a proxy for impaired or absent eccentric activity of the tibialis anterior muscle, slowing but not stopping the foot's descent toward the ground.[43] As stance phase continues, the flexible PSL allows the tibia to roll forward over the weight-bearing foot to accomplish a smooth ankle rocker of midstance to terminal stance. As the foot leaves the ground in initial swing, the PLS is able to hold the ankle at the desired neutral 90-degree position, which assists swing clearance and keeps the toes elevated so that next initial contact will be made at the heel. The flexibility inherent in the PLS provides a notable functional advantage over the SAFO.[45-47]

Owing to its narrow posterior upright and relatively shallow heel cup, a PSL is not as effective in stabilizing the calcaneus and talus during stance as are the SAFO, DAFO, or UCBL designs. This makes it less effective in controlling mediolateral foot position, especially for persons with flexible deformities of the forefoot, midfoot, or rearfoot.[48] In these circumstances the orthotist may opt to place medial and

lateral trim lines somewhere between the midmalleolar position of a SAFO and the narrower PLS to provide additional stability. This modification is sometimes referred to as a *semisolid AFO*. The modification provides better control of ankle motion but at the cost of limiting mobility during the ankle rocker of gait.[49] Note that the flexibility of a PLS and a semisolid AFO make them inappropriate for individuals with significant equinovarus or spasticity of the lower extremity: A high level of abnormal tone will overpower the control systems in these designs.

ADDITIONAL DORSIFLEXION ASSIST OPTIONS

There are a number of commercially available prefabricated and custom-molded AFO designs available as alternatives for individuals whose primary need is for dorsiflexion assistance as a substitution for weakness and/or impaired motor control at the ankle. Three of the more frequently used options are reviewed here: (1) dual carbon fiber spring orthosis (CFO), (2) wearable functional neuromuscular electrical stimulation units, and (3) novel commercially available alternative designs.

Carbon Fiber Spring Orthoses

The dual CFO, developed and tested primarily in Germany, is a modification of the traditional PLS design that cuts the PLS into a foot and calf section, then attaches overlapping carbon fiber springs (carbon fiber and Kevlar fibers impregnated with epoxy resin) between the sections (Fig. 9.10A).[50] Spring resistance is selected based on the individual's weight. This design aims not only to substitute for impaired or absent anterior compartment muscle activity but also to enhance the toe rocker of stance phase that is typically compromised by thermoplastic AFOs.[50] A more powerful push-off is attributed to loading of the spring during early and midstance as the tibia moves forward over the foot and releasing of the spring in transition from terminal swing to preswing.[51]

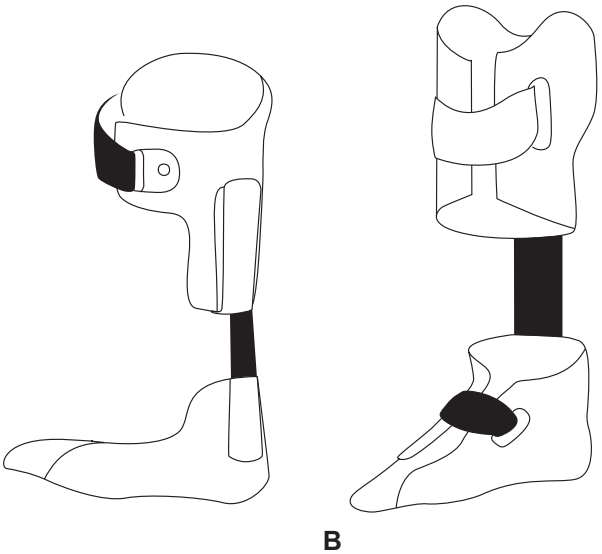

Fig. 9.10 (A) Note the carbon fiber springs inserted posteriorly between the foot and calf component of this carbon fiber orthosis. The springs provide dorsiflexion assistance for clearance in swing and prepositioning of the foot for initial contract, as well as preservation of the second and third rockers of stance phase. (B) The dual carbon fiber spring orthosis designed to provide assistance with plantarflexion/push-off for the transition from stance to swing for persons with weakness or paralysis of calf muscles/plantarflexors.

The CFO design has been adapted to enhance walking ability of children with neuromuscular conditions that contribute to impaired or absent plantarflexor muscle performance.[52,53] In this version, the carbon fiber spring is L shaped (see Fig. 9.10B) with its attachment to the foot component (a stiffer version of a supramalleolar DAFO) on the plantar surface rather than on the posterior heel. The slight distance between the spring and posterior foot section acts as a dorsiflexion stop during stance, allowing some dorsiflexion for ankle rocker until the two surfaces come into contact. The proximal carbon fiber spring is fit into a slot in the posterior of a custom-molded section that resembles the upper half of a total contact prosthetic socket. A vertical slot drilled into the proximal spring allows it to slide up and down for several centimeters during stance phase to minimize potential skin friction. This CFO appears to enhance transition through both ankle and toe rockers of gait and to provide assistance for push-off. This design has also been incorporated into a KAFO for children who require additional support or control at the knee and hip.[54]

Functional Neuromuscular Electrical Stimulation

For persons with impaired motor control resulting from disease or trauma of the central nervous system, several commercially available, wearable functional electrical stimulation (FES) units, also called *neuroprostheses*, are available (e.g., WalkAide, Hanger Orthopedic Group, Austin, TX; Odstock Dropped Foot Stimulator, Salisbury, UK; NESS L300 Foot Drop System, Bioness Inc., Valencia, CA). The individual wears a cuff that is positioned snugly just below the knee, rather than an orthosis that must fit into the shoe (Fig. 9.11). The cuff holds a small stimulator medially with electrodes positioned laterally over motor end points of the peroneal nerve.[55] Depending on the model, appropriate timing of the FES for dorsiflexion activity is determined by a switch worn in the shoe, an inclinometer, or an accelerometer. Most use surface electrodes to deliver the stimulus for muscle contraction, although cuffless versions with surgically implantable electrodes are available. Studies evaluating the device have demonstrated improved spatial and temporal characteristics and safety of walking in persons with acute and chronic stroke when worn as an orthosis alone or when integrated with rehabilitation interventions.[56,57] Similar findings support its use for persons with traumatic brain injury, multiple sclerosis, and Parkinson disease.[1,58-60]

Each of these devices must be adjusted to the individual's typical gait pattern. To be effective, all of these devices require an intact and healthy peroneal nerve. They would not be appropriate for persons with peripheral nerve injury or neuropathy.

Manufacturers note that such devices are contraindicated in individuals with demand pacemakers or defibrillators, healing fractures, metal implants in the limb, or history of phlebitis; the unit should be used with caution in persons with varicose veins, inflammation in or around the knee, or sensory impairment. Although most devices are resistant

Fig. 9.11 The Bioness L300 System, as an example of a wearable functional electrical stimulation unit, is used to trigger muscle contraction during appropriate points in the gait cycle. The L300 system (photo R) triggers dorsiflexion during swing phase. The L300+ system (photo L) incorporates a thigh component that can stimulate the knee flexors or extensors during swing and/or stance phase to assist with stance stability or swing limb advancement.

to splashes, immersion in water during bathing or swimming or saturation while shoveling snow, for example, will damage the unit, rendering it nonfunctional.

Commercially Available Dorsiflexion-Assist Designs

A number of manufacturers have developed carbon fiber orthoses to provide dorsiflexion assistance at the appropriate times in the gait cycle (e.g., Camp ToeOFF series, Allard USA, Rockaway, NJ; AFO Dynamic, Ossur Americas, Foothill Ranch, CA; Matrix and Matrix Max, Prolaborthotics USA, Napa, CA; WalkOn, Ottobock, Berlin, Germany; SpryStep, Townsend Thuasne USA, Bakersfield, CA). In contrast to thermoplastic designs, many of these orthoses use a cushioned anterior shin or medial shank piece, held in place by strapping, that transitions into a medial upright and continues into a full footplate (Fig. 9.12A to C). These orthoses are designed to preposition the foot for heel strike at initial contact, substitute for impaired anterior compartment to allow controlled lowering of the foot into foot-flat position during the heel rocker of loading response, provide some medial-lateral stability during stance while allowing forward progression of the tibia during the ankle rocker of stance phase, contribute to push-off in the transition from stance to swing, and support the weight of the foot for effective swing limb clearance.[61] Although there is some evidence that these dorsiflexion-assist designs have a positive impact on both the kinematics and energy cost of walking, there have been few published studies that directly compare them with traditional PLS orthoses or with articulating (hinged) thermoplastic AFOs or traditional metal double upright AFOs with dorsiflexion-assist orthotic ankle joints.[61]

Fig. 9.12 Examples of a carbon fiber composite dorsiflexion assist ankle-foot orthosis used to substitute for activity of the anterior compartment of muscles of the lower leg. (A) Townsend SpryStep and (B *right* and C) Allard ToeOFF offer support primarily for ankle dorsiflexion. They may offer some mild knee support during stance. There are some carbon fiber ankle-foot orthoses designed with increased strength that may assist greater with knee instability, such as Allard BlueRocker (B *left*), although not supportive enough to stabilize the moderately unstable stance knee.

HINGED THERMOPLASTIC ANKLE-FOOT ORTHOSIS

The thermoplastic hinged (articulating) ankle-foot orthosis (HAFO) allows sagittal plane motion at the ankle by incorporating a mechanical ankle joint between the foot and calf sections of the orthosis. This variation of the SAFO was designed primarily to allow the tibia to roll over the weight-bearing foot during stance, for a smooth ankle rocker, at the same time holding the foot in optimal alignment to control the impact of tone-related equinovarus forces throughout the gait cycle (Fig. 9.13A to D). In children with cerebral palsy and in adults after stroke, these orthoses reduce energy cost of walking (compared with barefoot), as well as improve stride length, cadence, and walking speed.[47,62,63] As compared with the SAFO, the HAFO also improves mobility in many functional activities, such as rising from the floor, ascending and descending stairs, and walking up or down inclines.[45,46,48] There is some indication that HAFOs lessen the magnitude of abnormal muscle activation associated with spasticity in children with cerebral palsy.[64] HAFOs appear to reduce risk of falls in adults with long-standing hemiplegia after stroke, improve static postural control, and have less negative impact on dynamic postural control in standing than SAFOs.[65,66] However, for some children with moderate to severe spastic diplegic cerebral palsy, the mobility provided by a HAFO compromises stability in early stance, reinforcing crouch gait pattern, reducing walking speed, and increasing energy cost as compared with a SAFO.[62]

The shape, dimensions, and force control systems of the HAFO are almost exactly the same as those of a SAFO, except it has two separate pieces linked by an orthotic ankle joint rather than being a single, solid piece. The HAFO has a larger width at the ankle than the SAFO to accommodate the mechanical ankle joint.

Hinged AFOs can be fabricated to allow free motion at the ankle, to allow limited range of motion (i.e., allow dorsiflexion and stop plantarflexion, or the inverse), or to provide some assistance to dorsiflexion, depending on what orthotic ankle joint option motion best meets the individual's needs and maximizes the resources they bring to the task of walking. A variety of mechanical thermoplastic joints is commercially available (Fig. 9.14A to C). Those with true articulations (e.g., the Oklahoma joint) have a single axis of motion that should be aligned as closely as possible to the anatomic ankle joint; other orthotic joints (e.g., the Gillette joint) are flexible and nonarticulating.

Traditional metal orthotic ankle joints have been incorporated into thermoplastic HAFOs as well; these designs are referred to as *hybrid orthoses*. Simple single axis joints provide mediolateral stability without restriction of available dorsiflexion or plantarflexion; a motion stop can be incorporated if there is need to limit plantarflexion beyond neutral (for stability in early stance) or dorsiflexion (to limit weight bearing on the forefoot in later stance) as the individual's needs dictate. A bichannel adjustable ankle joint (also referred to as a *double action ankle joint* or a *double Klenzak joint*) (Fig. 9.15A to C) can be used to provide assistance and/or limit motion based on an individual's capabilities and needs for support. If motion assistance is desired, a coil spring is placed in the channel and a screw is used to adjust compression until the desired level of assistance is achieved. If motion is to be blocked, a solid steel pin is inserted instead of the spring to stop motion beyond a particular point in the range of motion. Because of its versatility and adjustability, the double action ankle joint is often chosen when change in a patient's functional status (improvement or deterioration) is anticipated. Orthotic ankle joints allow the orthotist to adjust the available range of motion from none (as in a SAFO) through an array of limited anteroposterior stop settings. This would be an advantage when motor control around the ankle and knee is expected to improve over time, for example, in individuals who are recovering from an acute stroke.

The HAFO allows free dorsiflexion; however, when motor control is compromised, such that additional support is needed during stance, the orthotist may choose to incorporate a mechanism, such as a check strap, to adjust the amount of dorsiflexion allowed (see Fig. 9.14B). If the check strap is maximally tightened, the orthosis functions like a SAFO. The check strap can be loosened, lengthened, or elasticized as neuromotor control improves, allowing only as much forward progression of the tibia in the heel rocker as is safe and functional for the individual. This adaptation makes the HAFO versatile and useful when return of neuromotor control or function is anticipated.

It is important to note that a prerequisite for using this orthosis is at least 5 degrees of true ankle dorsiflexion, accomplished without compromise of subtalar or midtarsal joint position; for this reason, a HAFO may not be an appropriate choice for persons with severe spasticity that limits

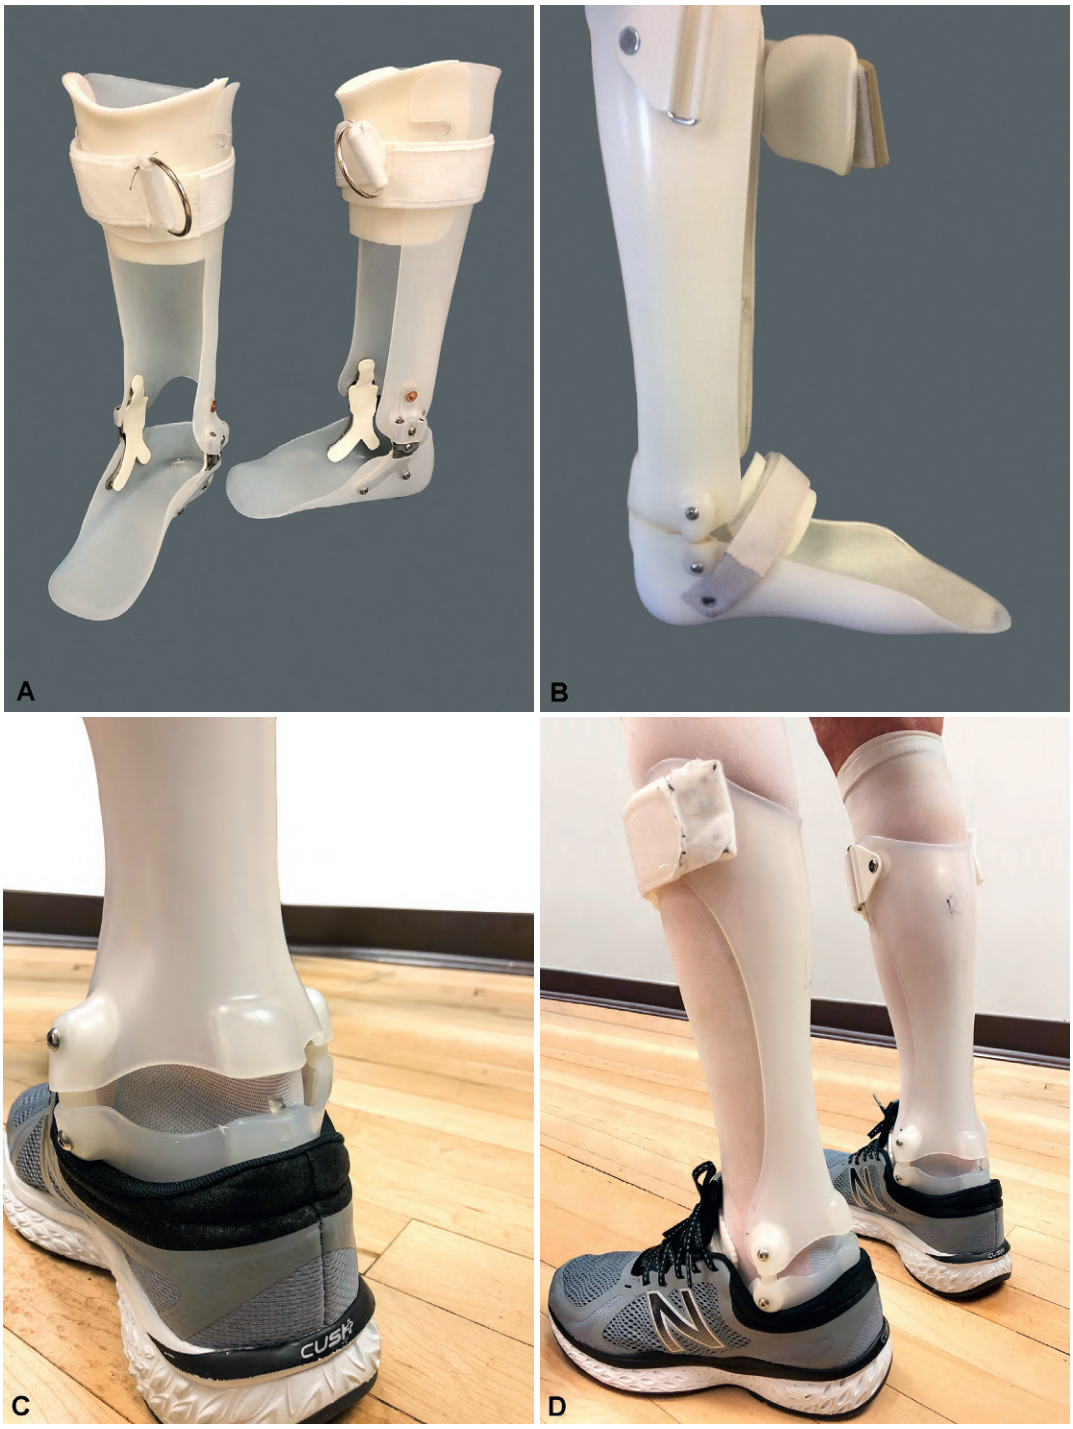

Fig. 9.13 (A) This hinged ankle-foot orthosis (HAFO), with compact double action ankle joint, allows forward motion of the tibia through the ankle rocker of stance phase and can be adjusted via springs or pins to allow more support or restriction. (B to D) This HAFO, with flexure ankle joints, has a built-in plantarflexion stop (when the posterior edges of the foot and calf section come into contact) and posterior strapping that can be adjusted to limit the amount of dorsiflexion available, based on the wearer's motor control and need for stability in stance.

ankle motion or those with significant instability or malalignment of the midfoot.

CONVENTIONAL DORSIFLEXION-ASSIST ANKLE-FOOT ORTHOSIS

The conventional double upright counterpart to the PLS uses a spring mechanism incorporated into the mechanical ankle joints of the orthosis. The uprights are connected to the distal stirrup at the mechanical ankle joint, and the stirrup is fixed between the heel and sole of the shoe. A coiled spring and small ball bearing are placed in a channel in the distal uprights that runs toward the posterior edge of the stirrup. When the spring is compressed at initial contact and early loading response, it resists plantarflexion, allowing a controlled lowering of the foot to the floor, substituting for the heel rocker of early stance. Recoil of the spring when the foot is unloaded in preswing and initial swing assists

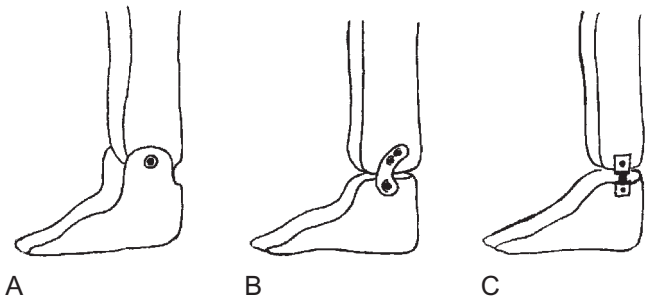

Fig. 9.14 Examples of thermoplastic ankle joints used in hinged ankle-foot orthosis. The overlap joint (A) and Oklahoma joint (B) are single axis joints, whereas the flexible Gillette mechanism (C) allows movement into dorsiflexion and plantarflexion without an actual articulation.

dorsiflexion for swing phase toe clearance.[62] The amount of dorsiflexion assist provided is determined by adjustment of a screw placed in the top of the channel to compress or decompress the spring further. Another option is the dual channel *(double Klenzak)* orthotic ankle joint (see Fig. 9.15); by placing a spring in one channel and a rod in the other, this mechanical ankle joint can provide adjustable dorsiflexion assistance and plantarflexion stop (in persons with impaired dorsiflexion muscle performance) or plantarflexion assistance and dorsiflexion stop (for those with motor control or muscle performance impairment of the gastrocsoleus complex).

Traditional or conventional double upright orthoses are typically used when the individual who needs dorsiflexion assistance and plantarflexion control has a comorbid condition that causes fluctuation in limb size (edema), such as congestive heart failure or the need for kidney dialysis, which would compromise the intimate fit of a thermoplastic orthosis. The downside of the double upright AFO is its less effective control of abnormal foot position and risk of skin irritation as the foot moves within the shoe. For persons with neuropathic foot conditions who are unable to directly perceive abnormal pressures and the discomfort of tissue stress, a custom-molded AFO that is intimately fit for the individual's foot would be the orthosis of choice unless significant fluctuating edema precludes this choice.

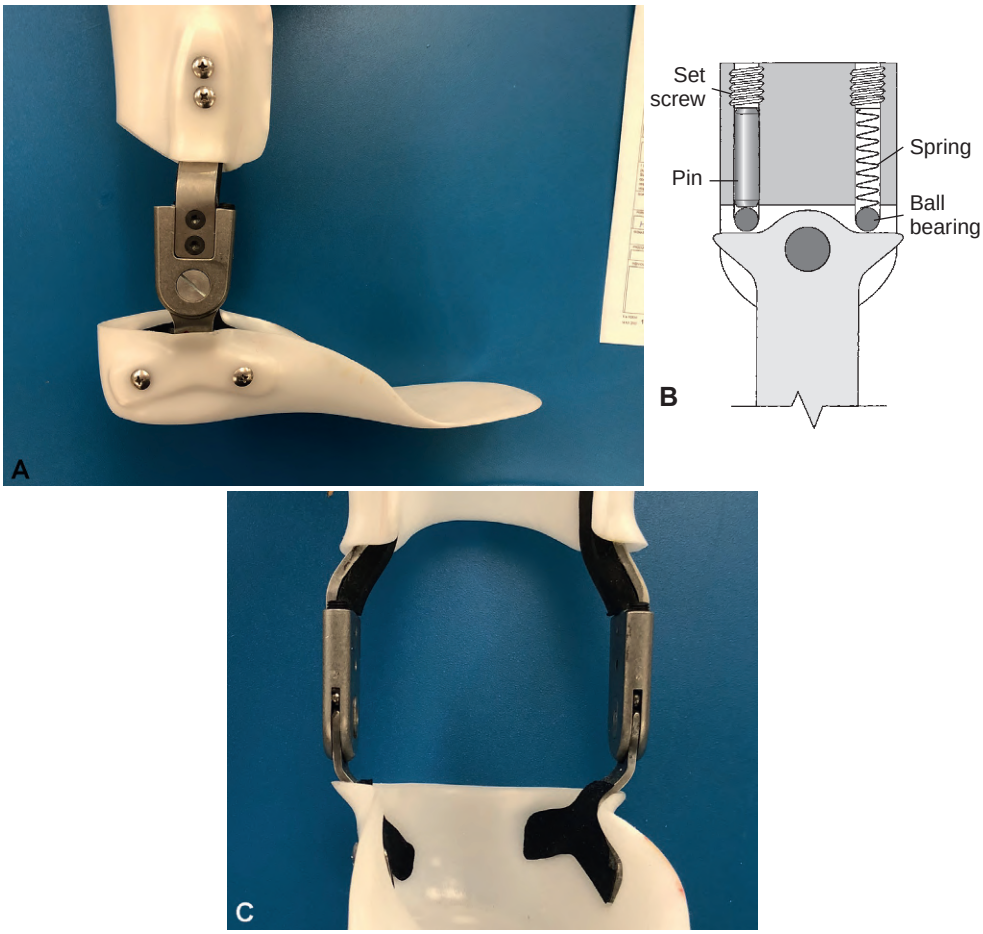

Fig. 9.15 (A) The double-action joint can be used in a conventional double upright, metal ankle-foot orthosis and a thermoplastic-metal hybrid ankle-foot orthosis. Motion is assisted if a spring is compressed within the channel or can be blocked by placement of a steel pin within the channel. (B) The internal anatomy of the double adjustable ankle joint. Ankle joint mobility restrictions (e.g., plantarflexion stop) result from the locations of the pins in the anterior and posterior channels of the orthotic joint. A spring may occupy one of the channels, as depicted here, to assist motion (e.g., dorsiflexion assistance). The ball bearings allow the brace uprights to pivot with ease over the brace stirrup. The set screw can be adjusted to change the relative positions of the rods in each of the channels. (C) The hinged ankle joint can also exist with a duel pin system to allow adjustment of the fixed angle and ankle range as the patient's functional status changes. The degree of limitation from the pins can be viewed anteriorly/posteriorly. ([B] From Zablotny CM. Use of orthoses for the adult with neurological involvement. In Nawoczenski DA, Epler ME [eds], *Orthotics in Functional Rehabilitation of the Lower Limb*. Philadelphia: WB Saunders; 1997:227.)

ANKEL-FOOT ORTHOSIS DESIGNS, TONE, AND POSTURAL CONTROL

Although some AFOs are described as having tone-reducing (TR-AFO) or tone-inhibiting (TI-AFO) effects and are prescribed for persons with hypertonicity (spasticity) from upper motor neuron diseases (stroke, cerebral palsy, traumatic brain injury), the evidence of this effect is primarily based on cross-sectional studies and case reports, rather than randomized controlled clinical trials.[67] Historically, such AFO designs have their roots in the principles of serial casting, which sought to lessen the impact of tonic plantar reflexes that reinforce extensor tone of the lower extremity in children with cerebral palsy.[68,69] An early review of how these principles were applied to AFO designs suggested that the orthosis incorporate the following[70]:

- A metatarsal bar or dome to alter loading on metatarsal heads
- A mechanism to encourage toe extension
- Additional loading on either side of the distal point of attachment of the Achilles tendon
- An ankle held in neutral subtalar and dorsiflexion position

Current evidence does not support a positive neurophysiologic consequence, and there is no alternative means to *quantify* muscle tone (the modified Ashworth Scale is a categoric measure, rather than a continuous measure).[71] Consensus statements of the International Society for Prosthetics and Orthotics suggest that the terms *tone reducing* or *tone inhibiting* should not be used to describe AFOs until stronger evidence of their efficacy for specific patient groups becomes available based on randomized controlled trials.[72]

Although the aim of AFO designs are to have a positive impact on quality and efficiency of walking (speed, stride, joint kinematics, kinetics, and energy cost), they vary in their impact on efficacy of postural responses and balance during functional activities while walking, standing, or moving between sitting and standing.[73,74] Because many individuals whose walking would improve if they used AFOs also have deficits in motor control that impact the efficacy of balance and postural responses and because risk for falling is high, it is important to consider the interaction of the orthosis with the individual's own movement resources.[75] A key question to consider is how the orthosis influences an individual's ability to dynamically control the body's center of mass within his or her base of support in standing and while transitioning and walking. Does the orthosis constrain, maintain, or improve the individual's limits of stability during functional tasks that are meaningful and important for that person? For some persons with motor control dysfunction, the limitation of ankle motion may enhance stability in stance enough to improve ability to perform functional tasks while standing. For others, the same AFO design may impair the ability to respond effectively to both internally generated and external perturbations that shift the center of mass toward the edges of the individual's limits of stability.

Studies evaluating the impact of AFOs on static and dynamic postural control are challenging to interpret because of variation in the AFO designs being evaluated, the outcome measures used to assess balance, and the patient groups included in the sample.[73] In general, the SAFO and semisolid AFOs positively impact on static balance but appear to delay or impair response to perturbations.[5,66,76] For persons with stroke using a PLS orthosis, evidence is relatively convincing that both static and dynamic postural control improve with use of the orthosis (when compared with no orthosis or to SAFO) as measured by Timed Up and Go (TUG) times, Berg Balance Scale score, and limits of stability testing.[77-79] There is little evidence about the impact of HAFOs and DAFOs on balance: The few available studies suggest a modest improvement in both static and dynamic postural control.[80]

How does this evidence impact clinical decision-making when selecting an orthotic design for a particular patient? The team must weigh the potential positive and negative influences of the orthosis on the ability to walk, as well as on postural control during all activities that are important to the individual who will be wearing the orthosis. There is not a clear best or worst AFO; instead the team must match the pros of the orthosis with the person's neuromuscular resources, physical characteristics, abilities, and desired activities, tempered by the prognosis associated with the condition or diagnosis.

When Should a Knee-Ankle-Foot Orthosis Be Considered?

The rehabilitation team considers KAFOs only when stability during stance cannot be effectively provided by one of the AFO options.[81] KAFOs are often prescribed when, in addition to impairment of ankle control, there is the presence of (1) hyperextension or recurvatum that jeopardizes structural integrity of the knee joint and/or (2) abnormal or excessive varus or valgus angulation that occurs during weight bearing in stance phase.[82] If not recognized and addressed appropriately, both threaten joint function and structure during walking and, with repeated abnormal loading, increase risk of permanent damage to supporting structures within the knee and development of degenerative joint disease.

The KAFO metal and leather design was used during the 1950s to make ambulation possible for those recovering from polio.[15] However, the weight of the orthosis increased energy cost of ambulation significantly and ultimately made use of a wheelchair the preferred method of mobility for those requiring bilateral KAFOs to walk.[83] The development of the lighter-weight Craig-Scott orthosis in the 1970s, the advent of thermoplastic custom-fit or custom-molded components in the 1980s, and emergence of stance-control (SC) orthotic knee joints since 2000 have contributed to reduction in energy cost of ambulation with KAFOs; walking while wearing these orthoses has become more reasonable.[81] However, currently, many individuals decide that walking with bilateral KAFOs is too slow and requires too much effort to be truly functional for daily use.

Many KAFO designs use a SAFO or an HAFO as the distal component and one or more thermoplastic thigh bars or cuffs as proximal components, with metal uprights with a variety of orthotic knee joints to interconnect them.[82]

CHALLENGES TO KNEE-ANKEL-FOOT ORTHOSIS USE

The key issues that must be addressed for safe ambulation with KAFOs are the same as those discussed earlier in the chapter for AFOs[83]:

- To provide stance-phase stability with minimal disruption of forward progression (especially through the ankle rocker of stance)
- To minimize disruption of swing limb clearance
- To prepare for an effective initial contact by holding the ankle in a neutral position

However, once the knee joint is encased in an orthosis, meeting these goals can be challenging, especially for persons who require bilateral KAFOs. These individuals typically have more proximal deficits in muscle performance, motor control, and postural control than those whose need for stability in stance and mobility in swing are addressed by any of the AFO designs.[84] Additional challenges that must be considered during the clinical decision-making process include:

- Position transfers (i.e., sit to stand) can become complex and demanding motor tasks
- Constraints on dynamic anticipatory and reactionary postural responses during activities in standing
- Need for additional stabilization in the form of an ambulatory assistive device (e.g. crutches, walkers)
- Decreased efficiency and/or increased energy expenditure with movement (which may significantly limit patients with underlying cardiovascular conditions or deconditioning).
- Difficulty with donning and doffing.

Any of these factors may lead to an individual abandoning the use of the orthosis. All of these should be considered when the cost of fitting, fabrication, and training for KAFO use is factored in.

KNEE FUNCTION AND ALIGNMENT

In early stance, under normal gait conditions, the GRF passes through the ankle, behind the knee, and through the hip, creating an external flexion moment at the knee (Fig. 9.16). To counteract this GRF-related flexion moment, the quadriceps muscles contract to prevent the knee from collapsing into further flexion, the hamstrings and hip abductors contract to stabilize hip position and maintain a level pelvis, and the gastrocnemius prepares to eccentrically control forward progression of the tibia.[85] This combination of muscle activity provides an internally generated knee extension moment that balances the external flexion moment at the knee generated by the GRF.[85] When musculoskeletal or neuromuscular impairment alters limb position or muscle activity at any lower extremity joint, the internal/external force system is no longer in equilibrium, and efficiency of walking and stability in stance will be compromised.[85] The magnitude of disruption of the equilibrium between externally and internally generated moments determines whether the individual will be able to use his or her own resources (often in compensatory patterns or deviations) to address the imbalance or if an AFO or KAFO is necessary for functional walking. Consideration of the magnitude of disruption of this equilibrium helps the team to determine whether an AFO can effectively influence the position of the GRF as it crosses the knee or if instead a KAFO is needed to restore equilibrium. If there is evidence of ligamentous instability that threatens anteroposterior or medial lateral stability at the knee or markedly abnormal varus or valgus of the knee, a KAFO would clearly be indicated.

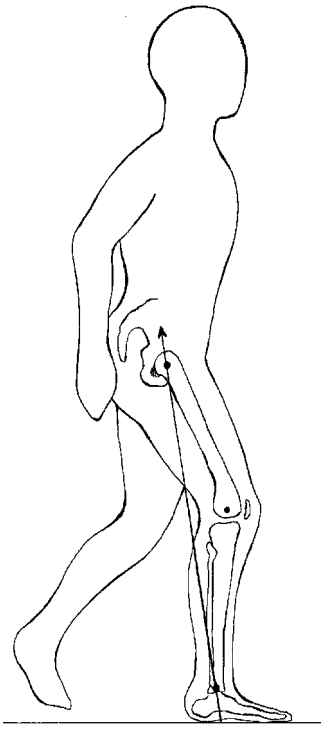

Fig. 9.16 The ground reaction force (GRF) passes through the ankle, behind the knee, and through the hip as loading response moves toward midstance, creating an external flexion moment at the knee. To achieve stability, muscle activity of the quadriceps, hamstrings, and gastrocnemius/soleus combine to create an internal extension moment to counterbalance the flexion moment of the GRF.

The evaluation process for KAFOs includes documentation of the individual's height and weight, the status of circulation and sensation in lower extremities, the condition and integrity of the skin, soft tissue density and bony prominences, as well as living, school, working, and leisure environments in which the KAFO is likely to be used. Specific attention is given to determination of available range of motion, ligamentous activity, fixed contractures, muscle performance, muscle and antigravity tone, leg length, and limb girth. The use of observational gait analysis, walking speed, other kinematic parameters, and, if appropriate, kinetic analysis is used to document preorthotic gait pattern. The team synthesizes this information to make a recommendation. The orthotist selects appropriate materials and components then fabricates and fits the orthosis, making adjustments as necessary.[84] The physical therapist and individual begin the process of functional training, with adjustments being made to the orthoses as indicated.

Knee-Ankle-Foot Orthosis Design Options

KAFOs, much like the AFOs that form their distal component, can be made of primarily metal materials (e.g., steel, aluminum, titanium alloys, carbon fiber), primarily thermoplastics, or as a hybrid combining both types of materials. Historically, the orthotic knee joints of a KAFO were locking

or free swinging; the development of SC knee units in the early 2000s have significantly changed function and energy cost for individuals who use SC-KAFO for function or for exercise.[86] Although a KAFO does not directly control hip motion, if the individual wearing bilateral KAFOs is trained to stand with a forward pelvis, lumbar lordosis, and an extended trunk, the GRF at midstance will pass anterior to the knee and posterior to the hip, creating an extensor moment that will enhance stability. In this position, the Y ligaments of the hip are elongated, contributing to an internal stabilizing force at the hips as well.[87] It is important to recognize that this strategy to achieve stable stance is not appropriate for children until musculoskeletal maturity is reached.[88] Use of this strategy may, if used frequently over a long period of time, contribute to the development of degenerative joint disease of the lumbar spine and chronic low back pain.

Like any orthosis, KAFOs can both facilitate and challenge function. What works for one person may be inappropriate for another who has different physical or emotional characteristics or a different medical condition. For persons who want to walk using a KAFO, the orthotist must be even more thoughtful about durability and weight, matching the alignment of anatomic and orthotic joints, the impact of the forces used in each of the control system across all planes of motion, the ease of donning and doffing the device, the adjustability of the orthosis, the need for maintenance or replacement of worn-out components, and whether the orthosis will be comfortable and cosmetically acceptable to the person who will wear it.[88]

CONVENTIONAL KNEE-ANKEL-FOOT ORTHOSES

During the early 1900s until the 1980s, most KAFOs were fabricated using a pair of uprights (stainless steel, titanium alloy, aluminum, or carbon composite) as a frame, with leather-covered posterior thigh and calf cuffs that buckled across the anterior thigh and leg to secure the orthosis on the limb, a pair of single axis locking orthotic knee joints, a pair of single axis dorsiflexion assistance orthotic ankle joints with a plantarflexion stop, and metal stirrups that attached between the heel and sole of the shoe (Fig. 9.17). At times, a leather anterior knee pad was added as an additional contact point for force application to stabilize the knee. These KAFOs were often worn over clothing during gait training and could later be worn under clothing if the individual so desired.

In most KAFO designs, a three-point pressure system is used to stabilize the knee in the sagittal plane to control flexion/extension: There is a single posteriorly directed force (applied by the anterior kneepad or by anterior thigh and calf straps, or both) and two anteriorly directed counterforces (applied by the posterior thigh band proximally and the shoe and posterior calf band distally) that keep the knee extended in stance. There are two additional force systems acting in the frontal plane: one to control valgus and one to control varus at the knee. Given the less-than-intimate fit of a conventional KAFO at the knee, the efficacy of the varus and valgus systems is likely to be less than optimal. The advantages of conventional KAFOs include their durability and adjustability; however, they tend to be heavier and less cosmetically pleasing than thermoplastic versions.

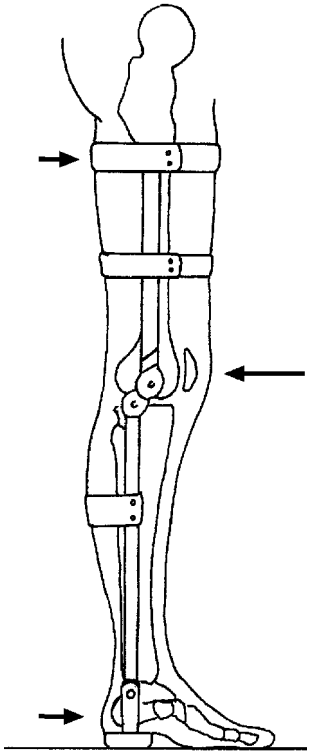

Fig. 9.17 Schematic diagram of the components and sagittal plane force system acting at the knee in a conventional knee-ankle-foot orthosis. The posteriorly directed force at the knee is counterbalanced by a pair of anteriorly directed forces at the posterior proximal thigh and posterior distal ankle.

In addition, if porous leather is used to cover thigh cuffs, the absorption of bodily fluids may render their KAFO malodorous over time. The advantages and disadvantages and the indications and contraindications of conventional KAFOs are summarized in Box 9.3.

Box 9.3 Advantages and Disadvantages of Conventional Knee-Ankle-Foot Orthoses

Advantages

- Strong
- Most durable
- Easily adjusted

Disadvantages

- Heavy
- Must be attached to shoe or shoe insert
- Less cosmetic
- Fewer contact points reduce control

Indications

- When maximum strength and durability are needed
- For individuals with significant obesity
- For individuals with uncontrolled or fluctuating edema (e.g., congestive heart failure, dialysis)

Contraindications

- When issues of energy expenditure make weight of the orthosis a factor
- When control of transverse plane motion is important

The Craig-Scott orthosis, also known as a *double-bar hip-stabilizing orthosis*, is a lightweight variation of a traditional KAFO designed for persons with paraplegia after spinal cord injury (SCI). The goal of this KAFO design is to maximize stability in stance with the minimal amount of bracing possible. A single thigh band and anterior strap are positioned just below the ischial tuberosity at the level of the greater trochanter; a single calf band and support are positioned just below the knee. Persons without active hip control are stable in standing with hip hyperextension, exaggerated lumbar lordosis, and a backward leaning trunk; stability is augmented by the orthosis' dorsiflexion-assist ankle joints and offset locking knee joints. With this combination of orthotic design and exaggerated posture, the GRF passes just anterior to the knee and posterior to the hip so that little or no muscular activity to provide internally generated counterforce is necessary. Although a reciprocal gait pattern with Lofstrand crutches typically requires the ability to volitionally activate hip flexions and quadratus lumborum (hip hikers) to initiate a step, persons with thoracic level SCI can use Craig-Scott orthoses and Lofstrand crutches using a two-point swing-through gait pattern.[87]

Conventional KAFOs are frequently used to preserve upright mobility for children with neuromuscular conditions (i.e., Duchenne muscular dystrophy).[89] A lightweight modular system that allows the orthotist to adjust the length of the uprights and quickly replace outgrown thigh or calf supports has been developed specifically for children with Duchenne muscular dystrophy.[90]

THERMOPLASTIC KNEE-ANKEL-FOOT ORTHOSES

A *molded thermoplastic* KAFO (also known as a hybrid thermoplastic and metal orthosis) is designed to have an intimate fit so that it can be worn under clothing and fits within the patient's shoe (Fig. 9.18). The distal component (a SAFO or an HAFO) and the proximal thigh component are vacuum formed over a rectified positive model of the patient's limb. The proximal component often encases the thigh from greater trochanter to femoral condyles and is closed with a pair of anterior Velcro straps. Orthotic knee joints and metal uprights (sidebars) connect the proximal and distal shells. The intimate total contact fit of molded thermoplastic allows significantly more effective control of the limb. The forces necessary for stabilization of the limb are distributed over a large surface area, reducing the possibility of discomfort or skin irritation. Such problems would arise only if the fit of the orthosis allows pistoning of the limb within the components while walking or if growth, weight gain, or edema makes the fit too snug, such that tissue is compressed and damaged while walking.

This design also controls the limb, using a series of overlapping three-point force systems. Flexion/extension control in the sagittal plane is the same one used in a conventional KAFO, except that the posterior counterforces are distributed over a wider surface area. The intimate fit provides more precise control in both the frontal and transverse planes; this is particularly important when dealing with segmental deviations arising from transverse plane rotation related to abnormal tone or longitudinal rotational deformity.[82]

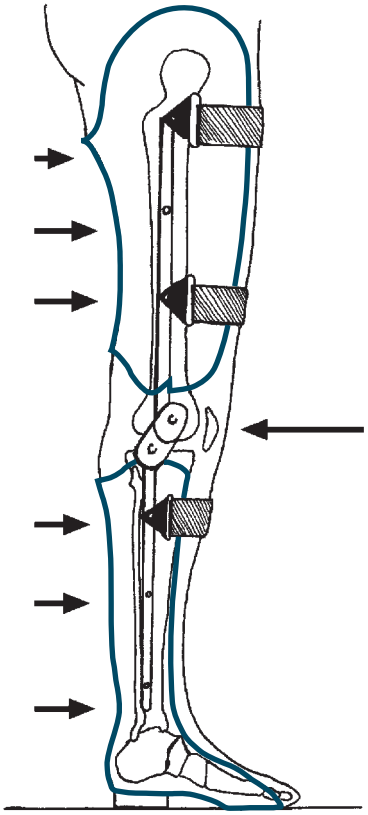

Fig. 9.18 Schematic diagram of the components and sagittal plane force systems that are necessary to control knee flexion/extension. Because the point of force application is distributed over the entire posterior surface of the intimately fitting orthotic shell, more precise and more comfortable control of the limb is possible.

Control of rotation is better accomplished with the total contact thermoplastic KAFO as compared with the double upright system of conventional KAFOs. However, this intimate fit is problematic for persons with medical conditions associated with fluctuating edema and changing limb volume (e.g., congestive heart failure, kidney dialysis), as well as those who cyclically gain and lose weight.

Similar to most thermoplastic AFOs, the use of different pairs of shoes (as long as heel height is constant) can also occur with thermoplastic KAFOs. However, one of the downsides of using thermoplastics is keeping cool while wearing them. As lightweight as they are, the large contact area inherent in thermoplastic KAFOs compromises dissipation of body heat; they may be uncomfortably warm. Advantages and disadvantages of thermoplastic KAFOs are summarized in Box 9.4.

CARBON COMPOSITE KNEE-ANKEL-FOOT ORTHOSES

Carbon composite materials have begun to be used in place of thermoplastics in KAFOs for persons with residual impairment for whom fatigue is a major concern (Fig. 9.19A and B).[91] On average, because carbon composite KAFOs

Box 9.4 Advantages and Disadvantages of Thermoplastic Knee-Ankle-Foot Orthoses

Advantages

- Lightweight
- Interchangeability of shoes
- Greater cosmesis worn under clothing

Disadvantages

- Can be hot to wear

Indications

- Intimate/total contact fit makes maximum limb control possible
- When energy expenditure makes weight of the orthosis an issue
- When control of transverse plane motion is needed

Contraindications

- Intimacy of fit is difficult when the individual is significantly obese
- Intimacy of fit is compromised when the individual has uncontrolled or fluctuating edema

(CC-KAFOs) are as much as 30% lighter in weight than other materials, the energy cost of walking with CC-KAFOs may be up to 10% less (as measured by maximum volume of oxygen [VO_2 max] and physiologic cost index).[92,93] Advantages of CC-KAFOs include improved cosmetics, increased walking speed, improved kinetic characteristics of walking, and exceptional durability.[92,93] It is important to note that the cost of CC-KAFOs may be nearly double that of a custom-molded thermoplastic KAFO.[92,93]

CONTROLLING THE ANKLE

The ankle joints used in KAFOs are the same as those that are available for AFOs: either nonarticulating solid (rigid) designs that hold the ankle in a fixed position (i.e., SAFO) or hinged orthotic joints that allow dorsiflexion (for forward progression of the tibia over the foot in stance), block plantarflexion, provide dorsiflexion assistance (to enhance swing phase clearance), or allow free dorsiflexion and plantarflexion within a specific range of motion.

The key question to consider in deciding which ankle control system is appropriate for a given individual is how orthotic control at the ankle and the GRF will impact knee function and forward progression during stance phase. If a locked ankle is necessary, the orthotist may opt to set the orthosis in several degrees of dorsiflexion to minimize compromise of forward progression and to allow the individual to achieve the stable hips-forward trunk-back stance position quickly (i.e., to achieve stability with the GRF passing anterior to the knee and posterior to the hip as soon as possible during stance). When ankle motion must be constrained to protect the joint, to control the impact of abnormal tone, or because of fixed deformity, the orthotist may use a rocker sole on the patient's shoe to simulate the normal rockers of gait. This strategy facilitates forward progression during stance by reducing the toe lever of the orthosis, improving the smoothness of the patient's gait, and reducing the likelihood of compensatory gait deviations.

An articulating or hinged orthotic ankle joint that allows some plantarflexion enhances the transition from initial contact to loading response (although the locked knee may compromise the shock absorption function of loading response). Similarly, a hinged orthotic ankle joint that

Fig. 9.19 (A and B) This carbon composite knee-ankle-foot orthosis has an anterior proximal shell with a posterior midshell and uses a stance control knee unit and a foot component similar to that of a hinged ankle-foot orthosis.

permits movement into dorsiflexion during stance enhances forward progression of the body over the foot during stance, especially when the orthotic knee is also locked.

CONTROLLING THE KNEE

Historically, if a patient with motor control or muscle performance impairment was unable to keep the knee stable in stance and an AFO was not able to provide the necessary stability, the only option was a KAFO with knee joints that remained locked at all times while walking.[94] This created a challenge for limb advancement in swing and often resulted in compensatory patterns such as circumduction or lateral leaning to the opposite side in an effort to clear the swinging leg. Although compensatory strategies accomplished the goal of limb clearance, they also markedly increased the energy cost of walking. Those who had functional motor control and muscle performance who required a KAFO to protect a mechanically unstable knee from extreme valgus or varus may be able to use unlocked single axis orthotic knee joints.

There are a number of options for orthotic knee joints that provide mechanical stability. The recent development of various SC-KAFO knee joints that allow free knee motion in swing but lock into extension during stance has had significant impact of KAFO prescription and use.[95,96] A brief overview of the mechanical joints is provided, and the impact of SC-KAFOs is considered in more detail. See Table 9.3 for a set of general guidelines for choosing the conventional orthotic knee joints based on the knee control they provide.

Single-Axis Knee Joints

The single-axis orthotic knee joint *(straight knee joint without drop lock or a free knee)* is essentially a simple hinge that allows full flexion and extension to neutral in the sagittal plane (most designs prevent hyperextension) while providing mediolateral stability (Fig. 9.20A). It is important that the medial and lateral orthotic joints be positioned at the approximate axis of the anatomic knee joint. Given the polycentric structure of the anatomic knee versus the single-axis structure of the orthotic knee joint, a small torque is likely, even if the single-axis orthotic joints are correctly positioned. For the majority of persons using the orthosis, this is not problematic. This knee joint is appropriate for those who have sufficient muscle performance resource to achieve knee stability in stance but need a KAFO to minimize or prevent recurvatum, protect a structural (mediolateral) unstable knee, or prevent excessive varus or valgus in stance.[96]

Single-Axis Locking Knee

When a locking mechanism is added to maintain knee extension, the KAFO with a single-axis knee joint becomes rigidly stable in all planes. A locked knee has traditionally been used for those whose motor control or muscle performance deficits make them unable to control the knee effectively during stance phase, such that they need additional external stability to prevent knee flexion as body weight is transferred onto the limb during stance.

The most commonly used locking mechanism is a simple ring or drop that captures the halves of the orthotic joint when fully extended, blocking subsequent movement into flexion or hyperextension (see Fig. 9.20B). A small ball bearing in the upright holds the drop lock in position until the individual or caregiver purposefully unlocks the orthosis. Optimally, there is a drop lock on both the medial and lateral uprights of the orthosis. Note that the knee must be fully extended for the lock to be engaged or disengaged; this can be challenging when transitioning between standing and sitting, especially for persons with limited hand function, significant lower extremity spasticity, or dependence on assistive devices when standing.

Table 9.3 Indications and Contraindications for Orthotic Knee Joint Designs

	ORTHOTIC KNEE DESIGN				
Desired Knee Control	**Single-Axis Unlocked**	**Single-Axis Locked**	**Offset Unlocked**	**Offset Locked**	**Variable Position Locked**
Stabilization of flail knee with use of knee extension moment and free knee joint motion	Contraindicated	Contraindicated	Indicated	Contraindicated	Contraindicated
Stabilization of flail knee without use of knee extension moment and free knee joint motion	Contraindicated	Indicated	Contraindicated	Indicated	Unnecessary
Control of genu recurvatum	Contraindicated	Indicated if orthosis will only be locked when ambulating	Indicated	Indicated when individual will lock knee intermittently	Contraindicated
Reduction of knee flexion contracture	Contraindicated	Lacks adjustability	Contraindicated	Lacks adjustability	Indicated
Control of genu valgum	Indicated	Indicated use of lock optional	Indicated	Indicated use of lock optional, unnecessary	
Control of genu varum	Indicated	Indicated use of lock optional	Indicated	Indicated use of lock optional, unnecessary	

Modified from *Short Course in Orthotics and Prosthetics—Course Manual.* Dallas, TX: University of Texas, Southwestern Medical Center; 1993: 8–22.

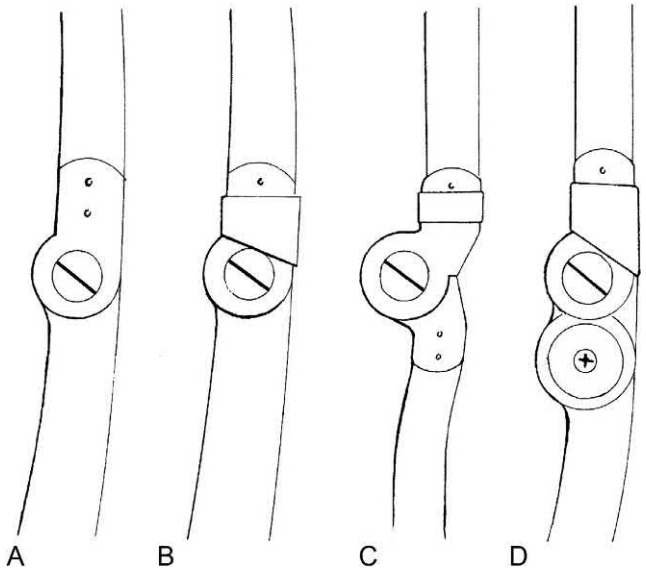

Fig. 9.20 Orthotic knee joints historically used in conventional and thermoplastic knee-ankle-foot orthoses. (A) A single-axis, or free, knee allows full flexion and extension while providing mediolateral and rotational stability to the knee joint. (B) A drop lock holds the knee in extension in standing, providing stability in all planes. It must be unlocked for knee flexion to occur when returning to sitting position. (C) Because the axis of the offset orthotic knee joint is positioned behind the anatomic knee axis, biomechanical stability of the orthosis is enhanced. It is available with and without a locking mechanism. (D) A variable-position, or adjustable, orthotic knee joint permits the orthotist to accommodate for changing range of motion or for fixed contracture at the knee.

An alternative lock that may be considered is a spring-loaded bail lock (also known as pawl or Swiss lock). The posterior bail connects the medial and lateral locks so that they can be locked or unlocked simultaneously. To unlock the KAFO when returning to sitting, the individual backs up against the edge of a seating surface (e.g., wheelchair, mat table, kitchen, or desk chair) and pushes the posterior bar into the seat to disengage the lock. This option is best used for persons with enough upper body strength and coordination to control the descent into sitting. There is a risk that the lock will disengage if the bail behind the knee is inadvertently bumped, and a fall will occur.

Offset Knee Joint

The offset knee joint (also known as a *posteriorly offset, free knee*) is aligned with its axis posterior to the axis of the anatomic knee (see Fig. 9.20C). In early stance, during double support, the ground reaction passes nearer to the axis of the orthotic joint, reducing the magnitude of the external flexion moment that is acting to flex the limb. With forward progression toward midstance, the GRF moves anterior to the orthotic joint, creating an extensor force that mechanically augments stance phase stability during single limb support. However, to be effective, the alignment between ankle and knee must be finely tuned. Transitions between sitting and standing become less problematic if the knee does not have to be unlocked. However, a drop lock or other locking mechanism can be added to stabilize the knee when the individual using the orthosis will be standing for long periods of time or when additional stability is advisable (e.g., when the patient is walking on uneven ground). An offset knee joint is often most suitable for those with lower motor neuron disease (e.g., poliomyelitis or low thoracic upper lumbar SCI).[96]

Variable Position Orthotic Knee Joint

The variable position locking orthotic knee joint *(dial lock, adjustable locking knee joint, serrated knee lock)* (see Fig. 9.20D) is used for those who are unable to fully extend the knee during stance because of knee flexion contracture. When there is a knee flexion contracture of more than 10 degrees, the GRF remains posterior to the anatomic knee joint during all of stance phase, and it becomes significantly more difficult for those with weakness or motor control impairment to generate the necessary muscle force for stance stability. For these individuals, the variable position knee joint is locked in the most extended position possible, providing an external mechanical stability.[15]

Stance-Control Orthotic Knee Joints

The initial SC options for KAFO orthotic knee joints were intended for individuals with a history of poliomyelitis who were coping with ineffective quadriceps activity, as well as postpolio syndrome.[97-99] Use of SC-KAFO has been extended to persons with stroke, brain tumor, acquired brain injury, incomplete SCI, spinal degenerative diseases, muscular dystrophy, multiple sclerosis, myopathy, radicular and peripheral nerve injury, and polyneuropathy. A variety of mechanisms (i.e., mechanical, hydraulic, or computer microchip electronic joints) are available (Fig. 9.21).[100-102]

Fig. 9.21 The Becker UTX is a mechanical stance-control knee-ankle-foot orthosis: The knee unit contains a cable-driven ratchet that locks the knee as it extends in terminal swing in preparation for stance phase and unlocks it at terminal stance to allow knee flexion necessary for limb clearance during swing phase. Note the lightweight lateral upright medial cable, anterior padded cuffs, and velcro-closing posterior straps.

All are designed to lock the orthotic knee joint in extension at initial contract and during most of stance, while unlocking the knee on heel rise during the toe rocker in the transition from terminal stance to preswing.[103] Hydraulic and electronic SC orthotic joints add resistance to knee flexion when the limb is loaded in less than a fully extended position, which potentially improves function when the wearer is ascending stairs or walking on uneven surfaces. Most SC orthotic knee joints are placed on the lateral upright of the KAFO. Pneumatic orthotic knee joints to assist with knee extension during swing are also available, added onto the medial or lateral uprights of the KAFO. Many of the SC knee units can be incorporated into KAFOs based on metal uprights, thermoplastic thigh and AFO components, or laminated designs. Characteristics of some of the commercially available SC and swing assist knee units are summarized in Table 9.4.

Most prescription guidelines for SC-KAFO indicate that the individual must demonstrate muscle strength of at least 3 of 5 on manual muscle testing at hip extensors and flexors and full extension of the anatomic knee joint. Contraindications for SC-KAFO use include fixed hip or knee flexion contracture, fixed plantarflexion contracture, significant spasticity, leg length discrepancy greater than 3 inches

Table 9.4 Stance-Control Knee-Ankle-Foot Orthosis Characteristics

Name	Manufacturer	Control System	Orthotic Components	Other Characteristics
Stance-control orthosis	Horton, Little Rock, AR.	Mechanical	Pushrod and cam system Thermoplastic stirrup at ankle causes pushrod to engage cam into friction ring to lock knee at initial contact, unloading in late stance repositions Pushrod to disengage cam from friction ring, allowing free knee flexion during swing	Dual uprights Three settings: locked, automatic, unlocked Lightweight but bulky May require larger shoe size to accommodate nested thermoplastic stirrup and AFO Most effective at constant walking speed and consistent stride length (not cadence responsive)
Free Walk	Otto Bock Healthcare, Duderstadt, Germany	Mechanical	Cable-driven pawl lock system Spring-loaded pawl locks the knee when in full extension during stance Unit unlocks with dorsiflexion of ankle in late stance to allow free knee flexion during swing	Single lateral upright with medial cable Very light weight Requires full knee extension to engage the lock, although uprights can be contoured to accommodate up to 10 degrees of knee flexion contracture Requires at least 5 degrees of mobility at ankle Requires at least 3/5 hip flexion and extension strength for safe and effective use Not appropriate for those with varus >10 degrees
UTX	Becker Orthopedic	Mechanical		
Swing Phase Lock 2	Fillauer Chattanooga, Tenn.	Mechanical	Gravity-activated pendulum system with weighted pawl lock Weighted pawl causes knee to lock when hip flexion in late swing Moves thigh anterior to body in preparation for initial contact in late stance, when thigh is posterior to body, weight pawl moves to unlocking position	Dual-upright, with SC gravity system in lateral upright Swing control spring to control/assist knee extension during swing phase can be incorporated into medial knee unit No cables or pushrods Not effective on stairs, inclines, uneven ground Four settings controlled by a remote push button switch: manual lock, manual unlock, automatic, or free swing
E-Knee	Becker	Microchip	Electromechanical system with pressure-sensitive footplate that feeds information to microprocessor to engage/disengage locking mechanism	Dual-uprights Can be used with thermoplastic and laminated materials Lithium battery must be charged daily Provides locking in increments of 8 degrees at any angle of knee flexion at initial contract No minimum strength or ROM requirements
Load Response	Becker	Mechanical	Spiral torsional spring designed to mimic shock absorption during loading response	Locking mechanism responsive for 0 to 18 degrees of knee flexion at initial contract Not effective for persons with fixed knee flexion contracture or valgus 15 degrees
GX-Knee	Becker	Mechanical and pneumatic	Pneumatic spring on lateral joint provides assistance with knee extension during swing phase	Does not provide mechanical stability in stance phase Requires 4/5 hip flexion and extension strength for safe use

Table 9.4 Stance-Control Knee-Ankle-Foot Orthosis Characteristics (Continued)

Name	Manufacturer	Control System	Orthotic Components	Other Characteristics
Full Stride	Becker	Mechanical	Cable-driven system	Requires full-knee extension to engage lock, although uprights can be contoured to accommodate knee flexion contracture Requires 5 degrees of ankle motion to achieve necessary cable excursion to operate locking mechanism
Safety Stride	Becker Orthopedic	Mechanical	Cable-driven system	Resists knee flexion in stance regardless of knee angle No minimum strength or ROM requirements GX swing assist system can be incorporated
Sensor Walk	Otto Bock Healthcare	Electromechanical	Unidirectional wrap-spring clutch-actuated by pressure sensors in heel and forefoot and motion sensor at knee	Heavy-duty custom KAFO accommodates up to 15 degrees of knee flexion contracture Powered by lithium-ion battery Locks knee joint when footplate indicates a stumble

(8 cm), valgus or varus deformity greater than 10 degrees, and excessive body weight (>220 lbs). Persons with cognitive impairment may not be able to comprehend how to safely use or maintain a SC-KAFO; SC options must be used with caution when cognitive ability and judgment are impaired.

The positive impact of SC knee joints on kinematics of walking is well documented. In addition to improving self-selected walking speed, cadence, and stride length, use of these orthotic knee joint improves symmetry of gait, reduces compensatory movement, and allows safer management of inclines and obstacles when compared with KAFOs with locked knees.[97-100] Persons who have used traditional KAFOs with locked knees for long periods before adopting SC designs benefit from additional functional training to be able to take full advantage of the mobility that a SC-KAFO provides.[104] The few studies that have examined wearers' experience with SC-KAFOs indicate better acceptance and general satisfaction with the devices in terms of effectiveness in improving mobility, dependability, and performance of the device and enhancing the wearer's sense of well-being.[105,106] The major concerns raised by wearers include ease of donning and doffing, weight of the orthosis, and cosmesis.[105,106]

MEDIALLY LINKED BILATERAL KNEE-ANKLE-FOOT ORTHOSIS DESIGNS

For persons with mid to low thoracic and lumbar SCI, several options have been developed to link a pair of conventional KAFOs in an effort to allow reciprocal gait without having to brace about the hip in a conventional HKAFO (Fig. 9.22). The Walkabout Orthosis and the Moorling Medial Linkage Orthosis, both of which use a single-axis hinge between the two medial uprights of the KAFOs, are most effective for individuals with some residual volitional hip flexion who have sufficient thoracolumbar spinal mobility, especially into lateral flexion.[107-109] In both of these systems, the linkage system limits abnormal abduction of the limbs during gait. Preparation for swing limb advancement begins with an exaggerated lateral lean for weight

Fig. 9.22 Themoplastic hip-knee-ankle-foot orthoses (HKAFOs), typically lighter in weight than conventional HKAFOs, also have a pelvic band and orthotic hip and knee joints. Because they distribute forces over a wider thigh and calf band, an anterior knee stabilization pad may not be necessary. Many incorporate a solid or articulating ankle-foot orthosis design, fitting inside the shoe rather than in an external stirrup.

shift onto the stance limb; the wearer then initiates swing using residual hip hiking or hip flexion ability. When compared with reciprocal gait HKAFO (see later), medially linked KAFOs provided better ability (less assistance required) to accomplish sit-to-stand transitions, but walking speed tended to be slower, management of inclines more problematic, and performance on measures of balance somewhat less effective.[110,111] In addition, persons with SCI who wore both devices over a 3-month period reported that both were useful for standing and there was no functional advantage of medially linked KAFOs over reciprocal gait HKAFOs in terms of mobility.[112] Hybrid systems, consisting of medially linked KAFOs and FES, have also been used as an approach to improve the ability to walk for persons with SCI.[113]

KAFO Delivery and Functional Training

Once fabrication is completed, the orthotist inspects the KAFO to ensure that selected components work as intended, that finish work of plastic edges and metal components are effective, that the placement and contours are appropriate to the individual's limbs, and that orientation of the axis of the orthotic ankle and knee match anatomic joint axis. This initial fitting process not only identifies the fit of the orthosis in its intended functional upright and weight-bearing positions but also closely examines potential for soft tissue irritation in vulnerable areas of the person's skin. Length of the uprights and position and alignment of components are carefully inspected. The goal is a comfortable standing position with no discomfort or skin irritation. If minor problems are identified, the orthotist often makes simple adjustments of fit and alignment before functional training. The team then evaluates the ability of the orthosis to meet the functional goals of the orthotic prescription.

If the team determines that fit is acceptable and that orthotic goals (a combination of joint protection, structural stability, especially in stance, and functional mobility) have been met, functional training then begins. In most cases, especially if a patient is new to the use of an orthosis, a wearing schedule is developed, tailored to the patient's specific needs and physical condition, in which the patient gradually increases to full-time wear.

Whether the orthosis is of conventional KAFO design or is an SC-KAFO, physical therapy programs should include:

- exercises to strengthen muscle groups and improve control of hip, knee, and core (trunk) musculature to maximize ability to use the device;
- practice donning/doffing the device;
- rising to standing and returning to sitting;
- activities to facilitate anticipatory and reactionary postural control and balance;
- gait training under various task-environment conditions
- practice on stairs, uneven surfaces, and inclines;
- functional training in variety of environments

Training should also focus on developing a clear understanding of the fit of the orthosis on the limb, proper adjustment of stabilizing straps, education about appropriate footwear, and management of the locking mechanisms and function of the knee unit. Wearers and their caregivers must understand the care and maintenance of the orthosis, which is a mechanical device with moving parts that requires regular cleaning and occasional lubrication of its mechanical parts.

When Is a Hip-Knee-Ankle-Foot Orthosis Indicated?

There is much less evidence available in the clinical research literature to guide prescription and selection of HKAFOs than for selecting AFOs and KAFOs. Because HKAFOs encompass the hip, pelvis, and sometimes the trunk, they tend to be much more cumbersome to use, more challenging to don and doff, more expensive to fabricate, and require more maintenance than AFOs and KAFOs. HKAFOs only partially restore functional mobility, often with high energy cost. The additional control of joint motion achieved by moving proximally with a hip joint and pelvic band or an attached lumbosacral orthosis must be balanced against the practical challenges that the wearer will face when using the device.

Persons who use HKAFOs for standing and for the limited mobility that they provide typically have much more neuromotor system impairment that those who use AFOs and KAFOs. These orthoses are most often prescribed for children with neurologic involvement and individuals with SCI but may also be appropriate for those with progressive neuromuscular disorders—in effect, for any person for whom the ability to stand may not only enhance function for some functional tasks but also contribute to bone health, skin integrity, efficacy of digestion, urinary and bowel health, respiratory capacity, cardiovascular fitness and exercise response, and the psychological benefit that comes from being upright when interacting with peers.[114] Children, with their lower center of mass, may not be quite as concerned about the consequences of a fall, but for adults, upright standing in HKAFOs may be made more challenging by concerns about the potential to fall and related consequences.[115]

Hip-Knee-Ankle-Foot Orthosis Design Options

As in the case of AFOs and KAFOs, HKAFOs can be fabricated with many different materials (e.g., metals, thermoplastics, carbon composites) and with orthotic ankle, knee, and hip components. Historically, during the years immediately following the polio epidemic until the mid to late 1980s, orthotists fabricated HKAFOs by adding a hip joint and pelvic band to conventional KAFOs. To better meet the developmental and educational needs of children with neurologic conditions, conventional HKAFO designs evolved into standing frames, parapodiums, and swivel walkers. Building on this, a number of HKAFOs specifically designed

to mechanically facilitate reciprocal gait were developed to meet the needs of persons with SCI.

CONVENTIONAL HIP-KNEE-ANKLE-FOOT ORTHOSES

Fig. 9.22 illustrates the configuration of conventional HKAFOs. These devices are designed to hold both lower extremities in a stable extended position for upright standing; persons wearing this orthosis use either a hop-to gait with walkers or a swing-through gait with a pair of crutches for ambulation. Typically, HKAFOs require an assistive device to use upper extremity and trunk compensatory mechanisms to advance the orthosis. On rare occasions, a single HKAFO might be used for persons with neuromuscular or musculoskeletal impairment affecting one lower extremity. Even after the incorporation of lightweight thermoplastic or carbon composite materials, the energy cost of ambulation with conventional HKAFOs is significant and often functionally prohibitive.

The most distal component of the HKAFO is usually a solid or dorsiflexion assist articulating AFO. These are typically set in a few degrees of dorsiflexion to direct the tibia forward enough that the individual's weight line falls anterior to the knee and posterior to the hip when in a tripod standing position with crutches or a walker. Traditionally, the orthotic knee joint is locked into extension, although for persons with incomplete SCI capable of reciprocal gait, a SC knee joint might be considered. Thermoplastic thigh cuffs are effective in resisting torsional forces that would otherwise act on the limb in standing. A variety of commercially available orthotic hip joints include various single axis designs that can be used in locked position, allow free motion when unlocked, or allow motion only within a limited range. The axis of motion (center) of the orthotic hip joint must be positioned just proximal and anterior to the greater trochanter to best match the anatomic axis of motion of the hip. Because orthotic hip joints are fixed to the pelvic band and to lateral uprights of the thigh section, they effectively restrict abduction/adduction and rotation of the limb as well. Single-axis hip joints meet the needs of most individuals who require HKAFOs to stand and to ambulate. There are also several types of dual-axis hip joints with separate mechanical control systems for flexion/extension and for abduction/adduction. The proximal pelvic band is positioned between the trochanter and iliac crest. The pelvic band provides solid support from a position slightly medial to the anterior superior iliac spines (ASIS) and around the posterior pelvis. The pelvic band can be fabricated from metal, laminated components, or thick thermoplastic and is typically closed anteriorly by a belt or webbing with a Velcro fastener.

For stability in standing, the individual typically stands in a tripod position, with crutch tips diagonally 12 to 18 inches forward and a slightly exaggerated lumbar lordosis. This position ensures that the individual's center of gravity (weight line) falls posterior to the hip joint, creating an extension moment at the hip, achieving stability by alignment. To achieve forward motion, the individual uses the "head-hips" principle with shoulder joints acting as a fulcrum (Fig. 9.23A to F). A quick forceful "pike" (chin tuck and forward inclination of the trunk) while pushing downward through the handles of the assistive device elevates the lower extremities from the ground. This is immediately followed by head, neck, and back extension to "throw" the lower extremities forward for the next initial contact. As soon as the feet contact the ground, the individual quickly advances the crutches to once again reach the stable "tripod" position.

To effectively use HKAFOs, hip and knee joints of the lower extremity must be flexible enough to be positioned in extension. Although exaggerated lumbar lordosis may compensate for mild hip flexion contracture in achieving upright position, over time and with repeated forceful loading of swing through gait, this lordosis will likely contribute to development of disabling low back pain. Prevention of flexion contracture or deformity of the hips and knees is a key component of physical therapy intervention, especially for growing children with neurologic conditions.

HIP GUIDANCE ORTHOSIS AND PARAWALKER

The hip guidance orthosis (HGO) and the Orthotic Research and Locomotor Assessment Unit (ORLAU) Parawalker allow individuals with impaired muscle performance (those unable to accomplish the lifting of body weight needed for swing through gait pattern with crutches) to "walk" with crutches with a lateral weight shift. The HGO and Parawalker require the use of an ambulatory assistive device; training usually begins in the parallel bars and progresses to over ground level surfaces using a rolling walker or bilateral Lofstrand crutches. The HGO orthotic hip joint is stable when weight is borne through the lower extremity during stance but allows a pendular swing of the unweighted extremity for swing clearance. This occurs because of the rigid support that the HGO provides during single limb stance, keeping the limbs parallel in the coronal plane, which enhances swing limb clearance as the opposite limb advances.[116] In the original evaluation of the HGO prescribed for children with myelomeningocele, the ability to sit unsupported (hands free) for extended periods was the best predictor of successful use of the HGO.[117] The Parawalker, similar in design, provides more proximal support to the thorax and trunk (making it even more rigid) and uses a smaller orthotic hip joint. Because of its higher proximal trim line, the Parawalker can be used for standing and limited mobility (i.e., therapeutic walking) for persons with SCI at upper thoracic levels.[118-120]

RECIPROCAL GAIT ORTHOSES

The reciprocal gait orthosis (RGO), originally designed for children with myelomeningocele and currently used for adults with SCI, extends a pair of thermoplastic KAFOs upward to include a pelvis and thoracic bands; providing rigid stability for stance, it uses a cable-coupling system to provide hip joint motion for swing phase (Fig. 9.24).[121,122] Its dual cable system operates by reinforcing extension of the stance limb as the swing limb flexes forward when unloaded by lateral weight shift. This reciprocal dual cable also reduces risk of "jack-knifing" during ambulation by preventing both hips from flexing at the same time. Like the HGO and Parawalker, the RGO requires the person

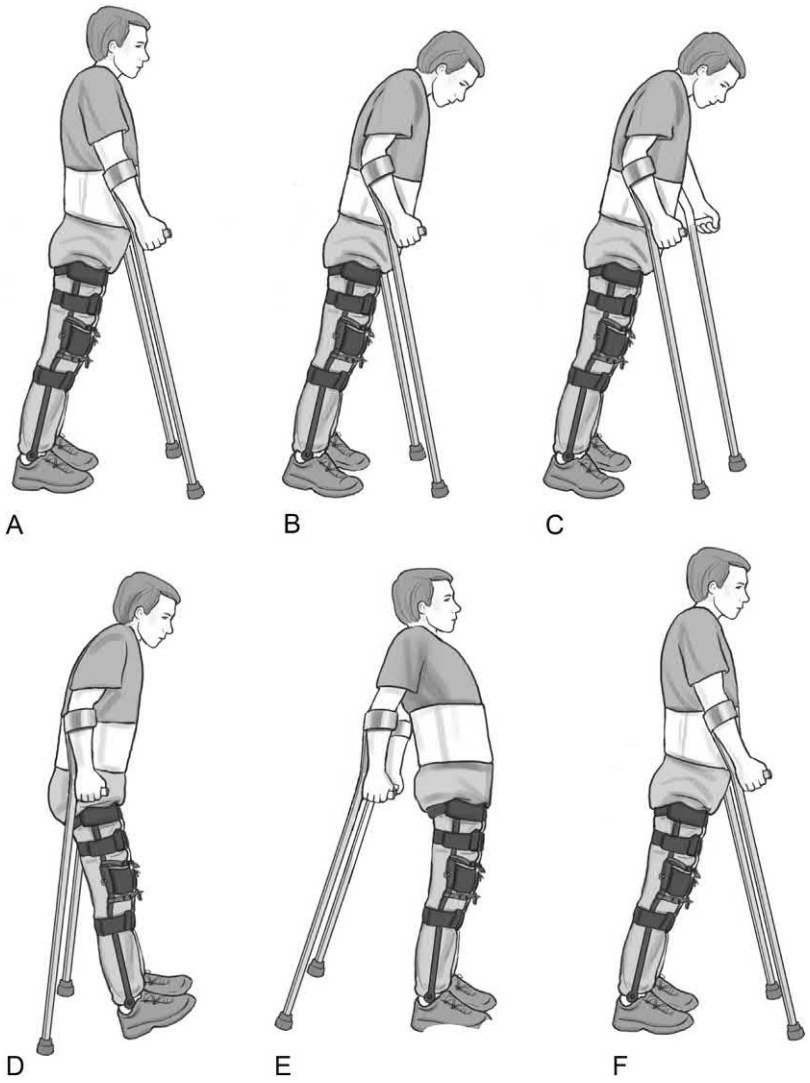

Fig. 9.23 Illustration of the head-hips principle in swing through gait using bilateral knee-ankle-foot orthoses and Lofstrand crutches, with shoulder joints acting as the fulcrum for movement. (A) Resting position is a stable hips forward, shoulders back posture, with a tripod formed by the individual's feet and the tips of the crutches. (B) Mobility is initiated with a quick and forceful chin tuck that (C) is combined with downward pressure through the crutches to unweight the feet. (D) A backward head movement then propels the lower body forward until (E) the hips are forward and shoulders are back to once again assume a stable inverted tripod position. Finally (F) the individual quickly propels off of the crutches to move them anteriorly to the stable starting position. (From Mulcahey MJ. Managemenr of the upper limb in individuals with tetraplegia. In Sisto SA, Sliwinski MM [eds]. *Spinal Cord Injuries: Management and Rehabilitation*. St. Louis: Mosby; 2009: 388.)

to use an assistive device (rolling walker, bilateral Lofstrand crutches, bilateral canes), relying on upper extremity motor control and muscle performance to a large degree to operate the system. The advanced RGO (ARGO) is an adaptation of the design, using a single cable, and engineered to allow standing with unilateral or no upper extremity support.[123,124] A prototype for an adjustable AGRO has been described; this would provide opportunity for a trial of ambulation with ARGO during rehabilitation to assist decision-making about capacity to use the device before a custom ARGO is fabricated.[125] There is some evidence that persons with neuromuscular conditions who consistently use an RGO or ARGO for therapeutic walking are less likely to develop significant secondary complications (i.e., contractures, decubitus ulcers, and/or scoliosis) than those with similar conditions who do not.[126]

HYBRID ORTHOSES: FUNCTIONAL ELECTRICAL STIMULATION

The most recent investigations of reciprocal orthoses for persons with upper motor neuron SCI have added FES to HGO/Parawalker and RGO/ARGO designs.[127,128] SC orthotic knee joints (described in the section on KAFOs) have also been incorporated in hybrid RGO-FES systems to afford a more natural pattern of swing limb advancement.[129] The major benefit of hybrid RGO-FES systems appears to be in greater distance covered, lower energy cost (as measured by physiologic cost index), and somewhat faster walking speed.[125,127,128] It is important to note that, although such hybrid systems are promising, they do not fully restore the ability to walk at preinjury levels. Walking speeds with hybrid devices have been reported to be

Fig. 9.24 The reciprocal gait orthosis uses a dual cable system to couple flexion of one hip with extension of the other. This coupling assists forward progression of the swing limb while ensuring stability of the stance limb.

between 0.20 and 0.45 m/s, whereas limited community walking becomes possible when walking speed is greater than 0.6 m/s, and usual waking speed for healthy adults ranges from 1.0 to 1.3 m/s, depending on height.[128-130]

Implications for Rehabilitation

The costs and benefits need to be carefully weighed when considering whether an orthosis that would facilitate therapeutic reciprocal walking would be appropriate for an individual with paralysis. The individual and/or the caregivers must clearly understand that these devices cannot fully restore the ability to walk at what would be considered community level. They must explore and embrace the goals of therapeutic walking: enhancement of bone health, cardiovascular conditioning, and digestive and urinary health, among others. For many individuals, gaining the motor skills necessary for safe use of the device may require substantial time and effort; training times reported in the literature range from 45 to 80 hours over a period of weeks to months. They must be ready to adhere to stretching protocols to ensure sufficient range of motion at the hip, knee, and ankle so that the device will both fit and operate optimally. They must be prepared to work to improve muscle performance and postural control of trunk and upper extremities so that they can use the orthosis most effectively. They must be willing to maintain a stable weight so that the orthosis will fit over many months or years. They must have the postural control necessary to (eventually) don and doff the orthosis without substantial assistance. They must understand the design of the orthosis and the function of its components enough to recognize when maintenance, adjustment, or repair is necessary. This is quite a bit to commit to; it is often wise to have the person interested in pursuing use of such an orthosis interact with someone else who has successfully used one to get a clear sense of what is required and what the potential outcomes are.

Outcome Measures in Orthotic Rehabilitation

How do the health care team, the individual using an orthosis and their caregivers, and the payers of the health care system determine successful use of a lower extremity orthosis, whether it be as simple as a UCBL insert for a child with mild diplegic cerebral palsy, an adult using an articulating AFO, a person with postpolio syndrome using a SC-KAFO, or a person with SCI using an ARGO? Initial criteria to consider might include:

- Can the person don and doff the orthosis independently?
- Does the person understand how the orthosis should fit on the limb, and can the person recognize signs that fit may not be appropriate (especially for growing children and for adults with peripheral or central sensory impairment)?
- Can the person transition from sitting to standing and back to sitting safely, independently, and with reasonable effort?
- Does the person have sufficient postural control to use the device not only on level nonresistant surfaces (e.g., tile or wood floors) but also on other surfaces (e.g., carpet, grass, inclines, stairs), which are likely to be encountered in the course of daily life?
- Children often play on the floor, and adults are often concerned with risk of falls. Can the person transition from the floor to standing safely, independently, and with reasonable effort? If not, can the person direct those who would offer assistance?
- Does the person know how to manage his or her body and assistive devices in case of a fall?
- Does the person understand the care and maintenance requirements of the device?

These questions, while ensuring that the individual is able to use the orthosis safely, do not sufficiently address the efficacy of the orthosis in enhancing the individual's ability to walk. Although observational gait analysis might allow the orthotist and physical therapist to evaluate changes an orthosis effects at each subphase of the gait cycle, this description of the quality of walking is not enough evidence to justify orthotic intervention. A variety of outcome measures must be used to address efficacy of an orthosis and the physical therapy intervention that facilitates its use.

WALKING SPEED

Probably the most robust indicator of the ability to walk is walking (gait) speed. Although technology such as motion analysis and the GAITRite system provide precise data about gait velocity, walking speed can be quickly and easily captured using a stopwatch over a known distance.[130,131] There is clear evidence for validity, reliability, and responsiveness of walking speed (measured over a 10-m distance), as well as information about typical walking performance values, correlations with fall risk and criteria for limited versus full community ambulation ability for most of the medical diagnoses in which a lower extremity orthosis may be prescribed (stroke, SCI, cerebral palsy, traumatic brain injury, among others).[130,132-140] Documenting comfortable and maximum walking speed at intervals without and with the orthosis at time of delivery and change in walking speed over the course of physical therapy intervention, along with discussion of the change in walking speed with respect to age-base and disease-reference norms, provide powerful information about efficacy of intervention.

ENDURANCE DURING WALKING

The ability to sustain walking over a period of time is also a key outcome of orthotic and physical therapy intervention. The most frequently used measure of endurance while walking is the 6-minute walk test (6 MWT), in which the distance that an individual walks during a 6-minute period is measured. Also valid is a 2-minute walking test. Clinometric properties of the 6 MWT have been evaluated for persons with stroke, SCI, cerebral palsy, traumatic brain injury, myelomeningocele, and chronic poliomyelitis.[141-146]

A self-report indicator of effort of physical activity that has also been used extensively in the clinical research literature is Rating of Perceived Exertion (RPE). In his original work, Borg presented a scale ranging from 6 (no effort) to 20 (maximum effort)[147]; a modified version, which uses a 1 to 10 scale (for adults) or color-coded schematic pictures of the face (for children and those with cognitive dysfunction) may be more interpretable for patients.[148,149] The question that use of RPE scale addresses is, "Does the orthosis reduce the perceived work (effort) of walking?" RPE scales have been used to assess efficacy of therapeutic intervention for persons with stroke, brain injury, SCI, and cerebral palsy.[128,150,151]

MOBILITY AND BALANCE WHILE WALKING

The ability to change direction and transition between surfaces (i.e., sit to stand) is also a key aspect of successful use of a lower extremity orthosis. During the TUG test, an individual must rise from a seated position, walk forward over a 3-m distance, turn around, walk back to the chair, and return to sitting, either at a usual pace or as quickly and safely as able.[152] Because most lower extremity orthoses constrain joint movement, and many of those who use them have neuromuscular impairments that place them at risk for falling, the TUG may provide a snapshot of dynamic postural control during walking with an orthosis. The TUG has been successfully used to assess functional status and predict outcomes in persons with neurologic and orthopedic conditions.[143,153-159] Self-reported measures, such as the Falls Efficacy Scale and Activities-Specific Balance Confidence (ABC) Scale, can supplement performance-based outcomes to measure the change in a patient's fear of falling pre- and post-bracing.[160-163]

Summary

This chapter explores the biomechanical design and component options of lower extremity orthoses used to facilitate the ability to walk for persons with a variety of neuromuscular impairments and at various ages and developmental stages of the life span. We have discovered that no orthosis can make walking "normal," although an appropriate orthosis can make walking more functional and less energy costly. We currently can evaluate how an orthosis will impact each of the rockers of stance phase, as well as the ability to clear the limb during swing phase. We currently have ideas about how footwear, such as an athletic shoe that provides a cushion heel and a rocker bottom, may compensate if an orthosis limits forward progression over the foot during stance. We have discovered that the selection of an appropriate orthosis involves input from many members of the rehabilitation team, not the least being the person who will wear the orthosis and his or her caregivers. We certainly have gained an appreciation that there is no "one size fits all" when it comes to choosing an orthosis but that orthotic prescription requires thoughtful deliberation about both the functional benefits and tradeoffs, as well as the financial cost of the device. We have learned that using an orthosis effectively requires much more than simply putting it on; there must be adequate time filled with appropriately challenging activities so that motor practice can build skill, postural control, and endurance necessary for functional walking. Finally, we have begun to consider strategies to assess outcomes of orthotic and physical therapy interventions for persons who require an AFO, KAFO, or HKAFO to accomplish their mobility goals.

Acknowledgments

The authors recognize professional colleagues Robert S. Lin, CPO (Director of Pediatric Clinical Services and Academic Programs, Hanger Orthopedic Group at the Connecticut Children's Medical Center, Hartford, CT.), Thomas V. DiBello, BS, CO (President, Dynamic Orthotics and Prosthetics, Inc., Houston, TX), and James H. Campbell, PhD, CO (Director of Research and Development, Engineering and Technical Services, Becker Orthopedic, Troy MI), whose excellent chapters on ankle-foot orthoses, knee-ankle-foot orthoses, and hip-knee-ankle-foot orthoses in the previous editions of this text provided a solid foundation for the this integrative chapter.

Case Examples

Recommendations are intended as ideas and guides for the clinician, not an all-inclusive or complete answer.

Case Example 9.1

P.M. is a 7-year-old child with a primary diagnosis of spastic diplegic cerebral palsy. He is anxious to keep up with his nonimpaired peers at school, but his moderate "crouch gait" (despite using Lofstrand crutches as assistive devices) limits his mobility and endurance. He is referred by his neurologist for evaluation in the interdisciplinary "brace clinic" at the local children's medical center.

On physical examination, P.M. is found to have moderate tightness and soft tissue shortening of his plantarflexors, distal hamstrings, adductors, and hip flexors. Although he exhibits moderate extensor-pattern spasticity in both lower extremities, sagittal and coronal plane motions of his hip, knee, and ankle are within 10 degrees of normal. Structurally, he exhibits 25 degrees of femoral anteversion and 15 degrees of internal tibial torsion. However, upon barefoot weight bearing, his foot progression angles appear to be normal, at approximately 10 degrees external (outward) angle.

QUESTIONS TO CONSIDER

- What are the most likely gait problems in each subphase of gait that might be effectively addressed by an AFO?
- What musculoskeletal (alignment and flexibility) and neuromuscular (control) impairments or characteristics, as well as developmental issues, will have to be considered by the team as they sort through orthotic options for this child?
- Which of the orthotic options (static vs. dynamic) might you choose for this child? What are the possible benefits and tradeoffs of each?
- How might you assess if the orthosis chosen is accomplishing the desired outcomes?

RECOMMENDATIONS OF THE TEAM

Given the finding of dynamic pes planus and valgus deformity and the boy's propensity to crouch during stance, the team recommends bilateral polypropylene SAFO be custom molded for P.M. When P.M. receives his AFOs, he attends several sessions of outpatient gait training. His gait pattern demonstrates improved plantarflexion–knee extension couples, with virtually all of the preorthosis knee persistent knee flexion eliminated. Subtalar joint alignment is also improved, with an effective support of the medial longitudinal arch.

FOLLOW-UP CARE

Three weeks later, the patient's mother schedules a follow-up visit because she observes, "The AFO is causing P.M.'s feet to turn in." On this return visit, observational gait assessment reveals an apparent 30-degree internal (inward) foot progression bilaterally. This is causing difficulty with clearance of the advancing limb during swing phase. Examination of the fit and alignment of the AFOs reveal appropriate design and fit, with effective subtalar neutral position.

The team recommends computerized gait analysis to be performed to determine the underlying factors leading to this significant change in foot progression angle despite appropriately fit and designed SAFO. The team suspects that this altered foot progression angle is most likely the result of underlying musculoskeletal deformities (tibial torsion and femoral anteversion) unmasked when compensatory motion of the subtalar and midtarsal joints during stance is restricted by the AFOs. In effect, when foot alignment is well supported by the AFO, the effect of excessive tibial torsion and femoral anteversion during gait become more evident.

It is not possible for an AFO to effectively address or control gait problems arising from existing underlying transverse plane (rotational) deformity. The team and family begin to consider the possibility of femoral/tibial derotation osteotomy as a solution to the gait problems that have emerged.

Case Example 9.2

A 40-year-old man presented to the emergency department with severe shooting back pain radiating down both legs (right greater than left) weakness of the feet, saddle anesthesia, and urinary incontinence for 2 to 3 weeks with worsening over the past 4 days. Magnetic resonance imaging revealed multilevel degenerative disease with severe central canal stenosis at L2-L3 and L3-L4, thoracic spine spondylosis with severe stenosis, and spinal cord compression C3-C7. He underwent C3-C7 and L2-L5 laminectomies. Persistent weakness and foot drop bilaterally postoperatively.

Past Medical History: remote history of motor vehicle accident with severe right knee trauma.

Social history: Patient lives with fiancé in second-floor apartment with one flight of outdoor stairs with a single railing to enter plus one flight of stairs without a railing to the third-floor bedroom and bathroom. Prior to injury, patient was independent with activities of daily living, instrumental activities of daily living, and mobility.

Patient goals: To walk. To return to his apartment. To resume his studies to complete his undergraduate degree including mobility on campus.

He is now admitted to the acute rehabilitation spinal cord injury unit for functional retraining. Present examination findings include:

Sensation: Intact light touch, localization throughout bilateral lower extremities

Proprioception: Impaired right great toe and ankle. Intact left great toe and ankle.

Integumentary: Intact

Range of motion: Right ankle dorsiflexion (DF) to neutral. Left ankle DF -6 degrees.

Strength MMT: Hip grossly 2-3/5. Knee extension 4/5. Knee flexion 2/5. Ankle 0/5 in all planes except left plantarflexion 1/5.

Gait: 40 feet with bilateral Lofstrand crutches with excessive knee flexion during weight acceptance, hyperextension thrust at early to midstance transition, excessive knee extension and genu varus during midstance and terminal stance phase, excessive plantarflexion throughout swing phase causing reduced foot clearance, excessive forward pelvic rotation and hip hike bilaterally during swing phase,

Continued on following page

Case Example 9.2 **(Continued)**

B Trendelenburg hip drop, with step lengths short with swing heel landing near stance toe.

- What are the critical phases of gait where the patient's body structure/function impairments are evident?
- Which of these gait abnormalities could be supported/reduced through the use of an orthosis?
- What are the positive outcomes expected when using an orthosis for this patient (i.e., how will it improve mobility and gait, influence tone, or protect a limb or body segment)?
- How might you assess whether the orthosis chosen is accomplishing the desired outcomes?

TEAM RECOMMENDATIONS

Weakness is evident during *weight acceptance* as demonstrated by excessive knee flexion and again during midstance as hyperextension thrust is a compensation to lock the knee into a stable position due to the inability to effectively use strength to stabilize tibia advancement. Weakness is also negatively affecting *swing limb advancement* reflexed in excessive plantarflexion and need for hip hike compensation.

An orthosis could stabilize the distal limb during stance, improving weight acceptance and reducing abnormal knee forces during forward progression. It could assist with functional shortening of the limb by limiting excessive plantarflexion, which could reduce the need for hip hiking and pelvic rotation compensations to clear the limb in swing.

An orthosis can be expected to reduce excessive biomechanical forces from abnormal foot and tibial position, as well as improve gait efficiency, reducing energy consumption and allowing further ambulation tolerance and greater independence.

Valid and highly recommended outcome measures for a patient with spinal cord injury that could be used to assess the patient's outcomes with the orthoses include the following: Walking Index for Spinal Cord Injury II (WISCI II), 10-meter walk test, Timed Up and Go, 6-minute walk test (Neuro EDGE SCI incomplete).

Case Example 9.3

An 81-year-old man presented to the hospital with weakness and was diagnosed with Guillain-Barré syndrome. He was treated with intravenous immunoglobulin/prednisone. His course was complicated by limb and bulbar weakness and aspiration pneumonia. He was transferred to an acute rehabilitation hospital for functional retraining.

Past Medical History: Hypertension, hyperlipidemia, prostate cancer s/p prostatectomy, small left rotator cuff tear

Social history: Patient lives at home with wife in a two-level home plus basement. There are three steps to enter with a railing from the garage or three steps to enter the front entrance with no railing. The bedroom is located on the first floor as is the bathroom; however, the shower has a 6-inch lip to enter. There is one flight of 8 + 8 steps with railing to access the patient's second-floor home office. Prior to injury, the patient was independent with ADLs, IADLs, and mobility. He was playing tennis 3 days per week and bicycling during warm-weather months.

Patient's goals: To get in and out of bed independently. To walk. To negotiate stairs to his second-floor office. To return to tennis.

Present examination findings include:

Sensation: Absent to diminished throughout bilateral lower extremities
Proprioception: Absent at bilateral great toe and ankles
Spasticity: 0/4 (modified Ashworth Scale)
Integumentary: Intact
Range of motion: Hamstring muscle lengths limited to approx. 80 degrees bilaterally via straight leg raise.
Strength MMT: Right hip grossly 1/5. Left hip flexion 1/5 otherwise left hip 0/5. Bilateral knee extension 1/5. Bilateral hip flexion 2-/5. Right ankle DF 0/5. Left ankle DF 1/5. Bilateral ankle plantarflexion 1/5. Upper extremity strength is grossly 3/5 except hand function is limited to 2/5 bilaterally with impairments in fine motor control.
Bed mobility: Supine to sit with maximal assist of one person
Transfers: Sit to stand dependent via standing frame or maximal assist of two persons

- What type of orthosis is most appropriate to consider for early standing and gait training with this patient?
- What are the positive outcomes expected when using an orthosis for this patient (i.e., how will it improve mobility and gait, influence tone, or protect a limb or body segment)?
- What are the expected disadvantages or tradeoffs that may be associated with use of an orthosis (i.e., the ways in which it may complicate daily activity, mobility, or preferred activities; the energy cost associated with its use; the relative expense of the device)?
- What are the indications that the orthosis may be useful to the patient (i.e., the match between the person's characteristics and needs and what the orthosis will provide)?
- Considering the prognosis for recovery with this patient, how might the patient's orthosis be progressed/changed as his motor control improves?

TEAM RECOMMENDATIONS

Prognostic indicators for patients with Guillain-Barré syndrome suggest that 80% are able to ambulate within 6 months and 84% are able to ambulate at 1 year. Therefore the SAFO can progress with the patient by adding a hinged or articulating ankle joint to allow tibial progression during stance or by cutting back the trim lines to lessen stability.

Factors impacting the decision for early orthosis include significant muscle weakness, absent sensation and proprioception, and no tone present. Given lower extremity muscle strengths grossly in the absent (0) to poor (1) range, this patient will need a highly stable orthosis to maintain the ankle and knee in position to effectively stand. His upper extremities are also weak, limiting the patient's ability to rely on them for support in standing further, indicating the need for a highly stable brace. With no tone present, the patient will not be able to rely on tone to substitute for lack of strength. There do not need to be any considerations for a brace that will minimize spasticity. The absence of sensation and proprioception suggests that the brace must be well fitting to reduce pressure and shear forces that could occur during mobility.

Case Example 9.3 **(Continued)**

Considerations for bracing selection could range from, at simplest, a custom-molded solid AFO to a more complex KAFO. In the interest of selecting the least restrictive prescriptive orthoses, a solid AFO would be an appropriate initial brace to provide stability to the ankle and knee by limiting tibia mobility, thus stabilizing the leg in standing.

A solid AFO will provide two primary patient benefits: stability in stance and assistance with clearance in swing.

The ankle ROM restrictions will provide distal stability to the limb in stance, limiting the degrees of freedom and allowing the patient and therapist to focus on proximal stability training at the core and trunk. The fixed ankle position will assist with swing limb clearance by limiting excessive plantarflexion during swing phase.

There may be increased caregiver burden for donning and doffing due to upper extremity weakness and impaired fine motor control.

The patient is unable to stand without an external standing device or two-person assist. Stabilizing the distal limb by orthoses may allow the patient increased standing tolerance and increased frequency of standing if it can be reduced to the assistance of a single caregiver.

Case Example 9.4

A 70-year-old man presented to the hospital with left leg pain of 3 months' duration and weakness over the past several weeks due to diabetic amyotrophy now with worsening of right leg weakness.

Past Medical History: arteriosclerosis, diabetes mellitus, umbilical hernia (repaired), bradycardia

Social history: Patient lives with his wife in a two-story home with 15 steps to enter from the garage level to the first floor. He has an additional flight of stairs to the second floor, where his bedroom and full bathroom are. On the first floor are a small living area, couch, and bathroom with shower stall. Patient has been staying on the couch on the first floor due to 11 falls in the past month on stairs. A few months prior to presentation, patient was regularly hiking on weekends and working as a homeland security agent. One month prior to injury he began using a right AFO short solid AFO due to foot drop and a cane. More recently he also began using a rolling walker.

Patient goals: To get his legs strong and to not have any more falls.

Present examination findings include:

Sensation: Absent light touch to bilateral feet, diminished light touch and localization throughout bilateral lower extremities distal to knee left worse than right.

Proprioception: Absent bilateral hallux. Diminished bilateral ankles.

Integumentary: Intact

Range of motion: Within functional limits but noted bilateral hamstring muscle length limitations.

Strength MMT: Left lower extremity grossly 2-/5 except knee extension 1/5.

Right hip flexion, adduction, and extension 4/5. Right hip abduction

3-/5. Right knee 3/5. Ankle dorsiflexion and plantarflexion 0/5.

Gait: 250 ft with rolling walker with minimal assistance except minimal to moderate assistance to recover when knees buckle. Patient wearing Right personal short semisolid AFO and left loaner Allard ToeOFF (carbon fiber) AFO. Gait is remarkable for left knee buckling when center of mass is anterior to the left foot during terminal stance, similar but less severe presentation of right knee. Decreased left heel strike at initial contact, absent foot clearance on left.

- Which of these gait abnormalities could be supported/reduced through the use of an orthosis?
- What are the positive outcomes expected when using an orthosis for this patient? (i.e., how will it improve mobility and gait, influence tone, or protect a limb or body segment).
- What are the expected disadvantages or tradeoffs that may be associated with use of an orthosis? (i.e., the ways in which it may complicate daily activity, mobility, or preferred activities; the energy cost associated with its use; the relative expense of the device)?
- Considering the prognosis for recovery with this patient, how might the patient's orthosis be progressed/changed as his motor control improves?

TEAM RECOMMENDATIONS

Given the patient's continued buckling with an AFO and his degree of weakness, a KAFO may be the most appropriate device to effectively assist with foot clearance and heel strike by stabilizing the ankle in near neutral while also providing limitations of tibial advancement and knee flexion during stance phase.

Use of an orthosis will allow control of knee and ankle joint range during weight bearing in stance phase. Limiting the range of both joints will prevent significant knee buckling, improving the patient's ability to ambulate safely, build confidence, and reduce fall risk.

Use of a KAFO is more complex for the patient to don and doff as part of activities of daily living. It is less cosmetically appealing compared with a less significant brace, such as an AFO. The brace will limit ROM during sitting tasks. The KAFO has more bulk and weight than an AFO, only which can increase energy demands during gait.

The prognosis for recovery of strength is fair to good for persons with diabetic amyotrophy; therefore, as the patient's motor control improves, the KAFO can be progressed to an AFO, providing more degrees of freedom for movement, reduced energy demand, and a less cumbersome donning/doffing process.

Case Example 9.5

A 69-year-old man presented to outpatient rehabilitation clinic with gait abnormalities in the setting of multiple sclerosis.

Past Medical History: hypertension, neurogenic bladder, rotator cuff syndrome, dyslipidemia, low back pain, osteoarthritis of the knee

Social history: Patient lives with his wife in a two-level home with stair slide to access the second floor. He is able to ambulate independently with a rolling walker. He has a manual wheelchair for community distances but rarely uses it.

Patient goals: To walk better. To walk in the community more.

Present examination findings include:

Sensation: Present but diminished light touch and localization in bilateral lower extremities distal to the knee.

Proprioception: Present bilateral ankle and hallux.

Integumentary: Intact

Range of motion: Within functional limits except bilateral ankle dorsiflexion limited to neutral.

Spasticity: 1+ bilateral ankle plantarflexors; 1+ bilateral hip adductors via modified Ashworth Scale.

Strength MMT: Lower extremities are grossly 2 to 3/5 throughout via functional observation except bilateral ankle dorsiflexion 2-/5 and bilateral ankle plantarflexion 2/5. Unable to formally manual muscle test due to inability to isolate single plane movement during testing in setting of increased lower extremity tone.

Gait: 40 ft with rolling walker and close supervision. Gait is remarkable for bilateral excessive plantarflexion during swing phase resulting in toe drag throughout; bilateral hip adduction with narrow base of support; short step lengths bilaterally; limited knee flexion during midswing phase and excessive knee extension, even hyperextension during stance phase.

- What are the critical phases of gait where the patient's body structure/function impairments are evident?
- Which of these gait abnormalities could be supported/reduced through the use of an orthosis?
- What are the positive outcomes expected when using an orthosis for this patient (i.e., how will it improve mobility and gait, influence tone, or protect a limb or body segment)?
- What are the expected disadvantages or tradeoffs that may be associated with use of an orthosis (i.e., the ways in which it may complicate daily activity, mobility, or preferred activities; the energy cost associated with its use; the relative expense of the device)?
- Considering this patient's diagnosis, how might the patient's orthosis be progressed/changed over time?

TEAM RECOMMENDATIONS

The patient's dorsiflexion weakness is evident during *swing limb advancement*. Plantarflexor spasticity may also be a contributing factor to the excessive plantarflexion seen during swing phase. Both of these body structure/function impairments result in a functionally long limb. Combined with weakness of the more proximal limb muscles and adductor tone, the patient has insufficient foot clearance.

Ankle dorsiflexion can be easily supported through the use of an orthosis. One option for this patient could be a neuroprosthesis such as Bioness 300 or WalkAid. Peripheral nerve integrity should be intact given the patient's diagnosis with an upper motor neuron disease process. Stimulation applied to the common peroneal nerve/anterior tibialis timed with swing phase can increase functional strength of ankle dorsiflexion and potentially reduce effects of antagonist spasticity. This will in effect make the limb shorter and easier to clear during swing, as well as provide a more normal heel strike at initial contact.

If adductor tone and proximal muscle weakness are limiting his ability to achieve hip and knee flexion during swing, a thigh component such as the Bioness L300+ can be added to the hamstring to cause knee flexion during swing phase, further shortening the limb and allowing improved swing limb advancement. It is important to note that hamstring flexion during swing phase is not normal muscle activity during gait, rather hamstrings would normally only be active eccentrically as the patient approaches terminal swing. In this case, the neuroprosthesis is being used as a compensatory strategy to reduce the energy associated with foot clearance and reduce risk of falls from inability to clear the limb.

Use of a neuroprosthesis will provide improved gait efficiency by reducing effort for swing limb advancement, reduce fall risk by improving limb clearance, and possibly provide functional strength recovery with continued stimulation use.

Neuroprostheses are associated with greater cost than more traditional bracing styles and therefore likely require a higher level of documentation of medical necessity and possibly greater advocacy on the part of the patient to obtain clinic/insurance coverage. In addition, the maintenance requirements are higher for battery life and electrode life, and some require the pad to be damp, which could require the patient to redampen midday.

The patient's cognition and sensation should be monitored over time. The use of a neuroprosthesis requires greater insight of the patient to ensure proper maintenance and wear and skin integrity checks. This patient has a degree of impaired sensation. This is not a contraindication for use of a neuroprosthesis but must be considered with other factors to ensure the patient maintains a healthy integumentary system. If the patient's sensation decreases, it will require greater cognitive awareness to monitor skin regularly. If the patient's cognition declines, he may require assistance from a caregiver for skin checks or require another type of brace if he cannot individually manage it.

10 Neurological and Neuromuscular Disease Implications for Orthotic Use☆

DONNA M. BOWERS and KEVIN K. CHUI

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Describe the contribution of the major components of the central nervous system (CNS) and the peripheral nervous system (PNS) to functional, goal-directed movement.
2. Describe the impact of CNS and PNS pathologies commonly encountered in physical therapy and their implications for orthotic practice.
3. Explain the interaction of muscle tone and muscle performance on goal-directed, functional movement.
4. Describe the characteristics of muscle tone in the CNS and PNS pathologies most commonly encountered in physical therapy and implications for orthotic practice.
5. Describe the contributions of various CNS and PNS components to, and key determinants of, effective postural control.
6. Describe the contributions of various CNS components to, and key determinants of, mobility and coordination during functional activity.
7. Discuss the roles of orthopedic and neurosurgical procedures, central and peripherally acting pharmacological agents, and various orthotic options for the management of hypertonicity.
8. Plan a strategy for examination and evaluation of persons with CNS and PNS dysfunction to determine the need for an orthosis or adaptive equipment.
9. Describe strategies for orthotic use to reduce the risk of developing secondary musculoskeletal impairments in persons with hypertonicity.
10. Describe strategies for orthotic and adaptive equipment use to support postural control in persons with hypotonicity.

Movement Impairment in Neurological and Neuromuscular Pathology

Pathologic conditions of the neuromuscular system manifest in a sometimes confusing array of clinical signs and symptoms. To select the most appropriate therapeutic interventions, be it exercise to promote neuroplasticity and neurorecovery, functional training, or the use of various orthoses and assistive devices to accommodate for impairment of a body system or structure, the clinician must develop a strategy to "classify" the movement disorder that has produced the observed impairments and functional limitations.[1] The clinician must understand the medical prognosis and potential progression of the disease process, as well as the lifestyles and risk factors that might contribute to secondary impairments that limit function over time (even if the disease is "nonprogressive") and their impact on the individual's growth and development. The context of a person's impairments, physical activity limitations, and desire to participate in chosen pursuits must be accounted for in deciding a course of physical therapy interventions, including the use of orthotics[1–3]

Health professionals use a number of organizational strategies as frameworks for decision making during rehabilitation of individuals with pathologic conditions leading to neuromuscular dysfunction. Many neurologists use a medical differential diagnosis process to determine that the lesion is located within the central nervous system (CNS) or involving structures of the peripheral nervous system (PNS) or the muscle itself.[4] They do this by triangulating evidence gathered through focused patient histories, which leads to examination of tone, deep tendon reflexes, observation of patterns of movement, postural control, and specific types of involuntary movement.[4–6] They may also interpret results of special tests such as nerve conduction studies, electromyography (EMG), computed tomography (CT), and magnetic resonance imaging (MRI).[7,8] These tests might pinpoint areas of denervation, ischemia, or demyelinization and help the health professionals arrive at a medical diagnosis.

In collaboration with neurologists, rehabilitation professionals are most interested in the functional consequences

☆The authors extend appreciation to Michelle M. Lusardi, whose work in prior editions provided the foundation for this chapter.

associated with the various neuromotor conditions. They examine the ways in which the resultant altered motor control (from the neurological pathologic condition) affects postural control, mobility and locomotion, and coordination (error control) during functional activities.[9,10] Rehabilitation professionals are not only concerned about function at the present time but also consider the long-term impact of neuromotor impairment on the person's joints and posture, especially in children who are growing with abnormal tone and postures.[11,12]

This chapter considers the ways that key components of the CNS and PNS contribute to functional movement. We explore the concepts of muscle tone and muscle performance, considering how their interaction influences an individual's ability to move. We investigate how abnormalities of tone resulting from CNS and PNS pathologic conditions are described in clinical practice. We consider the determinants of postural control and of coordination and how CNS and PNS pathologic conditions might lead to impairments of balance and movement. We provide an overview of the ways that commonly encountered CNS pathologic conditions impact muscle tone, muscle performance, postural control, movement, and coordination as a way of understanding how an orthosis or adaptive equipment might help improve an individual's ability to walk and use their arms/hands for functional movement in order to participate in meaningful activities and roles.[2] We consider how the physical therapy examination contributes to the determination of a need for an orthosis or adaptive equipment. We also explore the clinical decision-making process by asking key questions about how an orthosis might help (or hinder) function. Finally, we apply what we have learned using five clinical cases to develop orthotic prescriptions.

Differential Diagnosis: Where Is the Problem?

Most neurological and neuromuscular diseases affect either the CNS or the PNS; only a few diseases, such as amyotrophic lateral sclerosis, affect both CNS and PNS. Diseases of the CNS and of the PNS may contribute to motor or sensory impairment; however, there are patterns and characteristics of dysfunction that are unique to each. Selection of the appropriate orthosis, seating/wheelchair system, or assistive devices is facilitated when the therapist, orthotist, members of the rehabilitation team, patient, and patient's family understand the typical function and consequences of the disease process of the neurological subsystem that is affected.

THE CENTRAL NERVOUS SYSTEM

The CNS is a complex of dynamic and interactive subsystems that mediates purposeful movement and postural control, vital autonomic vegetative and physiological functions, and learning of all types.[13] Readers are encouraged to refer to a recent neuroanatomy or neuropathology textbook to refresh their understanding of CNS structure and function. Knowledge of the roles of various CNS structures and their interactions (for perception, problem solving, motor planning, and coordination) is foundational for evidenced-based clinical decision making when considering orthoses for individuals with neuromuscular dysfunction.

Some diseases affect a single CNS system or center (e.g., Parkinson disease affects the function of the basal ganglia in regulating agonist/antagonist muscle activity; a lacunar stroke in the internal capsule may interrupt transmission only within the pyramidal/corticospinal pathway) leading to a specific array of signs/symptoms characteristic of that system or center. Other pathologic conditions disrupt function across several systems: a thromboembolic stroke in the proximal left middle cerebral artery may disrupt volitional movement and sensation of the right side of the body, as well as communication and vision. Several exacerbations of multiple sclerosis may lead to plaque formation in the cerebral peduncles/pyramidal system, superior cerebellar peduncle/error control system, restiform body/balance system, and fasciculus gracilis/lower extremity sensation; in this case, it can be challenging but imperative to sort through the various types of impairments that may result in order to select the most appropriate therapeutic or orthotic intervention for the individual.

Pyramidal System

The *pyramidal system* is responsible for the initiation of volitional movement and plays a major role in the development of skilled and manipulative activities.[14] The cell bodies of pyramidal neurons are located in the postcentral gyrus/primary motor cortex. The motor cortex in the left cerebral hemisphere influences primarily the right side of the body (face, trunk, and extremities); the right cortex influences the left body. The axons of pyramidal neurons form the corticobulbar and corticospinal tracts, projecting toward alpha (α) motor neurons in cranial nerve nuclei and anterior horn of the spinal cord. To reach their destination, these axons descend through the genu and posterior limb of the internal capsule, the cerebral peduncles, the basilar pons, the pyramids of the medulla, and finally the opposite lateral funiculus of the spinal cord. A lesion at any point in the pyramidal system has the potential to disrupt volitional movement. The degree of disruption varies with the extent and functional salience of the structures that are damaged, manifest on a continuum from mild weakness (paresis) to the inability to voluntarily initiate and direct movement (paralysis).[14]

Immediately following insult or injury of the pyramidal system, during a period of neurogenic shock, there may be substantially diminished muscle tone and sluggish or absent deep tendon reflexes.[14] As inflammation from the initial insult subsides, severely damaged neurons degenerate and are resorbed, while minimally damaged neurons may repair themselves and resume function.[15,16] The more neurons that are destroyed, the greater the likelihood that hypertonicity will develop over time due to the altered balance of descending input of pyramidal and extrapyramidal systems. As the recovery period continues, individuals may begin to move in abnormal synergy patterns whenever volitional movement is attempted.[17,18] When the damage to the system is less extensive, individuals may eventually recover some or all volitional motor control; the more extensive the damage to the system, the more likely there will be residual motor impairment.[15,18]

Extrapyramidal System

The extrapyramidal system is made up of several subcortical subsystems that influence muscle tone, organize patterns of

movement from among the many possible movement strategies, and make both feedforward adjustments (in anticipation of movement) and refining feedback adjustments (in response to sensations generated as movement occurs) during performance of functional tasks.[19] The motor planning subsystem is a series of neural loops interconnecting the premotor and accessory motor cortices in the frontal lobes, the nuclei of the functional basal ganglia (caudate, putamen, globus pallidus, substantia nigra, subthalamus), and several nuclei of the thalamus. Damage to the premotor and accessory motor cortex leads to apraxia, the inability to effectively sequence components of a functional task and to understand the nature of a task and the way to use a tool in performance of the task.[20] If there is damage to the caudate and putamen (also called the *corpus striatum*), underlying muscle tone may fluctuate unpredictably (athetosis) and involuntary dancelike movements (chorea) are likely to occur.[21] Damage to the subthalamic nuclei can lead to forceful, often disruptive, involuntary movement of the extremities (ballism) that interrupts purposeful activity.[22] Damage to the substantia nigra characteristically leads to resting tremor, rigidity of axial and appendicular musculature (hypertonicity in all directions), and bradykinesia (difficulty initiating movement, slow movement with limited excursion during functional tasks), which are most commonly seen in persons with Parkinson disease.[23] Motor impairments resulting from damage to the ventral anterior nucleus and related thalamic nuclei are less well understood but may contribute to less efficient motor planning, especially when the individual is learning or performing novel tasks.[24]

Extrapyramidal structures influence muscle tone and readiness to move via a network of interconnections among motor centers in the brainstem. The reticulospinal tracts, originating in the lower pons and medulla, are thought to influence tone by acting on gamma (γ) motor neurons and their associated muscle spindles. They play a major role in balancing the stiffness required for antigravity position and the flexibility necessary for movement of the limbs through space during functional activity and are likely the effectors for tonic hindbrain reflexes.[19,25] The vestibulospinal tracts, also originating from the pons and medulla, influence anticipatory postural adjustment in preparation for movement and reactionary postural adjustments as movement occurs. These tracts are thought to be the "effectors" for postural control and balance.[19,26] The tectospinal tracts, originating in the collicular nuclei of the dorsal midbrain, influence linkages between the head and extremities (especially arms and hands) so that the visual and auditory systems can be used effectively to orient the head and body during tasks that require visual (eye-hand) and auditory (ear-hand) guidance.[16,26]

Coordination Systems

The error control, or coordination subsystem, has several interactive components.[27,28] Feedforward information (how movement is likely to occur) from the forebrain's motor cortex is relayed through the thalamus to the deep nuclei of the cerebellum via the middle cerebellar peduncle (brachium pontis). Feedback information generated during movement ("in flight") travels from the muscle spindle and anterior horn of the spinal cord via the inferior cerebellar peduncle (restiform body), as does sensory information from static and dynamic vestibular receptors (head position and movement in space) and the vestibular nuclei in the brainstem. Through the interaction of Purkinje cells in the cerebellar cortex and neurons in the deep cerebellar nuclei, the cerebellum judges how "in sync" these various types of information are (essentially asking the questions, "Did the movement occur as planned? Was the outcome of the movement as intended?") and suggests refinements for more precise and coordinated movement.[29] These adjustments are relayed to the red nucleus in the midbrain via the superior cerebellar peduncle (brachium conjunctiva) and are forwarded back to the thalamus and the motor cortex, as well as to the spinal cord via the rubrospinal tract. The rubrospinal tract is thought to be essential for refinement and correction of direction and control of movement as it occurs.[29]

Somatosensory and Perceptual Systems

The somatosensory system is composed of a set of ascending pathways, each carrying a specific sensory modality from the spinal cord and brainstem to the thalamus and postcentral gyrus of the cerebral cortex, reticular formation, or cerebellum. The anterolateral (spinothalamic) system carries exteroceptive information from mechanoreceptors that monitor protective senses (e.g., pain, temperature, irritation to skin and soft tissue).[25,30] This tract originates in the dorsal horn (substantia gelatinosa) of the spinal cord and the spinal trigeminal nucleus, crosses the midline of the neuraxis to ascend in the lateral funiculus of the spinal cord to the contralateral ventral posterior thalamus, and then continues to the postcentral gyrus. The dorsal column/medial lemniscus carries information from encapsulated receptors that serve as internal monitors of body condition and motion.[25,31] This tract ascends from the spinal cord to reach the nuclei gracilis and cuneatus in the medulla of the brainstem, then crosses midline to ascend to the contralateral ventral posterior thalamus and on to the posterior central gyrus. The postcentral gyrus (somatosensory cortex) is organized as a homunculus, with each region of the body represented in a specific area.[25,32] Sensation from the lower extremities (lumbosacral spinal cord) is located at the top of the gyrus near the sagittal fissure. Moving downward toward the lateral fissure, the next area represented is the trunk (thoracic spinal cord), followed by upper extremities and head (cervical spinal cord), and finally face, mouth, and esophagus (trigeminal nuclei) just above the lateral fissure. A lesion such as a multiple sclerosis (MS) plaque in one of the ascending pathways may result in a discrete area of loss of exteroception or of conscious proprioception in one area of the body; a lesion on the somatosensory cortex can lead to a more profound, multimodality impairment on the opposite side of the body.

Although sensory information is logged in at the postcentral gyrus, the location of the somatosensory cortex, interpretation and integration of this information occurs in the somatoperceptual system in the parietal association areas, with specialization in the right hemisphere.[30,32] These association areas give meaning to the sensations that are generated as people move and function in their environments. This is where people understand the relationships among their various extremities and trunk (body schema), as well as their relationship to and position within our physical environment. Damage to the parietal lobes leads to problems ranging from left-right confusion to the inability to

recognize and monitor the condition of a body part (neglect, agnosia), depending on how much of the association area is involved.[33,34]

Visual and Visual-Perceptual Systems

The visual system begins with processing of information gathered by the rods and cones in the multiple layers of specialized neurons in the retina, located in the posterior chamber of the eye. Axons from retinal ganglion cells are gathered into the optic nerve, which carries information from that eye toward the brain. At the optic chiasm there is reorganization of visual information, such that all information from the left visual field (from both eyes) continues in the right optic tract, and that from the right field continues in the left tract. This information is relayed, through the lateral geniculate body of the thalamus, via the optic radiations, to the primary visual cortex on either side of the calcarine fissure of the midsagittal occipital lobe.[35] Damage to the retina or optic nerve results in loss of vision from that eye. Damage to the optic chiasm typically leads to a narrowing of the peripheral visual field (bitemporal hemianopsia); a lesion of one of the optic tracts or radiations leads to loss of part or all of the opposite visual field (homonymous hemianopsia). Damage to the visual cortex can result in cortical blindness, in which visual reflexes may be intact but vision is impaired.[36]

Visual information is interpreted in the visual association areas in the remainder of the occipital lobe.[37] The visual association areas in the left hemisphere are particularly important to interpretation of symbolic and communication information, while spatial relationships are of more interest in the right hemisphere. Specific details about the environment, especially about speed and direction of moving objects with respect to the self and of the individual with respect to a relatively stationary environment, are important contributors to functional movement and to the development of skilled abilities.[38] Interconnections between the parietal and occipital association areas serve to integrate visual and somatic/kinesthetic perception and provide important input to motor planning and motor learning systems.[39]

Effective visual information processing is founded on three interactive dimensions: visual spatial orientation, visual analysis skills, and visual motor skills.[40] Developmentally, visual spatial orientation includes spatial concepts used to understand the environment, the body, and the interaction between the body and environment that are part of functional activity (e.g., determining location or direction with respect to self, as well as respect to other objects or persons encountered as people act in their environment). Visual analysis skills allow people to discriminate and analyze visually presented information, identify and focus on key characteristics or features of what people see, use mental imagery and visual recall, and respond or perceive a whole when presented with representative parts. The visual motor system links what is seen, to how the eyes, head, and body move; allowing one to use visual information processing skills during skilled, purposeful activities. This also provides the foundation for movements requiring eye-hand coordination, both large upper extremity movements such as throwing, and fine movement skills such as typing or manipulation of objects.[37]

Executive Function and Motivation

The ability to problem solve, consider alternatives, plan and organize, understand conceptual relationships, multitask, set priorities, and delay gratification, as well as the initial components of learning, are functions of the frontal association areas of the forebrain.[10,41,42] These dimensions of cognitive function are often described by the phrase *higher executive function*. Quantitative and other analytical skills are thought to be primarily housed in the frontal association areas of the left hemisphere, while intuitive understanding and creativity may be more concentrated in the right hemisphere. Most people tap the resources available in both hemispheres (via interconnections through the corpus callosum) during daily life, although some may fall toward one end or another of the analytical–intuitive continuum. Individuals with acquired brain injury involving frontal lobes often exhibit subtle deficits that have a significant impact on their ability to function in complex environments, as well as under conditions of high task demand; difficulty in these areas certainly compromises functional efficiency and quality of life.[43,44]

The neuroanatomical structures that contribute to the motivational system include the nuclei and tracts of the limbic system, prefrontal cortex, and temporal lobes; all play major roles in managing emotions, concentration, learning, and memory.[45] The motivational system not only has an important impact on emotional aspects of behavior but also influences autonomic/physiological function, efficacy of learning, interpretation of sensations, and preparation for movement (Fig. 10.1).[46] Dimensions of limbic function that influence motivation and the ability to manage challenges and frustration include body image, self-concept, and self-worth as related to social roles and expectations, as well as the perceived relevance or importance (based on reward or on threat) of an activity or situation.[47,48] *Central set* is a phrase used to describe the limbic system's role as a motivator and repository of memory on readiness to move or act.[46] Central set helps people predict movement needs relevant to a given situation or circumstance (considering both the physical and affective dimensions of the environment in which they are acting) from past experience.[49]

Consciousness and Homeostasis

The ability to be alert and oriented when functioning in a complex environment is the purview of the consciousness system and is a function of interaction of the brainstem's reticular formation, the filtering system of thalamic nuclei, and the thought and problem solving that occur in the association areas of the telencephalon, especially in the frontal lobes.[50] The reticular activating system, found in the inferior mesencephalon and upper pons of the brainstem, is the locus of sleep-wake and level of alertness.[51] The thalamus and the reticular formation help people habituate to repetitive sensory stimuli while they focus on the type of sensory information that is most germane to the task at hand.[52] The frontal association areas add content to one's consciousness: the ability to reason and to adapt to challenges encountered as one moves through daily life.[53] Alteration in quality and level of consciousness and behavior are indicators of evolving problems within the CNS.[54] Increasing intracranial pressure, the result of an expanding mass

or inflammatory response following trauma or ischemia, may be initially manifest by confusion or agitation; progression into a state of lethargy, stupor, or unresponsiveness (coma) indicates deteriorating compromise of the CNS structures.[55]

Homeostasis and the ability to respond to physiological stressors are functions of the components of the autonomic nervous system.[56] The nuclei of the hypothalamus serve as the command center for parasympathetic and sympathetic nervous system activity via projections to parasympathetic cranial nerve nuclei in the brainstem, the sympathetic centers of the intermediate horn in the thoracic spinal cord, and the parasympathetic centers in the lumbosacral spinal cord. The hypothalamus has extensive interconnections with the limbic system, bridging physiological and emotional/psychological aspects of behavior and activity.[57] The hypothalamus also integrates neural-endocrine function through interconnections with the pituitary gland.[58] Clearly, this relatively small area of forebrain plays a substantial integrative role in physiological function of the human body. Damage or dysfunction to this area therefore has significant impact on physiological stability and stress response.

PERIPHERAL NERVOUS SYSTEM

The PNS serves two primary functions: to collect information about the body and the environment and to activate muscles during functional activities. Afferent neurons collect data from the various sensory receptors distributed throughout the body and transport this information to the spinal cord and brainstem (sensory cranial nerves) for initial interpretation and distribution to CNS centers and structures that use sensory information in the performance of their various specialized roles.[25,33] The interpretation process can have a direct impact on motor behavior at the spinal cord level (e.g., deep tendon reflex) or along any synapse point in the subsequent ascending pathway (e.g., righting and equilibrium responses) as sensory information is transported toward its final destination within the CNS.[59] Efferent neurons (also described as lower motor neurons or, more specifically, α and γ motor neurons) carry signals from the pyramidal (voluntary motor) and extrapyramidal (supportive motor) systems to extrafusal/striated and intrafusal (within muscle spindle) muscle fibers that direct functional movement by enacting the CNS's motor plan.[26,60,61]

The cell bodies of these α and γ motor neurons live in the anterior horn of the spinal cord and in cranial nerve somatic motor nuclei. In the spinal cord, α and γ axons project through the ventral root, are gathered into the motor component of a spinal nerve, and (in cervical and lumbosacral segments) are reorganized in a plexus before continuing toward the targeted muscle as part of a peripheral nerve. In the brainstem, α and γ axons project to target muscles via motor cranial nerves (oculomotor, III; trochlear, IV; motor trigeminal, V; abducens, VI; facial, VII; glossopharyngeal, IX; spinal accessory, XI; hypoglossal, XII).[62] When α

and γ axons reach their target set of muscle fibers (motor unit), a specialized synapse—the neuromuscular junction—triggers muscular contraction.[63]

Pathologic conditions of the PNS can be classified by considering two factors: the modalities affected (only sensory, only motor, or a combination of both) and the anatomical location of the problem (at the level of the sensory receptor, along the neuron itself, in the dorsal root ganglion, in the anterior horn, at the neuromuscular junction, or in the muscle itself).[64,65] Poliomyelitis is the classic example of an anterior horn cell disease; Guillain-Barré syndrome is a demyelinating infectious-autoimmune neuropathy that impairs transmission of electrical impulses over the length of motor and sensory nerves. The polyneuropathy of diabetes (affecting motor, sensory, and autonomic fibers) is the classic example of a metabolic neuropathy. Radiculopathies (e.g., sciatica) result from compression or irritation at the level of the nerve root, while entrapment syndromes (e.g., carpal tunnel) are examples of compression neuropathies over the more distal peripheral nerve. Myasthenia gravis, tetanus, and botulism alter function at the level of the neuromuscular junction. Myopathies and muscular dystrophies are examples of primary muscle diseases.[65]

Determinants of Effective Movement

Regardless of the underlying neurological or neuromuscular disease, rehabilitation professionals seek to understand the impact of the condition on an individual's underlying muscle tone and motor control (ability to initiate, guide, sustain, and terminate movement), muscle performance (strength, power, endurance, speed, accuracy, fluidity), and postural control and balance (ability to stay upright, to anticipate how to make postural adjustment during movement, and to respond to unexpected perturbations) in order to move effectively during goal-directed, functional movement necessary for daily life.

MUSCLE TONE AND MUSCLE PERFORMANCE

Effectiveness of purposeful movement is determined by the interaction of underlying muscle tone and muscle performance. *Muscle tone* can be conceptualized as the interplay of compliance and stiffness of muscle, as influenced by the CNS. Ideally the CNS can set the neuromotor system to be *stiff* enough to align and support the body in functional antigravity positions (e.g., provide sufficient baseline postural tone). At the same time, it allows the system to be *compliant* enough in the limbs and trunk to carry out smooth and coordinated functional movement, and effectively respond to changing environmental conditions or demands as daily tasks are carried out.[66,67] In the tone continuum of stiffness to compliancy, the interplay of stiffness and compliance is optimal at the center, such that motor performance is well supported (Fig. 10.2, horizontal continuum). At the low-tone end of the continuum, where there is low stiffness and high compliance, individuals are challenged by inadequate postural control and inability to support antigravity movement, and by the inability to support proximal joints for effective use of limbs, particularly in antigravity motions. At the high tone end of the continuum, where there is high stiffness and low compliance, freedom and flexibility of movement are compromised. Among individuals, postural tone varies with level of consciousness, level of energy or fatigue, and perceived importance (salience) of the tasks they are involved with at the time.[26,68]

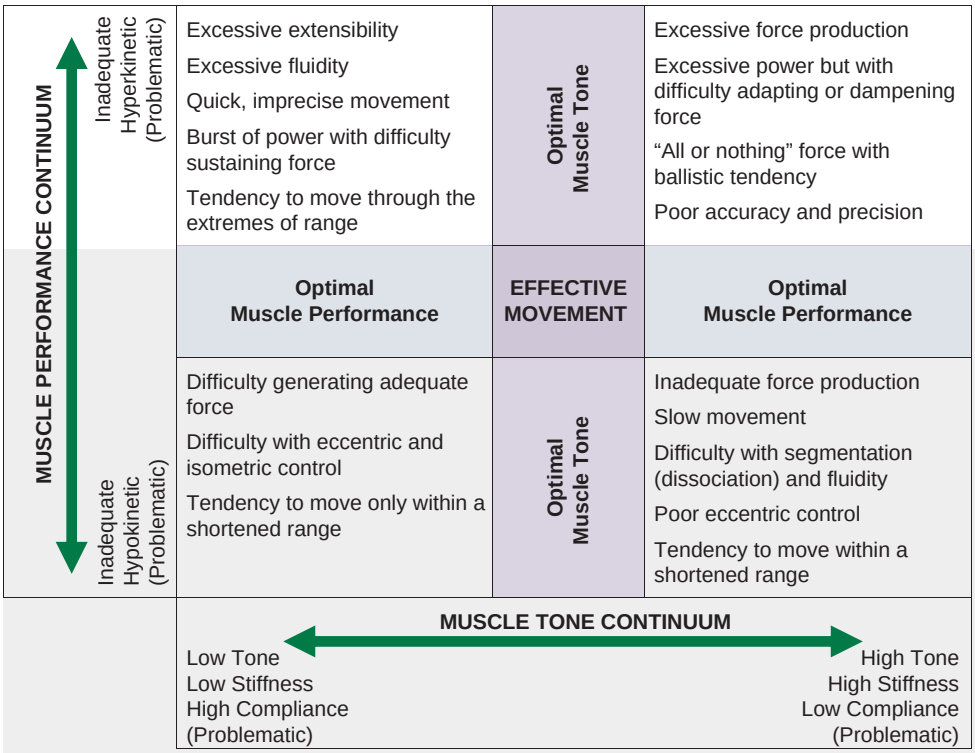

Fig. 10.2 A conceptual model of the interrelationship of muscle tone and muscle performance as they interact to influence functional movement. The muscle tone ranges from excessively compliant (easily extensible on passive movement) to excessively stiff (resistant to passive movement). The muscle performance continuum ranges from hypokinetic (exhibiting minimal movement during task activity) to hyperkinetic (exhibiting excessive movement during task activity). Movement is most effective at the intersection of optimal muscle tone (with balanced stiffness and compliance) and optimal muscle performance (with appropriate force production and adaptability of speed and power).

Effective purposeful movement occurs when *muscle performance* meets the demands of the movement task. The components of muscle performance are the ability to (1) produce sufficient force (strength); (2) produce at the rate of contraction required for the task at hand (speed); (3) sustain the concentric, holding/isometric, or eccentric contraction necessary to meet task demands (muscle endurance); (4) ramp up or dampen force production in response to task demands (accuracy and power); and (5) coordinate mobility and stability of body segments to complete the task (fluidity).[69] Muscle performance can also be conceptualized as having a continuum with optimal control of its components around the center and inadequate control on either side: hypokinesis (little movement) at one extreme, and hyperkinesis (excessive movement) at the other (see Fig. 10.2, vertical continuum).

While muscle tone and muscle performance are distinct contributors to movement, they are certainly interactive.[70,71] Movement is most effective and efficient if an individual's resources fall within the center of each continuum. A problem with muscle tone, muscle performance, or a combination of both leads to abnormal and less effective and efficient movement. Consider what will happen if there is a combination of low tone and inadequate hypokinetic muscle performance: individuals will have difficulty with postural control and proximal support for limb movement, force production, power, and eccentric and isometric control, such that movement tends to occur in shortened ranges, and for short periods of time (less sustainability of contraction/endurance). For example, an infant with Down syndrome (with low tone) struggles to sustain adequate support of the shoulder girdle in prone on elbows in order to lift one arm to reach for a toy (hypokinesis).

In the presence of low tone and hyperkinetic muscle performance, movement is fast but imprecise, with bursts of power that cannot be sustained. For example, a toddler with Down syndrome (with low tone) who is beginning to walk takes rapid and inconsistent steps (hyperkinesis). In contrast, the presence of high tone and hypokinetic muscle performance, movement is slow and stiff, with inadequate force production, compromised segmentation, impaired eccentric control (difficulty letting go), and constrained range. For example, an individual with Parkinson disease takes short steps and has little reciprocal arm swing when walking.

In the presence of high-tone and hyperkinetic muscle performance, there tends to be "all or nothing" force production, with somewhat ballistic and inaccurate movement occurring between the extremes of ranges. For example, a child with spastic quadriplegic cerebral palsy (CP) rising from sitting to standing often employs rapid mass extension (lower extremity and trunk), compromising his or her ability to move toward flexion in order to effectively rise; the child would also have difficulty lowering back into sitting without collapsing. Although muscle performance, especially the ability to generate force, does tend to decline with aging, the impact of inactivity is even more profound; all aspects of muscle performance can improve with appropriate training, even in the very old.[72–74]

Traditionally, an individual's muscle tone has been described clinically as hypertonic or spastic, rigid, hypotonic or low, flaccid, or fluctuating.

Hypertonus

Hypertonus is a term used to describe muscles that are influenced to be too stiff or are excessively biased toward supporting antigravity function. Spasticity is a type of hypertonus that typically occurs when there is damage to one or more CNS structures of the pyramidal motor system and is encountered as a component of many neuromuscular pathologies.[26,75–79] Decrements in underlying tone and muscle performance, in bipedal humans with impairment of the pyramidal system, most often occurs in a *decorticate* pattern: The upper extremity is typically biased toward flexion, such that the limb can be easily moved into flexion but not into extension (decreased compliance of flexors). The lower extremity is biased toward extension, such that the impaired compliance of extensors makes movement into flexion difficult (Fig. 10.3).[80] In persons with severe acquired brain injury the entire body may be biased toward extension, a condition or posture described as *decerebrate* pattern spasticity (Sherrington originally described this phenomenon as decerebrate rigidity).[80] Both decorticate and decerebrate conditions are unidirectional in nature; there is an increase of muscle stiffness and resistance to passive elongation (impaired compliance) in one group of muscles (agonists) with relatively normal functioning of opposing muscle groups (antagonists).

Spasticity is a velocity-dependent phenomenon. Under conditions of rapid passive elongation, spastic muscle groups "fight back" with increased stiffness, a result of a hypersensitive deep tendon reflex loop (Fig. 10.4). This has been described as *clasp-knife spasticity*, in which the spastic limb

Fig. 10.3 Hypertonicity following cerebrovascular accident. (A) The extensor pattern hypertonus in the affected lower extremity precludes swing-limb shortening normally accomplished by hip and knee flexion; instead, the individual uses an abnormal strategy such as pelvic retraction and hip hiking to advance the involved limb; swing is assisted by the ankle-foot orthosis (AFO) to prevent plantarflexion at the ankle. (B) The affected upper extremity shows a flexed posture. Although the extensor bias in the lower extremity may cause hyperextension at the knee, the AFO provides a counter force to allow knee flexion.

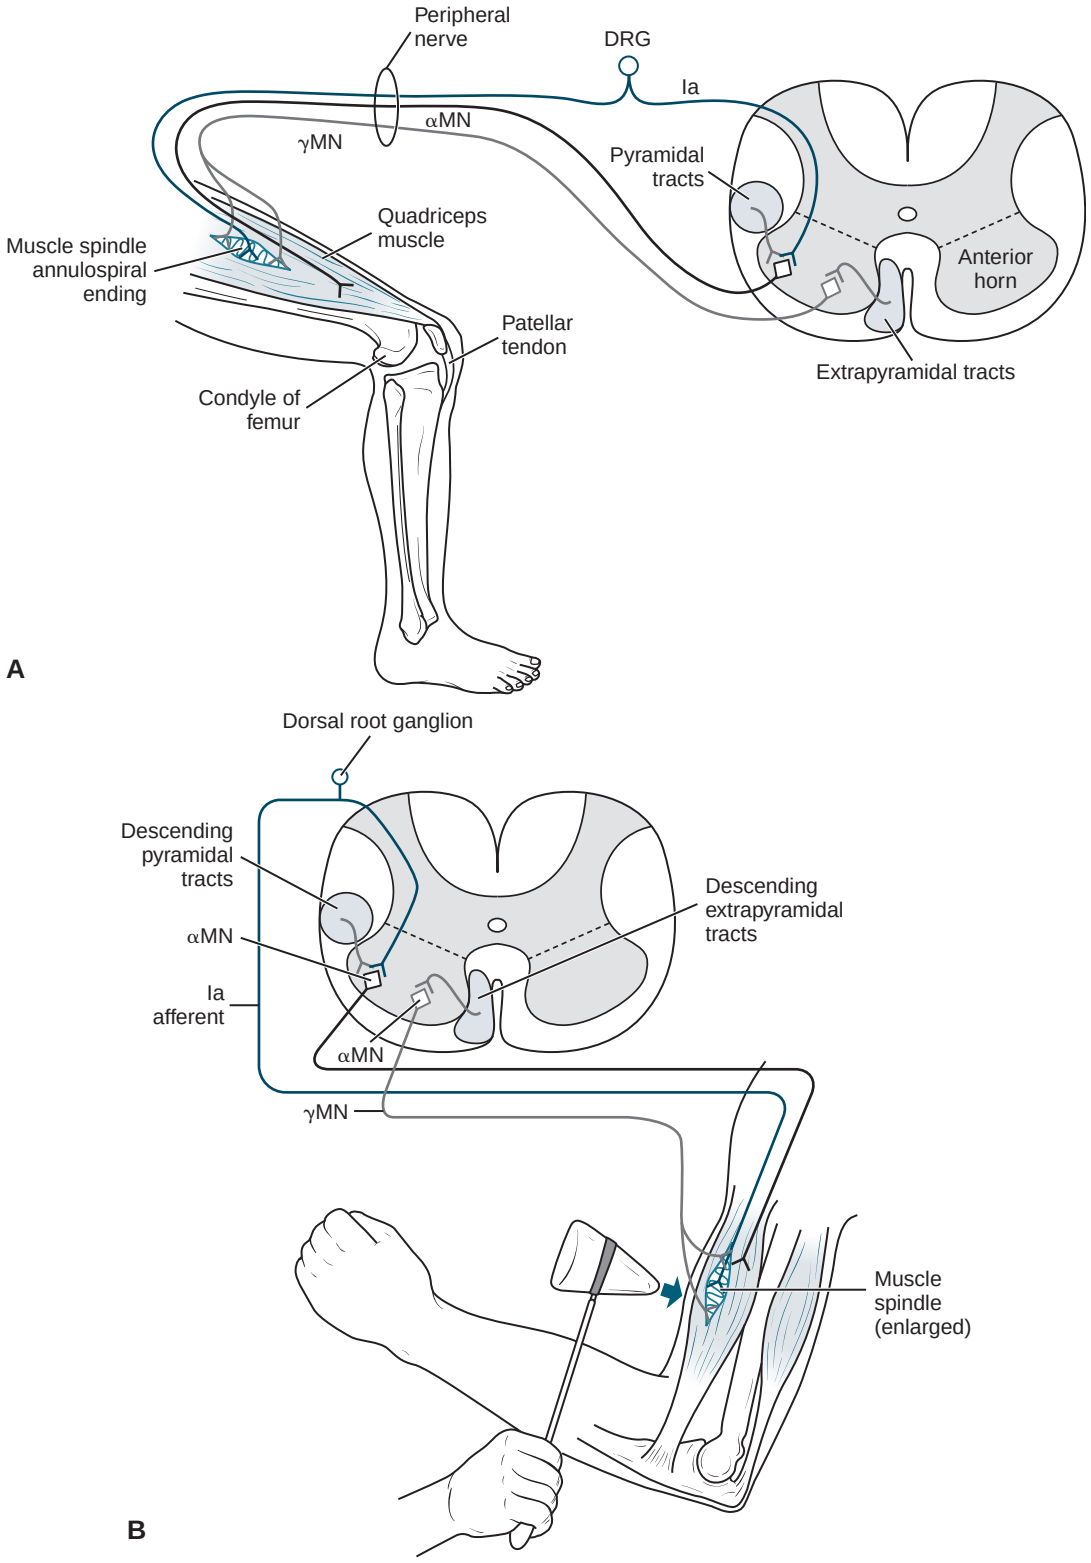

Fig. 10.4 Diagram of the deep tendon reflex loop: stimulation of the annulospiral receptor within muscle spindle of the quadriceps (A) and biceps brachii (B) (via "tap" on the patellar tendon with a reflex hammer) activates 1a afferent neurons, which in turn assist motor neurons in the anterior horn of the spinal cord. These motor neurons project to extrafusal muscle fibers in the quadriceps, which contract, predictably, as a reflex response. Sensitivity of muscle spindle (threshold for stimulation) is influenced by extrapyramidal input, reaching γ motor neurons *(γMNs)* in the anterior horn, which project to intrafusal muscle fibers within the muscle spindle itself. *αMN,* αMotor neuron; *DRG*, dorsal root ganglion.

"gives" after an initial period of resisting passive movement in the way that a pocket knife initially resists opening when near its initially closed position but then becomes more compliant once moved past a threshold position as it is opened. Growing evidence indicates that the stiffness encountered during passive movement has both neurological (spasticity) and musculoskeletal (changes in muscle and associated soft tissue) components that combine to increase the risk of contracture development.[81,82]

Given the unidirectional nature of severe hypertonus, it is common for persons with severe hypertonus to develop chronic atypical postures. The limb or body segment assumes an end-range position that the limb would not normally be able to assume (e.g., equinovarus with marked supination in an individual with severe acquired brain injury, equinovalgus with marked pronation in a child with CP).[80,81] If persistent, these fixed postures are associated with a significant likelihood of secondary contracture development.[83]

Hypertonicity is also associated with deficits in muscle performance, most notably diminished strength (force production), diminished ability to produce power (force production with increased speed), diminished ability to effectively isolate limb and body segments (segmentation), diminished excursions of movements within joints (i.e., moving within a limited range of motion [ROM]), and inefficiency with altering force production or timing of contractions to meet changing (fluid) demands of tasks (accuracy and functionality).[84–86] Muscle performance deficits can contribute to an imbalance of forces around a joint that leads to habitual abnormal patterns of movement. These habitual patterns are often biomechanically inefficient and, over time, contribute to the development of secondary musculoskeletal impairments such as adaptive shortening or lengthening of muscles and malalignment of joints.[83] Strengthening exercises can have a positive impact on function, even in the presence of hypertonicity.[85–87] Orthotics and adaptive equipment play a crucial role to position and support trunk, limbs, and joints to prevent or minimize development of contractures in individuals with hypertonicity.

Rigidity

Individuals with Parkinson disease and related neurological disorders often demonstrate varying levels of rigidity: a bidirectional, co-contracting hypertonicity in which there is resistance to passive movement of both agonistic and antagonistic muscle groups.[23,88] Co-contraction of flexor and extensor muscles of the limbs and trunk creates a bidirectional stiffness that interferes with functional movement. Rigidity is often accompanied by slowness in initiating movement (bradykinesia), decreased excursion of active ROM, and altered resting postures of the limbs and trunk (Fig. 10.5). The rigidity of Parkinson disease can be overridden under certain environmental conditions: Persons with moderate to severe disease can suddenly run reciprocally if they perceive danger to themselves or a loved one; once this initial limbic response has dissipated, they will resume a stooped and rigid posture, with difficulty initiating voluntary movement, limited active ROM, and bradykinesia. Because rigidity creates a situation of excessive stability of the trunk and limbs, orthoses are not typically a component in the plan of care for persons with Parkinson disease.[89]

Fig. 10.5 A person with Parkinson disease showing typical standing posture; note the forward head, kyphotic and forward flexed trunk, and flexion at hip and knees. The upper extremities are held in protraction with flexion. The altered position of the body's center of mass, when combined with rigidity and bradykinesia, significantly decreases the efficacy of anticipatory postural responses during ambulation, as well a response to perturbation.

Hypotonus

Hypotonus (low muscle tone) describes a reduced stiffness of muscle that does not effectively support upright posture against gravity or to produce adequate force during contraction; as a result, hypotonic muscles are more compliant than they are stiff.[90] In children, hypotonia can arise from abnormal function within the CNS (approximately 75%) or from problems with peripheral structures (peripheral nerve and motor units, neuromuscular junction, the muscle itself, or unknown etiology).[91] Hypotonia can be congenital (seen as "floppy" infants), transient (e.g., in preterm infants), part of the clinical presentation of CP, Down syndrome and other genetic disorders, as well as autism spectrum disorders.[91–96]

Hypotonic muscles are considerably more compliant on rapid passive elongation (i.e., less resistant to passive stretch) than muscles with typical tone, as well as those with hypertonus/spasticity. Because their postural muscles are less stiff, individuals with hypotonicity often have difficulty when assuming and sustaining antigravity positions.[97] To compensate for their reduced postural tone, individuals with hypotonicity may maintain postural alignment by relying on ligaments and connective tissue within joint capsule and muscle to sustain upright posture. With overreliance on ligaments in extreme ends of range, further degradation to joint structures often occurs. Additionally, individuals may rely on the upper extremities for postural support, such as a child who uses arms to aid in floor sitting or an adult who holds onto a table when standing. This reliance on upper extremities diminishes the ability to use those extremities for functional tasks. This has implications for

Fig. 10.6 Postural control is often inefficient in children (and adults) with hypotonicity or low tone. This 18-month-old child has insufficient muscle tone to maintain her trunk in an upright position; note the curvature of the thoracic and lumbar spine, with weight bearing on the sacrum (sacral sitting with kyphosis). This leads to shortening of the hamstrings over time, note right knee flexion.

seating and standing systems, or orthotic use to provide external support that will allow individuals to use their upper limbs for play, work, and daily activities[91] (Fig. 10.6).

In addition to postural control dysfunction, individuals with hypotonia often have difficulty with coordination of movements. This may be due to the decreased efficacy of afferent information collected by a lax muscle spindle during movement execution.[90] Children with hypotonia often have impaired control of movements at midrange of muscle length, suggesting that kinesthetic information is not being used efficiently to guide movement or that the ability to regulate force production throughout movements is compromised. In either case, muscle performance is notably less efficient, especially in activities that require eccentric control (e.g., controlled lowering of the body from a standing position to sitting on the floor).[91,97] Individuals with hypotonia have difficulty regulating force production and collaboration between agonists and antagonists is not well coordinated.[97]

Immediately after an acute CNS insult or injury there is often a period of neurogenic shock in which the motor system appears to shut down temporarily, with apparent loss of voluntary movement (paralysis) and markedly diminished or absent deep tendon reflex responses.[98–100] This phenomenon is observed following cervical or thoracic spinal cord injury and early on following significant stroke. During this period, individuals with extreme levels of hypotonus are sometimes (erroneously) described as having flaccid paralysis. Most individuals with acute CNS dysfunction will, within days to weeks, begin to show some evidence of returning muscle tone; over time, many develop hyperactive responses to deep tendon reflex testing and other signs of hypertonicity.[99] If they continue to have difficulty activating muscles voluntarily for efficient functional movement, these individuals are described as demonstrating spastic paralysis. Orthotics can be used to support joints in individuals with hypotonia to minimize degradation. For example, a child with hypotonia may use bilateral supramalleolar orthotics to provide improved postural support of the foot and ankle.[91]

Flaccidity

The term *flaccidity* is best used to describe muscles that cannot be activated because of interruption of transmission or connection between lower motor neurons and the muscles they innervate.[60,101] True flaccidity is accompanied by significant atrophy of muscle tissue, well beyond the loss of muscle mass associated with inactivity; this is the result of loss of tonic influence of lower motor neurons on which muscle health is based.[102]

The flaccid paralysis seen in persons with myelomeningocele (spina bifida) occurs because incomplete closure of the neural tube during the early embryonic period (soon after conception) prevents interconnection between the primitive spinal cord and neighboring somites that will eventually develop into muscles of the extremities.[103] The flaccid paralysis observed in persons with cauda equina level spinal cord injury is the result of damage to axons of α and γ motor neurons as they travel together as ventral roots to their respective spinal foramina to exit the spinal column as a spinal nerve.[104] After acute poliomyelitis, the loss of a portion of a muscle's lower motor neurons will lead to marked weakness; the loss of the majority of a muscle's lower motor neurons will lead to flaccid paralysis.[65] In Guillain-Barré syndrome, the increasing weakness and flaccid paralysis seen in the early stages of the disease are the result of demyelination of the neuron's axons as they travel toward the muscle in a peripheral nerve.[105] After injection with botulinum toxin, muscle tone and strength are compromised because of the toxin's interference with transmitter release from the presynaptic component of the neuromuscular junction.[106] Orthotics and adaptive equipment play a critical role in providing antigravity support for upright positioning and locomotion in individuals with flaccidity. Additionally, orthotics are used to prevent contracture in joints with unbalanced muscle activity. This allows individuals to participate in desired activities in the home, school, or community. For example, a child with a thoracic level myelomeningocele may require adaptive seating for school, while a child with lumbar level myelomeningocele may require orthotics for lower extremity support for ambulation, and a positioning device to prevent contractures of the hip adductors.[103]

Fluctuating Tone: Athetosis and Chorea

Athetosis is the descriptor used when an individual's underlying muscle tone fluctuates unpredictably.[107] Athetosis is characterized by random changes in postural tone, with variations from hypertonus to hypotonus. Athetosis, although less common than spastic CP, can have as significant (and often more pronounced) an impact on daily function.[108] Although etiology of athetosis is not well understood, it is most frequently described as a type of basal ganglia or thalamic dysfunction associated with bilirubin toxicity or significant perinatal anoxia.[107] Persons with athetosis typically demonstrate truncal hypotonia, with fluctuating levels of hypertonus in antigravity musculature and the extremities. In some individuals, movements appear to have a writhing dancelike quality (choreoathetosis) in addition to the tonal influences. Others may compensate

for postural instability by assuming end-range positions, relying on mechanical stability of joints during functional activity. Although persons with athetosis are less likely to develop joint contracture than those with long-standing hypertonicity, they are more likely to develop secondary musculoskeletal complications that compromise stability of joints, a result of extreme posturing, imbalance of forces across joint structures, and the need to stabilize in habitual postural alignment patterns for function.[109] Orthotic usage in individuals with athetosis must be evaluated carefully to consider the balance of supportive versus restrictive influences of the device.

POSTURAL CONTROL

Postural control has three key dimensions: (1) *Static postural control* is defined as the ability to hold antigravity postures at rest; (2) *dynamic anticipatory postural control* is the ability to sustain a posture during movement tasks that shift (internally perturb) the center of mass (COM); and (3) *dynamic reactionary postural control* is the ability to be able to withstand or recover from externally derived perturbations without loss of balance.[110] One has functional postural control if the COM can be maintained within one's base of support (BOS) under a wide range of task demands and environmental conditions. This requires some level of ability across the triad of static, anticipatory, and reactionary control.

The key interactive CNS systems involved in postural control include extrapyramidal and pyramidal motor systems, visual and visual-perceptual systems, conscious (dorsal column/medial lemniscal) and unconscious (spinocerebellar) somatosensory systems, the vestibular system, and the cerebellar feedback/feedforward systems.[111,112] Clinical measures used to assess efficacy of static postural control include timing of sitting or standing activities and measures of center of pressure excursion in quiet standing.[113] The Clinical Test of Sensory Interaction and Balance sorts out the contribution of visual, vestibular, and proprioceptive systems' contribution to balance, as well as the individual's ability to select the most relevant sensory input when there is conflicting information collected among these systems.[114]

Measures of anticipatory postural control consider how far the individual is willing to shift his or her COM toward the edge of his or her sway envelope.[115,116] Clinically, anticipatory postural control is often quantified by measuring reaching distance in various postures.[117–120] Measures of dynamic reactionary postural control consider the individual's response to unexpected perturbations (e.g., when pushed or displaced by an external force, when tripping/slipping in conditions of high environmental demand).[119–121] Although these three dimensions of postural control are interrelated, competence in one does not necessarily ensure effective responses in the others.[122]

Many individuals with neuromuscular disorders demonstrate inefficiency or disruption of one or more of the CNS subsystems necessary for effective postural control and balance.[123] An individual with mild to moderate hypertonicity or spasticity often has difficulty with anticipatory and reactionary postural control, especially in high task demand situations within a complex or unpredictable open environment.[124] Difficulty with muscle performance, such as impairment of control of force production or the imbalance of forces acting across a joint, might constrain anticipatory postural control in preparation for functional tasks such as reaching or stepping. Impairment of the ability to segment trunk from limb or to individually control joints within a limb may affect the individual's ability to react to perturbations in a timely or consistent manner.[125]

Persons with hypotonicity, on the other hand, often have difficulty with sustaining effective postural alignment in antigravity positions such as sitting and standing. They are likely to demonstrate patterns of postural malalignment such as excessive lumbar lordosis and thoracic kyphosis.[97] Because of difficulty with muscle force production (especially in midrange of movement), individuals with hypotonia also have difficulty with anticipatory postural control.[90] A lack of on-demand motor control contributes to difficulty moving within one's postural sway envelope; this may be observed as a tendency to stay in one posture for long periods of time, with infrequent alterations in position during tasks.[94] Reactionary control may also be altered, particularly with respect to the use of equilibrium reactions and the reliability of protective responses. Individuals with hypotonia have difficulty when a task requires them to absorb small-amplitude perturbations; they must use equilibrium or balance strategies more frequently than persons with adequate muscle tone.[90] Additionally, a lack of stability in joints, from both tonal and ligamentous laxity, contributes to an inability to safely stop an accelerating body part as it comes into contact with a surface during a loss of balance episode.[94]

MOVEMENT AND COORDINATION

Many functional activities require us to move or transport the entire body (e.g., mobility or locomotion) or a segment of the body (e.g., using one's upper extremity to bring a cup toward the mouth to take a drink) through space.[126,127] The locomotion task that receives much attention in rehabilitation settings is bipedal ambulation—the ability to walk. For full functional ability, individuals must be able to manage a variety of additional locomotion tasks: running, skipping, jumping, and hopping.[128] To fully understand an individual's functional ability, therapists and orthotists must also consider the environmental context in which ambulation is occurring.[129] What are the physical characteristics of the surface on which the individual needs to be able to walk or traverse? Is it level, unpredictably uneven, slippery or frictional, or structurally unstable? Is the ambulation task occurring where lighting is adequate for visual data collection about environmental conditions? Does it involve manipulation of some type of object (e.g., an ambulatory assistive device, a school backpack, shopping bags, suitcases)? Is it occurring in a familiar and predictable environment (e.g., at home) or in a more unpredictable and challenging open environment such as a busy school, supermarket, mall, or other public space? The task demands of locomotion in complex and challenging environments create more demand on the CNS structures involved in motor control (perceptual-motor function, motor planning, cerebellar error control), as well as on the musculoskeletal effectors (muscles and tendons, joints, ligaments, and bones) that enact the motor plan necessary for successful completion of the task that relies on body transport. Individuals with neurological and neuromuscular system problems related to

muscle tone, muscle performance, and postural control are typically less efficient, less adaptable, and more prone to fall when walking, especially if there are competing task demands and the environment is complex and challenging.[130]

The use of a limb segment can also be defined by the nature of the task and the circumstances in which the movement is performed. Upper extremity functional tasks can involve one or more components: reaching, grasping, releasing, manipulating, or any combination of these four purposes.[126] Upper extremity tasks can also be defined by considering the function to be accomplished by the movement: grooming, dressing, meal preparation, self-care, or writing. Many upper extremity mobility tasks are founded on effective postural control (e.g., making appropriate anticipatory postural adjustments as the COM shifts while throwing, lifting, lowering, or catching an object).[126] Complex mobility tasks require simultaneous locomotion and segmented use of extremities (e.g., reaching for the doorknob while ascending the steps toward the front door, throwing or catching a ball while running during a football or baseball game). For individuals with neurological and neuromuscular system dysfunction, the ability to safely and efficiently perform complex mobility tasks is often compromised due to abnormal muscle tone, impaired muscle performance, and poor postural control.[130]

Coordination can be thought of as the efficacy of execution of the movement necessary to complete a task. A well-coordinated movement requires effective simultaneous control of many different dimensions of movement: the accuracy of a movement's direction and trajectory; the timing, sequencing, and precision of muscle activation; the rate and amplitude of force production; the interaction of agonistic and antagonistic muscle groups; the ability to select and manage the type of contraction (concentric, holding, or eccentric) necessary for the task; and the ability to anticipate and respond to environmental demands during movement.[131] Coordination can be examined by considering the individual's ability to initiate movement, sustain movement during the task or activity, and terminate movement according to task demands.[132]

For movement and coordination to be functional, one must have muscle performance that is flexible/adaptable to varying demands.[133] Mobility or transport tasks cannot be performed independently (safely) unless the individual is able to (1) transition into and out of precursor positions (e.g., getting up from the floor into a standing position, rising from a chair), (2) initiate or begin the activity (e.g., take the first step), (3) sustain the activity (control forward progression with repeated steps), (4) change direction as environmental conditions demand (e.g., step over or avoid an obstacle), (5) modulate speed as environmental conditions demand (e.g., increase gait speed when crossing the street), and (6) safely and effectively stop or terminate the motion, returning to a precursor condition or position (quiet standing, return to sitting).[133]

For individuals with neuromuscular disorders who have difficulty with muscle performance, abnormal underlying tone, or impaired postural control, coordination of functional movement can be compromised in several ways. In order to approach and complete a movement task, the individual might rely on abnormal patterns of movement with additional effort and energy cost.[134] Many individuals with hypertonicity initiate movement with strong bursts of muscle contractions but have difficulty sustaining muscle activity and force of contraction through the full ROM necessary to perform a functional movement.[98,108] Deficits in timing and sequencing of muscle contractions, as well as difficulty with dissociation of limb and body segments, also contribute to difficulty with performance of functional tasks.[135] An adult with hemiplegia following a cerebrovascular accident may be able to initiate a reach toward an object but not be able to bring the arm all the way to the target.[136] The same individual may have difficulty with timing and segmentation, leading to inability to open the hand before reaching the target in preparation for grasping the object.[137,138] The muscle performance of many children with CP is compromised by inappropriate sequencing of muscle contractions when activation of synergists and antagonists happens simultaneously.[84,108] Conversely, an individual with hypotonus who has difficulty with stabilization often moves quickly with diminished accuracy and coordination.[90]

The following tables provide an overview of incidence/prevalence, etiology and risk factors, clinical presentation, and impact on muscle tone, muscle performance, postural control, and movement for of the most common pathologies that might include use of an orthosis: stroke (Table 10.1), CP (Table 10.2), spina bifida (Table 10.3), MS (Table 10.4), and spinal cord injury (Table 10.5).

Table 10.1 Stroke

Also known as	Brain attack, cerebrovascular accident
Incidence	Approximately 795,000/year in the United States[a] ~610,000 are first attacks. ~185,000 are recurrent attacks
Prevalence	2.7% of total US population have had stroke[a] Prevalence of stroke by age and sex: 20–39 years: Males = 0.3%, Females = 0.6% 40–59 years: Males = 1.8%, Females = 2.4% 60–79 years: Males = 6.5%, Females = 6.1% 80+ years: Males = 13.8%, Females =14.9%
ETIOLOGY AND RISK FACTORS	
Ischemic Stroke (87%)	
Thrombus	Hypertension, high blood cholesterol and other lipids, diabetes, overweight and obesity, smoking/tobacco use, nutrition, physical inactivity, family history/genetics, chronic kidney disease, sleep apnea, psychosocial factors

Table 10.1 Stroke (Continued)

Embolism	Disorders of heart rhythm (e.g., atrial fibrillation), atherosclerosis in carotid/vertebral arterial systems; previous embolic stroke
Hemorrhagic Stroke (10%)	
Intracranial hemorrhage	Uncontrolled hypertension, ruptured aneurysm
STROKE SYNDROMES (BY ARTERY)	
Middle cerebral (most common)	Contralateral hemiparesis/hemiplegia, lower face, UE > LE Contralateral sensory loss of lower face, UE > LE Contralateral homonymous hemianopia (optic tract) Possible dysarthria and dysphagia R hemisphere: visual-spatial or somatic perceptual impairment L hemisphere: communication impairment (various aphasias)
Lenticulo-striate (lacunar MCA)	Contralateral hemiparesis/hemiplegia, lower face, UE = LE Cortical functions (perception, communication) intact
Anterior cerebral	Contralateral hemiparesis/hemiplegia LE > UE Sensation often intact or only mildly impaired (contralateral) Incontinence "Alien hand" syndrome (involuntary/unintended movement) Motor (nonfluent/Broca) aphasia may occur
Posterior cerebral	Contralateral homonymous hemianopsia (optic radiations) Visual inattention L hemisphere: alexia (unable to read), with ability to write preserved
Thalamogeniculate (lacunar PCA)	Contralateral sensory loss, often severe Sensory ataxia (uncoordinated movement due to lack of proprioception) Thalamic pain and hyperpathia syndrome
Basilar (complete)	Loss of consciousness, coma High mortality
Superior cerebellar	Ipsilateral ataxia, falling to side of lesion Intention tremor Contralateral loss of pain temperature sensation from body Contralateral loss of proprioception Ipsilateral Horner syndrome (meiosis, ptosis, anhidrosis)
Anterior-inferior cerebellar	Ipsilateral facial paralysis (both upper and lower face) Ipsilateral loss of pain and temperature of entire face Contralateral loss of pain and temperature from body Loss of taste sensation, loss of corneal reflex, ipsilateral hearing loss, nystagmus, vertigo, nausea Ataxia and incoordination of limb movement Ipsilateral Horner syndrome (meiosis, ptosis, anhidrosis)
Vertebral	Contralateral loss of pain, temperature sensation from body
Posterior-inferior cerebellar (Wallenberg syndrome) (lateral medullary syndrome)	Ipsilateral loss of pain and temperature sensation from face Ipsilateral Horner syndrome (meiosis, ptosis, anhidrosis) Dysphonia, dysphagia, dysarthria, diminished gag reflex Nystagmus, diplopia, vertigo, nausea Ipsiversive falling (toward side of lesion), incoordination, ataxia
PROGNOSIS	Ischemic: severity depends on site of occlusion within arterial tree and the size of the area that is without blood flow Embolic: risk of recurrence is higher than in thrombosis; risk of hemorrhage at site of embolism Hemorrhagic: highest morbidity and mortality Static event, with evolving symptoms in weeks/months following initial damage, due to initial inflammatory response and subsequent tissue remodeling/healing.
MUSCLE TONE	Initial hypotonus (sometimes appearing to be flaccid) due to neurogenic shock. Some individuals remain hypotonic, most develop various levels of hypertonus in weeks/months following event. Hyperactive deep tendon reflexes evolve over time
MUSCLE PERFORMANCE	Upper extremity often biased toward flexion, with lower extremity biased toward extension. Impaired force production, speed and power, eccentric/isometric control, accuracy, and fluidity
POSTURAL CONTROL	Frequently impaired, especially if lesion included gray matter of R hemisphere, with perceptual dysfunction
MOBILITY AND COORDINATION	Asymmetry in ability to use trunk, limbs during functional activity; tendency to move in abnormal "synergy" (flexion UE, extension LE). Frequently require AFO and ambulatory device

AFO, Ankle/foot/orthosis; *L,* left; *LE,* lower extremity; *MCA,* middle cerebral artery; *PCA,* posterior cerebral artery; *R,* right; *UE,* upper extremity.

Table 10.2 Cerebral Palsy

Prevalence in the United States	1 in every 323 children born in the United States[a]
Prevalence in developed countries worldwide	2.0–2.5 per 1000 births[b]
Etiology	Associated with prenatal (34%), perinatal (43%), and postnatal (6%) events of hypoxia, infection, ischemia, or trauma affecting the brain[b]
Risk factors	Collection of multiple risk factors rather than one event; cerebral vascular accidents within a neonate's first 28 days most significant cause; premature birth contributes to one half or fewer of cases; low birth weight, perinatal or neonatal respiratory distress/anoxia, uterine or placental pathologies[b]
CLASSIFICATION OF CEREBRAL PALSY	
Topographic distributions:[b]	
Diplegia	Lower extremities affected more than upper extremities
Hemiplegia or hemiparesis	Unilateral upper and lower extremities
Quadriplegia or tetraplegia	All four extremities
Movement disorder distributions:[b] Spastic (77.4%)[a,b]	Involvement of motor cortex and sensorimotor cortical tracts (gray and white matter). Spasticity and hyperreflexia contribute to impaired posture and movement
Dyskinetic (5%–10%)[a] (dystonic or athetonic)	Involvement of the basal ganglia. Contributes to atypical posture and involuntary and sometimes stereotypical movement
Ataxic/cerebellar (5%)	Involvement of the cerebellum. Contributes to instability and altered posture, uncoordinated and imprecise movements
Mixed	Elements of spasticity and dyskinesia
GROSS MOTOR FUNCTION CLASSIFICATION SYSTEM[b,c]	Standard for describing motor disability in children with cerebral palsy. Includes Levels I through V in children between 6th and 12th birthday and children between 12th and 18th birthday
Children Between 6th and 12th Birthdays	Level I Walk at home, school, outdoors, and in the community. Can navigate stairs. Can run and jump. Difficulty with speed, balance, and coordination Level II Walk in most settings and navigate stairs with railing. May have difficulty with long distances, uneven terrain, inclines, obstacles, or crowded spaces. May need physical assistance, hand-held mobility device, or wheeled mobility for long distances. Minimal ability to run and jump. May need adaptations for recreational activities Level III Walk with a hand-held mobility device in indoor settings, navigate stairs with rail and assistance. Use wheeled mobility for long distances. Need adaptations for recreational activities Level IV Mobility requires physical assistance or powered mobility in most settings. Require adaptive seating and body support walker for home and school activities. For community activities, require transportation in manual or powered wheelchair Level V Require transportation in manual wheelchair, adaptive seating and standing systems. Require full assist for transfers and self-care
Children Between 12th and 18th Birthdays	Level I Walk at home, school, outdoors, and in the community. Can navigate stairs and curbs. Can run and jump. Difficulty with speed, balance, and coordination Level II Walk in most settings; environmental factors and personal preference influence mobility choices. May require hand-held mobility device for safety and assistance or rail for stairs. May use wheeled mobility for long distances in community. May need adaptations for sports and recreational activities Level III Walk with hand-held mobility device; need assistance or rail for stairs. Need physical assistance or upper extremity support for transfers. At school may use self-propelled manual wheelchair or powered mobility. In community are transported in manual chair or powered mobility Level IV Use wheeled mobility in most settings. Physical assist required (one to two persons) for transfers. Indoors may walk with assistance or body support walker. Outdoors are transported in manual chair or powered mobility Level V Transported in manual chair in all settings. Require adaptive seating and standing systems. Self-mobility is severely limited even with assistive technology

Table 10.3 Spina Bifida

Prevalence	Prevalence for babies born with spina bifida is highest in babies born to women of Hispanic decent: 3.80 per 10,000 births; Next non-Hispanic white: 3.09 per 10,000 births; and last Black or African American: 2.73 per 10,000 births[a]
Etiology	Unknown; genetics and environmental factors may play role[a]
Risk factors	Folic acid deficiency in early pregnancy[a,b,c] Maternal alcohol intake during pregnancy (occurs with fetal alcohol syndrome) Use of valproic acid for seizure management during pregnancy[b,c] Having high temperatures early in pregnancy
TYPES OF SPINA BIFIDA[a,b,c]	
Occulta	Abnormal formation of lumbar or sacral vertebrae, with intact spinal cord and spinal nerves, and full skin coverage. May be a progressive deterioration of function in late childhood into adulthood
Meningocele	Vertebral defect such that meninges and cerebrospinal fluid protrude but spinal cord, cauda equina, and spinal nerves remain within the spinal column. Vertebral defect may or may not be covered by skin. Often associated with minor to mild impairment of motor and sensory function
Myelomeningocele	Defect such that meninges and incompletely closed spinal cord protrude; associated with lower motor neuron dysfunction (flaccid paralysis) and complete sensory loss below level of lesion; may have spasticity of muscles innervated by spinal nerves just proximal to level of lesion. Urinary and fecal incontinence common, risk of neuropathic wounds high; risk of osteoporosis of lower extremities high
PROGNOSIS	Incomplete closure of neural tube soon after conception; leading to flaccid paralysis and total sensory impairment of all structures innervated at and below level of lesion. May be concurrent with hydrocephalus, often managed by ventriculoperitoneal shunt. Associated with multiple secondary musculoskeletal deformities including hip dysplasia, hip dislocation, knee valgus or varus, rearfoot valgus, forefoot equinovarus, scoliosis and kyphosis, osteoporosis, overuse injuries of upper extremities.[c] Static, nonprogressive condition; however postural impairments and decreasing levels of mobility occur with aging, particularly in adolescence and young adulthood. Depending on level of lesion, voluntary bladder and bowel control may also be impaired or absent
MUSCLE TONE	Typically flaccid paralysis below the segmental level of the lesion.[c] 9%–25% may have spasticity associated with central nervous system abnormalities
MOBILITY AND COORDINATION	Ranges from bipedal ambulation to wheeled mobility and may change depending on setting and mobility needs. Ambulation distances typically assessed by home, school, or community needs. Orthoses range from ankle/foot orthotic to reciprocating gait orthoses (hip/knee/ankle/foot orthotic). May or may not need assistive device. Wheeled mobility often needed for long distances including school and community venues Evaluation criteria to determine feasibility for ambulation and/or wheelchair mobility[c]: Household distances—evaluate for endurance; effectiveness of transfers; directionality; management of obstacles including doors; thresholds; efficiency/speed; safety; accessibility to all rooms/areas of house School distances—evaluate for endurance; effectiveness of transfers; stairs; curbs; ramps; indoor and outdoor surfaces; management of obstacles including classroom furniture, cafeteria furniture; doors and thresholds; efficiency/speed; safety; accessibility to all rooms/areas of school including bathrooms, special classrooms such as auditoriums, stages, art rooms, computer rooms, gymnasium, and playground Community distances—evaluate for endurance and sufficient speed for public places including medical offices, stores; entertainment and recreational venues; parks and outdoor spaces; effectiveness of transfers; stairs, curbs, and ramps; indoor and outdoor surfaces; management of obstacles including structures, furniture, and people; efficiency/speed; safety; accessibility to all areas of public buildings including bathrooms, lobbies, and parking areas

Table 10.4 Multiple Sclerosis

Incidence	10,000 new cases of MS are diagnosed yearly in the United States[a]
Prevalence	~ 400,000 people living with MS in the United States,[b,d] but it may be close to 1,000,000[c] Nationally, 90 per 100,000[b] to 149.2 per 100,000[d] Varies by location: 110–140 per 100,000 above the 37th parallel and 57–78 per 100,000 below the 37th parallel[c] Varies by gender: 224.2 per 100,000 for females and 149.2 per 100,000 for males[d] Varies by region: 192.1 per 100,000 in the East, 111.6 per 100,000 in the South, 165.0 per 100,000 in the Midwest, and 110.7 per 100,000 in the West[d]
Etiology	Unknown; CNS demyelinating disease affecting CNS subsystem

Continued on following page

Table 10.4 Multiple Sclerosis (Continued)

Risk factors	May be exposure to slow virus, environmental toxin, possible autoimmune components, risk higher among siblings (genetic predisposition), more common in women than men, more common among persons in northern latitudes; more common among Caucasians. Most commonly diagnosed in early to mid-adulthood
CLASSIFICATIONS OF MS[c]	
Possible MS	An individual experiences a clinically isolated syndrome (CIS): a single neurologic episode that lasts at least 24 hours, and is caused by inflammation/demyelination in one or more sites in the CNS, especially if lesions are present on MRI
Relapsing remitting (85%)	Cycle of exacerbations (new signs/symptoms) followed by partial to complete recovery during which there is no apparent worsening of the disease process
Progressive	Steadily worsening of symptoms from time of diagnosis, with incomplete recovery between exacerbations
PROGNOSIS	Unpredictable exacerbations result from inflammation and destruction of myelin around pathways within the CNS. Residual impairments are the consequence of slowed transmission of neural impulses across plaques interrupting connections between CNS structures May impact on any subsystem within CNS (voluntary motor, postural control, coordination, memory, perception, sensation) Definitive diagnosis made if there have been at least two different episodes of impairment, involving two different neurological subsystems, affecting two different parts of the body, at two different periods of time Variable course, with many different types of impairment accruing over time with repeated exacerbations Typically, onset of initial symptoms in young and mid-adulthood. Often diagnosis by exclusion; when neurological signs/symptoms cannot be attributed to other disease processes
MUSCLE TONE	Varies, depending on location and size of residual plaque. Some individuals may exhibit normal tone and deep tendon reflexes, in the presences of perceptual, postural, or coordination impairment. Others may demonstrate hypertonus and hyperactive reflexes is various muscles. Others may have hypotonus and impaired muscle performance
MUSCLE PERFORMANCE	Varies, depending on the location of MS plaque. If in pyramidal system, may have weakness, impaired muscle endurance, poor eccentric control, among others. If in cerebellar systems, may demonstrate ataxia, intention tremor, among others
POSTURAL CONTROL	Postural control and equilibrium responses may be impaired due to a combination of pyramidal and/or extrapyramidal motor system impairment, sensory impairment or somatosensory, spinocerebellar, or visual pathways, or damage of major integrative while matter structures such as the corpus callosum, or medial longitudinal fasciculus
MOBILITY AND COORDINATION	Mobility and locomotion may be impaired, along with postural control, depending on location of lesion. Some individuals with impaired muscle performance benefit from AFOs (for support and positioning of lower extremity in gait) associated with weakness or hypertonicity. Many choose to use ambulatory aides and assistive devices for function and safety. Some with significant multisystem impairment benefit from seating and wheeled mobility systems

Note that the US government does not track or report the incidence and prevalence of MS (https://www.nationalmssociety.org/About-the-Society/MS-Prevalence).

Table 10.5 Spinal Cord Injury

Incidence	~17,730 new cases in the United States per year, ~5.4 per 100,000[a]
Prevalence	~291,000 persons in the United States are living with SCI (range = 249,000 to 363,000)[a]
Etiology	Usually traumatic (e.g., vehicle crashes [39.3%], falls [31.8%], violence - primarily gunshot wounds [13.5%], sports/recreation activities [8%]), sometimes infectious (e.g., transverse myelitis) or ischemic (e.g., complication of abdominal aortic aneurysm repair)
Risk factors	Young age, male gender (~78%), drunk driving, participation in extreme sports, all-terrain vehicle accidents, military injury
SCI SYNDROMES	
Complete UMN[a] 12.3% Complete quadriplegia 19.6% Complete paraplegia	Quadriplegia (cervical cord injury) or paraplegia (thoracic cord injury) with spastic paralysis Consequence of compression, contusion, or ischemia of spinal cord as a result of vertebral fracture or dislocation sustained in fall, collision, diving, gunshot wound, or other high-impact event Exacerbated by resultant inflammatory process Spinal cord below level of lesion survives but is unhooked from brain and brainstem, only able to operate reflexively (e.g., neurogenic bladder and bowel function)
Incomplete[a] 47.6% Incomplete quadriplegia 19.9% Incomplete paraplegia	Similar mechanism of injury but with sparing of one or more areas of spinal cord such that there is some volitional motor function and sensation along with more typical UMN (for cervical and thoracic vertebral lesions) or LMNs (for lumbosacral vertebral

Table 10.5 Spinal Cord Injury (Continued)

	lesions) (e.g., central cord syndrome: upper extremity involvement > lower extremity involvement, often with preserved volitional bladder and bowel function) Becoming more common with advances in emergency care on newly injured persons Paraplegia consequence of compression, contusion of lumbosacral nerve roots (cauda equina) within the lower spinal canal, resulting in flaccid paralysis and sensory loss below the level of lesion
Prognosis	Improved emergency and acute medical management often result in incomplete lesion, with varying combinations of return of function and spastic paralysis
MUSCLE TONE	
Complete UMN	Initial hypotonicity during period of neurogenic shock. Many develop significant hypertonicity in the months after injury; some may have muscle spasm needing pharmacological intervention. Sudden increase in resting tone may signal unrecognized skin irritation, bladder distention or infection, or bowel impaction. At risk of secondary musculoskeletal deformity (contracture) due to longstanding abnormal tone and limited mobility
Incomplete	Also may demonstrate hypotonicity in the days immediately following injury. Some volitional muscle function may be apparent early on; spasticity may develop in other muscles over time. Muscles with spasticity similar to complete UMN injury
Complete LMN	Considered a lower motor neuron lesion with flaccid paralysis and absence of deep tendon reflexes at and below level of lesion
MUSCLE PERFORMANCE	
Complete UMN	Impaired and inadequate; reflexive function only
Incomplete	Muscles that remain innervated often initially weak; responsive to interventions to enhance force production, muscle endurance, power
Complete LMN	No muscle function and areflexic below level of lesion
POSTURAL CONTROL	
Complete UMN	Disconnection of lower motor neuron pool below level of lesion results in loss of volitional movement, as well as automatic postural responses, despite hypertonus. Deep tendon reflexes are often brisk, sometimes resulting in sustained clonus
Incomplete	Varies from significantly impaired to minimally impaired, depending on location and extent of lesion
Complete LMN	Postural control of trunk intact, although flaccid paralysis of lower extremities limit stability in standing without external support of orthoses
MOBILITY AND COORDINATION	
All types	May temporarily use spinal orthosis (CO, CTO, TLSO) until surgical stabilization of damaged vertebrae is well healed. Often require seating and wheelchair systems for mobility Persons with cervical level lesions may require upper extremity splints and adaptive equipment for activities of daily living, or resting splints or orthoses to manage abnormal tone and prevent contracture
Complete LMN	Persons with low thoracic and lumbosacral lesions may use AFO, KAFO, or HKAFO along with assistive device (rolling walker, crutches) for ambulation, either as part of rehabilitation or of fitness program; energy cost of ambulation for community distances often high enough to be impractical

AFO, Ankle/foot orthosis; *CO*, cervical orthosis; *CTO*, cervical thoracic orthosis; *HKAFO*, hip/ankle/foot orthosis; *KAFO*, knee/ankle/foot orthosis; *LMN*, lower motor neuron; *SCI*, spinal cord injury; *TLSO*, thoraco/lumbo/sacral orthosis; *UMN*, upper motor neuron.

When considering an upper or lower extremity orthosis or an adaptive equipment system to support the trunk for individuals with neurological or neuromuscular dysfunction, the rehabilitation team must clearly define what they hope the orthosis will accomplish and consider the needs of the individual and family. Goals for orthosis and adaptive equipment usage include provision of stability for trunk, limb segment, or specific joint for postural control; provision of stability for improved efficiency of movement, reduction of the influence of hypertonicity on movement, minimization/prevention of the development of contractures, and increasing participation in desired activities of the individual. There is no perfect orthosis or adaptive equipment piece that will address all dimensions of movement dysfunction; there are always trade-offs that must be taken into account.

Management of Neuromuscular Impairments

Effective care of persons with movement dysfunction secondary to neurological and neuromuscular pathologies requires collaboration of health professionals from many disciplines: neurologists, orthopedist, physiatrists, physical and occupational therapists, and orthotists, among others.[139–141] Physicians and surgeons manage spasticity and correct orthopedic deformity with medication and surgery. Nurses are involved in wellness care, as well as medical and surgical management. Rehabilitation professionals facilitate return of function after an acute event and provide functional training and postoperative rehabilitation for individuals across the spectrum of neurological and

neuromuscular pathologies. Orthotists contribute their knowledge of orthotic options to improve gait and function. The multidisciplinary approach leads to greater satisfaction with care and less risk of abandonment of orthoses and assistive devices by the person for which they were made.[142]

MEDICAL AND SURGICAL CARE

Medical management of CNS dysfunction often includes prescription of pharmacological agents. Physicians can select from a range of centrally acting tone-inhibiting medications (e.g., baclofen [Lioresal]) or pharmacological interventions that target lower motor neurons, peripheral nerves, or muscle (e.g., botulinum toxin injection, intrathecal baclofen) for individuals with significant hypertonicity.[143–149] A host of medications have become available to reduce the likelihood of exacerbation, delay disease progression, and manage fatigue for persons with MS.[150,151] Many individuals with CNS disorders also must cope with seizure management; many antiepileptic drugs affect tone, arousal, and ability to learn.[152] It is important for physical therapists and orthotists to be aware of the potential impact of neuroactive medications on an individual's ability to concentrate and learn, overall health status, and neuromotor control.[153,154] A summary of pharmacological agents used in the management of hypertonicity resulting from CNS disease in the management of MS and for seizure disorders is presented in Table 10.6.

Alternatively, physicians may recommend various neurosurgical procedures and orthopedic surgeries to correct deformity, improve flexibility, or reduce level of abnormal tone, with the goal of enhancing mobility and improving performance of functional tasks. Neurectomy and neurotomy, for example, may be used to manage severe equinovarus and upper extremity spasticity after stroke and for children with CP.[155–159] Selective dorsal rhizotomy effectively reduces problematic hypertonicity for children with CP but does not seem to reduce the future risk of developing deformity, which would then require orthopedic surgery.[160–162] Intrathecal baclofen pumps have been used as a strategy to manage severe spasticity in persons with traumatic brain injury, stroke, spinal cord injury, and CP.[163–165]

Despite pharmacological and positioning interventions, musculoskeletal deformities can still develop, particularly

Table 10.6 Pharmacological Interventions for Individuals With Neurological and Neuromuscular System Impairments

Trade Names	Generic Name (Class)	Administration	Indications	Adverse Effects
MANAGEMENT OF DYSTONIA AND CENTRAL NERVOUS SYSTEM-RELATED SPASM[a]				
NeuroBloc Myobloc	botulinum B toxin (neurotoxin)	Intramuscular	Facial spasm, spasmodic torticollis, blepharospasm	Pain at injection site, ptosis, eye irritation, weakness of neck muscles, dysphagia, dry mouth, heartburn
MANAGEMENT OF HYPERTONICITY, CLONUS, AND TICS[a]				
Botox Dysport	botulinum A toxin (neurotoxin)	Intramuscular or perineural injection, intrathecal	Chronic severe spasticity or dystonia	Pain or bruising at injection site, muscle weakness, tiredness, drowsiness, nausea, anxiety
Catapres	clonidine (antihypertensive)	Oral or transdermal	Spasticity in MS	Dry mouth, gastrointestinal disturbances, fatigue, headache, nervousness, insomnia, skin irritation (transdermal)
Ceberclon Klonopin Rivotril Valpax	clonazepam (benzodiazepine)	Oral	Spasticity in CP, dystonic, chorea, akathisia (also for seizures, panic attacks)	Sedation, dizziness, unsteadiness, incoordination, memory problems, muscle or joint pain, blurred vision, frequent urination
Dantrium	dantrolene sodium (skeletal muscle relaxant)	Oral or injection	Chronic severe spasticity of UMN origin	Drowsiness, dizziness, generalized weakness, malaise, fatigue, nervousness, headache
Ethanol	ethyl alcohol (neurotoxin)	Intramuscular or perineural injection	Severe spasticity, with serial casting follow-up	Neuritis, hyperesthesia, or paresthesia
Lioresal	baclofen (skeletal muscle relaxant)	Oral, injection, or intrathecal	Chronic severe spasticity for conditions including SCI, ABI, MS; not effective in CP	Sedation, confusion, hypotension, dizziness, ataxia, headache, tremor, nystagmus, paresthesia, diaphoresis, muscular pain or weakness, insomnia, behavioral changes
Neurontin	gabapentin	Oral	Adjunct to other antispasticity medications for SCI and MS	Drowsiness, dizziness, ataxia, fatigue, nystagmus, nervousness, tremor, diplopia, memory impairment
Phenol	phenol	Intramuscular or perineural injection	Severe lower limb spasticity (with serial casting follow-up) pain control	Damage to other neural structures
Robaxin	methocarbamol	Oral or injection	Short-term relief of muscle spasm or spasticity	Sedation, drowsiness, lightheadedness, fatigue, dizziness, nausea, restlessness

Table 10.6 Pharmacological Interventions for Individuals With Neurological and Neuromuscular System Impairments (Continued)

Trade Names	Generic Name (Class)	Administration	Indications	Adverse Effects
Valium	diazepam	Oral or injection	Short-term relief of muscle spasm or spasticity	Sedation, drowsiness, fatigue, ataxia, confusion, depression, diplopia, dysarthria, tremor
Zanaflex Sirdalud	tizanidine (skeletal muscle relaxant)	Oral	Spasticity from MS or SCI	Sedation, drowsiness, fatigue, dizziness, mild weakness, nausea, hypotension, GI irritation
MANAGEMENT OF DYSESTHESIA/NEUROPATHIC PAIN[b]				
Carbatrol Epitol Tegretol Dilantin Neurontin Zonegran Norpramin	carbamazepine phenytoin gabapentin zonisamide desipramine (anticonvulsants)	Oral	Trigeminal neuralgia, pelvic pain, intense episodic/lancinating/burning pain, pins/needles, cramping, dysesthetic extremity pain, tonic spasms, other neurogenic pain, nocturnal spasms	See Seizure Medications
Adapin Sinequan Triadapin Zonalon Elavil Imavate Janimine Tofranil Vivactil	doxepin amitriptyline imipramine protriptyline (tricyclic antidepressants)	Oral	Chronic neurogenic pain (e.g., dysesthetic extremity pain such as burning, tingling)	Drowsiness, blurred vision, dizziness, GI and urinary disturbances, tachycardia, hypotension, weight gain, fatigue, headache
MANAGEMENT OF SEIZURES[c]				
Amytal	amobarbital (barbiturate)	Intravenous	Status epilepticus	Sedation, nystagmus, ataxia, vitamin K and folate deficiency
Ativan	lorazepam (benzodiazepine)	Intravenous	Status epilepticus	Sedation, ataxia, changes in behavior
Atretol Convline Epitol Macrepan Tegretol	carbamazepine (iminostilbene)	Oral	Complex partial seizures, tonic-clonic seizures, trigeminal neuralgia, bipolar disorder	Ataxia, diplopia, drowsiness, fatigue, dizziness, vertigo, tremor, headache, nausea, dry mouth, anorexia, agitation, rashes photosensitivity, heart failure
Celontin	methsuximide (succinimide)	Oral	Alternative to ethosuximide for absence seizures	Nausea, vomiting, headache, dizziness, fatigue, lethargy, dyskinesia, bradykinesia
Cerebyx	fosphenytoin (hydantoin)	Intravenous	Status epilepticus	GI irritation, confusion, sedation, dizziness, headache, nystagmus, ataxia, dysarthria
Depacon	Sodium valproate (carboxylic acid)	Oral or injection	All types of seizures	Ataxia, tremor, sedation, nausea, vomiting, hyperactivity weakness, incoordination, risk of hepatotoxicity
Depakene	valproic acid (carboxylic acid)	Oral	Absence seizures, as adjunct for other seizure types	Nausea, sedation, ataxia headache nystagmus, diplopia, asterixis, dysarthria, dizziness, incoordination, depression, hyperactivity, weakness, risk of hepatotoxicity
Depakote	divalproex sodium (carboxylic acid)	Oral	Complex partial seizures, absence seizures, as adjunct for other seizure types	Headache, asthenia, nausea, somnolence, tremor, dizziness diplopia, risk of hepatotoxicity
Diamox	acetazolamide (sulfonamide)	Oral	Absence seizures, myoclonic seizures	Drowsiness, dizziness
Dilantin Diphen Diphentoin Dyantoin Phenytex	phenytoin (hydantoin)	Oral or injection	Status epilepticus, tonic-clonic seizures, simple complex seizures	Ataxia, slurred speech, confusion, insomnia, nervousness, hypotension, nystagmus diplopia, nausea, vomiting
Felbatol	felbamate (2nd generation)	Oral	Partial seizures, absence seizures Used for severe seizure disorders unresponsive to other medications	Aplastic anemia, liver failure, insomnia, headache, dizziness, loss of appetite, nausea, vomiting

Continued on following page

Table 10.6 Pharmacological Interventions for Individuals With Neurological and Neuromuscular System Impairments (Continued)

Trade Names	Generic Name (Class)	Administration	Indications	Adverse Effects
Gabitril	tiagabine (2nd generation)	Oral	Partial seizures	Generalized weakness, dizziness, tiredness, nervousness, tremor, distractibility, emotional lability
Keppra	levetiracetam (2nd generation)	Oral	Adjunct for partial seizures in adults	Sedation, dizziness, generalized weakness
Klonopin Rivotril	clonazepam (benzodiazepine)	Oral or injection	Myoclonic seizures, absence seizures, kinetic seizures	Drowsiness, dizziness, ataxia, dyskinesia, irritability, disturbances of coordination, slurred speech, diplopia, nystagmus, thirst
Lamictal	lamotrigine (2nd generation)	Oral	Partial seizures, tonic-clonic seizures	Dizziness, headache, ataxia, drowsiness, incoordination, insomnia, tremors, depression, anxiety, diplopia, blurred vision, GI disturbances, agitation, confusion, rash
Luminol Solfoton	phenobarbital (barbiturate)	Oral or injection	Status epilepticus, all seizure types except absence seizures	Drowsiness, lethargy, agitation, confusion, ataxia, hallucination, bradycardia, hypotension, nausea
Mebaral	mephobarbital (barbiturate)	Oral	Tonic-clonic seizures, simple and complex partial seizures	Drowsiness, sedation, nystagmus, ataxia, folate and vitamin K deficiency
Mesantoin	mephenytoin (hydantoin)	Oral	Partial seizures, tonic-clonic seizures used if Dilantin is not effective	Similar to Dilantin, but more toxic
Milontin	phensuximide (succinimide)	Oral	Alternative to Zarontin for absence seizures	Nausea, vomiting, headache, dizziness, fatigue, lethargy, bradykinesia, dyskinesia
Mysoline	primidone (barbiturate)	Oral	All seizure types except absence seizures, essential tremor	Ataxia, vertigo, drowsiness, depression, inattention, headache, nausea, visual disturbances
Nembutal	pentobarbital (barbiturate)	Intravenous	Tonic-clonic seizures, simple and complex partial seizures	Sedation, nystagmus, ataxia, vitamin K and folate deficiency
Neurontin	gabapentin (2nd generation)	Oral	Partial seizures in adults and children older than 3 years, neuropathic pain	Drowsiness, dizziness, ataxia, fatigue, nystagmus, nervousness, tremor, diplopia, memory impairment
Peganone	ethotoin (hydantion)	Oral	Tonic-clonic seizures; used if Dilantin is not effective	Similar to Dilantin, but more toxic
Seconal	secobarbital (barbiturate)	Intravenous	Tonic-clonic seizures, partial seizures	Sedation, nystagmus, vitamin K and folate deficiency
Topamax	topiramate (2nd generation)	Oral	Partial seizures, adjunct to tonic-clonic seizures	Ataxia, confusion, dizziness, fatigue, paresthesia, emotional lability, confusion, diplopia, nausea
Thosutin Zarontin	ethosuximide (succinimide)	Oral	Absence seizures	Drowsiness, headache, fatigue, dizziness, ataxia, euphoria, depression, myopia, nausea, anorexia
Tranxene	clorazepate (benzodiazepine)	Oral	Adjunct for partial seizures	Sedation, ataxia, changes in behavior
Trileptal	oxcarbazepine (iminostilbene)	Oral	Partial seizures, tonic-clonic seizures	Ataxia, drowsiness, nausea, dizziness, headache, agitation, memory impairment, asthenia, ataxia, confusion, tremor, nystagmus
Valium Valrelease	diazepam (benzodiazepine)	Injection	Status epilepticus, severe recurrent seizures	Drowsiness, fatigue, ataxia, confusion, depression, dysarthria, syncope, tremor, vertigo
Zonegran	zonisamide (2nd generation)	Oral	Adjunct for partial seizures in adults	Sedation, ataxia, loss of appetite, fatigue

in the growing child. Surgical interventions are used to correct musculoskeletal defaults of the spine and limbs, realign joints for better mechanical advantage, improve ease of caregiving and hygiene management, promote cosmesis, or reduce and prevent pain. Tendon lengthenings or transfers are commonly used to correct contractures and provide greater functional ROM to improve the ability to walk in children with CP.[84,166–169] Derotation osteotomies are another option that have traditionally been used to improve or correct deformity and improve walking ability in children with CP.[170–173] Because children with CP and acquired brain injury who have significant hypertonicity are at risk for developing neuromuscular scoliosis, various spinal surgeries are used to improve spinal alignment and reduce pelvic obliquity, to improve physiological and daily function, and to reduce caregiver burden.[174–176] Rather than subject children with CP to multiple surgeries over time, many centers perform multiple procedures at the same time.[177,178] To achieve maximum benefit, rehabilitation is a necessary component following any of these surgeries.[84,179–181]

Individuals with significant spasticity are commonly managed with a combination of these strategies to most effectively diminish the impairment, improve the functional ability, and help them participate in activities that are important to them.[182–184] Increasingly, instrumented gait analysis is being used inform clinical decision making in selecting the most appropriate intervention or combination of interventions for ambulatory individuals with functional limitation secondary to neuromuscular pathologies and their associated secondary impairments.[185–188]

REHABILITATION

Rehabilitation professionals use a variety of examination strategies to determine the nature and extent of dysfunction across systems that are associated with a particular pathological condition. The components of a complete evaluation when considering orthotic or equipment decisions include asking specific history questions, a biomechanical analysis of the limb(s)/segment(s), examination of neuromotor status, motor control, functional movement ability, integumentary integrity, sensory processing, cognitive function, and psychosocial factors. See Table 10.7 for an example.[9,189] The physical therapist evaluates this information to (1) determine an appropriate movement-related physical therapy diagnosis, (2) predict potential outcomes (prognosis), and (3) structure an appropriate plan of care.[189–191]

Physical therapists use adaptive equipment, orthoses, and seating as key components of an effective plan of care for persons with neuromotor/neurosensory system dysfunction.[192–196] Consideration of the use of an orthotic or other equipment must be made in the context of the patient's activity needs/desires and participation in life activities that contribute to quality of life.[197]

Orthoses are used to:

1. align or position limb segments to enhance voluntary limb movement and improve function (e.g., an ankle-foot orthosis [AFO] to provide prepositioning of the foot during swing limb advancement and stability during the stance phase of gait);
2. minimize the influence of abnormal tone on posture and movement (tone-inhibiting designs);
3. provide individuals with a variety of comfortable and safe positions in which they can sleep, eat, travel, work, or play;
4. promote joint alignment and minimize risk of contracture development and other secondary musculoskeletal sequelae (especially in growing children);
5. protect a limb following orthopedic surgery performed to correct deformity or instability;
6. enhance alignment following pharmacological intervention with botulinum toxin; and
7. provide alternative methods for mobility.

The risk for developing secondary musculoskeletal impairments is high in the presence of hypertonicity.[108,197–200] Passive stretching programs alone are generally ineffective as a management strategy for reducing risk for contracture development.[201,202] Prolonged positioning for several hours a day is a critical adjunct to stretching.[203–205] Adaptive equipment can be used to provide structural alignment for prolonged periods of time to maintain extensibility of muscles, decrease the effect of muscle imbalance across joints, and provide postural support, particularly to increase effectiveness in daily activities such as feeding and play.[206–208] An adaptive seating system, for example, would provide upright postural support for sitting; maintain spinal alignment and pelvic positioning; support optimal hip, knee, and ankle positions; and promote the best position for upper extremity function.[206–210] Positioning devices for supported standing are often used to maintain extensibility of muscles, to promote bone mineral density through weight bearing, and to promote musculoskeletal development such as acetabular depth in a developing child with hypertonicity (Fig. 10.7).[211–213] Other examples of positioning devices include prone, supine, and sidelyer systems, bathing and toileting seating systems, and a variety of mobility alternatives such as gait trainers.[214–217] Although there are many options for adaptive equipment designed to assist function and caregiving for persons with neurological and neuromuscular dysfunction, knowledge about options and limitations in funding limit access for many who might otherwise benefit from such devices.[218–221]

Serial corrective casts have long been used as a primary intervention for individuals with significant hypertonus to provide a prolonged elongation of soft tissue over a long time period. They increase the length of a contracted muscle and its supportive tissues and reset the threshold for response to stretch reflex.[155–160,203] Some splints or dynamic orthoses are used primarily at night to provide 8 or more hours of stretch on a regular basis; others can be worn during daily activities to provide a longer period of stretch (Fig. 10.8).[222–226] More recently, serial casting and dynamic splinting have been used in conjunction with pharmacological interventions for the management of spasticity in both children and adults with severe hypertonicity (Fig. 10.9).[203,222,227,228] Although the pharmacological agent may reduce the degree of spasticity in hypertonic muscles, concomitant shortening of the muscles and tendons must be addressed while the neurological influence is altered, as should concomitant deficits in other dimensions of muscle performance and motor control.[229–231] A young child with CP—spastic diplegia, for example—may receive botulinum injections to the gastrocnemius and soleus muscles to reduce the severity of spasticity as an alternative to early orthopedic surgery.[232,233]

Table 10.7 Elements of a Physical Therapy Examination in Consideration for Prescription/Use of Orthoses, Adaptive Equipment, or Serial Casting

Examination Element	Examination Strategies	Implications for Orthosis, Equipment or Cast
Chief complaint: What is the *MOVEMENT PROBLEM* that brings the individual to physical therapy?	Interview of individual and caregivers	Ambulation/gait dysfunction—consider need for LE orthosis. Reach, grasp, manipulation dysfunction—consider need for UE orthosis
History of current illness, past medical history: How did the *MOVEMENT PROBLEM* develop or evolve? Explore duration of the presenting problem; previous and concurrent pharmacological management; previous and concurrent orthopedic or neurosurgical management; previous orthotic management; Current health status; Comorbidities and their management	Review of medical record Interview with individual and caregivers Consultation with clinical colleagues	Consider what strategies are currently working or not. Consider combination of strategies that might be possible. For example, hypertonicity reduction medication coupled with an orthosis
Biomechanical evaluation: ROM, flexibility (especially of multijoint muscles), muscle length, alignment of joints, pelvis, and spine, torsional/rotational deformity of hip, femur, tibia,	Goniometric measurement; Evaluation of muscle length (e.g., Thomas test, straight-leg raise); integrity of ligaments and supportive structures; radiograph; inclinometer	Consider strategies for contracture management. For example, Botox injection followed by serial casting or orthosis. If contracture may be "permanent" or severe, consider accommodation needs for positioning. For example, heel wedge to accommodate fixed plantarflexion contracture
Postural alignment in sitting and standing	Spatial relationships of head, upper trunk/limb girdle, mid trunk, lower trunk/pelvic girdle, extremity symmetry	Consider seating or standing adaptations and/or seating/standing systems
Anthropomorphic characteristics	Height, weight, limb length, limb girth, body mass	Implications for sizing
Neuromotor status: Muscle tone (compliance vs. stiffness) Deep tendon reflex testing Antigravity stiffness/postural tone Involuntary movement	Resistance to passive movement at various speeds Palpation tone scales (e.g., modified Ashworth), descriptive category (hypertonic/spastic, rigid, hypotonic, fluctuating, flaccid) amplitude of response, pattern of response (distal-proximal), symmetry of response	Consider strategies and combination of strategies to manage hypertonicity
Motor control: Recruitment/adaptation of contractions Segmentation of limbs, joints within a limb	Ability to move between concentric, eccentric, and holding contractions during functional activity Ability to initiate, sustain, and terminate contraction and movement. Influence of abnormal synergy or abnormal developmental reflexes	Determine if trunk or extremities require positioning or orthosis to provide control (minimize tonal influence, support body structure)
Muscle performance: Strength Speed/power Accuracy Timing Fluidity Muscle endurance Relationship of agonist/antagonist	Observation of antigravity movement Manual muscle testing, dynamometer Isokinetic testing Description: hypokinetic, functional, hyperkinetic Control for concentric, eccentric, isometric contractions, repetitions to test endurance	Consider postural support requirements for UE tasks; trunk and LE support requirements for LE tasks
Postural control	Static balance tests (e.g., timed single limb stance) Anticipatory balance tests (e.g., reach distances, ability to change direction) Reactionary balance test: perturbation	Consider postural support requirements for UE tasks; trunk and LE support requirements for LE tasks
Functional movement ability, functional task abilities ADL	Ability to adapt movement strategies in different environmental conditions and to different task demands. Observation of movement during task Self-report of individual or caregiver Various ADL scales Ability to don/doff orthosis	Consider orthoses to improve efficiency, effectiveness of movement. Consider equipment that may assist in task completion

Table 10.7 Elements of a Physical Therapy Examination in Consideration for Prescription/Use of Orthoses, Adaptive Equipment, or Serial Casting (Continued)

Examination Element	Examination Strategies	Implications for Orthosis, Equipment or Cast
Dexterity, coordination, agility	Observation of performance during functional activity Special tests Developmental scales and profiles	Consider orthoses to improve efficiency, effectiveness of movement
Transitional movements and transfers To/from floor Sit to stand Bathroom transfers Car transfers	Assistance required Level of difficulty Task analysis to identify where in movement difficulty occurs and contributors to difficulty	Consider LE orthosis for standing and movement needs; consider seating needs, wheelchair usage. Consider mechanical lift needs
Mobility and locomotion	Observational gait analysis, with and without orthosis Gait speed, other kinematic measures Use of assistive devices Level of assistance required Gait lab kinetic measures (moments, torques, force plate, activity via video, and EMG analysis	Consider orthosis needs for gait cycle impairments. Consider assistive device needs
UE function and use of hands	Observation during various fine and gross UE motor tasks	Consider UE orthosis needs
Cardiovascular endurance	Heart rate, blood pressure, oxygen saturation during activity Ratings of perceived exertion during tasks 6-Minute walk test Fatigue scales	Consider orthosis for efficiency, to decrease energy expenditure
Environmental assessment (home, work, school, leisure)	Environmental safety checklists Interview with individual and caregivers about characteristics of environments in which individual must function	Consider environmental adaptations
Integumentary integrity Skin condition	Inspection for neuropathic, dysvascular, or traumatic wounds Document callus and scarring Document pressure sensitive areas Document protective sensation, insensate weight-bearing areas	Consider protection of vulnerable areas; consider custom fit to minimize/prevent wound development
Sensory organization and processing Sensory integrity	Adequacy of vision (acuity, peripheral vision, tracking, visual field loss) Screening for exteroception, proprioception ability Document insensate areas, especially of hands/feet Document paresthesia and dysesthesia	Consider protection of vulnerable areas; consider custom fit to minimize/prevent wound development
Perceptual function Visual spatial perception Awareness of position in space Awareness of body parts	Observation of movement during functional tasks Developmental tests, measures Special perceptual tests, measures	Consider workstation, home adaptations
Cognitive function: Ability to learn and remember Ability to problem solve Motivation Distractibility/focus Ability to manage frustration, uncertainty	Reports of teachers, clinicians; neuropsychological testing; Observation when presented with challenge; Self-report of individual and caregivers	Consider ability to manage orthosis, cleaning and maintenance of devices. Consider ability to don/doff orthosis. Consider ability to know if fit feels wrong and ability to seek appropriate assistance
Communication	Adequacy of hearing and auditory processing; Ability to understand language; Ability to use language; Oral-motor function (dysarthria); Impact of position on voice	Consider ability to understand and follow instructions for proper fit, wearing schedules
Psychosocial factors Desired participation in leisure or play activities, school or work-related activities. Family and caregiver Quality of life	Typical activities and roles: demands and barriers encountered for activities. Availability and capacity of others to assist with respect to use of orthosis Self-efficacy scales Patient/caregiver satisfaction with orthosis/device	Consider use of orthosis, adaptive equipment for different environments. Consider training of caregiver if needed

Truman H, Racette W. Orthotics: evaluation, intervention, and prescription. In: Umphred DA, ed. *Neurological Rehabilitation*. 6th ed. St. Louis: Mosby; 2013:1037–1052.

SELECTING THE APPROPRIATE ORTHOSIS

Rehabilitation professionals play an active role in deciding what type of orthosis would be most appropriate for an individual with neuromuscular impairment. A number of factors contribute to the decision-making process; the collective wisdom of physical and occupational therapists, orthotists, physicians, family, and the patient who might benefit from orthotic intervention is necessary for appropriate and effective casting or orthotic intervention.[192,234,235]

Fig. 10.7 Example of adaptive equipment (stander) available to assist appropriate alignment and function in the presence of impairment of muscle tone, muscle performance, postural control, or difficulty with movement and coordination.

The primary goal of orthotic or adaptive equipment prescription is to select the device and components that will best improve function, given the individual's pathologic condition and prognosis, desired activities, and participation needs, both in the immediate situation and over time. To do this, the cast, splint, or orthosis might provide external support, control or limit ROM, optimally position a limb for function, reduce the risk of secondary musculoskeletal complications, or provide a base for adaptive equipment that would make function more efficient. What evidence is available to support clinical decision making with respect to orthotic prescription? Although many professionals rely on expertise gained by working with persons with neuromotor impairment over years of clinical practice, a growing number of articles on orthotic design for particular patient populations in the rehabilitation and orthotic research literature are available to guide decision making not only for individuals with hypertonicity but also for those with spinal cord injury, myelomeningocele, and muscular dystrophy.[195,234–241] Evaluation of the effectiveness of the orthotic intervention is becoming increasingly important in clinical decision making. Several articles related to specific outcome measures for effectiveness of orthotic use and patient satisfaction have recently been published.[242–245]

This chapter has discussed general orthotic and adaptive equipment usage; however, lower extremity orthotics are often a significant component of physical therapy practice, particularly for ambulation and gait dysfunction. When the primary goal of orthotic intervention is to improve safety and functionality during ambulation, it is imperative to identify where in the gait cycle abnormal tone or muscle performance is impaired (refer to Chapter 5 for more information on critical events in each subphase of gait, as well as detailed information about strategies to examine gait). Systematic consideration of

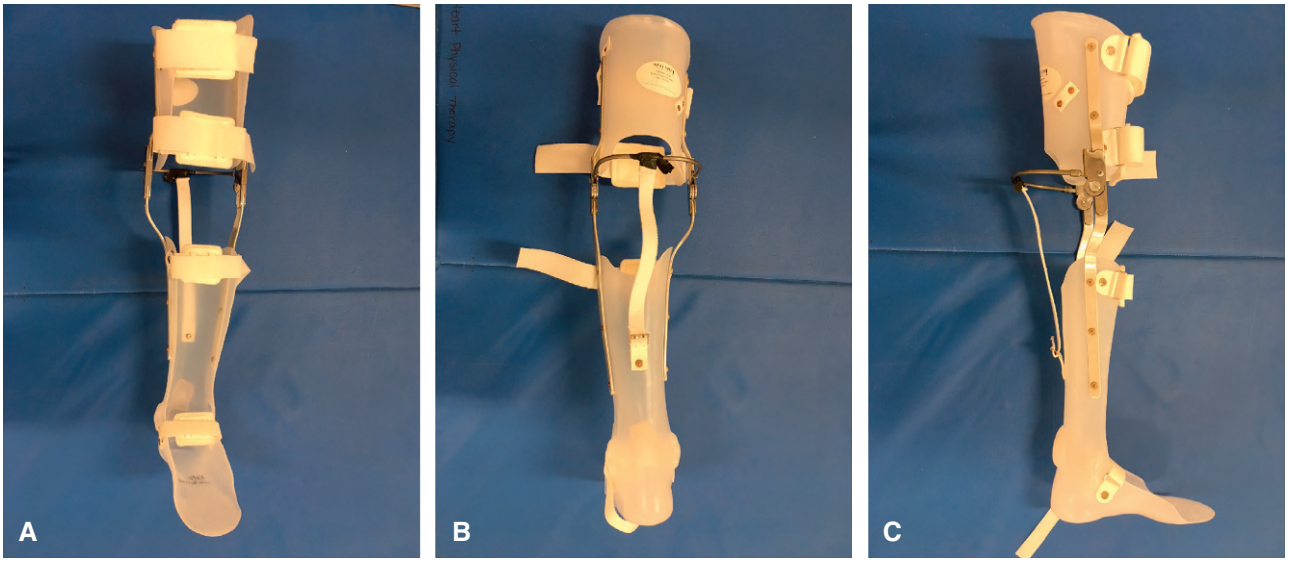

Fig. 10.8 Example of knee/ankle/foot orthosis *(KAFO)* with knee extension stop. (A) Front view. (B) Back view. (C) Side view.

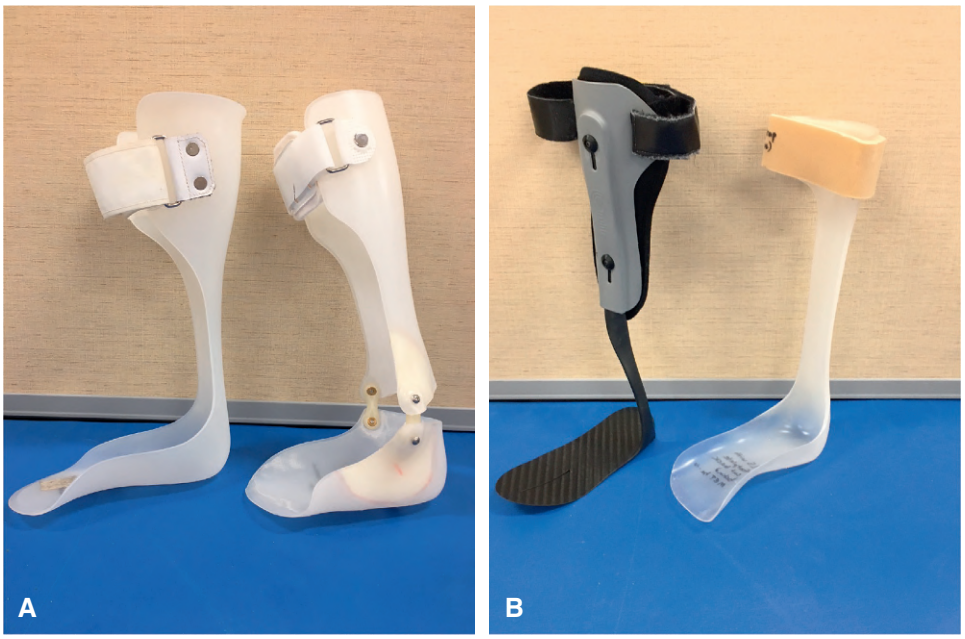

Fig. 10.9 Examples of ankle/foot orthoses *(AFO)*. (A) Pictured on the left is a custom molded solid AFO and pictured on the right is a custom molded hinged AFO. (B) Pictured on the left is a carbon fiber floor reaction AFO and pictured on the right is a custom molded posterior leaf spring AFO.

a series of questions can help identify where within the gait cycle (considering both stance and swing phases) problems occur.[246–248]

Rehabilitation professions must recognize that no orthosis will normalize gait for persons with neurologically based gait difficulties. Whenever an external device is placed on a limb, it is likely to solve one problem while at the same time creating other constraints on limb function. The therapist, orthotist, and patient collectively problem solve during the orthotic prescription phase to prioritize the difficulties the individual is having during gait and then select the design and components that will allow the person to be most functional while walking, with the least additional constraint on other mobility and functional tasks.

The rehabilitation team at Rancho Los Amigos National Rehabilitation Center has developed an algorithm that is particularly useful in guiding clinical decision making and sorting through possible orthotic options for adults with neuromotor impairment (ROADMAP: Recommendations for Orthotic Assessment, Decision Making, and Prescription).[192] When considering orthotic interventions for persons having difficulty with ambulation, this team suggests asking the following questions:

1. Is there adequate ROM in the lower extremities to appropriately align or position limb segments in each subphase of gait?
2. Does the individual have the motivation and cognitive resources necessary to work toward meeting the goal of ambulation?
3. Does the individual have enough endurance (cardiovascular and cardiopulmonary resources) to be able to functionally ambulate? If endurance is not currently sufficient, might it be improved by a concurrent conditioning program?
4. Does the individual have adequate upper extremity, trunk, and lower extremity strength; power; motor control; and postural control for ambulation (with an appropriate assistive device, if necessary)? If these dimensions of movement are not currently sufficient, might they be improved with concurrent rehabilitation intervention?
5. Is there sufficient awareness of lower limb position (proprioception, kinesthesia) for controlled forward progression in gait? If not, might alternative sensory strategies be learned or used to substitute for limb position sense?

If the answers to most of these questions are "yes," the individual is considered to be a candidate for orthotic intervention. The next determinant is knee control and strength: If the individual has antigravity knee extension with the ability to respond to some resistance (manual muscle testing grade of 3+ strength), even if there is impaired proprioception in the involved limb, then an AFO may be appropriate. If there is impairment of strength or of proprioception (or both), then the team is more likely to recommend a knee/ankle/foot orthosis (KAFO). Box 10.1 is an example of a decision tree used to guide the selection of components.

Especially important is that the individual who will use the orthosis and caregivers, as appropriate, are actively involved in the decision-making process. To make an informed decision, the person needing an orthosis must understand both the benefits and constraints associated with the orthotic designs and components being considered. He or she must be able to consider the range of orthotic options, as well as medical/surgical intervention and additional rehabilitation interventions that might affect his or her ability to walk. The entire team must consider what the individual who will be wearing the orthosis wants to accomplish, as well as the preferences he or she might have in terms of ease of donning/doffing, wearing schedule, and cosmesis of the device being recommended. Beginning with a trial orthosis, perhaps

Box 10.1 Decision Tree for Orthotic Options

Is a KAFO Indicated?

- Is there at least antigravity with some resistance (MMT 3+/5 strength) in quadriceps bilaterally?
- Is proprioception intact bilaterally?

If yes: continue with the assessment for ankle-foot orthosis (AFO)
If no: KAFO may improve gait—continue assessment process

Which KAFO Components Are the Most Appropriate?

- Is there at least antigravity with some resistance (MMT 3+/5 strength) in one lower extremity?
- Is proprioception intact in at least one lower extremity?

If no: consider trial of bilateral KAFOs or a reciprocal gait orthosis
If yes: unilateral KAFO may be indicated—continue assessment to determine if knee locking mechanism is necessary

Can the Knee Be Fully Extended, Without Pain, During Stance?

If no: consider KAFO with knee lock
If yes: consider KAFO with variable knee mechanism and continue assessment

Is There at Effective Active Control of Knee Extension During Stance?

If no: consider stance control knee mechanism
If yes: consider free motion knee mechanism. Continue with AFO decision tree to determine appropriate ankle control strategy

Is an AFO Indicated?

- Is there impairment of ankle strength?
- Is there impairment of proprioception?
- Is there hypertonicity of plantarflexors?
- Is there a combination of all of the above?

If no: may not require lower extremity orthosis
If yes: lower extremity orthosis may improve gait—continue assessment process

Which AFO Design and Components Are the Best Option?

- Does impaired strength hamper foot position in stance or swing?
- Does impaired proprioception hamper foot placement in stance or swing?
- Does hypertonicity/spasticity hamper foot position in stance or swing?

If no: consider adjustable articulating ankle joint (allows full DF and PF)
If yes: consider limiting or blocking ankle motion and continue assessment process

Is There More Than Minimal Impairment of Static and Dynamic Postural Control in Standing?

- Is there significant spasticity?
- Is proprioception significantly impaired?

If no: consider adjustable articulating ankle joint that blocks PF beyond neutral ankle position and continue assessment
If yes: consider solid-ankle AFO or adjustable articulating ankle that is fully locked (consider rocker bottom shoe)

- Is there also plantarflexion strength $\leq$MMT 4 in standing?
- Is there also excessive knee flexion and dorsiflexion during stance?
- Is there also excessive plantarflexion with knee hyperextension during stance?

If no: consider adjustable articulating ankle joint with PF stop, and continue assessment
If yes: consider adjustable articulating ankle joint with PF stop and limited DF excursion, and continue assessment

- Is there also dorsiflexion strength $\leq$4 in standing?

If no: consider adjustable articulating ankle with PF stop, limited DF excursion instance, no DF assist necessary
If yes: consider adjustable articulating ankle with PF stop, limited DF excursion, and DF assist for effective swing phase

DF, Dorsiflexion; *KAFO*, knee-ankle-foot orthosis; *MMT*, manual muscle testing; *PF*, plantarflexion.

a prefabricated or multiadjustable version would be helpful before finalizing the orthotic prescription, especially if it is unclear whether ambulation will eventually be possible. Certainly, most individuals with neuromuscular conditions that compromise their ability to walk benefit from a chance to experience what ambulation with an orthosis requires, given their individual constellation of impairments. Some may decide that using orthoses and an appropriate assistive device for functional ambulation throughout the day meets their mobility needs. Others may opt, because of the energy cost of walking with knee-ankle-foot orthoses or hip-knee-ankle-foot orthoses, to use a wheelchair for primary mobility and reserve the use of orthoses to exercise bouts aimed at building cardiovascular endurance. Some may decide that orthotic intervention will not meet their needs and pursue other avenues to address mobility and endurance issues. Once a decision is made and the orthosis or adaptive equipment has been procured, education and practice are key components to successful adoption and usage of the device. The patient and the family/caregiver need specific training for each device including don/doff, putting patient into or out of the device, visual inspection for proper fit, and wear/use schedules. Additionally, training must include the assessment of skin integrity after use. Following trail usage and time for practice with the device for a period of time, the rehabilitation team must assess the patient/family/caregiver satisfaction with the product. Education, time, and practice with the product are the best indicators of long-term usage with functional benefits.[242–245]

Summary

This chapter reviews several factors that influence the need for orthotics and adaptive equipment usage in the presence of neurological and neuromuscular disorders. The factors discussed include the functions and roles of structures and systems in both the CNS and the PNS; the impairments that are likely to occur when particular structures or systems are damaged by injury or disease process; abnormalities of tone and muscle performance; influence of impaired motor control on an individual's ability to move effectively and

efficiently (including ambulation); the likelihood of developing secondary musculoskeletal impairments; and some of the pharmacological and surgical options available to manage hypertonicity and correct deformity that may develop over time. Strategies to determine gait cycle dysfunction in an individual with various neuromotor impairments are explored, as well as the orthotic options that might best address those limitations that the individual faces. This chapter provides a strong foundation for physical therapy examination and considerations for orthotic/equipment prescription. Next, the reader should consider physical therapy interventions that follow orthotic acquisition. The following case examples provide an opportunity for readers to focus on wearing, using, and caring for the prescribed orthosis, including (1) strategies to enhance motor learning when a new ambulatory aid (orthosis and/or assistive device) is introduced, (2) practice using the device under various environmental conditions (surfaces, obstacles, people moving within the environment), and (3) the ability to use the orthosis and ambulatory assistive device during functional activities, beyond walking, at comfortable gait speed.

Case Example 10.1 **A Young Child With Spastic Diplegic Cerebral Palsy**

T.H. is a 4-year-old child who was born prematurely at 32 weeks' gestation and was diagnosed with spastic diplegic cerebral palsy (CP) at 10 months of age. She is being evaluated for potential botulinum A injection as a strategy to manage significant extensor hypertonicity that is increasingly limiting her ability to ambulate as she grows. At present she uses bilateral articulating ankle-foot orthoses with a plantarflexion stop and a posterior rolling walker for locomotion at home and at preschool. Her articulating orthoses allow her to move into some dorsiflexion as she transitions to and from the floor during play. She has difficulty pushing to stand from half-kneel secondary to poor force production of hip and knee extensors. Muscle endurance is impaired, contributing to a crouch gait position, especially as she tires after a full day of activity. She falls frequently when she tries to run. She has been monitored in a CP clinic at the regional children's hospital; the team is concerned that she is developing rotational deformity of the lower extremities, as well as plantarflexion contracture and forefoot deformity due to her longstanding hypertonicity.

QUESTIONS TO CONSIDER

- In which subphases of the gait cycle is function or safety compromised when T.H. ambulates without her orthoses?
- In what way does T.H.'s hypertonicity contribute to her difficulty with floor mobility and ambulation?
- In what ways does T.H.'s inadequate muscle performance contribute to her difficulty with floor mobility and ambulation? What are the most likely dimensions of muscle performance that are impaired, given her diagnosis of spastic diplegia?
- Are there primary or secondary musculoskeletal impairments that are influencing her function and safety during ambulation? How do her age and future growth influence her risk for developing secondary impairments?
- Given her constellation of impairments, how can ambulation become more efficient and effective?
- What orthotic options (design, components) are available to address T.H.'s impairment of locomotion and related functional limitations? What are the pros and cons of each?
- What alternative or concurrent medical (surgical/pharmacological) interventions might assist improvement in safety and function for T.H.?
- What additional rehabilitation interventions might assist improvement in function and safety for T.H.?
- How do you anticipate T.H.'s orthotic needs might change as she develops and grows?
- What outcome measures are appropriate to assess efficacy of orthotic, therapeutic, pharmacological, or surgical intervention for T.H.?

Case Example 10.2 **A Child With Spastic Quadriplegic Cerebral Palsy**

J.T. is an 11-year-old boy with significant spastic quadriplegic cerebral palsy (CP) who is in the midst of a preadolescent growth spurt. He currently uses a custom seating system in a wheelchair for assisted mobility at school and in the community. At home he divides his time between an adaptive seating system and using a ceiling-mounted tracking system for assisted standing and mobility. J.T.'s mom reports that it is becoming increasingly difficult to transfer him in and out of the chair and help him with self-care activities because of upper extremity flexor tightness, increasing hip and knee flexion contractures, plantarflexion tightness, and his growing size.

In addition, when supine, J.T.'s resting position is becoming more obviously "windswept," with excessive right hip external rotation and excessive left hip internal rotation, causing a pelvic obliquity and rotation in his spine. He receives physical therapy at school several times each week to help him with functional abilities in the classroom and around school, with additional outpatient visits focusing on improving postural control and muscle performance. Both of his therapists are becoming concerned about his increasing limitation in range of motion (ROM), as well as the risk for increasing hip rotational deformity and spinal deformity as he grows. His outpatient therapist accompanies J.T. and his mother to the CP orthotics clinic at the regional children's medical center to explore the possibility of functional bracing or dynamic orthoses, or both, to manage the musculoskeletal complications that are developing because of his spasticity. They also have questions about surgical and pharmacological intervention.

QUESTIONS TO CONSIDER

- In what way does J.T.'s hypertonicity contribute to his difficulty with mobility/locomotion and other functional activities?
- In what ways does J.T.'s impaired muscle performance contribute to his difficulty with functional activities?
- In what ways does J.T.'s impaired postural control contribute to his difficulty with locomotion/ambulation? What are the

Continued on following page

Case Example 10.2 A Child With Spastic Quadriplegic Cerebral Palsy (Continued)

most likely dimensions of his impairment in postural control, given his diagnosis of spastic quadriplegic CP?
- Are any primary or secondary musculoskeletal impairments influencing J.T.'s function and safety during mobility and transfer tasks?
- Given his constellation of impairments, what compensatory strategies is J.T. likely to use to accomplish his functional tasks at school and at home?
- Which of J.T.'s anticipated or observed impairments are remediable? Which will require accommodation?
- What orthotic options (design, components) are available to address J.T.'s impairments and functional limitations? What are the pros and cons of each?
- What adaptive equipment options are available to address J.T.'s impairments and functional limitations? What are the pros and cons of each?
- Given the pelvic obliquity and spinal rotation, what secondary musculoskeletal complications need to be monitored as J.T. grows? How might these concerns be addressed by seating or orthoses?
- What alternative or concurrent medical (surgical/pharmacological) interventions might assist improvement in safety and function for J.T.?
- What additional rehabilitation interventions might assist improvement in function and safety for J.T.?
- How do you anticipate J.T.'s orthotic and equipment needs might change as he develops and grows?
- What outcome measures are appropriate to assess efficacy of orthotic, equipment, therapeutic, pharmacological, or surgical intervention for J.T.?

Case Example 10.3 A Young Adult With Acquired Brain Injury and Decerebrate Pattern Hypertonicity

P.G. is a 17-year-old girl who sustained significant closed-head injury in a motor vehicle accident 3 weeks ago. She was admitted to the brain injury unit at the regional rehabilitation hospital earlier this week. Now functioning at a Rancho Los Amigos Cognitive Level 5 (confused and inappropriate), P.G. exhibits significant decorticate posturing whenever she attempts to move volitionally (right greater than left). She has marked limitations in passive range of motion (ROM) at the elbow and wrist, as well as equinovarus at the ankle, both of which are limiting her ability to stand and effectively propel her wheelchair. While sitting, she falls when she tries to throw a ball to her therapist. Her gait is characterized by large range ballistic extensor thrust throughout stance, which impedes forward progression. She is most focused and responsive to intervention when involved in ambulation-oriented activities. Currently, her hypertonicity is being managed with oral baclofen (Lioresal). However, her therapists are concerned that contracture formation continues. During rehabilitation rounds, the physiatrist, neurologists, and therapists agree that a trial of serial casting should be added to her regimen to enhance her rehabilitation.

QUESTIONS TO CONSIDER

- In which subphases of the gait cycle is function or safety compromised when G.P. attempts to ambulate?
- In what way does G.P.'s hypertonicity contribute to her difficulty with postural control and locomotion/ambulation?
- In what ways does G.P.'s impaired muscle performance contribute to her difficulty with postural control and locomotion/ambulation? What are the most likely dimensions of her impairment in muscle performance, given her diagnosis of acquired brain injury?
- Are any primary or secondary musculoskeletal impairments influencing her function and safety during ambulation? What do you think is likely to develop as she recovers from her head injury?
- Given her constellation of impairments, what compensatory strategies is G.P. likely to use to accomplish the task of locomotion?
- Which of G.P.'s anticipated or observed impairments are remediable? Which will require accommodation?
- What orthotic options (design, components) are available to address G.P.'s impairment of locomotion and related functional limitations? What are the pros and cons of each?
- What orthotic options (design, components) are available to address G.P.'s impairment of specific joints? What are the pros and cons of each?
- What alternative or concurrent medical (surgical/pharmacological) interventions might assist improvement in safety and function for G.P.?
- What additional rehabilitation interventions might assist improvement in function and safety for G.P.?
- How do you anticipate G.P.'s orthotic needs might change as she recovers over the next year?
- What outcome measures are appropriate to assess efficacy of orthotic, therapeutic, pharmacological, or surgical intervention for G.P.?

Case Example 10.4 Two Individuals With Recent Stroke

You work in the short-term rehabilitation unit associated with the regional tertiary care hospital in your area. This week two gentlemen recovering from stroke sustained 3 days ago were admitted to the unit for a short stay in preparation for discharge home. Both indicate that their primary goals at this time are to be able to walk functional distances within their homes, manage stairs to enter/leave the house, and get to bedrooms on the second floor. You anticipate that they will receive intensive rehabilitation services for 5–8 days, with home care for follow-up after discharge.

M.O., 73 years old with a history of hypertension, mild chronic obstructive pulmonary disease, and an uncomplicated myocardial infarction 2 years ago, has been diagnosed with a lacunar infarct within the left posterior limb of internal capsule. On passive motion, he has been given modified Ashworth scores of 3 in his right upper extremity and 2 in his right lower

Case Example 10.4 **Two Individuals With Recent Stroke (Continued)**

extremity. When asked to bend his knee (when supine), he demonstrates difficulty initiating flexion, and when he finally begins to move, his ankle, knee, and hip move in a mass-flexion pattern; he is unable to isolate limb segments. When asked to slowly lower his leg to the bed, he "shoots" into a full lower extremity synergy pattern. He rises from sitting to standing with verbal and tactile cueing, somewhat asymmetrically, relying on his left extremities. Once upright, he can shift his center of mass (COM) to the midline, holding an effective upright posture, but feels unsteady when shifted beyond midline to the right. With encouragement and facilitation, he can shift weight toward his right in preparation for swing-limb advancement of the left lower extremity, and he is pleased to have taken a few steps, however short, in the parallel bars. Before his infarct, he was an avid golfer and enjoyed bowling. He is fearful that he will never be able to resume these activities.

E.B. is a 64-year-old recently retired car mechanic with an 8-year history of diabetes mellitus previously controlled by diet and oral medications who has required insulin since his stroke. Magnetic resonance imaging indicates probable occlusion in the right posteroinferior branch of the middle cerebral artery, with ischemia and resultant inflammation in the parietal lobe. Because E.B. has been afraid of hospitals for most of his life, he resisted seeking medical care as his symptoms began, arriving at the emergency department 12 hours after the onset of hemiplegia. He currently displays a heavy, hypotonic, somewhat edematous left upper extremity. He is unusually unconcerned about the fact that he has had a stroke and tells you that he should be able to function "well enough" when he returns home to his familiar environment. On examination, he demonstrates homonymous hemianopsia, especially of the lower left visual field, and impaired kinesthetic awareness of his left extremities. You observe that he appears to be unaware when his lower upper extremity slips off the tray table of his wheelchair and his fingers become entangled in the spokes of the wheel as he propels forward using his right leg. When assisted to standing in the parallel bars, he does not seem to be accurately aware of his upright position, requiring moderate assistance to keep him from falling to the left. When asked to try to walk forward a few paces, he repeatedly advances his right lower extremity, even when prompted to consider the position and activity of his lower left extremity.

QUESTIONS TO CONSIDER

- In what ways are the stroke-related impairments observed in these two gentlemen similar or different? How can you explain these differences?
- In what subphases of the gait cycle is function or safety compromised when each of these gentleman attempts to ambulate?
- In what way does each gentleman's abnormal tone contribute to his difficulty with postural control and locomotion/ambulation?
- In what ways does each gentleman's impaired muscle performance contribute to his difficulty with postural control and locomotion/ambulation? What are the most likely dimensions of each man's impairment in muscle performance, given his etiologic condition and location of stroke?
- Are any primary or secondary musculoskeletal impairments influencing each man's function and safety during ambulation? How does each man's age and concomitant medical conditions influence his risk for developing secondary impairments?
- Given each gentleman's constellation of impairments, what compensatory strategies are likely to be used to accomplish the task of locomotion in each man?
- Which of each gentleman's anticipated or observed impairments are remediable? Which will require accommodation?
- What orthotic options are available to address each gentleman's impairment of locomotion and related functional limitations? What are the pros and cons of each?
- What alternative or concurrent medical (surgical/pharmacological) interventions might help improve in safety and function for each individual?
- What additional rehabilitation interventions might help improve function and safety for M.O. and E.B.?
- How do you anticipate each gentleman's orthotic needs, which might change as he recovers from central nervous system damage?
- What outcome measures are appropriate to assess the efficacy of orthotic, therapeutic, pharmacological, or surgical intervention for each gentleman?

Case Example 10.5 **A Young Adult With Incomplete Spinal Cord Injury**

Z.C. is a 23-year-old man who sustained an incomplete C7 spinal cord injury 3 weeks ago when he lost control and crash-landed during a failed acrobatic stunt during a half-pipe snowboard competition at a local ski resort. After being stabilized on site, he was quickly airlifted to a regional spinal cord injury/trauma center. Methylprednisolone was administered within 1.5 hours of injury, and his cervical fractures were repaired by fusion (C5 through T1) the day after injury; he now wears a Miami J cervical orthosis. He was admitted to your rehabilitation center 5 days ago. He demonstrates no activity of triceps brachii bilaterally but reports dysesthesia in the C7 and C8 dermatomes and can point his index finger on the left. He is aware of lower limb position in space and can activate toe flexors and extensors, plantarflexors, knee extensors, and hip flexors and abductors at 2+/5 levels of strength. Deep tendon reflex at the Achilles heel is brisk bilaterally, whereas more proximal lower extremity reflexes are diminished. He demonstrates positive Babinski reflex bilaterally. Biceps and wrist extensor deep tendon reflexes, initially diminished, are now rated 2+; the triceps reflex, initially diminished, is now quite brisk. He requires moderate assistance of 1 to come to sitting from supine but can hold a static posture in sitting, demonstrating a limited sway envelope when attempting to shift his weight anteriorly, posteriorly, and mediolaterally. He requires moderate assistance of 1 to rise from seated in his wheelchair to a standing position in the parallel bars. He is determined to "walk" out of the facility on discharge, which is anticipated after 3 more weeks of rehabilitation.

QUESTIONS TO CONSIDER

- Given Z.C.'s history and present point in recovery from spinal cord injury, what is the anticipated prognosis concerning his functional performance and ability to ambulate?

Continued on following page

Case Example 10.5 A Young Adult With Incomplete Spinal Cord Injury (Continued)

- In what subphases of the gait cycle is function or safety likely to be compromised when Z.C. attempts to ambulate?
- In what way does Z.C.'s abnormal tone contribute to his difficulty with postural control and locomotion/ambulation? What strategies would be useful in documenting/assessing the severity and type of his abnormal tone?
- In what ways does Z.C.'s impaired muscle performance contribute to his difficulty with postural control and locomotion/ambulation? What are the most likely dimensions of his impairment in muscle performance, given his etiologic condition and level of injury?
- Are any primary or secondary musculoskeletal impairments likely to influence Z.C.'s function and safety during ambulation? How do Z.C.'s age and concomitant medical conditions influence his risk for developing secondary impairments?
- Given Z.C.'s constellation of impairments, what compensatory strategies is he likely to use to accomplish the task of locomotion?
- Which of Z.C.'s anticipated or observed impairments are remediable? Which will require accommodation?
- What orthotic options (design, components) are available to address Z.C.'s difficulty with locomotion and related functional limitations? What are the pros and cons of each?
- What alternative or concurrent medical (surgical/pharmacological) interventions might assist improvement in safety and function?
- What additional rehabilitation interventions might assist improvement in function and safety for Z.C.?
- How do you anticipate Z.C.'s orthotic needs might change as he recovers from his spinal cord injury?
- What outcome measures are appropriate to assess the efficacy of orthotic, therapeutic, pharmacological, or surgical intervention for Z.C.?

11 Orthoses for Knee Dysfunction ☆

S. TYLER SHULTZ

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Describe the various types and classifications of knee orthoses.
2. Appreciate normal knee function.
3. Identify common knee conditions for which bracing is a component of conservative intervention.
4. Compare and contrast the purposes, indications, and limitations of prophylactic, functional, and rehabilitative knee orthoses.
5. Apply current research evidence to clinical decision making with regard to knee bracing as an intervention, including biomechanical and functional implications.
6. Use evidence of effectiveness to select the most appropriate knee orthosis to a given patient scenario.
7. Provide clinical rationale for utilizing knee orthoses as an intervention for impairments at the tibiofemoral and patellofemoral joints.

Introduction

Knee orthoses are used as a common intervention in orthopedic and physical therapy practice, not only for the treatment of knee impairments, but also for injury prevention. The clinical goals of using knee orthoses include pain reduction, joint protection, functional or recreational improvement, and injury prevention. However, the effectiveness of bracing to meet these clinical goals by providing joint unloading, external stability, or patellofemoral tracking is not universally accepted by clinicians.[1]

Knee orthoses can be organized by their intended function: prophylactic, functional, and rehabilitative knee braces. Prophylactic knee braces are designed and used to protect athletes from sustaining debilitating injuries, usually ligamentous, without inhibiting overall knee function and mobility.[2] Prophylactic bracing continues to be used despite inconclusive evidence supporting brace ability to protect the user from injury.[2,3] Clinically, these braces tend to be used with individuals who are deemed to be at high risk for knee injury, based on their chosen sport and individual history of previous knee dysfunction. Functional knee orthoses (FKOs) attempt to provide external support and biomechanical stability to the joint. FKOs can be further categorized based on impairment or limitation in knee structure with which they are intended to help. FKOs that are designed for individuals who have ligamentous instability, for example, provide external support that would limit the same knee motion as the ligament. These braces can also serve a rehabilitative function, as seen with patients who have suffered anterior cruciate ligament (ACL) rupture and have undergone surgical repair. Furthermore, rehabilitative braces function to provide protection and progressive range of motion (ROM) to the joint (Fig. 11.1). Rehabilitative braces include unloading braces and patellofemoral braces. These braces are used to decrease joint load across the tibiofemoral and patellofemoral joints and reduce pain in the arthritic joint. Orthoses for patellofemoral disorders are rehabilitative braces that often attempt to correct patellar tracking (Fig. 11.2). Each of these different types of braces can be custom-designed for patients or prefabricated. This chapter will describe in further detail the design, function, effectiveness, and clinical decision making involved with the use of these knee orthoses.

In order for a clinician to select and prescribe the appropriate knee orthoses for a patient, a patient-centered approach must be used. The clinician needs not only to understand the purpose for bracing, but also to have an underlying mastery of normal knee structure and function. For example, the knee brace prescribed to an individual following a tear of the ACL would be different than the brace used to treat medial knee osteoarthritis (OA). The implications of a pathologic condition of the knee, as well as the functional goals of braces, will be presented. Indications for bracing in the management of patients with knee injury and dysfunction are also discussed. Clinical scenarios will be presented to assist in developing clinical decision-making regarding brace use in different patient presentations.

Anatomy of the Knee

The articulations at the tibiofemoral joint and the patellofemoral joint form the knee complex. An understanding of the anatomy and biomechanics of each respective joint is critical in knowing the potential stresses and implications of pathologic conditions of the knee that can occur at the knee complex.

☆The author extends appreciation to Anthony E. "Toby" Kinney and Ellen Wetherbee, whose work in prior editions provided the foundation for this chapter.

Fig. 11.1 Example of a common style of postoperative brace. Notice the longer areas of support to the thigh and calf areas. The sidebars are connected with a hinge that allows for limiting or progressing range of motion available at the joint. (Courtesy Breg. Retrieved from https://www.breg.com/wp-content/uploads/product_images/Post_Op.png.)

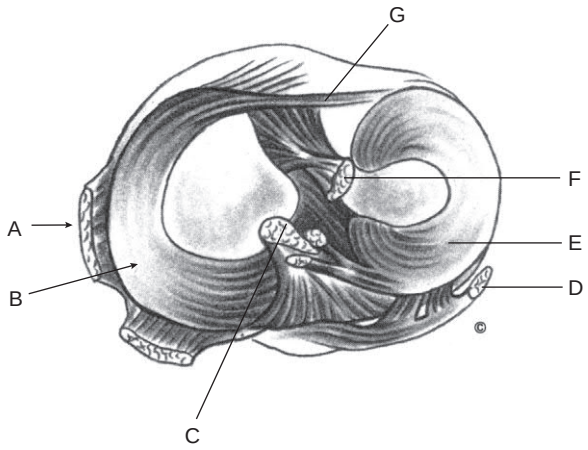

Fig. 11.3 In this view of the surface of the tibia, we can identify the medial collateral ligament *(A)*, the C-shaped medial meniscus on the large medial tibial plateau *(B)*, the posterior cruciate ligament with the accessory anterior and posterior meniscofemoral ligaments *(C)*, the tendon of the popliteus muscle *(D)*, the circular lateral meniscus on the smaller lateral tibial plateau *(E)*, the anterior cruciate ligament as it twists toward the inside of the lateral femoral condyle *(F)*, and the transverse ligament *(G)*. (From Greenfield BH. Rehabilitation of the Knee: A Problem Solving Approach. Philadelphia: FA Davis; 1993.)

THE TIBIOFEMORAL JOINT

The knee joint is a hinge-like articulation between the medial and lateral condyles of the femur and the medial and lateral tibial plateau (Fig. 11.3). Because of the shape and asymmetry of the condyles, the instantaneous axis of knee flexion/extension motion changes through the arc of motion. As the knee moves from extension to flexion, the instant center pathway moves posteriorly.[4] In open chain movements (non–weight-bearing activities), the tibia rotates around the femoral condyles. In closed chain movements (weight-bearing activities), an anatomical locking mechanism is present in the final degrees of extension as the longer medial femoral condyle rotates medially on the articular surfaces of the tibia. Consequently, if the instant center of pathway changes, it will alter the optimal joint mechanics and therefore result in abnormal knee stressors. The alignment between an adducted femur and relatively upright tibia creates a vulnerability to valgus stress in many weight-bearing activities. The capsule that encases the knee joint is reinforced by the collagen-rich medial and lateral retinaculum. The medial and lateral menisci rest on the tibial plateau. They are fibrocartilaginous, nearly ring-shaped disks that are flexibly attached around the edges of the tibial plateau (see Fig. 11.3). These menisci increase the concavity of the tibial articular surface, enhancing congruency of articulation with the femoral condyles to facilitate normal gliding and distribute weight-bearing forces within the knee during gait and other loading activities.[5] The menisci also play an important role in nutrition and lubrication of the articular surfaces of the knee joint.

Stability to the tibiofemoral joint is provided by sets of ligaments. The medial (tibial) collateral ligament (MCL) and the lateral (fibular) collateral ligament (LCL) are extrinsic ligaments. The collateral ligaments counter valgus and varus forces that act on the knee. In addition, two intrinsic ligaments of the tibiofemoral joint, the ACL and the posterior cruciate ligaments (PCL) check translatory forces that displace the tibia on the femur. The location of attachments makes each of these ligaments most effective at particular points in the knee's normal arc of motion.[5] Additionally, contraction of the quadriceps and knee flexor muscle groups produce compressive forces that help stabilize the knee. Muscles of the hip and lower leg also make contributions to the mechanics of the femur and tibia, respectively, which impact the movements of the knee complex.

Medial Collateral Ligament

The MCL is a strong, flat membranous band that overlays the middle portion of the medial joint capsule (Fig. 11.4).

It is most effective in counteracting valgus stressors when the knee is slightly flexed to fully extended. Approximately 8 to 10 cm in length, it originates at the medial epicondyle of the femur and attaches to the medial surface of the tibial plateau. The MCL can be subdivided into a set of oblique posterior fibers and anterior parallel fibers.

A bundle of meniscotibial fibers, also known as the *posterior oblique ligament*, runs deep to the MCL, from the femur to the midperipheral margin of the medial meniscus and toward the tibia. These fibers connect the medial meniscus to the tibia and help form the semimembranosus corner of the medial knee. Additionally, the medial patellar retinacular fibers play a reinforcing role.[6]

Lateral Collateral Ligament and Iliotibial Band

The LCL resists varus stressors and lateral rotation of the tibia and is most effective when the knee is slightly flexed. The LCL runs from the lateral femoral condyle (the back part of the outer tuberosity of the femur) to the proximal lateral aspect of the fibular head (see Fig. 11.4). The tendon of the popliteus muscle and the external articular vessels and nerves pass beneath this ligament.

Another lateral structure that acts on the knee complex is the iliotibial band (ITB). The ITB is positioned slightly anterior to the LCL and is taut in all ranges of knee motion. Its lateral position allows it to stabilize against varus forces along with the LCL.

Anterior Cruciate Ligament

The ACL runs at an oblique angle between the articular surfaces of the knee joint and prevents forward shift and excessive medial rotation of the tibia as the knee moves toward extension (Fig. 11.5). The ACL attaches to the tibia in a fossa just anterior and lateral to the anterior tibial spine and to the femur in a fossa on the posteromedial surface of the lateral femoral condyle. The ACL's tibial attachment is somewhat wider and stronger than its femoral attachment. Some authors divide the fasciculi that make up the broad, somewhat flat ACL into two or three distinct bundles. The ligament's anteromedial band, with fibers running from the anteromedial tibia to the proximal femoral attachment, is most taut in flexion and relatively lax in extension. The posterolateral bulk (PLB), which begins at the posterolateral tibial attachment, is most taut in extension and relatively lax in flexion. An intermediate bundle of transitional fibers between the anteromedial band and PLB tends to tighten when the knee moves through the midranges of motion. This arrangement of fibers ensures tension in the ACL throughout the entire range of knee motion. The ACL is most vulnerable to injury when the femur rotates internally on the tibia when the knee is flexed and the foot is fixed on the ground during weight-bearing activities.[7]

Posterior Cruciate Ligament

The PCL restrains posterior displacement of the tibia in its articulation with the femur, especially as the knee moves

toward full extension.[5] The PCL is shorter and less oblique in orientation than the ACL; it is the strongest and most resistant ligament of the knee. PCL fibers run from a slight depression between articular surfaces on the posterior tibia to the posterolateral surface of the medial femoral condyle (see Figs. 11.3 and 11.5). Like the ACL, the PCL can be divided into anterior and posterior segments. The larger anterior medial band is most taut between 80 and 90 degrees of flexion and is relatively lax in extension. The smaller PLB travels somewhat obliquely across the joint, becoming taut as the knee moves into extension. The PCL plays a role in the locking mechanism of the knee as tension in the ligament produces lateral (external) rotation of the tibia on the femur in the final degrees of knee extension. The PCL may also assist the collateral ligaments when varus or valgus stressors are applied to the knee.[5]

Coursing along with fibers from the MCL is the meniscofemoral ligament, which stretches between the posterior horn of the lateral meniscus and the lateral surface of the medial femoral condyle. The anterior meniscofemoral band (ligament of Humphry) runs along the medial anterior surface of the PCL and may be up to one third its diameter. The posterior meniscofemoral band (ligament of Wrisberg) lies posterior to the PCL and may be as much as one half its diameter. The meniscofemoral ligaments pull the lateral meniscus forward during flexion of the weight-bearing knee to maintain as much articular congruency as possible with the lateral femoral condyle.

POSTEROLATERAL CORNER OF THE KNEE

The lateral meniscus is somewhat more mobile than the medial meniscus because of the anatomy of the posterolateral corner of the knee. The arcuate complex and posterolateral corner run from the styloid process of the fibula, joining the posterior oblique ligament on the posterior aspect of the femur and tibia. The arcuate ligament is firmly attached to the underlying popliteus muscle and tendon. The tendon of the popliteus muscle separates the deep joint capsule from the rim of the lateral meniscus.

PATELLOFEMORAL JOINT

The *patella*, a sesamoid bone embedded in the tendon of the quadriceps femoris, is an integral part of the extensor mechanism of the knee. The patella functions as an anatomical pulley, increasing the knee extension moment created by contraction of the quadriceps femoris by as much as 50%. It also guides the forces generated by the quadriceps femoris to the patellar ligament, protects deeper knee joint anatomy, protects the quadriceps tendon from frictional forces, and increases the compressive forces to which the extensor mechanisms can be subjected.[5]

Although the anterior surface of the patella is convex, the posterior surface has three distinct anatomical areas: a lateral, medial, and odd facet. The lateral and medial facets are separated by a vertical ridge. The odd facet articulates with the medial condyle at the end range of knee extension (Fig. 11.6). The posterior patellar surface is covered with hyaline articular cartilage, except for the distal apex, which is roughened for the attachment of the patellar tendon. Pressure between the patella and trochlear groove of the femur increases substantially as the knee flexes. During knee

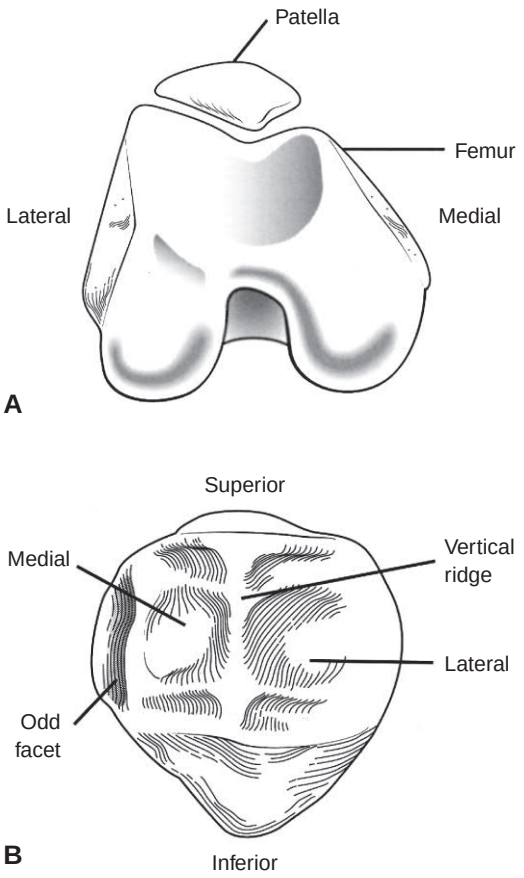

Fig. 11.6 (A) The normal position of the patella in the intercondylar groove of the distal femur. (B) Underside of the patella with its three facets and vertical ridge. (Reprinted with permission from Belyea BC. Orthoses for the knee: the patellofemoral joint. In: Nawoczenski DA, Epler ME, eds. *Orthotics in Functional Rehabilitation of the Lower Limb*. Philadelphia: Saunders, 1997.)

flexion, the patella moves in a complex but consistent three-dimensional pattern of flexion/extension rotation, medial/lateral rotation, medial/lateral tilt, and a medial/lateral shift relative to the femur.[8,9] These motions occur biomechanically in the X, Y, and Z planes.

The stability of the patella is derived from the patellofemoral joint's static structural characteristics and dynamic (muscular) control. Static stability is a product of the anatomy of the patella – the depth of the intercondylar groove, and the prominent and longer lateral condyle of the femur. The sulcus angle, formed by the sloping edges of the condyles, is normally between 114 and 120 degrees; however, it can vary significantly from person to person.[10] Wiberg[11] divides the patellofemoral joint into six types based on the size and shape of facets (Table 11.1). The depth of the patellar trochlea and the facet pattern are important in patellar stability.

Dynamic stability of the patellofemoral joint is derived primarily from activity of the quadriceps femoris as well as from the tensile properties of the patellar ligament (Fig. 11.7). The four components of the quadriceps muscle act together to pull the patella obliquely upward along the shaft of the femur, whereas the patellar ligament anchors it almost straight downward along the anatomical axis of the lower leg. The tibial tubercle is typically located at least 6 degrees lateral to the mechanical axis of the femur.

Table 11.1 Classification of Patellar Types, Listed From Most to Least Stable

Patellar Type	Description
I	Equal medial and lateral facets, both slightly concave
II	Small medial facet, both facets slightly concave
II/III	Small, flat medial facet
III	Small, slightly convex medial facet
IV	Very small, steeply sloped medial facet with medial ridge
V (Jagerhut)	No medial facet, no central ridge

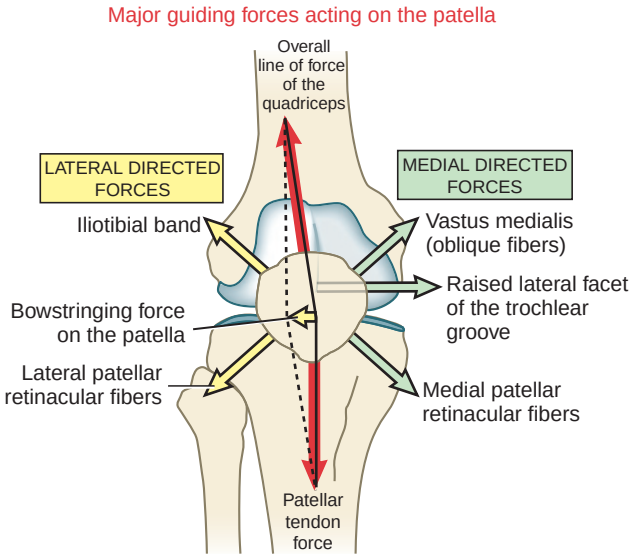

Fig. 11.7 A schematic diagram of structures that act on the patella. (Reprinted with permission from Neumann DA. *Kinesiology of the Musculoskeletal System: Foundations for Rehabilitation*. 3rd ed. St. Louis: Mosby Elsevier, 2017.)

Because the structure of the patellofemoral articulation and the muscular/ligamentous forces that act on the patella are complex, patellar dynamics involve much more than simple cephalocaudal repositioning as the knee is flexed or extended. Van Kampen and Huiskes[9] describe the three-dimensional motions of the patella as flexion rotation, medial rotation, wavering tilt, and lateral shift. All of these patellar movements (except flexion) are influenced by the rotation of the tibia and the dynamic stabilization of the muscles that act on the patella.

Biomechanics of Knee Motion

Although it is beyond the scope of this chapter to comprehensively cover the biomechanics of knee motion, it is important to have a basic foundation of knee biomechanics to understand the use of knee orthoses as an intervention for pathologic conditions of the knee. Evaluating and managing injuries of the knee requires an in-depth understanding of the biomechanical characteristics of the knee joint. The *kinematics of the knee* describe its motion in terms of the type and location and the magnitude and direction of the motion. The *kinetics of the knee* describe the forces that act on the knee, causing movement.[5] Kinetic forces are classified as either external forces that work on the body (e.g., gravity) or as internal body-generated forces (e.g., friction, tensile strength of soft tissue structures, muscle contraction).

Motion in the tibiofemoral joint can be best understood by separating the motion into its physiological and accessory components. Physiological motion can be controlled consciously, most often through voluntary contraction of muscle. Osteokinematic (bone movement) and arthrokinematic (joint surface motion) are examples of physiological motion. Accessory motion occurs without conscious control and cannot be reproduced voluntarily. Joint play, which is elicited by passive movement during examination of a joint, is an example of an accessory motion. The magnitude and type of accessory motion possible are determined by the characteristics of a particular articulation and the properties of the tissues that surround it. The arthrokinematics of the tibiofemoral joint will vary depending upon whether the lower extremity is in a weight-bearing or loaded position. For example, with tibial-femoral extension the tibia moves anteriorly relative to the femur, and with femoral-tibia extension the femoral condyles slide from anterior to posterior, while rolling anteriorly.[6]

One of the important accessory component motions of the tibiofemoral joint is its *screw home* or locking mechanism. In the final degrees of knee extension, the tibia continues to rotate around the large articular surface of the medial femoral condyle. This motion cannot be prevented or changed by volitional effort; it is entirely the result of the configuration of the articular surfaces. When the knee is flexed to or beyond 90 degrees, however, conscious activation of muscles can produce physiological (osteokinematic) external (lateral) or internal (medial) rotation of the tibia on the femur.

Three osteokinematic motions are possible at the tibiofemoral joint. Knee flexion/extension occurs in the sagittal plane around an axis in the frontal plane (x-axis). Internal/external rotation of the tibia on the femur (or vice versa) occurs in the transverse plane around a longitudinal axis (y-axis). Abduction and adduction occur in the frontal plane around a horizontal axis (z-axis). The arthrokinematic movements of the tibiofemoral joint are rolling, gliding, and sliding (Fig. 11.8). It is important to note that the roll-glide ratio is not constant during tibiofemoral joint motion: Approximately 1:2 in early flexion, the roll-glide ratio becomes almost 1:4 in late flexion.[12] Rolling and gliding occur primarily on the posterior portion of the femoral condyles. In the first 15 to 20 degrees of flexion, a true rolling motion of the femoral condyles occurs in concert with the tibial plateau. As the magnitude of flexion increases, the femur begins to glide posteriorly on the tibia. Gliding becomes more significant as flexion increases.

From a kinematic standpoint, the ACL and PCL operate as a true gear mechanism controlling the roll-glide motion of the tibiofemoral joint. With rupture of either or both of the cruciate ligaments, the gear mechanism becomes ineffective, and the arthrokinematic motion is altered. In an ACL-deficient knee, the femur is able to roll beyond the posterior half of the tibial plateau, increasing the likelihood of damage or tear of the posterior horn of the medial or lateral meniscus.

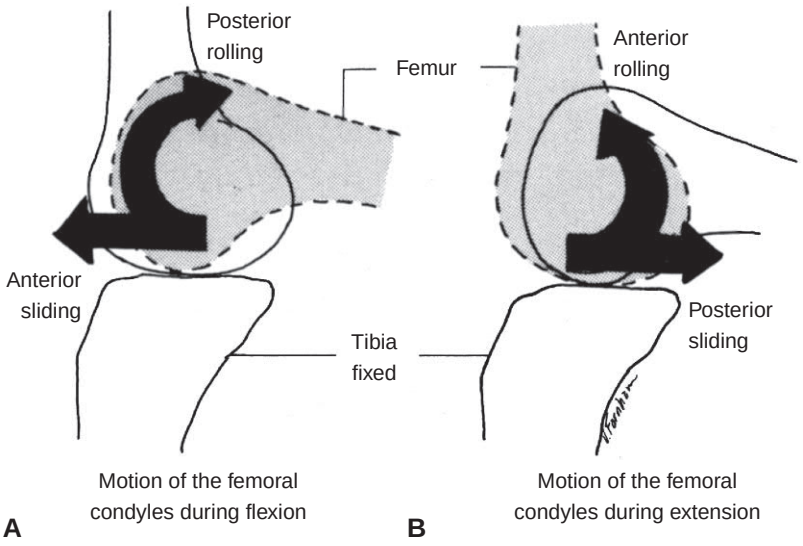

Fig. 11.8 Diagram of femoral motion on a fixed tibia. (A) As the knee flexes, the femoral condyles roll posteriorly *(curved arrow)* while gliding/sliding forward *(straight arrow)*. (B) As the knee extends, the condyles roll forward *(curved arrow)* while gliding posteriorly *(straight arrow)*. (From Hartigan E, Lewek M, Snyder-Mackler L. The knee. In: Levangie PK, Norkin CC [eds], *Joint Structure and Function: A Comprehensive Analysis*, 5th ed. Philadelphia: David, 2011, p. 355.)

Because the knee has characteristics of a hinge joint and an arthrodial joint, two types of motion (translatory and rotatory) can occur in each plane of motion (sagittal, frontal/coronal, transverse). For this reason, knee motion is described as having six degrees of freedom. The three translatory motions of the knee include anteroposterior translation of 5 to 10 mm, mediolateral translation of 1 to 2 mm, and compression-distraction motion of 2 to 5 mm. The three rotatory motions occur in flexion/extension, varus/valgus, and internal (medial)/external (lateral) rotation.[5,12]

Knee Orthoses Components

Commercially available knee orthoses are comprised of different components, depending on the purpose of the brace (Fig. 11.9). Braces to unload or protect the joint will likely have some type of sidebar support and connect with either a freely moving hinge or one that can be set to limit knee ROM (see Fig. 11.1). Sidebars can be constructed of plastic, metal, or a composite substance. Sidebars can prevent varus and valgus motion at the joint. Straps are provided to help secure the brace to the lower extremity, often utilizing hook-and-loop closure. Other orthoses may include components that rest on the anterior or posterior aspect of the lower leg to limit anterior or posterior translation of the tibia, an important treatment consideration following cruciate ligament injury.

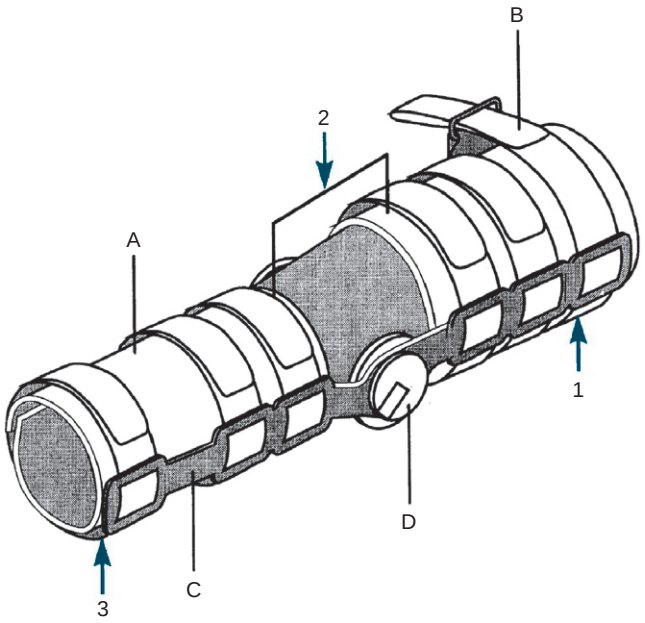

Fig. 11.9 The components of most commercially available rehabilitation knee orthoses include open cell foam interface that encases the calf and thigh *(A)*; a nonelastic adjustable Velcro strap for closures *(B)*; lightweight metal, composite, or plastic sidebars *(C)*; and single-axis or polycentric hinge that can be locked or adjusted to allow or restrict motion *(D)* within the therapeutically desired range of motion. The force systems of these orthoses apply a pair of anteriorly directed forces at the proximal posterior thigh *(1)* and distal posterior calf *(3)*, against a posteriorly directed force *(2)* applied over or on either side of the patella. Varus and valgus stressors are resisted by the sidebars. (Reprinted with permission from Redford JB, Basmajian JV, Trautman P. Lower limb orthoses. In: *Orthotics: Clinical Practice and Rehabilitation Technology*. New York: Churchill Livingstone, 1995;195:230.)

Prophylactic Knee Orthoses

Knee injuries are extremely common, accounting for at least 60% of sporting injuries.[1] Among knee injuries in athletes, soft tissue injury to knee ligaments are of particular concern. Ligamentous injury often results in extensive lost playing time and cost due to surgical repair and rehabilitation. Prophylactic knee orthoses (PKOs) are knee braces that are designed to mitigate or altogether prevent soft tissue injury, usually ligamentous, to the healthy knee (Fig. 11.10). However, the use of these braces for injury prevention purposes continues to be debated in scientific literature.[1]

PKOs are nonadhesive devices that are external to the joint itself. Usually worn by athletes, these braces are designed to prevent injury to the soft tissue structures of the knee from contact or noncontact injuries. It is important to note that there is significant variation in brace design

Fig. 11.10 CTi Custom Knee Brace from Ossur. Example of a custom fit PKO. This brace is custom fabricated for a more precise fit. This brace can be further individualized based on the physical activity requirements of the patient. (© Össur.)

among manufacturers, but the basic goal of ligament protection remains the same despite design. To prevent injury to the MCL or LCL, a brace would need to limit the amount of valgus or varus force, respectively, that the joint receives. For ACL protection, the PKO needs to limit anterior tibial translation forces. For clinicians, understanding the design and intended purpose of a brace in conjunction with the physical demands of the athlete's sport is critical to prescribing an appropriate PKO.

BIOMECHANICAL IMPLICATIONS

The application of a PKO can have effects on joint kinetics and kinematics, proprioception of the knee joint, as well as muscle activation, limb stiffness, and athletic performance. Specific brace design may have an impact on any or all of these factors in a healthy knee.[13]

Noncontact ligamentous knee injuries often occur when an athlete makes a cutting maneuver or lands on a hard surface after jumping, such as with a basketball rebound. Ewing et al.[14] examined the effects of simulating a jump landing from various heights on lower extremity joint kinetics among healthy athletes with and without prophylactic bracing. The results indicate that bracing altered hip flexion angle at initial contact and peak dorsiflexion angle, notably more in female athletes than in male athletes. These results are significant, as the hip and ankle have been shown to play a crucial role in decelerating the center of mass and protecting the knee during landing. The increase in hip flexion angle observed in this study could serve to protect the ACL during landing, especially in female athletes. The authors observed that ground reaction forces (GRFs) were not altered by the use of a PKO. Other significant observations included increases in peak hip extension moment, peak hip negative power, and hip negative work that were observed with PKO use.

Sinclair et al.[3] examined the effects of PKO use on knee joint kinetics and kinematics during netball specific movements. Netball is physically demanding and is characterized by high-level athletic movements such as jumping and cutting performed on a hardwood surface. The authors examined joint kinetics during running, jumping, and cutting maneuvers in athletes with and without PKO. They found that joint kinetics showed no significant change in braced or unbraced conditions. They did however observe significant reduction in transverse plane kinematics—internal and external rotation ROM—when wearing the brace during all maneuvers. Less significantly, the test subjects reported increased perceived knee stability.

Mortaza et al.[2] examined the isokinetic force production of knee flexion and extension in healthy subjects wearing a PKO, neoprene sleeve, or no brace. The authors reported no effect of bracing on the subject's muscle strength and power during flexion and extension movements. Although the PKO did not enhance muscle performance, the finding that the PKO did not diminish muscle performance is significant.

Baltaci et al.[13] found that across five different types of PKOs, maximal muscle force was enhanced. It is believed that the reduction in ROM produced by these braces allowed for an increase in maximal force production. The differences in muscle performance reported by the Mortaza and Baltaci studies may be due to the difference in assessment method. Whereas Mortaza et al.[2] examined muscle performance with isokinetic testing, Baltaci et al.[13] examined force produced during closed chain knee extension force production only.

One proposed model for how PKOs can provide stability to the knee is by increasing lower limb muscle stiffness. Ewing et al.[15] found an increase in active stiffness of the hamstrings and vasti muscles during landing procedures in healthy individuals. Hobara et al.[16] found that PKO use increased lower limb stiffness during hopping as compared with no brace but not significantly different than when individuals used an ankle brace. These findings suggest that muscle activation patterns are not altered with brace use but decrease lower limb muscle stiffness.[15,16] The connection between lower limb muscle stiffness and ligament protection is not well understood at this time.

Proprioception is highly complex and involves the coordination of multiple receptors found in the joint capsule, ligaments, and skin with the central nervous system. Lack of proprioception is thought to be related to episodes of instability and joint injury.[17,18] Increasing proprioception of a joint through the use of a brace may reduce injury risk by improving overall joint control.[17] A review by Dargo et al.[19] found that the addition of neuromuscular and proprioceptive exercises to a prevention program decreased the incidence of knee injury and ACL rupture. The addition of proprioceptive and neuromuscular exercises to an ACL rehabilitation program can help prevent injury recurrence.[20]

Bottoni et al.[17] tested proprioception by comparing athletes' ability to determine movement at the knee without a brace, with a PKO, and with a neoprene sleeve. This repeated-measures study found that the use of a PKO or a neoprene sleeve had no influence, either positively or

negatively, on the proprioception of the knee. However, the test subjects were not tested in a weight-bearing position; applying these findings to closed chain or athletic movements is difficult. Baltaci also examined proprioception in healthy individuals wearing PKOs, however they tested in a weight-bearing position. The authors report an enhancement in knee proprioception with five different PKOs compared with an unbraced condition.[13] In a systematic review and meta-analysis performed by Ghai et al.,[21] the effects of PKOs on joint proprioception and stability were reported. The authors report that conflicting evidence exists to support the notion that PKOs have an effect on joint proprioception. Several high-quality studies report enhancements in proprioception, whereas negligible effects were reported in others. These results speak to the impact that different PKO designs can have on knee function.

EVIDENCE OF EFFECTIVENESS

When considering the use of a PKO in a healthy patient population, it is important to consider that there is no published data available on the role of bracing in preventing ligamentous injury in healthy knees.[22] As previously discussed, the effects these braces have on joint kinematics, proprioception, and muscle performance should not hinder a healthy athlete's performance, so any additional ligamentous protection gained from brace use would be beneficial.

However, the use of bracing has been advocated in athletes who are determined to be at high risk for ligamentous knee injury or in those individuals who are ACL deficient or have ACL reconstructed knees. Intrinsic risk factors include a narrow intercondylar notch, weak ACL, generalized joint laxity, lower extremity alignment, and gender—with women being more at risk than men.[23] Extrinsic risk factors include quadriceps and hamstring strength imbalances, altered neuromuscular control, and the athlete's playing style and surface.[23] In a systematic review by Bodendorfer et al.,[1] several factors for identifying at-risk population are identified: being between the ages of 13 and 18, and participating in pivoting and jumping sports (basketball, football, soccer, and skiing among others). The authors conclude that this population may benefit from prophylactic bracing but recognize the limitation in available data at this time. In individuals who are ACL deficient, bracing can be an effective way to prevent further injury that could be sustained for extra anterior tibial translation. Bracing following ACL reconstruction and its efficacy is further discussed later in the chapter.

Two large scale epidemiological studies have examined the injury rates among football players wearing PKOs.[24,25] Both studies found that bracing can be effective in preventing MCL injury in football players. Sitler et al.[25] found that although the brace may reduce MCL injury rate, it did not significantly affect severity when an injury was sustained. The Albright et al.[24] study also supported prophylactic bracing for MCL injury prevention in football players, especially in linemen and linebackers. These individuals would be considered at high risk based on the criteria set forth by Bodendorfer et al.[1] A more recent systematic review by Salata et al.[26] found that bracing did not have a significant effect on MCL injury rate in football players, and cited a lack of evidence to support PKO use in the healthy population.

Potential negative effects of PKO use are not fully understood. An older study by Highgenboten et al.[27] found increased metabolic demand in individuals wearing knee braces, which was related to the weight of the brace. Brace design has continued to evolve in response, using more light-weight materials to reduce the metabolic demands associated with brace use. Further research to determine the metabolic demands of newer, lightweight braces is warranted. Additionally, healthy patients who wear PKOs often report an increased sense of security.[3] This sense of security may be false, as the ability for these braces to prevent injury in healthy individuals is not fully understood.

RECOMMENDATIONS

In some individuals, brace use may increase not only muscle performance, but also increase lower limb stiffness and knee proprioception without significantly changing joint kinetics.[2,3,13-15] Currently, there is a lack of current research to suggest that PKOs significantly reduce knee function, or reduce ligamentous injury risk. In a normal healthy population, PKO use is not warranted based on the available literature at this time. However, in those individuals identified as high risk for ACL injury, bracing may offer a viable way to reduce injury risk and should be recommended. Clinicians should recognize individuals who are high risk and prescribe an appropriate PKO in an effort to mitigate injury risk.

Orthoses for Anterior Cruciate Ligament Insufficiency

The anterior and posterior cruciate ligaments function to provide stabilization of the knee joint in multiple directions. The ACL attaches superiorly to the femur on the posterior medial aspect of the lateral condyle. Distally, the ACL attaches anteriorly and laterally to the intercondylar notch of the tibia. The primary role of the ACL is to limit anterior translation of the tibia on the femur, and the PCL functions to limit posterior translation of the tibia on the femur.[28] Additionally, the ACL provides some stability in the transverse and frontal planes, limiting both tibial rotation and abduction.[28] Besides these mechanical functions, the ACL also plays an important role in knee joint proprioception.[29] The critical function of the cruciate ligaments from a mechanical and proprioceptive perspective is complex, and beyond the scope of this chapter. However, a basic understanding of the joint mechanics is necessary to appreciate the design and function of orthoses, as well as prescribing appropriate devices to individuals with ACL injury.

As discussed previously in this chapter, the purpose of a PKO is to prevent injury to the soft tissue structures of the knee from contact or noncontact injuries. In the event that an injury to the ligamentous support structures of the knee does occur, an FKO is often prescribed (Fig. 11.11A). The purpose of an FKO is to provide the mechanical stabilization that is usually provided by intact support structures. For example, a patient who has suffered an ACL rupture may be provided with a brace to prevent anterior translation of the tibia. Utilizing an FKO can serve two main purposes: First, it may be used to protect the joint from further injury

Fig. 11.11 (A) Axiom Elite Ligament Knee Brace by Breg. Example of a knee brace that could be used for either prophylactic purposes or following collateral ligament repair. The rigid metal frame and dual hinges provide support and protection. (B) Rebound ACL Brace by Ossur. Example of a knee brace that is used for nonsurgical treatment of ACL rupture or following surgery for ACL reconstruction. (A, Courtesy Breg. Retrieved from: https://www.breg.com/wp-content/uploads/product_images/Axiom_Elite_Standard_Straight-001-705x705.png. B, © Össur.)

that may occur due to the lack of ligamentous support. The chronic instability and altered kinematics may lead to increased injury risk of other ligaments, the meniscus, or the articular cartilage.[6] Secondly, an FKO can be used to protect a surgical repair of a ligament or other support structure in the knee while it heals or during athletic activities.

ACL INSUFFICIENCY

ACL injuries are the most common ligamentous knee injuries.[1,29] Due to the complex role of the ACL in mechanical stabilization and proprioception, individuals who are ACL deficient often report symptoms of instability and "giving way" in the knee. Although many individuals elect to undergo surgical repair of the ACL, there is a subset of the population that is able to return to previous levels of function without an intact ACL. This group is collectively known as "copers," whereas those with continued reports of instability are deemed non-copers. FKO use in copers would serve the purpose of protecting the joint from further injury by providing an external mechanical force to the joint to replicate the normal function of the ACL (see Fig. 11.11B). Several studies have explored the ability of an FKO to replicate those normal functions.

Biomechanical Implications

Giotis et al.[30] examined the effects of bracing on tibial rotation during high load activities in ACL patients. By comparing the ACL intact knee to the ACL-deficient knee during several different tasks, the authors were able to determine if excessive tibial rotation was occurring and if bracing could potentially limit those effects. Subjects were tested during stair descent with pivoting, and a drop landing followed by a pivot. The results of this analysis reveal that there is increased tibial rotation in the ACL-deficient knee compared with the intact knee, and that bracing the deficient knee resulted in a significant decrease in tibial rotation.

Jalali et al.[31] used video fluoroscopy to examine the effect that knee bracing has on anterior tibial translation during lunging in individuals who are ACL deficient. In this study, the braces used were custom fabricated but were characteristic of an FKO. No significant differences were reported for anterior tibial translation in braced and unbraced conditions. This lack of findings is significant as often the purpose of an FKO is to provide the anterior stability of the knee lost by ACL rupture. Additionally, one might assume that a custom fabricated FKO would be superior in providing this support as compared to an off-the-shelf brace.

Pierrat et al.[32] also examined the ability of FKOs to reduce anterior tibial translation in individuals who are ACL deficient. Contrary to the Jalali et al.[31] study, the authors examined the amount of anterior translation during low grade loads and used off-the-shelf braces. They found that at a low force, which resulted in low anterior displacement, an FKO can replace the mechanical role of the ACL.[32] However, they determined that an FKO cannot fully replace the role of the ACL, as braces generally reach a firm "stop" in a linear manner, whereas the intact ACL increases stiffness as load increases in a nonlinear manner. It is likely that these braces are not effective for higher knee loads or activities that produce higher levels of anterior tibial displacement, although further research is necessary.

Functional Implications

Palm et al.[29] studied the effect of ACL deficiency on knee joint proprioception and postural control. They reported a

significant difference in overall postural stability between injured and noninjured knees, with injured knees having less stability. Fernandes et al.[33] also found decreased postural control in ACL-deficient athletes during static and dynamic activities. The Palm et al. study examined the effect of a commercial knee sleeve, which consisted mainly of a compressive sleeve with patellar pads. After application of the sleeve, the authors noted an increase in overall postural stability by nearly 22%, finding that this increased postural control to a level similar to that of the uninjured knee.[29] Clinically, a bulkier FKO is often used to manage patients who have isolated ACL deficiency. The results of this study indicate that a simple sleeve can improve the overall stability and postural control in these individuals and may be sufficient when compared with bulkier FKOs.

Mortaza et al.[34] examined the effect that FKOs have on the isokinetic muscle performance and functional performance in individuals who have ACL-deficient knees. Functional tests included single-leg crossover hopping distance and vertical jump height. The results indicated that FKO use did not have any positive or negative effect on knee performance in either of the examined groups. However, small effects of the brace on peak knee extension torque and power were measured. The authors conclude that although not statistically significant, these findings have rehabilitation implications in reducing muscle function asymmetry during the rehabilitation process.

Recommendations

Although these studies demonstrate that an FKO does not limit the anterior tibial translation that often causes a feeling of joint instability, they may still be helpful by increasing postural stability and proprioception.[29,31,32] Additionally, they may also be helpful for low-load activities or when limiting tibial rotation to avoid further injury is the main goal of use.[1,32,35] It is important to remember an FKO cannot match the nonlinear stiffening exhibited by the healthy ACL as demand is increased.[32] Therefore it is important for the clinician to consider the use of FKOs in the rehabilitation of ACL-deficient individuals. For example, if an individual is planning to undergo ACL repair, and the goal is to limit the subjective feeling of instability, a brace may be useful to increase postural stability and proprioception. In the preoperative ACL patient, a simple sleeve can often provide this support without the bulkiness of a traditional FKO.[29] In those individuals who elect to not have surgery to repair the ACL, bracing can provide support for low-level activities, but likely not enough external support for high loading activities.

POSTOPERATIVE ACL RECONSTRUCTION

Immediately after surgery for ACL reconstruction, current practice is to provide bracing to protect the quadriceps-inhibited knee from a sudden flexion moment in weight bearing.[36,37] For this reason many surgeons opt to prescribe an FKO for the purpose of protecting the surgical repair from re-rupture. Over the course of rehabilitation, bracing may serve the additional purpose of providing more stability as the patient progresses to more intense exercise or sport specific training.[37] Despite being common practice, FKO use during the rehabilitation phase following ACL repair has become more controversial over the past years as more information is gathered about the effect bracing has on the ACL-reconstructed knee.[36]

Biomechanical Implications

In an in vivo, prospective controlled study, Giotis et al.[30] collected data on the amount of tibial rotation present during high-loading activities in ACL-reconstructed knees. Tibial rotation was measured during immediate pivoting after stepping down from a stair and immediate pivoting after landing from a jump down from a step. The researchers measured tibial rotation in both the operative and nonoperative knees, with a knee sleeve, a knee orthosis, and no bracing. It was determined that excessive tibial rotation remains during dynamic pivoting maneuvers following ACL reconstruction, and bracing can reduce this rotation, but does not restore normative function. This study protocol was used to examine the same effects in individuals who are ACL deficient and found similar results.[35] It is important to consider that this study used only male participants who had bone-patellar tendon-bone graft, and who were on average 26 months postoperative.[30] It may be difficult to apply these findings to females or other graft types, however, it is important to consider the long-term effects on tibial rotation following ACL injury.

In a follow-up study, Giotis et al.[38] examined the same outcomes in individuals who underwent ACL repair with a hamstring tendon graft. Again, only male patients who were a minimum of 24 months postoperative were examined. In this population a similar finding was reported; tibial rotation during high-level dynamic activities was reduced when wearing a brace but not to the extent of a healthy ACL. In both graft types, using an orthosis resulted in superior outcomes as compared to the knee sleeve, and the knee sleeve was superior to the unbraced condition.[30,38]

Limiting anterior tibial translation in addition to tibial rotation to reduce stress on the repaired ACL may also be a theoretic reason for bracing in the postoperative population. Multiple studies have shown that bracing is not an effective way to replicate the physiologic function of an intact ACL in this regard.[31,32] Due to this, excessive tibial translation has not been extensively studied in a postoperative population. LaPrade et al.[39] examined the differences between dynamic and static braces on the posteriorly directed forces from the brace on the proximal tibia during open and closed chain knee movements in healthy individuals. Dynamic braces were found to be superior to static braces, most closely matching physiological ACL function. As previously reported, the ACL stiffens in a nonlinear way during active knee ROM, and dynamic bracing attempts to match this phenomenon.[32]

Role in Rehabilitation

Common impairments following ACL reconstruction include pain, effusion, muscle weakness, and ROM loss, among others. The use of bracing during the rehabilitation phase following ACL repair is generally not supported in the literature to reduce these impairments.[37,40,41] In a review by Nyland et al.,[37] the authors conclude that the evidence supporting postsurgical brace use tends to decrease across the healing continuum following ACL repair. A systematic review by Kruse et al.[40] found that bracing after ACL repair is neither necessary nor beneficial and may actually

increase the cost of the procedure. Additionally, the review found that bracing did not result in significant benefits in ROM or laxity. In a long-term prospective study, Mayr et al.[41] found that postoperative bracing showed no advantage in regard to anteroposterior laxity or visual analog pain scale among those individuals who used a postoperative brace, with pain levels being less in those who did not use a brace. Postoperative bracing has also been found to have no effect on joint effusion.[42] During gait in adolescent patients, bracing had no effect on altered kinematic and kinetic asymmetries between surgical and noninjured limbs.[43] A review by Sugimoto et al.[44] found inconsistent evidence that bracing provided improvements in joint position sense in this population.

Despite these findings, there may be patients who would benefit from brace use. One such population is those with kinesiophobia, or fear of re-injury.[45,46] Harput et al.[45] found that bracing provided a reduction in kinesiophobia, allowing patients to have improved knee function and return to preinjury levels when compared with kinesiology taping or no brace conditions. A systematic review by Lowe et al.[46] suggests using a brace following ACL reconstruction after return to sport for ligament protection and to reduce kinesiophobia. It is the role of the clinician to recognize those individuals who demonstrate kinesiophobia and may benefit from complementary brace use in addition to comprehensive rehabilitation following ACL reconstruction.

Although the findings of recent research suggest bracing after ACL reconstruction is unnecessary, it remains commonplace for patients and surgeons to utilize braces following surgery. Nyland et al.[37] noted that during rehabilitation, "safe training without brace use is essential to stimulate joint loads needed for tissue healing, collagen health, restoration of biomechanical tissue integrity, and to develop a more responsive neuromuscular control system." It remains the job of the rehabilitation team to appropriately prescribe exercises and activities that result in the intended healing, without reliance on external bracing. Weaning patients from brace use requires careful consideration of the patients' function, kinesiophobia level, and patient confidence. This decision should always be made with the collaboration of the patient and the surgeon.

Once the patient has successfully completed a comprehensive rehabilitation program and is ready to return to sport, functional bracing may once again be utilized. A review by Lang et al.[47] found that brace use for the first 6 to 12 months following return to sport can increase the athlete's confidence. The systematic review by Lowe et al.[46] arrived at a similar conclusion, suggesting brace use for 6 to 12 months following return to sport to decrease kinesiophobia and improve patient confidence, allowing for return to previous level of competition.

Preventing reinjury to the ACL once an athlete returns to play is another primary goal of rehabilitation. The review by Lowe et al.[46] found limited evidence to suggest bracing decreases the rate of re-injury. However, individuals who participate in high-risk activities would benefit from brace use to reduce reinjury rates.[1] Adolescent patients may also benefit from bracing to prevent rerupture, as they have higher rates of reinjury compared with other populations, however, there is not conclusive evidence to suggest bracing can or cannot prevent reinjury.[47]

Recommendations

Postoperative bracing can reduce tibial rotation, but not restore it, regardless of graft type in patients following isolated ACL repair.[30,35,38] Bracing is not effective in matching physiological ACL function of limiting anterior tibial translation, as a mature repair will provide this function.[31,32,39] No brace effectively mimics native ACL function. Therefore bracing is not generally supported to address the common impairments seen following ACL repair.[37,40,41] The American Academy of Orthopedic Surgeons (AAOS) finds there is moderate evidence for lack of evidence for FKO use following ACL reconstruction.[48] Patients with kinesiophobia after surgery, those who participate in high-risk sports, or adolescent athletes may benefit the most by using bracing after surgical repair.[1,45-47] Given the increasingly high rates of surgical success and continued surgical innovation, there is generally no conclusive scientific evidence to support the routine use of an FKO following ACL repair, especially when patients complete a comprehensive rehabilitation program.[1,36]

Orthoses for Osteoarthritis

In healthy tibiofemoral and patellofemoral joints, the articular surfaces are covered in articular cartilage. The role of the articular cartilage is to provide for smooth movement of the knee by reducing friction and providing even force distribution across joint surfaces. Articular cartilage by nature is both avascular and aneural in adult humans. This cartilage is composed of a complex matrix of water, chondrocytes, and proteoglycans.[28] OA is characterized by a disruption or alteration of the cartilage matrix, usually resulting in surface fibrillation, fissures, and eventual removal of cartilage from the underlying bone.[28] OA is a common source of knee pain and discomfort and is associated with high rates of disability. The development and progression of OA is multifactorial, and there are multiple models that outline the development and progression of the disease that are beyond the context of this chapter.

OA that develops in either the tibiofemoral or patellofemoral joint causes considerable pain and disability and imposes a major economic burden on those affected and society as a whole.[49] The inability of the cartilage to sustain loads and distribute forces in the tibiofemoral joint often results in degradation of the cartilage and a reduction of joint space, known as collapse, in one or more compartments of the knee. This breakdown can cause pain and swelling, with unicompartmental collapse causing a change in the alignment of the joint.[50] OA that affects the medial compartment of the tibiofemoral joint may cause an increase in genu varus alignment, whereas lateral collapse may cause an increase in genu valgus alignment. Patients with knee OA report joint pain and demonstrate ROM loss. These symptoms are typically exacerbated in weight-bearing activities, such as the stance phase of gait, negotiating stairs, or getting up from sitting. Conservative interventions, such as exercise, bracing, injections, or medications are commonly used in managing knee OA, with total or unicompartmental joint arthroplasty utilized when symptoms cannot be managed with conservative interventions.

Braces have been designed to help alleviate these symptoms, as well to address inappropriate joint loading as a

Fig. 11.12 Ossur unloader one brace. This is an example of a medial unloading brace used in the treatment of moderate to severe osteoarthritis of the knee. The location of the hinge, sidebars, and straps provide leverage to unload a single compartment in the knee. (© Össur.)

result of unicompartmental collapse. Unloading braces are designed for this specific purpose, and consist of external stays, hinges, and straps (Fig. 11.12). As with PKOs and FKOs, they can be used off-the-shelf or custom made for a specific individual. They aim to decrease the compressive load, or "unload" the surface, and restore joint alignment.[51] They can be used to address varus or valgus alignments. Valgus unloading braces used to reduce the load on the medial compartment are more common, as medial compartment OA with varus alignment is the most common type of unicompartmental knee OA.[52] The use of these braces has become more popular as clinicians and patients attempt to reduce pain and avoid or prolong the need for joint arthroplasty. In contrast to unloading bracing, some clinicians opt for soft brace use, especially for those patients with mild to moderate OA.[49] A systematic review with meta-analysis showed promising benefit, with moderate improvements in pain and small to moderate improvements in function.[49] Based on the current research, the OA Research Society International guidelines for managing knee OA gives unloader bracing a recommendation score of 76% for reducing pain.[53] The AAOS found inconclusive evidence regarding brace use and were not able to recommend for or against brace use in the treatment of OA.[54] Some of the inconsistency with regards to brace prescription may be explained by the highly individualized nature of the presentation and progression of OA, as well as the lack of long-term controlled research.

BIOMECHANICAL IMPLICATIONS

The ability for valgus bracing to provide this desired unloading effect has long been unclear, and the focus of much research and clinical debate.[52,55-57] In a systematic review and meta-analysis, Moyer et al.[52] found that valgus bracing can decrease knee joint loads, with moderate- to high-effect sizes. Specifically, these changes in biomechanics were found during walking and through multiple mechanisms. The authors of this study offered the following mechanisms of action: direct medial compartment load, indirect load distribution, muscle co-contraction, and increase in medial knee joint space. However, this research was not able to identify individuals who would respond well to bracing or what prescriptive criteria should include. In the patellofemoral joint, bracing has been shown to alter the patellar position in a static weight-bearing position.[58] Patellofemoral joint OA is further discussed later in this chapter.

Instability of the tibiofemoral joint in patients with OA can result in altered muscle activation patterns as the muscles attempt to dynamically stabilize the joint. However, this change in muscle activation patterns may also increase the joint load, ultimately becoming counterproductive. Fantini et al.[59] examined the effects an unloader brace would have on muscle activation patterns during gait among individuals with medial knee OA. The researchers found significant decreases in muscle activity during walking with an unloading brace, suggesting the external brace provided additional mechanical stabilization. Petersen et al.[55] found similar results, finding that brace use and the resulting decrease in muscle co-contraction may contribute to decreased pain. When studied in a healthy population, a similar study found no change in muscle activation patterns in braced and unbraced conditions.[60] In a sample of individuals with end-stage OA, utilizing a newly designed pneumatic unloader knee brace over the course of 3 months resulted in a significant increase in quadriceps and hamstring strength compared to the unbraced group.[61] These findings suggest that an unloading brace may provide for mechanical stability in those with knee OA but does not have a similar effect in those with healthy joints. New or novel designs of unloading braces need further examination to determine their effects on muscle activation and strength.

The varus alignment that develops as a result of medial compartment collapse changes the force distribution within the tibiofemoral joint. Due to this malalignment, the GRFs experienced during ambulation is shifted medially; this shift is known as the knee adduction moment (KAM) and results in increased load in the medial tibiofemoral compartment.[55] Reduction of the KAM is one of the proposed mechanisms of action described by Moyer et al.[52] A significant reduction in KAM through the use of an unloading brace has been described in various biomechanical studies among individuals with OA.[55,57,62-66] In a systematic review by Petersen et al.[55] the authors found consensus among the research that a valgus unloader brace significantly reduced the KAM forces in the arthritic knee. The reduction in KAM force from unloading brace use has been shown to be up to 26%, and up to 10% with soft brace use.[63,66] Fu et al.[64] found an even larger reduction in KAM when knee bracing was used in conjunction with lateral wedging insoles with arch support. When compared with FKO bracing, unloading braces seem to be more effective in reducing the KAM.[65] New brace technology that combines valgus effect with tibial external rotation and distraction to further decrease medial joint compression has shown promising

effects on KAM, but further research will be needed to establish the effectiveness of this design.[57]

EVIDENCE OF EFFECTIVENESS

In many cases the biomechanical changes that come from unloader brace use as described by Moyer et al.[52] translate into pain reduction for patients with knee OA. With decreased pain, conservative intervention approaches can then focus on addressing other impairments and improving overall function. Soft braces may provide for pain reduction and improved function in those individuals with mild OA; however an unloading brace is likely to be required in individuals with joint deformity[49,67] (Fig. 11.13). Meta-analysis of randomized trials supports the ability of an unloading brace to reduce pain and improve overall function.[68] A recent systematic review by Gohal et al.[69] found that valgus unloader braces are an effective treatment for reducing pain in this population.

More specifically, unloader braces have been shown to improve gait. Improving walking as a treatment outcome has been rated as very important in up to 89% of this population.[70] The systematic review by Petersen et al.[55] found that the reduction in pain experienced by brace users resulted in increased walking speed, increased step length, and in some cases, increased gait symmetry. Similar findings are discussed in a literature review conducted by Maleki et al.[71] who identified increased gait speed and increased step length in individuals using unloading braces. Due to the reduction in the KAM, patients have been shown to increase gait speed and overall knee ROM during the stance phase of gait.[63] In a survey of unloading brace users, Briggs et al.[70] found significant improvements in quality of life, pain, stiffness, and overall function. In patients with mild OA, using a soft brace was found to result in decreased 10 m Walk and Get-up and Go times, indicating increased speed.[67] This study also found an increase in patient confidence in level and perturbed walking.[67] Braces that provide for a decrease in pain and improvement in patient function allows for patients to maintain a healthy activity level and to increase overall physical health.[70]

Other orthoses that may be used in conservative management include lateral wedged insoles. When compared to valgus bracing, lateral wedged insoles have been found to produce a similar reduction on KAM forces, pain reduction, and gait parameters.[72,73] When used in conjunction, valgus unloading braces and lateral wedged insoles produce greater reductions in KAM than either used independently.[64] The addition of stochastic resonance electrical stimulation to a knee sleeve has been shown to not offer significant improvements over the sleeve use itself.[74] The use of a transcutaneous joint stimulator was shown to be ineffective in reducing pain in isolation but offers some improvements when used with an unloader brace.[75] These results suggest that electrical stimulation in isolation is not likely to produce the desired treatment effect, but could be augmented by the addition of an unloading brace.

Aside from the beneficial treatment effect of these braces, like all treatments, they do not come without potential side effects. Negative side effects of brace use are not commonly researched and are occasionally reported when present. Potential side effects include small reductions in available active range of motion and skin irritation from poorly fitting braces. As a general rule with knee orthoses, brace fit can be improved with the use of a custom brace versus an off-the-shelf model. Another possible limitation to effectiveness is

Fig. 11.13 (A) Hinged knee brace with straps produced by Donjoy. This brace provides moderate compression with increased support from dual hinged sidebars. This brace would be appropriate for patients with mild to moderate OA. (B) OA Fullforce Knee Brace by DonJoy. Notice the longer lateral support on the femoral component of the brace. When combined with straps and hinges, this brace unloads the medial aspect of the knee. (A, Courtesy of DonJoy; B, Courtesy DJO Global. Retrieved from https://www.djoglobal.com/sites/default/files/styles/product_large/public/11-1578_OAFullforce_hires.jpg?itok=ubXIPAFS.)

patient adherence to brace usage and brace cost.[76] Unloading braces in particular tend to be larger and bulkier than smaller sleeves, which may limit a patient's ability to effectively don and doff the brace. Long-term (>1 year) brace usage has shown to be low, at 28% in this population.[76] There is no clear prescriptive criteria for the use of bracing in OA either, which may present a limitation in providing braces to appropriate patients.

RECOMMENDATIONS

Recent research suggests that unloading braces can alter tibiofemoral and patellofemoral joint positions, both statically and dynamically.[52,58] Unloading braces are also effective in decreasing muscle co-contraction, providing an increase in joint stability without sacrificing muscle strength.[55,59,61] Additionally, both unloader and soft braces reduce the KAM force experienced during gait, which distributes forces more uniformly in the joint, thereby reducing pain.[55,57,62-66] These biomechanical changes result in decreased pain and improved function, specifically gait parameters. These improvements result in increased quality of life and confidence in patients with knee OA.[70] Further research is needed to examine the effects that new brace designs to the market have on biomechanics, pain, and function among this patient population.[57,61] The majority of these recent studies focus on relatively short-term effects of brace use. Due to the chronic and progressive nature of OA, it would be beneficial to examine both the long-term effects of brace use and the possibility for slowing the progression of the disease.[77]

Conservative intervention continues to be the first line of treatment for patients with knee OA. Physical therapy, exercise, weight reduction, bracing, and antiinflammatory medications are among the most common conservative interventions.[78,79] Physical therapy carries an Osteoarthritis Research International recommendation grade of 89%, regular exercise carries a grade of 96%, and bracing was graded at 76%.[53] Despite the inconclusive opinion from the American Academy of Orthopaedic Surgeons, the addition of a brace to these interventions may prove to be useful, but more long-term randomized studies are necessary. Identifying which patients will benefit from the addition of bracing to a conservative program can be difficult for many practitioners and may present as a barrier to brace use. Establishment of an industry-wide validated model of brace implementation would prove to be greatly beneficial. However, clinicians may be able to match patient impairments with the known biomechanical effects of certain braces to produce a desired treatment effect. As a general rule, those with a passively correctable varus or valgus deformity as a result of unicompartmental OA are ideal patients for unloader brace use.[78] In those patients with mild OA, a soft brace may be an effective treatment.[51]

Orthoses for Patellofemoral Disorders

It is important to consider the contributions of the patellofemoral joint to both normal tibiofemoral joint motion and painful conditions of the knee. The patella is a sesamoid bone positioned in the tendon of the quadriceps femoris. On its posterior, it has two large facets medially and laterally, and a small odd facet on the medial aspect.[28] These facets articulate with the medial and lateral femoral condyles during flexion and extension movements of the knee, respectively. When the knee is extended and the quadriceps relaxed, there is relatively little contact between the patella and the femur. Normal alignment finds the patella positioned just laterally to the femoral trochlear notch at rest.[28] Under normal conditions the patella functions to increase the moment arm of the quadriceps tendon, therefore the patella is critical to normal function of the quadriceps muscle and tibiofemoral joint.[28] During tibiofemoral flexion, the patella glides distally on the femur. At the same time the patellofemoral joint surface experiences an increase in compressive force.[28] During knee extension, the patella glides superiorly on the femur. In addition to superior and inferior translation, there is movement of the patella medially and laterally, as well as tilting and rotation during tibiofemoral flexion and extension.[28] The term "patellar tracking" is often used to describe this complex set of motions that occur at the patellofemoral joint. Compressive force at the patellofemoral joint is also affected by other factors besides tibiofemoral joint angle, such as weight-bearing or external loading. Abnormal knee function and pain have been hypothesized to be caused by problems with static or dynamic patellofemoral alignment, tracking, and force distribution across the joint surface or a combination thereof. Models that explain normal and abnormal patellofemoral joint motion and force distribution are far more complex, however, and are beyond the scope of this chapter. Having knowledge regarding normal function is important to understanding the purpose of patellofemoral orthoses.

Patellofemoral orthoses, like other knee braces, are a form of conservative treatment that are frequently used in conjunction with other nonoperative measures. They function to reduce the pain experienced in the anterior knee and retropatellar area in individuals with patellofemoral pain syndrome (PFPS) or patellofemoral OA by modifying patellar position.[80] Designs of orthoses for this purpose are highly variable and range from simple straps to knee sleeves to full patellar support braces (see Figs. 11.2 and 11.14). Patellofemoral braces are generally less bulky than tibiofemoral counterparts and can be worn under trousers.[81] There are significant differences in prescriptive criteria and little consensus among health care professionals regarding the use of these orthoses.[82]

PATELLOFEMORAL OSTEOARTHRITIS

OA that affects the patellofemoral joint can be a significant cause for anterior and retropatellar pain. Due to the compressive nature of the patellofemoral joint, patellofemoral OA tends to be a particularly painful condition. Bracing in this population is thought to decrease contact stress across the patellofemoral joint by encouraging proper alignment or tracking, thereby reducing painful compression.[58,81] Restoring normal forces across a larger surface area on the facets of the posterior patella may reduce focal stress through any one area that has degenerative changes. Bracing is also thought to increase proprioceptive input and facilitate a feeling of stability, which may encourage

Fig. 11.14 Patella strap by DonJoy. Example of a compressive strap worn directly over the patellar tendon. (Courtesy DJO Global. Retrieved from: https://www.djoglobal.com/sites/default/files/styles/product_large/public/images/products/patella-front.jpg?itok=ukUDqXKl.)

participation in physical activity.[50] Unlike bulky FKOs or other tibiofemoral braces, knee sleeves used in this population are typically soft and can be worn underneath long pants.

Biomechanical Implications

Weakness of the quadriceps is a common impairment that is observed in individuals with OA of the knee. In a recent secondary analysis of a randomized controlled trial, Callaghan et al.[83] studied the effect of wearing a knee brace on quadriceps strength in individuals who have patellofemoral OA. This study utilized an off-the-shelf knee sleeve, which allowed full ROM of the knee. This type of brace is commonly used in the treatment of patellofemoral pain syndrome (PFPS) and for general knee joint support. After 6 and 12 weeks, there was found to be no difference in maximum voluntary contraction or arthrogenous muscle inhibition, meaning the use of the brace did not reduce the strength or activation of the quadriceps.

Correcting improper patellar tracking or position may also be a goal in the treatment of patellofemoral OA. In a small scale ($n = 26$), patella position and patellofemoral joint space were measured using MRI.[58] The results of this study indicate that bracing increases the contact area between the posterior patella and femoral trochlea, thereby distributing forces in a more even manner when compared to a nonbraced condition.[58] Although promising, this research was conducted in a static position, which reduces the clinician's ability to apply the results to more dynamic functional activities that are often impaired, such as ambulation.

In another randomized study by Callaghan et al.[81] pain and bone marrow lesion size was measured in the patellofemoral compartment in patients with patellofemoral OA. Participants were randomized to braced or nonbraced conditions for a treatment duration of 6 weeks. At the end of the study, there was a significant improvement in pain with activity as scored on the Knee Osteoarthritis Outcome Score (KOOS) in the group that used bracing. Additionally, a significant decrease in bone marrow lesion size was observed in the brace group. The short-term results of this study represent a very significant finding, as OA is a chronic condition, suggesting that components can be addressed in as little as 6 weeks.

Conservative Management

The positive results on the KOOS of the previous study by Callaghan et al.[81] are in contrast to those reported by Yu et al.,[84] who found that the addition of a patellofemoral brace to a multidisciplinary program did not provide additional benefits. Participants in this study were assessed at multiple intervals up to 1 year. The authors report that the addition of bracing as an intervention did not result in superior outcomes in terms of pain or function as compared with a nonbraced rehabilitation program at any follow-up point. A randomized clinical trial by Crossley et al.[85] demonstrated improvements in KOOS scores, indicating improved pain and function after 3 months of conservative treatment. Although the conservative management in this study did not include brace use, it does support the efficacy of conservative interventions in the treatment of patellofemoral OA.

Recommendations

OA affecting the patellofemoral joint frequently results in pain and decreased function in affected individuals. Conservative management of a multidisciplinary nature has been shown to improve these outcomes in both short- and long-term follow-up studies.[84,85] The effects of the addition of a brace to conservative management is not well understood. Current literature suggests that brace use will not weaken or inhibit quadriceps function, can change the static position of the patella, and possibly have a positive effect on bone marrow lesion size.[58,81,83] No large-scale negative effects of brace use have been reported in the recent literature. Bracing for patients with patellofemoral OA may be used to complement a conservative multidisciplinary approach to improve pain and function.

PATELLOFEMORAL PAIN SYNDROME

PFPS is a global term used to describe pain that occurs in the anterior patellar or retropatellar areas. Symptoms in the area are generally worsened during prolonged sitting, descending stairs, walking down slopes, athletic activities, squatting, or kneeling.[23,80,82,86,87] The repetitive nature of these activities contributes to the onset of symptoms. PFPS is a common disorder of the knee, affecting 10% to 20% of the general population, with females, especially athletic women being more commonly affected.[88,89] Due to the complex nature of normal patellar function, it is likely that there is a wide variety of biomechanical reasons that patellar tracking becomes abnormal.[90] Despite etiology of PFPS remaining unclear, the basic premise of PFPS is that abnormal movement of the patella in the femoral trochlear results in altered force distribution and pain in the

joint.[80,91] When possible, identifying the underlying cause of altered tracking would be beneficial for directing conservative treatment, including orthoses use, for those with PFPS. For example, if a patient demonstrates excessive lateral tracking of the patella, a brace designed to apply a medially directed force may be used to keep the patella situated in the femoral trochlea. Additional conservative treatment might include quadriceps strengthening, stretching of lateral thigh and knee structures, and avoidance of painful activities. A review of conservative management alone and in combination with orthoses use is provided later in this chapter.

Biomechanical Implications

Patellar strapping is commonly used to control pain in individuals with PFPS related to patellar tendinopathy.[92] These straps have been researched with regards to proprioception, pain, muscle activity, and dynamic alignment.[86,92-94] Unfortunately, the vast amount of literature pertaining to these orthoses is under powered. In those individuals who have patellar tendinopathy and low proprioceptive acuity, a patellar strap has been shown to demonstrate similar improvements in proprioception.[92] However, those with normal proprioceptive acuity and PFPS did not demonstrate any improvement by utilizing a patellar strap.[92] A randomized controlled trial conducted by de Vries et al.[93] demonstrated that patellar straps were found to decrease pain during athletic activities but were not superior to placebo taping. Patellar straps have also been shown to decrease vastus lateralis muscle activation prior to single limb landing, possibly resulting in decreased tensile stress on the patellar tendon.[94] In a later study, Rosen et al.[86] found that patellar straps reduced pain in single limb landing and resulted in improved patellar alignment.

Sinclair et al.[87] examined the use of a knee sleeve on controlling patellar tracking and pain during common sport movements, such as running and cutting, in athletes. The results of their study suggest significant reduction of patellofemoral force, resulting in decreased pain and improved overall function. When used for longer periods of time, a knee sleeve has been shown to improve knee pain and improve gait parameters in individuals with PFPS, and significant increase in gait speed, step length, and knee flexion angles have been reported.[95]

Conservative Management

Effective exercise interventions should target the underlying impairments found to contribute to patellofemoral pain. Commonly, targeted strengthening of the quadriceps, hip extensors, and hip abductors are utilized.[23,90] Limiting patellofemoral loading during exercise interventions is advocated. Other frequently used interventions include muscle stretching of the hamstrings, hip flexors, quadriceps, triceps surae, and ITB.[23] Patient education of the nature of PFPS, avoidance of aggravating activities, and indications for brace use should also be included.[90]

Petersen et al.[91] conducted a randomized clinical trial of over 150 participants to examine the effects physical therapy alone and in combination with knee bracing had on pain and function in individuals with PFPS. Both groups in the study demonstrated improvements in pain and functional outcome measures in the short and long term. However, the group that received bracing and physical therapy in combination demonstrated greater improvements in pain and function in the short term. At a 1-year follow-up, both groups demonstrated similar improvements. The findings of this larger scale, higher powered study are significant for brace prescription. They suggest that early intervention with a combination of bracing and physical therapy is important and leads to greater short-term improvements. Barton et al.[90] arrived at a similar conclusion, that bracing can be an effective intervention for short-term pain relief, but is likely not as effective in the long term. In a Cochrane review by Smith et al.[80] the authors conclude that there is very low-quality evidence that using a knee orthosis in combination with physical therapy may not reduce pain.

Recommendations

The overall low quality of available evidence and dissonance among the evidence that does exist shows the need for improved and continued research methodology to help guide clinicians' utilization of orthoses for PFPS. Additionally, it makes the task of prescribing such an orthosis challenging. Solinsky et al.[82] explored the factors influencing brace prescription for PFPS across sports medicine professionals (physicians, physical therapists, and athletic trainers). The findings suggest that there is little consensus among the professions and significant differences in prescription criteria, as well as bracing frequency. This implies that depending on which professional a patient encounters, they are likely to be assessed and prescribed orthoses in a different manner. PFPS should initially be managed with conservative intervention, which is individually tailored to the impairments of the patient and may include the use of a patellofemoral orthosis. When used, orthoses should be used in conjunction with selected exercise and behavior modification interventions.

Summary

This chapter reviews the normal structure and function of the tibiofemoral and patellofemoral joints and the common pathologic conditions that affect these joints. The different categories of orthoses for the knee complex are prophylactic orthoses, functional orthoses, and rehabilitation orthoses. Emphasis was placed on unloading knee orthoses and patellofemoral orthoses as a subcategory of rehabilitation orthoses. A review of the literature was presented. Although there continues to be debate among the research and clinicians regarding the use of these orthoses, improvements in the quality and strength of recommended orthoses has improved compared with previous orthoses. Identifying appropriate patients who would benefit from brace use is key to brace prescription. Interprofessional communication among the patients and the health care team, with input from the patient, is essential. This chapter discusses the application of the current research to allow the clinician to make the best possible decision for their patient's care. It is important for clinicians to continue to view knee orthosis use in a complementary sense to other conservative interventions, such as a comprehensive evidence-based rehabilitation program.

The intent of this chapter is to provide clinicians with the ability to evaluate the design and the intended treatment effects of a given knee orthosis and for appropriate application in the clinical setting. This chapter also highlights evidence in current research, including gaps in present knowledge. These gaps include the long-term effects of knee orthosis use and effects of new or novel brace design with the hopes of encouraging participation in ongoing research on the topic.

Case Example 11.1

M.G. is an 18-year-old college freshman who is referred to you with the diagnosis of an acute left anterior cruciate ligament (ACL) tear for management of knee pain and swelling. She reports feeling a large pop in her knee followed by immediate swelling after an awkward landing playing intramural volleyball. Complete ACL tear was confirmed with MRI. The incident happened 1 week ago, and she has been on bilateral crutches since. She would like to return to playing intramural volleyball and softball and is scheduled for surgical repair in 4 weeks.

On examination, she demonstrates significant weakness of the left quadriceps and hamstrings, significant knee joint effusion, knee flexion of 100 degrees, knee extension lacking 8 degrees, and difficulty with weight bearing, ambulation, balance, and stairs. She reports a feeling of instability, like her knee is going to buckle, when she tries to ambulate without assistance.

QUESTIONS TO CONSIDER

1. Given M.G.'s history and current presentation, what additional tests and measures would aide in your evaluation process? What other functional tests could be performed?
2. What are your short-term goals with this patient, knowing that she will undergo surgical repair in 4 weeks?
3. Based on M.G.'s goals and your understanding of current literature, what would your recommendations for brace use be at this time?

M.G. comes back to your clinic to begin postoperative rehabilitation 14 days after her surgery. Surgery was successful and uncomplicated, using a hamstring autograft. She demonstrates appropriate healing at this point. She was provided with a functional knee brace postoperatively. She has been compliant with brace use and her home exercise program. She reports a feeling of increased knee stiffness and demonstrates active flexion of 80 degrees and active extension lacking 3 degrees. She has a follow up with the orthopedic surgeon tomorrow.

QUESTIONS TO CONSIDER

1. Based on current research, is the use of an FKO warranted at this point in her rehabilitation? If not, how would you address that with the patient and her physician?
2. M.G. is curious regarding the use of a brace once she returns to playing recreational sports. What advice can you give her? How might you include bracing in your plan of care at that point?

RECOMMENDATIONS

The use of an FKO in the postoperative rehabilitation phase is not supported by current evidence to reduce impairments associated with surgery.[37,40,41,48] After successfully treating M.G. postoperatively, she has returned to pain-free daily function and light running with no pain or reactive effusion. Among other interventions, you have incorporated neuromuscular training to facilitate proprioception and dynamic strengthening to prepare her for return to sport. Based on her selected sports, sex, and age, you identify that she may be at higher risk for reinjury of the ACL and recommend that she obtain an FKO to wear while she plays sports.[1,46,47]

Case Example 11.2

F.L. is 72-year-old retired construction worker referred to your clinic for the management of right knee pain. Radiographs obtained from his physician reveal medial compartment tibiofemoral OA with considerable joint space narrowing. His knee pain has been getting progressively worse over the past 2 years. He walks 9 holes of golf twice per week and reports considerable pain on the medial aspect of the knee with prolonged standing and walking. At this point, F.L. cannot stand for more than 20 minutes without pain. He also has pain and stiffness with going up and down stairs and getting up from sitting. He reports that he has had two joint injections to the knee over the past 6 months, which provided short-term relief. Previously, he had used a neoprene knee sleeve which provided on-and-off results.

You treat F.L. with a physical therapy regimen centered on strengthening and joint mobility to improve his overall function. After 4 weeks of treatment, F.L. demonstrates minimal improvements in pain and function. F.L.'s physician recommends that F.L. undergo a total knee arthroplasty. However, F.L. does not want to have the procedure because of the associated risks and lengthy postoperative rehabilitation. He asks for your recommendation about other conservative interventions.

QUESTIONS TO CONSIDER

1. What are your short- and long-term physical therapy goals with this patient?
2. Given your knowledge of the disease process of osteoarthritis, what is his prognosis?
3. Based on the patient's goals and expectations and utilizing your understanding of current research, what is your recommendation regarding brace use with F.L.? What evidence supports your decision?
4. Besides brace use, what are other conservative interventions that may be appropriate for this patient?

RECOMMENDATIONS

Utilizing the most current evidence available, you decide that wearing a valgus unloading brace may help diminish F.L.'s pain and increase his functional ability and his quality of life. You work closely with an orthotist to determine the most appropriate brace for this individual case. During the process, you educate F. L. that the evidence suggests that he can expect short-term benefits from brace use, but the long-term outcomes are not well understood. You emphasize that he should continue with his current regimen of strengthening, mobility exercises, and aerobic exercise in addition to using the valgus unloading brace.

12 Orthoses in Orthopedic Care and Trauma☆

MELISSA THACKER, BRADLEY CONNER, and MICHELLE M. LUSARDI

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Review the characteristics of normal bone structure and function across the life span.
2. Describe the most common musculoskeletal injuries that occur at various points in the life span.
3. Identify orthotic interventions for congenital and growth-related musculoskeletal impairments.
4. Classify fracture of bone by type and severity and describe the interventions most often used by orthopedists and orthopedic surgeons on the basis of fracture type.
5. Discuss the different orthotic options for fracture management: joint immobilization, fracture bracing, and external stabilization in common orthopedic injuries to the extremities.
6. Delineate the roles of health care team members in the rehabilitation and orthotic management of individuals with congenital and acquired musculoskeletal impairment.

Orthoses play a significant role in orthopedic and rehabilitative care of individuals with many different types of musculoskeletal pathologic conditions and impairments. Dysfunction of the musculoskeletal system can be the result of congenital or developmental disorders or can be acquired as a result of overuse injury, systemic disease, infection, neoplasm, or trauma at any point in the life span. This chapter focuses on the use of orthoses to manage congenital and developmental musculoskeletal problems in children and fractures of long bones of the lower extremity.

The understanding of how orthoses are helpful in the care of those with musculoskeletal impairments is founded on knowledge of the development and physiology of musculoskeletal tissues (bone, cartilage, ligaments, menisci, muscles, and their tendons or aponeuroses); the kinesiological relationships among these tissues; and an understanding of how these tissues remodel in response to physical stressors (forces).[1,2] This chapter begins with an overview of the anatomy of bone, its growth and remodeling, and the principles behind the rehabilitation (examination and intervention) of persons with disorders of bone. Then the authors look specifically at disorders of the hip joint and orthotic/orthopedic strategies for limb fractures.

Bone Structure and Function

In anatomy classes and texts, students learn that the mature adult human skeleton is composed of 206 bones (Fig. 12.1), ranging from the long bones of the extremities, the blocklike vertebrae of the spine, the encasing protective ribs and skull, and the multiarticulating carpals and tarsals of the wrist and ankles that enable positioning of the hands and feet for functional activities.[3,4] Bony prominences formed during development from the force of muscle contraction at tendinous origins and insertions are identified.[1] Students scrutinize articular surfaces to understand how joints move, consider the hyaline cartilage that protects the joint from repeated loading and shear during activity, and learn to examine the ligaments that maintain alignment for normal joint function. From a skeletal model or examination of bone specimens in anatomy laboratory, it is not intuitively apparent that living bone is a dynamic and metabolically active tissue serving multiple purposes and physiological roles.[5] These include storage and homeostasis of calcium, phosphate, magnesium, sodium, and carbonate (via ongoing osteoblastic and osteoclastic activity in conjunction with kidney function); production of erythrocytes, granular leukocytes, and platelets in the marrow; physical growth and development (by responsiveness to the pituitary hormones at the epiphyseal plate); provision of a protective and functional frame for the organs of the thorax and abdomen (how would people breathe without ribs?); and body weight support when the body is either at rest or in motion during functional activities.[6]

Bone is a dense, regular, connective tissue derived from embryonic mesoderm. It contains a combination of specialized cells (osteoblasts, osteocytes, osteoclasts) embedded in a matrix of minerals (70%), protein (22%), and water (8%). The many bones of the human body can be described as long or short tubular bone (e.g., the femur, tibia, metatarsals, phalanges), flat bone (e.g., the pelvis or skull), irregular bone (e.g., the tarsals and carpals), sesamoid bone embedded within tendons (e.g., patella), or accessory bones (e.g., ossicles of the middle ear). Alternatively, they can be classified as primarily cortical (dense) or cancellous (trabecular) bone

☆The authors extend appreciation to William J. Barringer, Melvin L. Stills, Joshua L. Carter, and Mark Charlson, whose work in prior editions provided the foundation for this chapter.

on the basis of the density and arrangement of their components. Long bones are subdivided into regions, each of which has its own blood supply (Fig. 12.2). The diaphysis (shaft) is supplied by one or more nutrient arteries that penetrate the layers of the bony cortex, dividing into central longitudinal arteries within the marrow cavity. The flared metaphyses serve as an area of transition from cortical to cancellous bone and are supplied by separate metaphysical arterioles. The epiphyses are metabolically active areas of cancellous bone with supportive trabeculae, with an extensive capillary network derived from epiphyseal arteries. The epiphysis is actively remodeled over the life span in response

to weight bearing and muscle contraction during activity.[7] In childhood and adolescence, before skeletal maturation, the bony metaphyses and epiphyses are connected by cartilaginous epiphyseal (growth) plate, which calcifies and fuses throughout various periods of development. The periosteum is a layer of less dense, vascularized connective tissue that overlies and protects the external surface of all bone and houses osteoblastic cells necessary for bone deposition and growth. The periosteum is replaced by articular (hyaline) cartilage within the joint capsule. The endosteum, a thin connective tissue lining of the marrow cavity of long bones and the internal spaces of cancellous bone of the marrow

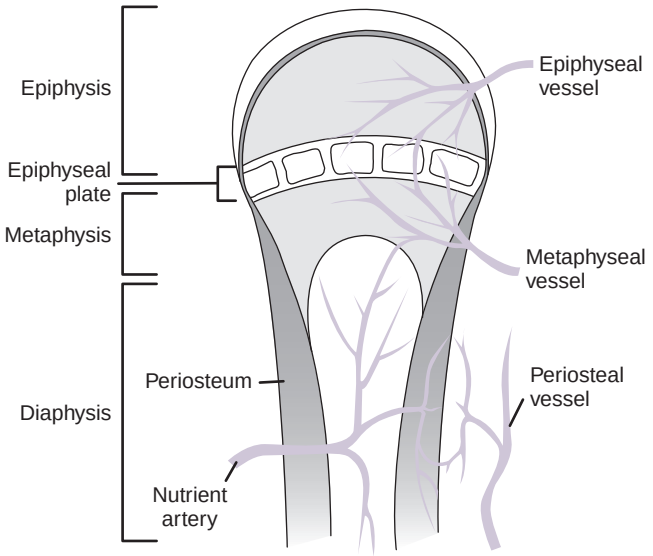

Fig. 12.2 Diagram of the regions (epiphysis, epiphyseal plate, metaphysis, and diaphysis) of a long bone and their arterial vascular supply. (Modified from Lundon K. *Orthopedic Rehabilitation Science, Principles for Clinical Management of Bone.* Boston: Butterworth Heinemann; 2000.)

space, also houses osteoblasts. Both linings are active as part of osteogenesis during growth and fracture healing.

Cortical bone is the most highly mineralized type of bone found in the shafts (diaphyses) of the long bones of the body and serves as the outer protective layer of the metaphysis and epiphysis of tubular bone, as well as the external layers of flat, irregular, and sesamoid bones. Most of the bones in the human skeleton (80%–85%) are primarily cortical with cancellous/trabecular bone in the metaphyseal and epiphyseal region. Cross section of a long tubular bone reveals three layers of cortical bone: the inner or endosteal region next to the marrow cavity, the metabolic intracortical or haversian region with its haversian canals surrounded by concentric layered rings (osteons) and Volkmann canals containing a perpendicularly arranged anastomosing capillary network, and the dense outer periosteal region (Fig. 12.3).

Cancellous (trabecular) bone with its honeycomb or spongy appearance is much more metabolically active and much less mineralized than cortical bone. Cancellous bone is composed of branching bony spicules (trabeculae) arranged in interconnecting lamellae to form a framework for weight bearing (Fig. 12.4A). In the vertebral bodies, for example, trabeculae are arranged in an interconnecting horizontal and vertical network oriented perpendicular to the lines of weight-bearing stress into a boxlike shape (see Fig. 12.4B). In contrast, trabeculae in the proximal femur form an archlike structure to support weight-bearing forces between the hip joint and femoral shaft in living bone, cavities between trabeculae are filled with bone marrow. When bone becomes osteoporotic, the cavities enlarge due to loss of bone mass.

Three types of cells are embedded within the various compartments of bone. *Osteoblasts*, bone building cells, synthesize and secrete the organic matrix of bone (osteoid) that mineralizes as bone matures. They are located under periosteum and endosteum and are active in times of bone growth and repair. *Osteocytes* are matured and inactive osteoblasts that have become embedded within bone matrix. Osteocytes remain connected to active osteoblasts via long dendritic processes running through the canaliculi (small channels) within the bone matrix. Both osteoblasts and osteocytes are responsive to circulating growth hormones, growth factors, and cytokines, as well as mechanical stressors and fluid flow within the bone itself.[8,9] Osteocytes are thought to be involved in mineral exchange, detection of strain and fatigue, and control of mechanically induced remodeling.[10] *Osteoclasts*, derived from precursor cells in bone marrow, are macrophage-like cells that can move throughout bone to resorb bone by releasing minerals from the matrix and removing damaged organic components of bone.[11,12]

The epiphyses of long bones, the vertebrae, and large flat bones house nociceptors and mechanoreceptors and a network of afferent sensory neurons that contribute to exteroceptive (primarily pain) pathways.[13] The periosteum has a particularly rich neural network with branches that continue along with penetrating nutrient arteries into the haversian canals into the diaphysis.

Bone Growth and Remodeling Over the Life Span

During childhood and adolescence, growth occurs through the process of modeling, in which bones increase in length and diameter and are reshaped until the epiphyseal plates calcify and skeletal maturity is achieved (typically in mid-adolescence for females and early adulthood for males).[14] In adulthood, bone health is maintained by the ongoing process of remodeling, in which there is a balance and coupling between osteoblastic deposition of new bone substance and osteoclastic resorption of existing bone.[15] This ongoing process of turnover means that the internal architecture of living bone is actively restructured and replaced at a rate of approximately 5% per year in cortical bone and up to 20% per year in cancellous bone.[5] The rate of bone formation, resorption, and turnover is influenced by both systemic hormones and other substances (e.g., parathyroid hormone, calcitonin, vitamin D from the kidney, growth hormone, adrenocorticosteroids, estrogen, progesterone, androgens); local cell-derived growth factors; and availability of essential nutrients (calcium, fluoride, vitamin A, vitamin D, and vitamin E).[16–18] These substances, along with blood or urinary levels of certain enzymes active during turnover and metabolites of bone resorption, are monitored as biomarkers to track progression of bone diseases associated with high rates of bone resorption (e.g., Paget disease, osteoporosis, hyperparathyroidism) and to determine efficacy of medical-pharmaceutical interventions for these diseases.[19–21]

In the prenatal period and in infancy, the flat bones of the skull develop as the fetal mesenchyme that forms the periosteum begins to ossify (intramembranous ossification). Most long bones, as well as the vertebrae and pelvis, develop from a cartilaginous framework or template. In this process of endochondral bone formation, cartilage cells mature and eventually ossify.[7] During childhood and adolescence, bones grow in both length and diameter and are dynamically modeled toward their mature configurations.[22] During puberty, accumulation of bone mass accelerates; by the end of puberty, as much as 90% of mature bone mass is established.[23] For young children with abnormal skeletal development, orthoses attempt to capitalize on the dynamic modeling process, applying external forces to influence bone

shape and length.[24] For approximately 15 years following puberty, after closure of the epiphyseal plates of the long bones, bone mass continues to increase—a process described as *consolidation*.[22] Gender differences in peak bone mass have been well documented: Average peak bone mass in women is approximately 20% less than that of men. Early in the midlife period, both men and women enter a period of gradual endochondral bone loss that appears to be genetically determined; the rate of bone loss is also influenced by hormonal status, nutrition, smoking and alcohol use, and activity level.[25–28] It is estimated that males will lose between 15% and 40% of cancellous bone mass and 5% to 15% of cortical bone mass over their lifetime. In women, menopause accelerates the rate of bone loss; there may be up to a 50% decrease from peak cancellous bone mass and 30% decrease in cortical bone mass over their lifetimes.[29] Significant loss of bone mass is associated with increasing vulnerability to fracture, especially among postmenopausal women.

Orthoses in the Management of Hip Dysfunction

Hip orthoses are important in the management of hip disorders in infants and children, as well as in the postsurgical care of children and adults. An understanding of the designs of and indications for various hip orthoses is essential for physicians and rehabilitation professionals working with individuals who have orthopedic problems of the pelvis, hip joint, or proximal femur. For children with developmental dysplasia of the hip (DDH) or Legg-Calvé-Perthes disease (LCPD), hip orthoses are the primary intervention for prevention of future deformity and disability. Hip orthoses are essential elements of postoperative care and rehabilitation programs for children with musculoskeletal and neuromuscular conditions who have had surgical intervention for bony deformity or soft tissue contracture. Hip orthoses can also be major postoperative interventions for adults who have had repair of a traumatic injury or a complex total hip arthroplasty. In cases of recurrent hip dislocations, hip orthoses may be indicated to provide external support to prevent future occurrence of dislocation. The efficacy of orthotic intervention is influenced by patient and caregiver adherence: The key to successful use of these orthoses is clear, and open communication exists among the physician, therapist, orthotist, and family concerning the primary goals of the orthosis, its proper application and wearing schedule, and the possible difficulties that may be encountered. Positive health care outcomes and happy patients and families are contingent on the ability of the health care team to communicate.

WHEN ARE HIP ORTHOSIS INDICATED?

Most nontraumatic hip joint dysfunction or pathology occurs either in childhood or in late adult life and is frequently related to one or more of the four following factors:

1. Inadequate or ineffective development of the acetabulum and head of the femur in infancy
2. Avascular necrosis of the femoral head associated with inadequate blood supply during childhood
3. Loss of cartilage and abnormal bone deposition associated with osteoarthritis
4. Loss of bone strength and density in osteoporosis

Orthotic intervention is an important component in the orthopedic management of many of these conditions. Most often, hip orthoses are used to protect or position the hip joint by limiting motion within a desirable range of flexion/extension and abduction/adduction. It is important to note that hip orthoses alone are not effective in controlling internal/external rotation of the hip joint. If precise rotational control is desired, a hip-knee-ankle-foot orthosis (HKAFO) must be used.

HIP STRUCTURE AND FUNCTION

The hip (coxofemoral) joint is a synovial joint formed by the concave socketlike acetabulum of the pelvis and the rounded ball-like head of the femur (Fig. 12.5). Because of the unique bony structure of the hip joint, movement is possible in all three planes of motion: flexion/extension in the sagittal plane, abduction/adduction in the frontal plane, and internal/external rotation in the transverse plane. Most functional activities blend movement of the femur on the pelvis (or of the pelvis on the femur) across all three planes of motion.

The hip joint has two important functions. First, it must support the weight of the head, arms, and trunk during functional activities (e.g., erect sitting and standing, walking, running, stair climbing, and transitional movements

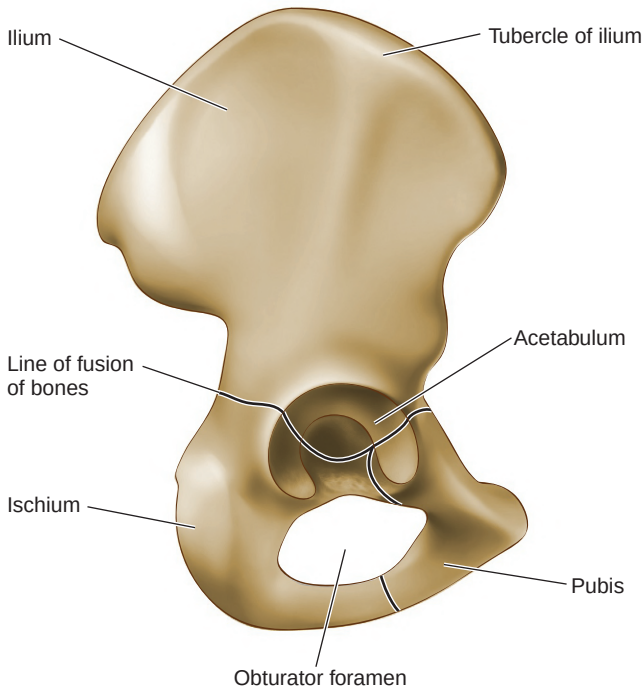

Fig. 12.5 Anatomy of the hip. (From Berry DJ, Lieberman JR. *Surgery of the Hip*. Volume 2, Sections VII–XII. Philadelphia: Elsevier; 2013.)

in activities of daily living). Second, it must effectively transmit forces from the pelvis to the lower extremities during quiet standing, gait, and other closed chain activities.[30]

The acetabulum is formed at the convergence of the pubis, ischium, and ilium. Its primary orientation is in the vertical, facing laterally, but it also has a slight inferior inclination and an anteverted, or anterior-facing, tilt. Developmentally, the depth of the acetabulum is dynamically shaped by motion of the head of the femur during leg movement and weight bearing. The acetabulum is not fully ossified until late adolescence or early young adulthood. The articular surface of the acetabulum is a horseshoe-shaped, hyaline cartilage–covered area around its anterior, superior, and posterior edges. A space along the inferior edge, called the acetabular notch, is nonarticular, has no cartilage covering, and is spanned by the transverse acetabular ligament. The acetabular labrum is a fibrocartilaginous ring that encircles the exterior perimeter of the acetabulum, increasing joint depth and concavity. The center of the acetabulum, the acetabular fossa, contains fibroelastic fat and the ligamentum teres, and is covered by synovial membrane.

The femoral components of the hip joint include the femoral head, the femoral neck, and the greater and lesser trochanters. The spherical articular surface of the femoral head is covered with hyaline cartilage. Because the femoral head is larger and somewhat differently shaped than the acetabulum, some portion of its articular surface is exposed in any position of the hip joint. The femur and acetabulum are most congruent when positioned in a combination of flexion, abduction, and external rotation. The proximal femur, composed primarily of trabecular bone, is designed to withstand significant loading while also permitting movement through large excursions of range of motion. The orientation of the femoral head and neck in the frontal plane, with respect to the shaft of the femur, is described as its angle of inclination (Fig. 12.6).

In infancy the angle of inclination may be as much as 150 degrees but decreases during normal development to approximately 125 degrees in mid-adulthood and to 120 degrees in later life.[31] The orientation of the proximal femur

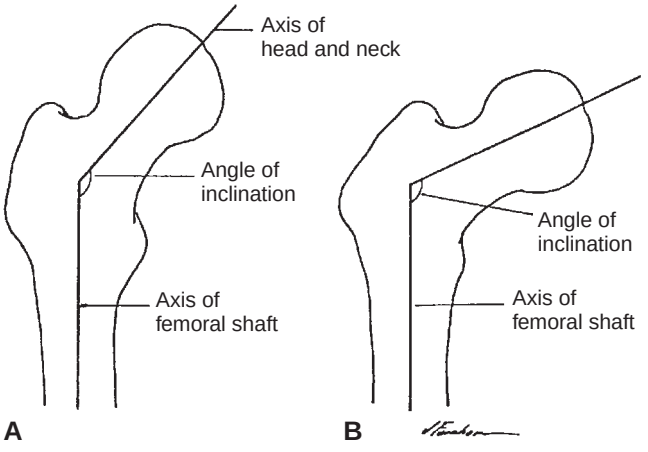

Fig. 12.6 (A) Normal angle of inclination between the neck and shaft of the femur is 125 degrees in adults. A pathological increase in the angle of inclination is called *coxa valga,* and a pathological decrease in the angle of inclination (B) is called *coxa vara.* (From The hip complex. In: Norkin CC, Levangie PK, eds. *Joint Structure and Function: A Comprehensive Analysis*. 2nd ed. Philadelphia: FA Davis; 1992:305.)

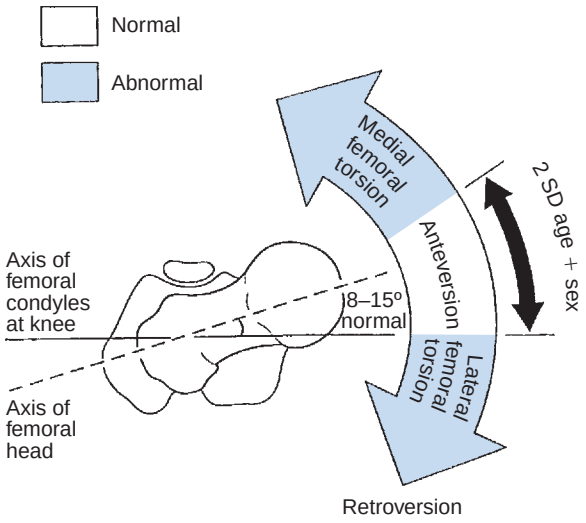

Fig. 12.7 Normal relationship between the axis of the femoral neck and the axis of the femoral condyles (viewed as if looking down the center of the femoral shaft) is between 8 and 15 degrees. Excessive anteversion leads to medial (internal) femoral torsion. Insufficient angulation, retroversion, is associated with lateral (external) femoral torsion. (From Staheli LT. Medical femoral torsion. *Orthop Clin North Am.* 1980;11:40.)

to the shaft and condyles in the transverse plane, called the *angle of anteversion*, is also a key determinant of hip joint function (Fig. 12.7). Anteversion may be as much as 40 degrees at birth, decreasing during normal development to approximately 15 degrees in adulthood.[31] These two angulations determine how well the femoral head is seated within the acetabulum and, in effect, the biomechanical stability of the hip joint. The functional stability of the hip joint is supported by a strong fibrous joint capsule and by the iliofemoral, ischiofemoral, and pubofemoral ligaments. Fibers of the capsule and ligaments are somewhat obliquely oriented, becoming most taut when the hip is in an extended position.

INFANTS AND CHILDREN WITH DEVELOPMENTAL DYSPLASIA OF THE HIP

DDH is the current terminology for a condition previously called *congenital dislocation of the hip*. This new term includes a variety of congenital hip pathologies including dysplasia, subluxation, and dislocation. This terminology is preferred because it includes those infants with normal physical examination at birth who are later found to have a subluxed or dislocated hip, in addition to those who are immediately identified as having hip pathologies.[32–34]

INCIDENCE AND ETIOLOGY OF DEVELOPMENTAL DYSPLASIA OF THE HIP

Instability of the hip due to DDH occurs in 11.7 of every 1000 live births, with most of these classified as hip subluxation (9.2/1000), followed by true dislocation (1.3/1000) and dislocatable hips (1.2/1000).[33,35] Commonly, female, family history, and breech presentation are reported as risk factors for DDH.[36–38] A higher incidence of DDH is also found among newborns with other musculoskeletal abnormalities

including torticollis, metatarsus varus, clubfoot, or other unusual syndromes.[36,37,39] Other factors have been identified in late presenting DDH. Late presenting DDH is defined as a diagnosis after 3 months of age. In late presenting DDH, a history of swaddling and cephalic presentation were found to have increased risk of DDH. Cephalic presentation incidence was attributed to a decrease in monitoring due to normal birth presentation. With late presenting DDH, the likelihood of irreducible hip dislocations is high.[40]

At birth the acetabulum is quite shallow, covering less than half of the femoral head. In addition, the joint capsule is loose and elastic. These two factors make the neonate hip relatively unstable and susceptible to subluxation and dislocation. Normal development of the hip joint in the first year of life is a function of the stresses and strains placed on the femoral head and acetabulum during movement. In the presence of subluxation or dislocation, modeling of the acetabulum and femoral head is compromised. The most common clinical signs of DDH include asymmetry of the gluteal folds, unequal length of the femur bone (Galeazzi sign), dislocation of the hip with adduction (Barlow maneuver), and repositioning of the femur into the acetabulum with abduction associated with an audible "click" or "clunk" (Ortolani sign; Fig. 12.8).[41] On clinical examination, a "clunk" (Ortolani sign) felt when upward pressure is applied at the level of the greater trochanter on the newborn or infant's flexed and abducted hip (see Fig. 12.8) indicates that a dislocated hip has been manually reduced.[42] The goal of orthotic management in DDH is to achieve optimal seating of the femoral head within the acetabulum while permitting the kicking movements that assist shaping of the acetabulum and femoral head for stability of the hip joint.[43,44] This is best achieved if the child is routinely positioned in flexion and abduction at the hip. If DDH is recognized early and appropriate intervention is initiated, the hip joint is likely to develop normally. If unrecognized and untreated, DDH often leads to significant deformity of the hip as the child grows, resulting in compromised mobility and other functional limitations.

EARLY ORTHOTIC MANAGEMENT OF DEVELOPMENTAL DYSPLASIA OF THE HIP: BIRTH TO 6 MONTHS

In 1958 Professor Arnold Pavlik of Czechoslovakia described an orthosis for the treatment of dysplasia, subluxation, and dislocation of the hip.[45,46] The orthosis he developed, the Pavlik harness, relies on hip flexion and abduction to stabilize the hip at risk. Although a multitude of braces and orthoses have been used historically in the treatment of hip instability, including hip spica casts, the Frejka pillow, the Craig splint, the Ilfeld splint, and the von Rosen splint, the Pavlik harness has become widely accepted as a mainstay for the initial treatment for the unstable hip in neonates from birth to 6 months of age.

At first glance, the Pavlik harness seems a confusing collection of webbing, hook-and-loop material, padding, and straps. In reality, this dynamic orthosis (Fig. 12.9) has three major components:

1. A shoulder and chest harness that provides a proximal anchor for the device
2. A pair of booties and stirrups used as the distal attachment
3. Anterior and posterior leg straps between chest harness and booties used to position the hip joint optimally

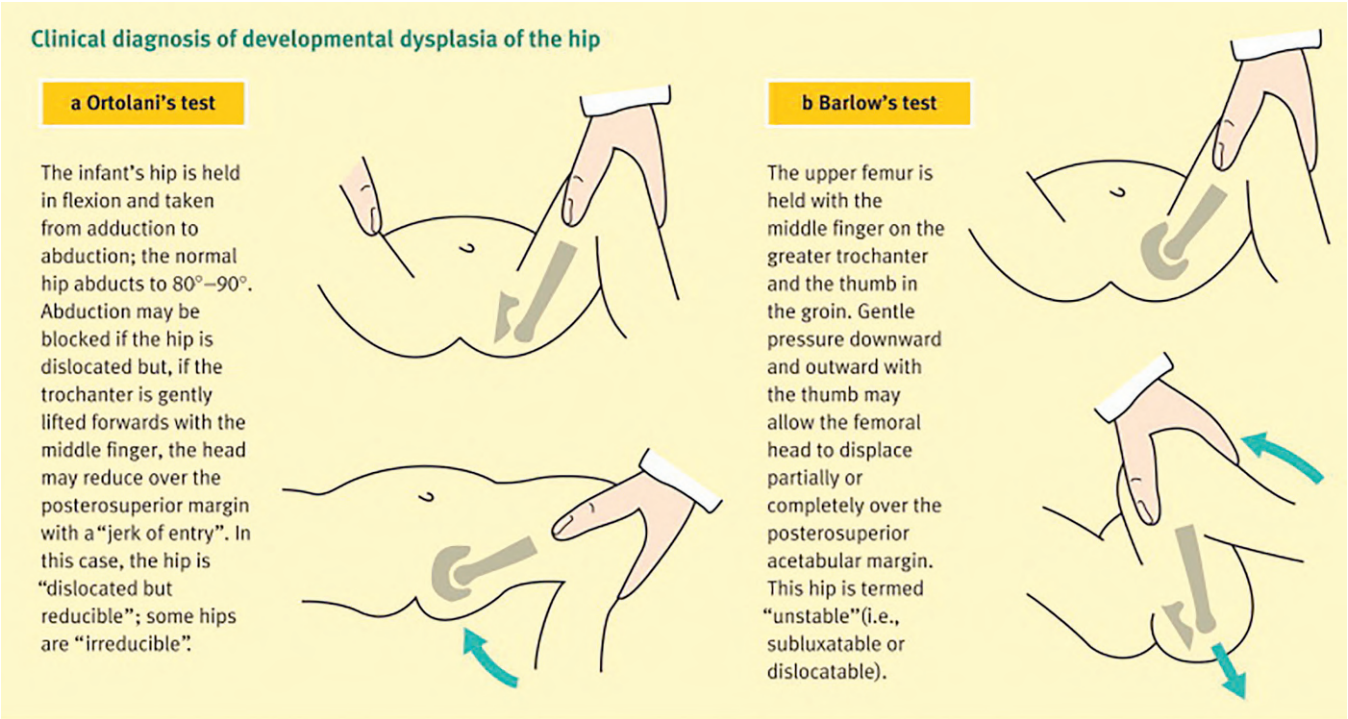

Fig. 12.8 Clinical diagnosis of developmental dysplasia of the hip. (From Campion JC, Benson M. Developmental dysplasia of the hip. *Surgery.* 2007;25[4]:176–180, Copyright 2007 Elsevier Ltd.)

Fig. 12.9 A Pavlik harness positions the infant's lower extremities in hip flexion and abduction in an effort to position the femoral head optimally within the acetabulum, assisting normal bony development of the hip joint. The anterior leg straps allow hip flexion but limit hip extension; the posterior flaps allow abduction but limit adduction. (Courtesy of Wheaton Brace Company.)

The anterior strap allows flexion but limits extension, whereas the posterior strap allows abduction but limits adduction. The child is free to move into flexion and abduction, the motions that are most likely to assist functional shaping of the acetabulum in the months after birth.[45–47] To be effective, however, the fit of the harness must be accurately adjusted for the growing infant and the orthosis must be properly applied. The family/caregiver must be involved in an intensive education program when the newborn is being fit with the Pavlik harness. Nurses, physical and occupational therapists, pediatricians, and orthopedic residents who work with newborns also need to understand the function and fit of this important orthosis. The guidelines for properly fitting a Pavlik harness include the following key points[43,48]:

1. The shoulder straps cross in the back to prevent the orthosis from sliding off the infant's shoulders.
2. The chest strap is fit around the thorax at the infant's nipple line.
3. The proximal calf strap on the bootie is fit just distal to the knee joint.
4. The anterior leg straps are attached to the chest strap at the anterior axillary line.
5. The posterior leg straps are attached to the chest strap just over the infant's scapulae.

In a correctly fit orthosis, the lower extremity is positioned in 100 to 120 degrees of hip flexion, as indicated by the physician's evaluation and recommendation. The limbs are also positioned in 30 to 40 degrees of hip abduction. The distance between the infant's thighs (when the hips are moved passively into adduction) should be no more than 8 to 10 cm. In a well-fit orthosis, extension and adduction are limited, whereas flexion and abduction are freely permitted: The infant is able to kick actively within this restricted range while wearing the orthosis. This position and movement encourage elongation of adductor contractures, which in turn assists in the reduction of the hip and enhances acetabular development. Three common problems indicate that the fit of the harness requires adjustment[43,49]:

1. If the leg straps are adjusted too tightly, the infant cannot kick actively.
2. If the anterior straps are positioned too far medially on the chest strap, the limb is positioned in excessive adduction rather than the desired abduction.
3. If the calf strap is positioned too far distally on the lower leg, it does not position the limb in the desired amount of hip flexion.

Optimal outcomes in infants with DDH are associated with early aggressive intervention of the unstable hip using the Pavlik harness.[50,51] Families and health care professionals must seek proper orthopedic care to avoid misdiagnosis and mistreatment. One of the most common misdiagnoses is mistaking dislocation for subluxation and implementing a triple- or double-diapering strategy for intervention. Although this strategy does position the infant's hip in some degree of flexion and abduction, bulky diapers alone are insufficient for reducing dislocation.

Initially, most infants wear the Pavlik harness 24 hours a day. The parents can be permitted to remove the harness for bathing, at the discretion of the orthopedist. Importantly, especially early in treatment, the fit and function of the orthosis must be reevaluated frequently to ensure proper position in the orthosis. The many straps of the Pavlik harness can be confusing to even the most caring of families. The proper donning and doffing sequence should be thoroughly explained and demonstrated to the family. Additional strategies to enhance optimal reduction of the hip such as prone sleeping should be encouraged.

Families must be instructed in proper skin care and in bathing the newborn or infant wearing the orthosis. Initially, they may be advised to use diapers, but not any type of shirt, under the orthosis. The importance of keeping regularly scheduled recheck appointments for effective monitoring of hip position and refitting of the orthosis as the infant grows cannot be overstressed to the parents or caregivers.[51–53] Missed appointments often result in less than optimal positioning of the femoral head with respect to the acetabulum, a less than satisfactory outcome of early intervention, and the necessity of more invasive treatment procedures as the child grows.

As a general rule, the length of treatment in the harness is equal to the child's age when a stable hip reduction is achieved plus an additional 3 months. Thus if a stable reduction is achieved at 4 months of age, the total treatment time would be 7 months. Over time, when hip development is progressing as desired, the wearing schedule can be decreased to night and naptime wear. This often welcomed change in wearing time can begin as early as 3 months of age if x-ray, ultrasound, and physical examination demonstrate the desired bone development. When the orthopedist determines that the hip is normal according to radiographs and ultrasound and is satisfied with the clinical

examination, the orthosis can be discontinued. If development of the hip is slow or the infant undergoes rapid growth, it may be advisable to continue the treatment with another type of hip abduction orthosis designed for older and larger babies, to maintain the position of flexion and abduction for a longer period of time.

MANAGEMENT OF DEVELOPMENTAL DYSPLASIA OF THE HIP: AGE 6 MONTHS AND OLDER

For older infants and toddlers (4–18 months) whose DDH was unrecognized or inadequately managed early in infancy, intervention is often much more aggressive and may include an abduction brace, traction, open or closed reduction, and hip spica casting.[33,54–56] For infants who are growing quickly or whose bone development has been slow, an alternative to the Pavlik harness is necessary. After the age of 6 months, especially as the infant begins to pull into standing in preparation for walking, the Pavlik harness can no longer provide the desired positioning for reduction. Often, the infant is simply too large to fit into the harness. By this time, families who have been compliant with harness application and wearing have grown to dislike it and are ready for other forms of intervention.

A custom-fit prefabricated thermoplastic hip abduction orthosis is often the next step in orthotic management of DDH. This orthosis consists of a plastic frame with waist section and thigh cuffs, waterproof foam liner, and hook-and-loop material closures. The static version is fixed at 90 degrees of hip flexion and 120 degrees of hip abduction (Fig. 12.10). An adjustable joint can be incorporated into the abduction bar; however, hip flexion is maintained at 90 degrees. This orthosis appears to be static, but the child is able to move within the thigh sections while the safe zone for continued management of hip position is maintained.

Many families view the hip abduction orthosis as an improvement over the Pavlik harness: The caregivers and the infant are free from cumbersome straps, the orthosis is easily removed and reapplied for diaper changing and hygiene, and the orthosis itself is waterproof and easier to keep clean. Parents and caregivers can hold the infant without struggling with straps, and the baby is able to sit comfortably for feeding and play.

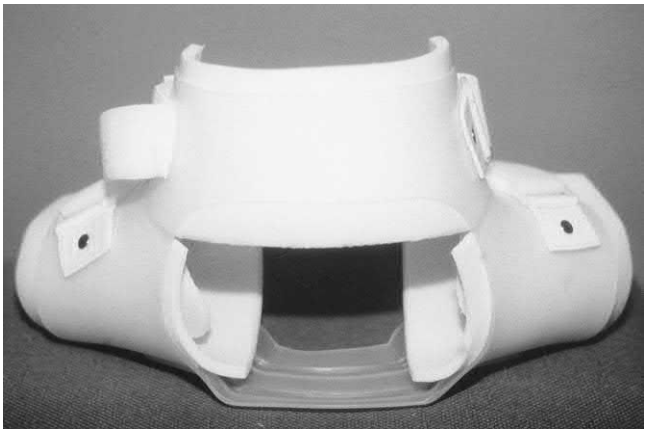

Fig. 12.10 A posterior view of a static hip abduction orthosis that positions the infant in 90 degrees of hip flexion and 120 degrees of hip abduction.

Because most hip abduction orthoses are prefabricated, the knowledge and skills of an orthotist are necessary to ensure a proper custom fit for each child. To determine what the necessary modifications are, the orthotist evaluates three areas:

1. The length of the thigh cuffs. Thigh cuffs are trimmed proximal to the popliteal fossae. Cuffs that are too long can lead to neurovascular compromise if the child prefers to sleep in a supine position, as the risk of compression of the legs against the distal edge of the cuffs is present.
2. The width of the anterior opening of the waist component. Although the plastic is flexible, the opening may need to be enlarged for heavy or large-framed infants.
3. The foam padding of the thigh and waist components. All edges must be smooth to avoid skin irritation or breakdown, and the circumference of the padding should fit without undue tightness.

Modifications may require reheating or trimming of the plastic or foam padding. Usually this fitting takes place in the orthotist's office or the clinic setting, where the necessary tools are readily available. Once the fit is evaluated and modified as appropriate for the individual child, the parents or caregivers are instructed in proper donning/doffing and orthotic care.

The static hip abduction orthosis is used in either of two ways. First, the orthosis may be a continuation of the course of treatment established by the Pavlik harness, as determined by the orthopedist's evaluation of the child's hip. As a continuation of treatment, the orthosis can be worn day and night; most often, however, it is reserved for nighttime use while the child is sleeping.[41,43,54] The use of the orthosis at night is believed to assist development of acetabular growth cartilage. If the orthosis is worn consistently for several months and evidence of effective reduction and reshaping of the joint is present, it is less likely that more aggressive forms of treatment will be necessary as the child grows.

The second application for the hip abduction orthosis is for follow-up management for children with DDH who require an orthopedic intervention such as traction, surgical reduction, or casting. In this case the orthosis provides external stability to the hip during the postoperative weeks and months, while the baby regains range of motion and continues to grow and progress through the stages of motor development. This extra stability reduces parental and physician concern about dislocation and other undesired outcomes of the orthopedic procedure.

The static hip abduction orthosis has obvious advantages over plaster or synthetic hip spica casts, including greater ease in diaper hygiene and bathing, and is often welcomed by families as a positive next step in treatment. Fitting requires the knowledge and skills of an orthotist familiar with proper fitting techniques and who can manage potentially irritable babies just freed from a confining hip spica cast.

GOALS OF ORTHOTIC INTERVENTION FOR CHILDREN WITH DEVELOPMENTAL DYSPLASIA OF THE HIP

To be effective, orthotic intervention for DDH must have a set of clearly described treatment objectives against which success can be measured. The components necessary for effective orthotic interventions for children with DDH include the following:

1. Clearly presented verbal, psychomotor, and written instructions for the child's family or caregivers, with an additional goal of minimizing stress in an already stressful situation.
2. Effective communication among members of the health care team about the appropriate use and potential pitfalls of the orthosis. This often includes education about the orthosis provided by the orthotist and careful monitoring of family compliance and coping by all members of the team (orthotists, orthopedists, pediatricians, therapists, nurses, and other health professionals who may be involved in the case).
3. Safe and effective hip reduction to minimize the necessity of more aggressive casting or surgery. This requires proper orthotic fit and adjustment, as well as consistency in wearing schedules.

The ultimate goal is to facilitate normal development of the hip joint, providing the child with a pain-free, stable, functional hip that will last throughout his or her lifetime.

COMPLICATIONS OF ORTHOTIC MANAGEMENT OF DEVELOPMENTAL DYSPLASIA OF THE HIP

In most cases the Pavlik harness, perhaps followed by abduction splint use as the child grows, is a successful intervention for DDH. A small percentage of infants with DDH managed by the Pavlik harness (<8%) develop complications, the most serious of which is avascular necrosis of the femoral head, which may be caused by overtightening the posterior straps to force a position of abduction.[33,52-59] Children who have complications differ from those without complications in a number of ways. They tend to have larger acetabular angles (>35 degrees) and less total coverage of the femoral head within the acetabulum (<20%) on radiography or ultrasound, have an irreducible dislocation at initiation of orthotic intervention, have delayed diagnosis and intervention (older than 3 months of age), and have not demonstrated a prior ossific nucleus on radiograph or ultrasound.[52,53,57,60] A concern of continued research into the development of DDH screening protocols is the over screening and overtreatment, which is leading to a rise in avascular necrosis development.[36]

ORTHOTIC MANAGEMENT OF LEGG-CALVÉ-PERTHES DISEASE

LCPD is a pathologic condition of the hip that affects otherwise healthy school-aged children. Although the clinical signs and symptoms of LCPD, as they differ from tuberculosis involving the hip, were first described by Arthur T. Legg in 1910,[61] the etiology of this condition is not clearly understood and its treatment and orthopedic management continue to be controversial. The hallmark of LCPD is a flattening of the femoral head, thought to be a result of an avascular necrosis insult. Left untreated, LCPD leads to permanent deformity and eventual osteoarthritis in the adult hip. The disease is four times as common in boys between the ages of 4 and 8 years old as in girls, although outcomes in girls tend to be less satisfactory.[62–64] LCPD generally involves only one hip; only approximately 12% of cases are bilateral. It is rare within the black population. Exposure to smoking in utero, obesity, low socioeconomic status, and repetitive high impact activities have also been associated as risk factors with the development of LCPD.[65–68] Several options for orthotic management of LCPD have evolved. All are designed to help maintain a spherical femoral head and normal acetabulum.

Etiology of Legg-Calvé-Perthes Disease

The etiology of LCPD remains controversial more than 100 years after it was first described. Most researchers believe that LCPD is a result of some event or condition that compromises blood flow to the femoral head and leads to avascular necrosis. The exact mechanism that triggers this compromise is unknown. Some theories focus on an acute trauma that damages the vascular system of the femoral head, whereas others suggest that repeated episodes of a transient synovitis may compromise blood flow.[63,69,70] Another theory suggests an abnormality of thrombolysis in children who develop LCPD.[71] A genetic predisposition to delayed bone age that exposes vessels to high rates of compression as they pass through cartilage to the bony head has also been suggested.[69] Although the exact etiology of LCPD remains a mystery, it is certainly linked to episodes of avascular necrosis in the femoral head. The goal of intervention in children with LCPD is to assist revascularization of the femoral head and to restore normal anatomical shape and alignment of the hip joint.

Evaluation and Intervention for Legg-Calvé-Perthes Disease

LCPD should be suspected in children with one or more of the following signs or symptoms[72,73]:

1. A noticeable limp, often with a positive Trendelenburg sign
2. Pain in the hip, groin, knee, or a combination of these locations
3. Loss of range of motion of the hip joint

When these symptoms are present, radiographic, ultrasound, or magnetic resonance imaging studies of the hip are used to discriminate between LCPD (Fig. 12.11) and other hip disorders (e.g., slipped capital femoral epiphysis, fracture, rheumatic disease, infection).[74] These studies are used by the orthopedist to determine severity and progression of the disease, considering the stage of the disease, the shape of the femoral head, the degree of congruence with the acetabulum, and the length and angle of the femoral neck.[75,76] A variety of classification systems have been developed to rate severity of involvements. The Catterall system describes four groups on the basis of the location of involvement and identifies four "head at risk" signs for the orthopedist or radiologist to focus on in interpreting radiographs.[77] Studies of the interrater and concurrent reliability of the Catterall systems have not all been

Fig. 12.11 A radiograph of a child with Legg-Calvé-Perthes disease comparing the shape and density of the head of the femur and of the capital epiphysis on the normal *(right side of image)* and affected *(left side of image)* right hip.

positive.[78–80] The Salter-Thompson system rates severity of involvement on the basis of the location and extent of subchondral fracture that may be observed early in the disease process.[81,82] The Herring system examines the condition of the lateral pillar of the femoral head on radiographs.[74,80,83] Refer to texts on orthopedic conditions in pediatrics for further information about classification.[69,70] LCPD is a self-limiting process that often resolves in 1 to 3 years. The disease progresses through three stages:

1. Necrotic stage: avascular necrosis
2. Fragmentation stage: resorption of damaged bone
3. Healing/reparative stage: revascularization, reossification, and bony remodeling

Factors that influence the eventual outcome of the disease include age at onset, severity of damage to the femoral head and epiphysis, and quality of congruency of the acetabulum and femoral head.[63,64,69,70]

Because the disease process is self-limiting, the optimal intervention strategy is controversial. The three most commonly used avenues of treatment for LCPD are observation, surgical intervention, and conservative orthotic management. Decisions about treatment are often guided by age of the child, extent of femoral head deformity, and severity of incongruency between the femoral head and acetabulum.[69,70,84] More recent data suggest that patients younger than 6 years of age at the time of disease onset are best managed nonsurgically, whereas the treatment for patients older than 8 years may involve surgery and is less well defined.[85]

For children with minimal bony deformity, observation and exercise may be the most appropriate intervention.[86] Because the child is likely to continue to limp until sufficient revascularization and remodeling have occurred (which may require several years), parents may be uneasy, preferring instead a more aggressive intervention. Parents are reassured when close clinical follow-up is performed, with periodic reexamination by x-ray evaluation to monitor progression of the disease process.

Surgical intervention is based on the principle of containment, optimally positioning the femoral head within the acetabulum. Proximal femoral derotation osteotomy is used to decompress and center the femoral head within the acetabulum for more functional weight bearing in an extended position.[87,88] A pelvic osteotomy, which repositions the acetabulum over the femoral head, is sometimes necessary when a significantly enlarged or subluxed femoral head cannot be effectively repositioned by femoral derotation osteotomy.[89,90] Shelf arthroplasty to reshape the acetabulum to better accept the femoral head has also been used as an intervention.[91–93] The outcome of surgery is likely to be most positive for children who have full hip range of motion preoperatively. Parents must understand the goals and risks of the surgical procedure and must be actively involved in postoperative rehabilitation efforts.

The goal of conservative orthotic management of LCPD is similar to that of surgical intervention: to contain the femoral head within the acetabulum during the active stages of the disease process so that optimal remodeling can occur.[44,93] Much debate has taken place concerning whether surgery, observation and therapy (LINK), or orthotic intervention is most efficacious. If both are viable methods of treatment, the end result should be the same: a well-shaped femoral head and pain-free hip. Comparing the efficacy of surgical versus orthotic management of LCPD is challenging because of relatively low incidence as well as differences in study design and definition of control for variables such as age of onset, duration of the disease, gender, and inadequate interobserver reliability of classification systems.[94,95] Although two reports published in 1992 question the efficacy of orthotic treatment,[96,97] other studies advocate orthotic treatment even in severe cases of the disease. Because studies have reported success, as well as lack of success for all three types of intervention (noncontainment/observation, surgery, and the use of orthoses), the most appropriate management of LCPD has not been clearly determined.

Orthotic Management in Legg-Calvé-Perthes Disease

Currently the most commonly used orthosis in the nonoperative management of LCPD is the Atlanta/Scottish-Rite hip abduction orthosis (Fig. 12.12). The design of this

Fig. 12.12 An Atlanta/Scottish-Rite hip abduction orthosis used in the conservative management of Legg-Calve-Perthes disease. This orthosis has three components: the pelvic band, the free-motion hip joints, and thigh cuffs. This orthosis has an abduction bar to provide increased stability and maintains desired position of abduction. (*J Pediatr Orthop.* 2011;31[2]:Supplement.)

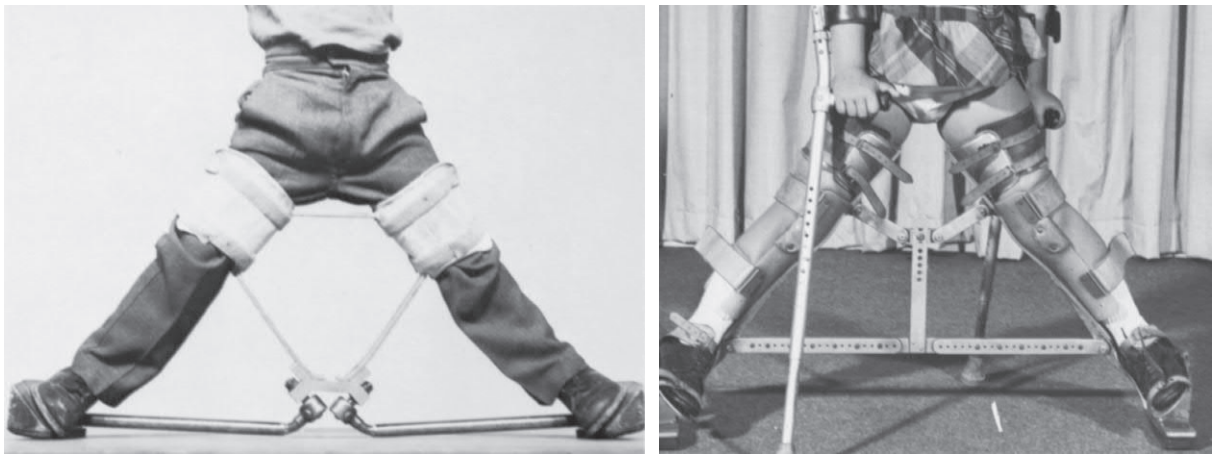

Fig. 12.13 Earlier designs for hip abduction knee-ankle-foot orthoses used to manage Legg-Calvé-Perthes disease. The Toronto hip-knee-ankle foot orthosis (A) and Newington orthoses (B) were more cumbersome to don and to function with than the Atlanta/Scottish-Rite hip abduction orthoses. (From Goldberg B, Hsu JH, eds. *Atlas of Orthotics and Assistive Devices*. 3rd ed. St. Louis: Mosby; 1997.)

orthosis allows the child to walk and be involved in other functional activities while containing the femoral head in the acetabulum with abduction of the hips.[98–100] The Atlanta/Scottish-Rite orthosis has three components: a pelvic band, a pair of single-axis hip joints, and a pair of thigh cuffs. An abduction bar may also be included, interconnecting the thigh cuffs with a ball-and-socket joint as an interface. This orthosis holds each hip in approximately 45 degrees of hip abduction, permits flexion and extension of the hip, and can be worn over clothing. While in the orthosis, the hips are abducted and flexed but the patient has no limitation in knee range of motion and therefore can sit or walk without difficulty. The orthosis is not designed to control internal rotation of the hip. This type of orthosis is most effective if the child who is wearing it has close to normal range of motion at the hip joint. Limitations in range of motion cause the child to stand asymmetrically in the orthosis, which effectively reduces the amount of abduction and containment of the femoral head.

Historically (in the 1960s and 1970s), a number of other orthoses were developed on the basis of the principles of containment of the femoral head. The Toronto orthosis (Fig. 12.13A) and the Newington orthosis (Fig. 12.13B) hold both limbs in 45 degrees of abduction with internal rotation but, unlike the Atlanta/Scottish Rite orthosis, require the use of crutches for safe mobility.[101,102] These orthoses are cumbersome to wear and significantly affect the ease of daily function. Because the efficacy of the Atlanta Scottish-Rite orthosis is as high as or higher than the efficacy of the Toronto and Newington orthoses, the latter two orthoses are not commonly used in current management of children with LCPD.[44,103] In addition, orthoses like an "A-frame" may be used after several weeks of Petrie casting, another nonsurgical treatment option enforcing hip abduction.[85] The use of the "A-frame" device with daily ROM exercises has been found to be successful following adductor tenotomy and abduction casting for improving spherical congruency of the femoral head.[104]

If the disease process progresses and the hip begins to lose additional range of motion, the orthotist may be the first to recognize this problem. The parents may bring the child to the clinic for an orthotic adjustment because the thigh cuffs have become uncomfortable. If loss of additional range of motion is noticed by parents or by therapists who are working with the child, an immediate referral to the orthotic clinic or physician is necessary. The Atlanta/Scottish-Rite orthosis is not designed to increase range of motion; its primary function is to hold the hips in abduction comfortably. Using the orthosis to restore range of motion defeats the purpose of the orthotic design and compromises treatment principles.

Communication among the orthopedist, orthotist, therapist, and family is essential. Parents must understand that this is a demanding form of treatment. Typically, the orthosis is worn continually for 12 to 18 months. Once radiographic evidence of femoral head reossification is seen, time in the orthosis is gradually reduced.

Absolute compliance with the wearing schedule is necessary for maximum effectiveness: A well-designed and well-fit orthosis can only work if it is being used. The first few days and weeks in the orthosis are often stressful for the parent and the child. With the hips held in an abducted position, routine tasks including walking may require assistance until the child learns effective adaptive strategies. Physical therapists may work with the child on crutch-walking techniques on level surfaces, stairs, inclines, and uneven surfaces. They may make suggestions for adaptation of the home and school environments so that sitting and transitions from flooring, chairs, and standing quickly become manageable. If family education and support efforts are effective and enable parents and children to weather this difficult initial stage in orthotic management well, the likelihood of compliance in the remaining months of intervention is significantly enhanced. Expectations for continued care and follow-up, including adjustments following growth and increases in range of motion, should be conveyed to family and caregivers to ensure success.

PEDIATRIC POSTOPERATIVE CARE

Numerous musculoskeletal and neuromuscular conditions, in addition to LCPD and developmental dysplasia, may necessitate surgical intervention for children with hip and

lower extremity dysfunction or deformity. Orthoses that control hip and leg position are often used in the weeks and months after surgery as an alternative to traditional plaster casts or as a follow-up strategy once casts are removed. Although a cast may be applied in the operating room for immediate postoperative care, orthoses are often fit soon afterward and effectively shorten the time that a child spends in a cast. Hip orthoses are used when immobilization and support will be required for a long period of time, when complications arise, or when a child's special needs demand their use.

One of the major benefits of an orthosis (as compared with a plaster cast) is in regard to hygiene, especially for children who have not yet developed consistent bladder and bowel control. Additional benefits of postoperative hip orthoses include the following:

1. Being much lighter than traditional casts, hip orthoses reduce the burden of care for parents and caregivers who must lift or carry the child.
2. Hip orthoses can be removed for inspection of surgical wounds and for bathing and skin care.
3. Hip orthoses can be removed for physical therapy, range of motion, mobilization, strengthening, or other appropriate interventions.
4. Thermoplastic orthoses are waterproof; therefore, residues of perspiration or urine can be easily cleaned and sanitized with warm soap and water.
5. A well-fit orthosis is less likely to cause skin irritation or breakdown and, unlike a cast, can often be adjusted if areas of impingement develop.
6. The position and amount of abduction can be easily adjusted.
7. A hip orthosis can be custom designed for a patient with complicated needs, especially those who have had multiple surgical procedures.

Postoperative Hip Orthoses

Two basic designs are available for children's postoperative orthoses. The first is composed of thigh cuffs that fit between the knee and hip joint, an abduction bar, and hook-and-loop material closures (Fig. 12.14). This orthosis can be fabricated from measurements taken before surgery and fit with no delay as soon as the cast is removed. It can also be fit in lieu of a cast if the surgical procedure was minor or when static positioning of the hip is required. This type of orthosis is commonly used after adductor release or varus osteotomy with adductor release or for the management of a septic hip. A postoperative hip orthosis is most often used for extended periods of nighttime-only wear but in some circumstances can also be worn during the day.[105] In many clinics this orthosis is used after hip procedures in children with cerebral palsy.

Parents and caregivers find the postoperative hip orthosis a welcome relief from a cast. Despite its simple appearance, families should be given special instructions about how the orthosis is worn and cared for. These orthoses typically will have removable liners that can be cleaned to ensure proper hygiene. It can be worn over clothing or pajamas or next to the skin if necessary. It should not cause skin irritation or discomfort on either side of the hip joint. If the patient experiences any hip joint pain, the orthotist should consult with the orthopedist to determine if the angle of abduction can be safely adjusted. Overzealous attempts to abduct the hip can cause pain and reduce compliance. Occasionally, this orthosis may be difficult to keep in place even though it has been properly fit. A simple suspension belt can be added to ensure optimal positioning.

The second option for postoperative care is a modification of a knee-ankle-foot orthosis (KAFO). This orthosis is composed of two thermoplastic KAFOs without knee joints but with an abduction bar and hook-and-loop material closures (Fig. 12.15). Fabrication of this type of orthosis requires that plaster or fiberglass impressions be taken: Simple length and circumferential measurements are not adequate to ensure proper fit. Ideally, these impressions are taken at the first postoperative cast change. The orthosis is then fabricated, and fitting occurs during the next clinic appointment. Taking the impressions before surgery is not advisable. Postoperatively, each joint will be at a new angle, compromising

Fig. 12.14 A postoperative hip abduction orthosis has two components: a pair of thigh cuffs held in position by an abduction bar.

Fig. 12.15 For postoperative management of children after extensive bony and soft tissue surgery, knee-ankle-foot orthoses with the addition of an abduction bar are often used subsequent to cast removal. Rotation of the hip is well controlled by the intimate fit of the orthosis, including the ankle-foot complex. When precise control of the hip is necessary, the postoperative hip abduction orthosis encompasses the pelvis as well.

the fit of the orthosis based on preoperative impressions. This type of orthosis is recommended for patients who have had bony procedures around the hip, as well as extensive soft tissue procedures such as hamstring or heel cord release, which require protection in the early stages of healing. In our clinic, this orthosis is most often used for children with cerebral palsy or myelomeningocele. In some circumstances, when more precise control of the hip joint is desirable, the orthosis can be extended upward to include the pelvis.

Because of the intimate fit of this orthosis, parents and caregivers must be given careful education concerning proper fit and cleaning. Especially important is a careful inspection of the posterior aspect of the calcaneus: This area is vulnerable to skin breakdown from prolonged pressure and may be overlooked during skin checks that focus on the healing surgical wounds. Because the foam lining and thermoplastic material do not breathe, perspiration cannot effectively evaporate. The orthosis should be removed periodically for cleaning to minimize the risk of skin maceration or infection from microorganisms that thrive in warm moist environments.

The postoperative orthosis has proven useful in the overall orthopedic management of children with musculoskeletal or neuromuscular diseases. The orthosis is an effective substitute for heavy casts, especially when skin irritation and incontinence are concerns. The postoperative hip orthosis helps ensure healing in the optimal joint position and reduces the likelihood of recurrence of the deformity that prompted surgical intervention.

MANAGEMENT OF THE ADULT HIP

Orthotic intervention for the hip in the adult population is limited, focusing on two groups of patients. Hip orthoses are most commonly used as postsurgical and postcast care of adult patients who have sustained a complex hip or proximal femoral fracture from a traumatic event such as a motor vehicle accident, industrial accident, or fall. In some circumstances a hip orthosis can be used for older adults after a total hip procedure, revision of a total hip, or fracture associated with total hip arthroplasty.[106,107] Although injury that affects the hip can occur at any point in the life span, most adults with trauma-related fractures who are managed with hip orthoses are young and middle-aged, and many of those who are undergoing a new or revised total joint arthroplasty are 65 years or older. As the number of older adults increases in the U.S. population, so will the number of hip fractures. One estimate suggests that as many as 512,000 hip fractures will occur in the United States by the year 2040.[108]

In both of these circumstances, stabilization of the orthopedic injury and rehabilitation planning are important issues. Patients with this type of injury of the hip often require extensive physical therapy programs. Clinicians must understand age-related pathophysiological changes that affect the healing musculoskeletal system, the impact and detrimental effects of prolonged bed rest, and the optimal point at which an orthosis should be integrated into the overall treatment plan.

Fig. 12.16 Lateral view of a hip-knee-ankle-foot orthosis, prescribed for postoperative management after a complex total hip arthroplasty. Note the pelvic band, free hip joint, supportive thigh cuff, and free knee joint. The ankle-foot orthosis component is necessary for effective control of rotary forces through the femur and hip joint. (From Luqmani R, Robb J, Porter D, et al. *Textbook of Orthopaedics, Trauma, and Rheumatology*. 2nd ed. Edinburgh: Mosby; 2013.)

Total Hip Arthroplasty

Although a hip orthosis is usually not indicated in most simple, elective total hip arthroplasties, in some circumstances this orthosis can assist healing and rehabilitation. Hip orthoses can be used for patients with significant osteoporosis in whom femoral fracture occurs during total joint surgery or for those who require emergency total joint replacement as a result of trauma. Hip orthoses are also used for patients who are undergoing revision of a total hip replacement as a consequence of recurrent dislocation or of aseptic loosening of the femoral component. If control of rotation is desired, an HKAFO can be prescribed to provide additional support and protection to healing structures.

Most HKAFOs have a pelvic band and belt and an adjustable hip joint that can be locked or can allow free motion or limit motion within a specific range (Fig. 12.16). An adjustable anterior panel can be added to the thigh section if a fracture has occurred during the surgical procedure and requires additional protection. The knee joint can also be locked, free motion, or adjustable for specific ranges of motion, depending on the patient's need. The ankle-foot orthosis (AFO) component is necessary to provide maximum control of unwanted rotation of the hip.

Typically, HKAFOs are custom fabricated on the basis of an impression of the patient's limb. This increases the likelihood of an optimal fit and allows customization of the orthosis to meet the specific needs of the patient. If this approach is

not amenable to certain health care environments, prefabricated custom-fit HKAFOs and hip orthoses are available as alternatives to custom-molded orthoses.[107] These orthoses are fabricated from components that are then custom fit on the basis of the patient's limb measurements. Most postoperative hip orthoses are designed to limit flexion and adduction of the hip joint. They try to prevent dislocation by supporting the optimal position of the hip joint within a safe range of motion and by providing a kinesthetic reminder when patients attempt to move beyond these ranges.[107] Many of the prefabricated hip orthoses that are commercially available are unable to provide maximum control of rotation because they do not encompass the foot. Careful evaluation of the patient is required to determine which alternative is most appropriate. In both cases, the orthosis is worn whenever the patient is out of bed and, in some instances, while the patient is in bed as well. The orthosis is usually worn for at least 8 weeks after total hip revision.

Because lower extremity orthoses add weight to a lower extremity that is already compromised, orthotists must be sensitive to the selection of lightweight materials and components. This is especially true for older patients, who may have limited endurance because of cardiac or respiratory disease. Although the initial orthosis may restrict joint motion to provide external stability to a vulnerable hip joint, the orthotic hip, knee, and ankle joints can be adjusted to meet the patient's needs as the rehabilitation program progresses. Hip orthoses and HKAFOs may be important adjuncts for rehabilitation in the following ways:

1. A well-fit hip orthosis provides protection against dislocation in patients who are predisposed to this problem.
2. Hip orthoses protect and support healing fracture sites, often allowing earlier mobility and gait training than would otherwise be possible.
3. Early and safe weight bearing for older patients with dislocation or fracture reduces the risk of secondary complications associated with prolonged bed rest or immobility.
4. The orthotic hip, knee, and ankle joints can be adjusted to restrict or permit motion to match the patient's specific needs at initial fitting and as the treatment program progresses.

Following surgical intervention after fracture or total joint arthroplasty, the focus of the rehabilitation program shifts to mobility training, strengthening, flexibility, and endurance. The decision to recommend a hip orthosis is individual, influenced by the severity of the musculoskeletal problem, the patient's particular circumstances, and the experience and preferences of the health professionals involved in postoperative care. Few definitive guidelines or documentation are available concerning the efficacy of hip orthoses in the postoperative management of hip fracture or arthroplasty. An orthosis is best used to augment the goals of rehabilitation, including the return to preoperative ambulatory status, safe and protected weight bearing during ADLs, facilitation of union of the fracture site, and ultimately return to presurgical social and self-care independence.

Another population that may benefit from a hip abduction orthosis is patients that have had recurrent hip dislocations. In these patients, there may be a ligamentous laxity that has developed due to history of dislocations with or without an incidence of hip replacement. Surgical intervention may not be indicated in these situations, although the external stabilization of a hip abduction orthosis may help allow a limited range of motion. Range of motion limitations are directed by the treating physician in opposing motions that contributed to the dislocation. Utilizing hip abduction orthoses in these situations will provide external stabilization and allow for return to daily activity with kinesthetic reminder of limitations on hip joint motion. Patients will wear this orthosis at all times and will be directed to work with a physical therapist for strengthening of hip muscles once sufficient healing of hip joint has taken place.

Posttrauma Care

The other group of individuals who may benefit from hip orthoses are those who have experienced traumatic fractures of the femur, hip, or pelvis as a result of motor vehicle accidents, industrial accidents, or falls from great heights. Most of these patients are fit with their orthosis after stabilization of the fracture with internal fixation. The HKAFO is similar in design to the orthosis described for older patients after hip fracture or arthroplasty. Depending on the need for external support and stability, the hip joint can be locked to prevent flexion and extension or may allow motion within a limited range. For some patients, it may be necessary to incorporate a lumbosacral spinal orthosis to achieve the desired control of pelvic and hip motion. The AFO component provides control of hip rotation in the transverse plane.

When complete immobilization is warranted after orthopedic trauma of the lower spine, pelvis, and hip, a custom-molded thermoplastic version of a hip spica cast can be fabricated. This hip orthosis has anterior and posterior components, extending from the mid- to lower thoracic trunk to just above the femoral condyles of the fractured extremity and to the groin of the intact extremity. This design provides maximum stability and can be used in lieu of or after casting. The position of the lower extremity within the orthosis is determined by the type and extent of the surgical repair. When the patient is lying in the supine position, the anterior component can be removed for skin inspection and personal care. Similarly, the posterior component can be removed when the patient is prone. This is an advantage for patients with open wounds or difficulty with continence and is especially appreciated if immobilization will be required for an extended period.

Many patients who are recovering from musculoskeletal trauma involving the pelvis and hip joint require physical therapy for gait and mobility training after surgery and an intensive rehabilitation program to regain preinjury muscle strength, range of motion, and functional status. The orthopedic surgeon and therapists, as well as the patient and family, must clearly understand the advantages provided and the mobility limitations imposed by postsurgical hip orthoses. An optimal orthosis can assist rehabilitation if fabricated with lightweight but durable components that can be adjusted as the patient progresses, while meeting the individual patient's need for stability or supported mobility of the hip. An appropriate hip orthosis also

enhances early mobility and protected weight bearing, reducing the risk of loss of function related to bed rest and deconditioning.

Fracture Management

A fracture occurs when there is disruption in the continuity of bone.[109] Fractures are common consequences of trauma from falls, sports, work-related injuries, motor vehicle accidents, or violence.[110–112] Many disorders and diseases (e.g., osteopenia, malnutrition, paralysis, osteoporosis) and medications (e.g., corticosteroids), as well as primary or metastatic malignancies of bone, increase vulnerability to fracture.[113,114] Habitual activity level over the life span, health habits (e.g., smoking), and gender and age (e.g., bone density and menopausal status) influence bone density and, subsequently, the risk of fracture during daily activity.[115–118] Orthopedic intervention for fractures is dictated by the severity of the fracture, as well as etiology. Simple fractures, those with minimal fragmentation or displacement, are often managed with closed reduction followed by initial management in a plaster or fiberglass splint to provide stabilization, while allowing for swelling, and then a period of immobilization in a plaster or fiberglass cast or a custom-fit, prefabricated fracture orthosis until bony union is achieved.[119] More complex fractures, those with multiple fragments or significant displacement, often require open (surgical) reduction with internal fixation (ORIF; with plates, screws, or wires), prosthetic replacement (arthroplasty), or stabilization in an external rigging or fixator until there has been sufficient bony healing.[120]

The care provided to individuals recovering from a fracture is founded on understanding the mechanism of injury, fracture classification, and process of bone repair and healing.[121,122] The orthopedic surgeon and orthotist choose from a variety of casts, cast braces, splints, and fracture orthoses to provide the most effective fracture management strategy for each patient on the basis of the fracture type and location, degree of reduction, skin condition, mobility needs, and likelihood of compliance. Geographical and personal preferences regarding design, device selection, and treatment influence the choice of fracture management strategy, as do the training and experience of the health professionals involved. Few strategies for immobilization can provide 100% rigid fixation. Absolute immobilization is only possible with direct skeletal attachment. A variety of factors influence the quality of fit and function of any cast, cast brace, splint, or fracture orthosis. Each device has the potential to contribute to a successful result but only if used appropriately, with absolute attention to detail by each of the treatment team members.

MECHANISMS OF FRACTURE HEALING

Three distinct stages of physiological fracture healing occur: inflammation, repair, and remodeling.[122] Fracture damages bone, its periosteum, nutrient vessels, marrow, and often surrounding soft tissue and muscle. Disruption of vascular supply leads to ischemia and necrosis of bone cells and other injured tissues. These damaged tissues release inflammatory mediators into intracellular space, triggering an inflammatory response: A shift in plasma from capillary to intracellular space leads to significant edema. Migration of polymorphonuclear leukocytes, macrophages, and lymphocytes to the injured area is the first step in clearing necrosis. A hematoma forms; in a simple nondisplaced fracture on the shaft of a long bone, this hematoma provides the initial reconnection of edges of the fracture (Fig. 12.17A). In more complex fractures, the process of reducing the fracture to align bony fragments further irritates tissues, augmenting the inflammatory response that is the first necessary step in fracture healing. This initial inflammatory response to fracture can last 5 or more days, depending on the severity of injury and extent of tissue disruption.

The next stage of healing is the repair stage, a period of cell migration, proliferation, and granulation. The combination of chemotactic factors and bone matrix proteins

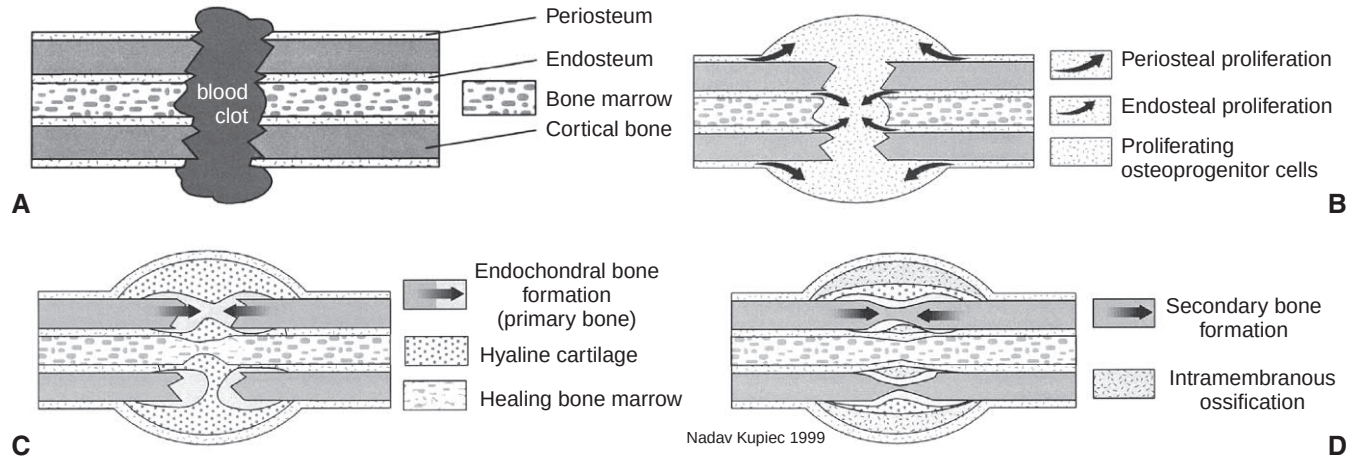

Fig. 12.17 Healing and repair of a long bone fracture. (A) Disruption of blood vessels in the bone, marrow, periosteum, and surrounding tissue at the time of injury results in extravasation of blood at the fracture site and the formation of hematoma. (B) Initiation and development of the fracture callus. (C) Note the simultaneous occurrence of chondrogenesis, endochondral ossification, and intramembranous bone formation in different regions of the fracture site. (D) Union of a long bone fracture. (From Lundon K. *Orthopedic Rehabilitation Science: Principles for Clinical Management of Bone.* Boston: Butterworth-Heinemann; 2000.)

released by damaged bone and during inflammation triggers the initiation of bony repair. The hematoma organizes into a fibrin "scaffold," and cells within the hematoma begin to release growth factors and other proteins that trigger cell migration and proliferation of osteoblasts from the periosteum and endosteum, as well as synthesis of a fracture callus matrix for bony repair (see Fig. 12.17B and C).[123] Initially the pH of the area around the fracture is acidic, and the fracture callus is primarily cartilaginous. As the repair stage progresses, the pH becomes more alkaline, creating an environment that enhances activity of the alkaline phosphatase enzyme, and subsequently mineralization of the cartilage of the fracture callus into woven bone tissue (see Fig. 12.17D). The deposition of new cartilage within the callus is accompanied by both endochondral and intramembranous ossification. Clinical union of the fracture during the repair stage can last up to 3 months postinjury (hence the need for long periods of immobilization).

The final stage of healing is the remodeling stage, during which the new bone woven within the callus is reshaped into the more mature lamellae of long bone and excess callus resorbed. During this phase, osteoclasts are active to reshape trabeculae and lamellae along the lines of weight-bearing forces. The process of maturation of the callus into a fully repaired bone can last a year or more, especially in complex fractures, whether managed by casting or ORIF. Factors that influence the duration of the remodeling stage include age, severity of injury, nutritional status, concurrent chronic illness, and medication use (especially corticosteroids).[124]

FRACTURE CLASSIFICATIONS

Fractures are classified as either open or closed injuries on the basis of the presence of an open communication between the fracture and the outside world through a disruption of the soft tissues and skin.[125] In a closed fracture, the soft tissue envelope of muscles and skin around the bone fracture site is completely intact. Although muscle around the fracture site may be significantly damaged, the intact skin provides a barrier that prevents bacterial invasion of the injured muscle or bone. When an open or compound fracture occurs, the soft tissue envelope has been violated: The wound leaves muscle and fractured bone open to the environment and susceptible to infection. In many cases, bone may actually protrude through the skin. Open injuries are orthopedic emergencies; patients are taken urgently to the operating room for debridement of the wound and fracture. Severely damaged or contaminated tissue is removed, and the wound is carefully cleaned in an effort to avoid infection and provide optimal circumstances for healing.[120] The fracture is then stabilized with a cast or surgical implant.

Gustilo and Anderson[125] have developed a classification system applied interoperatively that rates the severity of open or compound fractures. The least severe is a type I injury, in which a small wound with minimal soft tissue damage (1 cm) communicates with the fracture. The wound in a type II fracture is generally between 1 and 12 cm, and significant soft tissue injury may be present underneath the laceration or wound. In a more severe, type III injury, the wound diameter is often greater than 12 cm, there is considerable periosteal stripping, and barely enough muscle or skin is present to cover the injured or fractured bone adequately. Type III open fractures are subdivided into another three categories—A, B, and C—on the basis of whether the soft tissue can cover the bone and whether neurological or vascular involvement is present in association with the open fracture. It should be noted that more important than the size of the skin defect is the damage to soft tissues and periosteum in determining type. Therefore a 1-cm open hole in a crushed and comminuted fracture may well be classified as a type III.

The particular location and pattern of fracture determine whether the fracture is stable and can be effectively managed with a cast or brace, or unstable, requiring surgical intervention. A fracture with concurrent joint dislocation creates an extremely unstable condition, requiring surgical management of the fracture/dislocation and a long period of rehabilitation.

Fractures (whether closed or open) are described as displaced or nondisplaced on the basis of the degree of malalignment or overlap that is observed on a radiograph (Fig. 12.18). They are described as complete or incomplete, depending on whether the bone has fully transected. In children, a greenstick fracture is an incomplete oblique or spiral fracture that extends only partially through bone. Exact location of the fracture is also important: Fractures of the diaphysis or metaphysis of a long cortical bone are extraarticular (Fig. 12.19), whereas those involving the epiphysis within the joint capsule are intraarticular. Intraarticular fractures, especially when displaced, have a high likelihood of causing posttraumatic arthritis, and often require surgical reconstruction of the joint surface.

Extraarticular fractures (Fig. 12.20A) can be transverse (mostly perpendicular to the axis of the bone), oblique (diagonal to the axis of the bone), or spiral (typically a result of

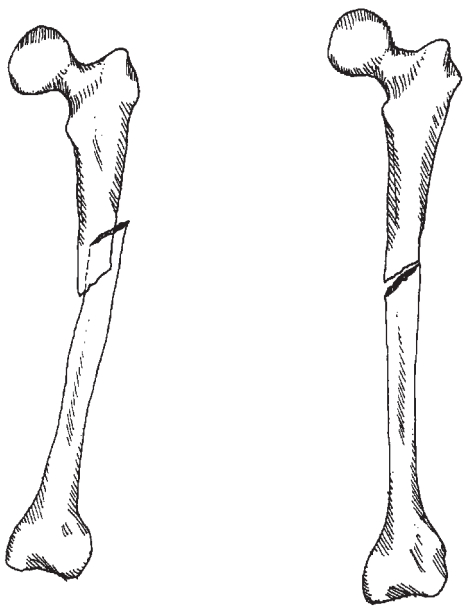

Fig. 12.18 Diagram of a displaced and nondisplaced fracture of the diaphysis of the femur. (From Gustilo RB. *The Fracture Classification Manual*. St. Louis: Mosby; 1991.)

torsional forces), depending on the direction of force contributing to the injury and the resulting alteration in bone configuration. When one or more substantive fragments are seen on the radiograph, the fracture is segmental; if there are multiple small fragments, the fracture is comminuted. In high-impact, complex fractures, there is often enough destruction of bone that there will be loss of bone length or substance. Fractures of the metaphysis are determined to be nondisplaced or displaced, simple, compressed, or comminuted (see Fig. 12.19). Before and during puberty (during times of rapid bone growth), there can be displacement of the proximal or distal epiphysis from the metaphysis through the cartilaginous epiphyseal plate (Fig. 12.21); the proximal (subcapital) epiphysis of the femur is particularly vulnerable.

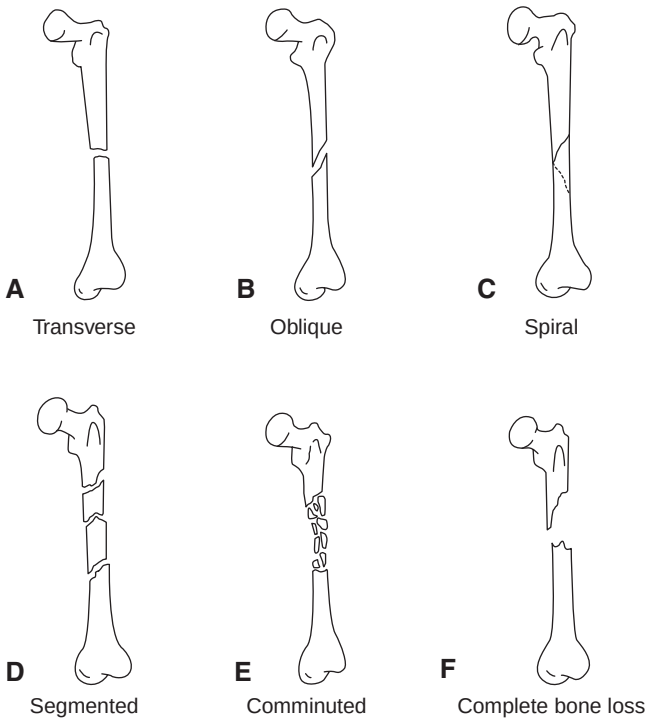

Fig. 12.19 Examples of types of long bone fractures illustrated in the diaphysis of the femur. A transverse fracture (A) is primarily perpendicular to the long axis of the bone, whereas an oblique fracture (B) diagonally transects the bone. A spiral fracture (C) is the result of a rotary force during injury. Segmental fractures (D) have one or more noncontinuous segments, whereas a comminuted fracture (E) has multiple small fragments. In cases of significant trauma, there may actually be loss of bone substance (F). (Modified from Gustilo RB. *The Fracture Classification Manual*. St. Louis: Mosby; 1991.)

Intraarticular fractures (Fig. 12.20B) are classified as linear, comminuted, impacted, or having a percent of bone loss (Fig. 12.22); complex intraarticular fractures involve both proximal and distal components of the joint (Fig. 12.23) and typically require ORIF.

In the proximal femur, fractures of the metaphysis are described as intertrochanteric fractures (extracapsular, linear or oblique, through or between the trochanters) or femoral neck fractures (intracapsular across the neck of the femur) or comminuted (with multiple fragments of neck and or trochanters; Fig. 12.24). These fractures fall into the category of hip fractures, and typically require ORIF or replacement with a femoral prosthesis (hemiarthroplasty) or even a total hip arthroplasty (Fig. 12.25). Fractures of the acetabulum are the result of either a longitudinal force through the femur into the pelvis or an upward oblique lateral force through the greater trochanter; if the hip happens to be adducted at the time of injury, this may lead to posterior dislocation (Fig. 12.26).

Fractures of the pelvis are classified as stable or unstable on the basis of the extent of damage that disrupts the circumferential integrity of the pelvis (Fig. 12.27). Persons with unstable fractures of the pelvis are at risk for life-threatening hemorrhage, as well as residual genitourinary

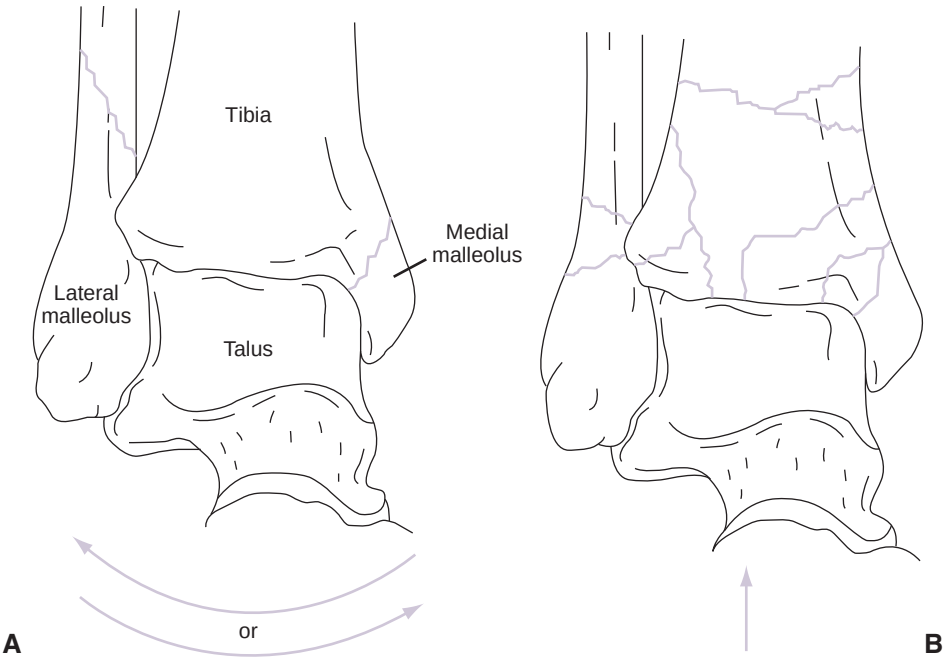

Fig. 12.20 (A) Extraarticular metaphyseal fracture of the malleoli of the tibia and fibula is often the result of rotational injuries. or neurological complications, given the vessels, nerves, muscles, and organs that are housed within the pelvis.[126]

Fractures of irregularly shaped bones such as the tarsals and vertebrae tend to fall into three categories. Stress fractures result from repetitive loading of the bone, are often nondisplaced, and can disrupt either the inner scaffolding of the cancellous bone or the outer shell of cortical bone. Simple stress fractures typically heal well with immobilization; more complex stress fractures may require surgical stabilization. Pathological fractures occur when there is underlying disease (e.g., osteoporosis, Charcot osteopathy, neoplasm) that compromises bone density or metabolism. In pathological fractures the trabeculae are overwhelmed by the magnitude of force exerted through the bone, and the bone is compressed or fractured into fragments. Management of pathological fractures can be challenging, as bone healing is often compromised by the underlying disease process. Traumatic fractures are often comminuted; depending on severity, they may be managed by immobilization in a cast or orthosis, ORIF, or placement of an external fixation apparatus (Fig. 12.28).

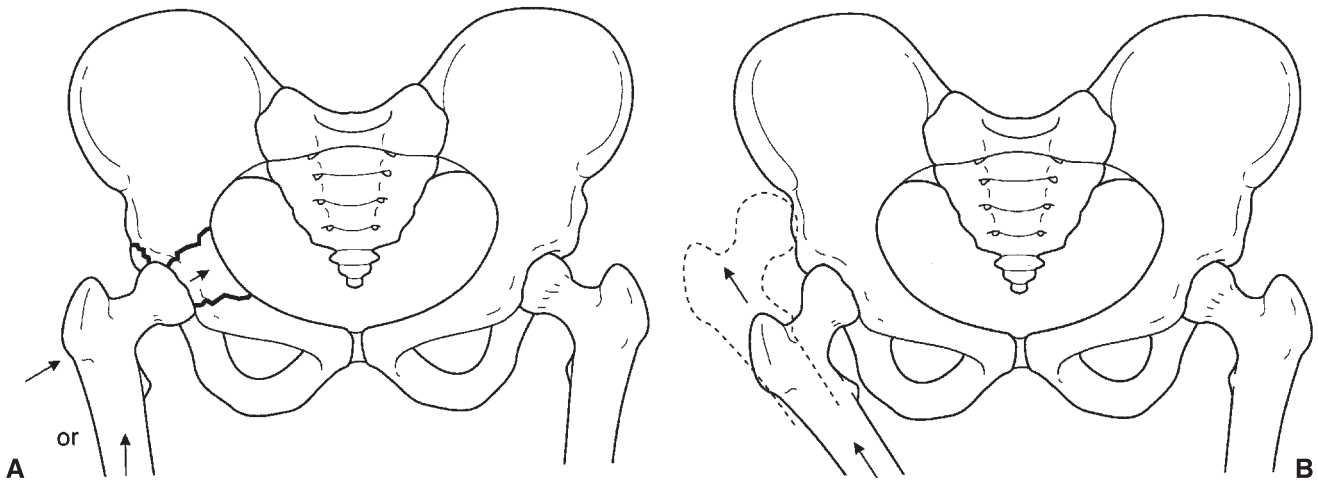

Fig. 12.24 (A) Acetabular fractures occur from a lateral blow over the greater trochanter or a proximally directed force transmitted up the length of the femur. (B) If the limb is injured with the hip in adduction and flexion, a posterior hip dislocation is likely. (From Clark CR, Bonfiglio M, eds. *Orthopaedics: Essentials of Diagnosis and Treatment*. Philadelphia: Churchill Livingstone; 1994.)

CASTS AND SPLINTS

The primary goal of fracture management is to restore musculoskeletal limb function of the injured extremity with optimal anatomical alignment, functional muscle strength, sensory function, and pain-free joint range of motion. The most common methods used for immobilization of closed fractures include casts, splints, fracture orthoses, or a hybrid cast-orthosis.[119,127] Immobilization may also be used after ORIF of open fractures.

In choosing the appropriate immobilization strategy for an individual's fracture, the orthopedist considers several

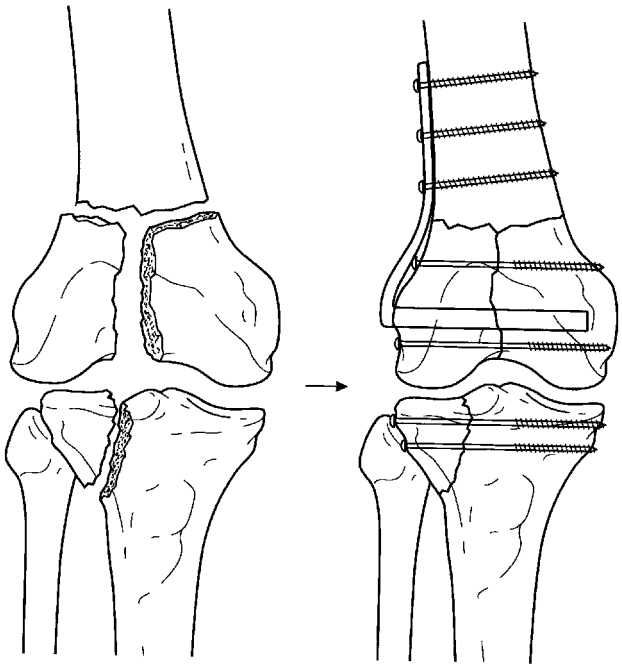

Fig. 12.26 Major intraarticular fractures of the distal femur and proximal tibia are typically managed by surgical open reduction with internal fixation using a combination of bone screws or nail and an external plate. (From Clark CR, Bonfiglio M, eds. *Orthopaedics: Essentials of Diagnosis and Treatment*. Philadelphia: Churchill Livingstone; 1994.)

issues. The first is the stability of the fracture site and how well a device will be able to maintain fracture reduction and achieve the desired anatomical result. The condition of the skin and soft tissue is also an important consideration, especially if wounds are present that must be accessed for proper care. Limb volume must be evaluated, especially if edema is present or anticipated: How will limb size change over time in the device? Length of immobilization time varies as well: Is the device designed for a short-term problem, or will protection of the limb be necessary for an extended period? Will the device need to be removed for hygiene or wound care? Can the limb be unprotected while sleeping or when not ambulating? Availability (time to application) may also influence decision making. Casts and cast braces can be applied quickly. Custom orthoses need additional fabrication and fitting time; an alternative means of protection is often required while the device is being fabricated.

The individual's ability to comply consistently and reliably with weight-bearing restrictions and other aspects of fracture management must also be considered. Factors such as cognitive ability, emotional status, motivation, and physical ability, as well as the availability of assistance and environmental demands, influence the decision to provide additional external support. An unstable fracture managed by ORIF may not require additional support for those with sufficient strength and balance who have a clear understanding of the healing process. If the individual with a fracture cannot understand the need to protect the involved limb from excessive loading or is physically unable to do so, additional external support is essential. If compliance is questionable, the device of choice is usually a nonremovable cast or cast brace.

To effectively stabilize a fracture, the joints above and below the fracture site must be immobilized. The period of immobilization varies with fracture severity and location; in most cases the cast remains in place from 6 to 8 weeks or until a radiograph indicates that bone healing has progressed sufficiently for safe weight bearing and function. The time for immobilization is often less for children, due

to their rapid healing response. Although immobilization is essential for effective bone healing, it also has significant consequences on other tissues: While in a cast, patients are likely to develop significant joint stiffness (contracture), as well as disuse atrophy and weakness of the muscles of the immobilized limb. Once the cast is removed, rehabilitation professionals are called on to help the patient regain preinjury muscle performance, flexibility, and range of motion.

A cast is a rigid, externally applied device that provides circumferential support to an injured body part.[108] Casts immobilize a body segment to maintain optimal skeletal alignment (Figs. 12.29 and 12.30). Once a cast has been applied, a radiograph can be used to assess the effectiveness of skeletal alignment. The cast may need to be modified, wedged, or replaced to improve alignment.[128]

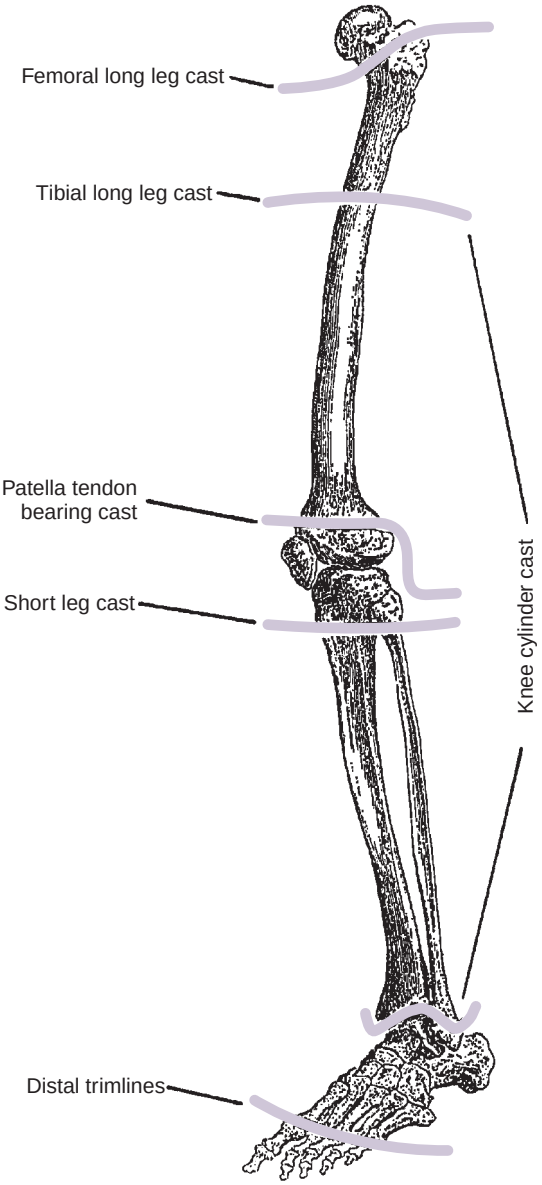

Fig. 12.29 Proximal and distal trimlines used in standard lower extremity casts. Typically, the joints above and below the fracture site are immobilized. Trimlines can be extended to provide better control and stabilization.

Fig. 12.30 Medial view of a patella tendon-bearing cast (From Bruce Reider AB, Davies GJ, Provencher MT. *Orthopaedic Rehabilitation of the Athlete: Getting Back in the Game.* Philadelphia: Elsevier; 2015.)

A splint is a temporary supportive device, usually fabricated from rigid materials, held in position on the fractured extremity with bandages or straps. Splints can be used for temporary immobilization before casting or surgical stabilization. They can be used to maintain fracture reduction while waiting for swelling to diminish or fracture blisters to clear or to provide comfort. The most commonly used splints include sugar tong splints (a long, U-shaped, padded plaster forearm splint named for its similarity to the tool used to pick up sugar cubes), short or long leg splints, thumb spica splints, ulnar or radial gutter splints, and coaptation splints.[117]

Casting and Splinting Materials

Before the 1800s, fracture casts were made from linen bandages soaked in beaten egg whites and lime. The modern era in fracture care began with the discovery of plaster of Paris (calcium sulfate), first used in the Turkish Empire as reported by Eaton in 1798.[129] Plaster of Paris was used in Europe in the early 19th century, and a Flemish surgeon (Mathijsen) is credited with combining the use of plaster of Paris and cloth bandages to form casts for the treatment of fractures in 1852.[128–130]

Plaster of Paris is created when heat is used to dehydrate gypsum. When water is added to plaster of Paris powder, the dehydration process is reversed, and crystals of gypsum are formed again. The new crystals interlock in a chemical exothermic (heat-producing) process.[131] The setting process is complete when heat is no longer being produced, although the cast remains wet to the touch until the excess water used in the process evaporates. Maximum cast strength is not reached until the plaster is completely dry. Drying time varies with the thickness of the cast, ambient humidity, and the type of plaster used. In most instances maximum cast strength is reached in approximately 24 hours.

Various types of plaster of Paris with different working characteristics are available. Manufacturers may add accelerators to the material that shorten the setting time: The limb has to be held still for less time while the plaster sets. Although this may be advantageous when a cast is applied to the limb of an anxious child or when an unstable fracture is cast, it also means that less working time is available to manipulate the extremity and optimally shape the cast. Setting time can be prolonged slightly if cold water is used. If warm or hot water is used to reduce setting time, care must be taken to protect the limb from injury from the higher heat that can be generated during the setting process.[128] Cast temperatures as high as 68.5°C have been reached with water temperatures of 40°C; burns can occur if cast temperature is maintained at 44°C for 6 hours or more.[132,133] To minimize any potential for burns in cast or splint application, room temperature tepid water (24°C) is recommended. If higher water temperatures have been used, the newly casted limb must not be placed on a pillow or other type of support that is likely to retain or reflect heat. Cast burns can also occur when insufficient padding has been placed between the plaster of Paris and the surface of the skin. Cast burns are avoidable if simple procedures are followed.

Cast strength is determined by three factors: the type of casting material used, the thickness of the cast, and the effectiveness of lamination among the layers of the cast material. The cloth mesh material that serves as the carrier for the plaster of Paris provides little strength for the cast. A plaster cast must be kept absolutely dry to prevent it from becoming soft and ineffective in immobilization.

The difficulties associated with the use of plaster of Paris have led to the development of newer and improved casting materials. Polyurethane-impregnated casting tapes have gained widespread popularity because of their superior strength, light weight, shorter setting time, cleaner application, and low exothermic reaction. Polyurethane casts are also radiolucent, permitting x-ray evaluation of fracture site healing while the limb remains encased in the cast.

Polyurethane is a plastic material that can be impregnated into a fabric substrate. Although the polyurethane bonds the layers of substrate together, it is actually the substrate that determines the strength of the cast. A variety of substrate materials are available. The weave determines how elastic the material will be during cast application and how strong the cast will be when set. Cotton, polyester, fiberglass, polypropylene, and blends of these materials and others are used in synthetic casting tapes.[131,132,134,135]

Immersing the synthetic casting tape in room temperature water for 10 seconds begins a heat-producing exothermic reaction and causes the material to harden (polymerize). Setting is complete for most synthetic casting materials in 5 to 10 minutes. Because of this short setting time, the rolls of bandage material cannot be opened until they are ready to be applied as a cast. The application process requires skill and must move quickly to ensure adequate molding time. Unlike plaster of Paris, the plastic bandage does not need to be massaged to ensure proper lamination between the layers of material. Also unlike plaster of Paris, which can easily be washed from the hands or clothing, polyurethane is not easily removed: Adequate protective padding must be placed around the patient's limb and protective gloves worn to safeguard the applicator's hands. Polyurethane resin in its natural state is tacky. An additive may be incorporated into the casting tape to reduce its tackiness. In some cases the manufacturer provides special gloves with an antitacky additive to further minimize the tack.[131] The exothermic polymerization of polyurethane resin produces much less heat (44.9°C in 40°C water) than that of setting plaster of Paris. In addition, heat is quickly dissipated so that burns are much less likely to occur when synthetic materials are used. To further minimize the risk of burns, immersion of cast tape in room temperature water (24°C) is recommended.[128, 132,136]

Cast Application

Stockinet is the first layer of a cast, applied over the skin, before any padding is added. The most common stockinet material is cotton. Synthetic materials such as polyester or polypropylene or Gore-Tex can be chosen in place of cotton because they do not retain water like cotton materials do. Stockinet also helps position dressings over wounds and provides extra circumferential control of soft tissue within the cast. Stockinet is folded over the proximal and distal edges to finish the cast (and prevents inadvertent removal of cast padding by a nonresponsible individual or a child).

Next, a layer of cast padding is added over the stockinet. A variety of materials are available to pad casts. Sheet cotton comes in various forms and is used to provide a barrier between the rigid walls of the cast and surface of the skin. Some cast materials have been elasticized for easier application and conformation, and others require more technique to ensure that they uniformly conform to the body part being casted.

Although synthetic cast tapes are not affected by water, cast padding or stockinet does retain water. The risk of skin maceration and breakdown is present if the inside of a cast remains damp for long periods of time. Some manufacturers market cast padding that reportedly permits exposure to water; however, manufacturer recommendations must be followed carefully.

The thickness of cast padding varies; ⅛ to ¼ inch is sufficient for most individuals. The goal is to protect bony prominences and soft tissue from the rigid walls of the cast while effectively immobilizing the fracture site. Soft tissue usually does well with a fairly thin, uniform two- or three-layer wrap. Extra padding is added to smooth and protect the irregular surfaces around bony prominences. Excessive padding reduces the ability of the cast to provide adequate immobilization. A well-molded cast that accurately follows the anatomical contours of the extremity requires less padding. Cast padding also provides a barrier so that the cast can be removed more easily when it needs to be changed or is no longer necessary.

Lower Extremity Casts

The short leg cast is used in the management of fractures involving the distal tibia or fibula, or both; the ankle joint; or the rear foot or midfoot. The foot is positioned in a

functional neutral ankle position (90 degrees) or in slight dorsiflexion. This positioning prevents a plantarflexion contracture from developing by the time of cast removal. The foot can also be casted in a plantarflexed position to accommodate repair of an Achilles tendon rupture. The proximal trimline falls at the level of the tibial tubercle; the distal trimline usually encloses the metatarsal heads. The area around the fibular head is protected by adding extra cast padding to minimize the risk of compression of the peroneal nerve. A cast shoe should be used to protect the bottom of the cast if weight bearing is to be permitted.

For persons with midshaft fractures of the tibia, a patellar tendon–bearing (PTB) cast may be applied. This design incorporates a patellar tendon bar, which directs some of the limb loading force to the external shell of the cast, thus protecting the full length of the tibia against bending moments (see Fig. 12.30). This type of cast or orthosis is not effective, however, in reducing axial loading of the tibia or hind foot. The PTB is most often used when extra stability is desired for individuals who will be allowed some degree of weight-bearing activity. The cast is applied with the ankle maintained in neutral or slightly dorsiflexed position to minimize potential hyperextension moment at the knee in stance. Trimlines are similar to those used for a PTB transtibial prosthetic socket: at the midpatella (or sometimes suprapatella) anteriorly but trimmed and slightly flared posteriorly to permit knee flexion of at least 90 degrees. Proximally, the cast is well molded to the tibia in the area of the medial flare and around the patella.[137,138] Care must be taken to ensure that no pressure is placed on the peroneal nerve.

A knee cylinder cast is often applied when there have been fractures of the patella or surgical repair of the knee joint when the knee must be immobilized in full extension. To ensure the necessary stability for the knee joint, the proximal trimline encompasses the lower two thirds of the thigh and the distal trimline the entire tibial segment to just above the malleoli. The cast can be applied using either plaster of Paris or synthetic casting tape. To limit the risk of pistoning when the person wearing the cast is standing or walking, the cast is carefully molded to fit the contours of the medial femoral condyle.

For closed fractures of the upper tibia, knee joint, or lower femur, a long leg cast provides the necessary stability for healing. Depending on the site of fracture and its relative stability, the limb is immobilized in nearly full extension or in a bent-knee position.[138] A straight knee cast is usually applied with a slight (5-degree) knee flexion angle to enhance patient comfort. Bent knee casts are usually chosen when non–weight bearing must be ensured during ambulation or to aid in controlling rotation of the tibia. With the relatively mobile arrangement of soft tissue that surrounds the femur, it is challenging to provide adequate immobilization, especially for persons who are particularly muscular or overweight. For this reason, control of rotational forces through the femur within a long leg cast is questionable. If the cast is being used to stabilize the tibia, the proximal trimline is at the junction of the middle and proximal third of the femur. If the cast is being used to stabilize the distal femur, the proximal trimline is at the level of the greater trochanter. Distally, the cast immobilizes the ankle and extends to a point just beyond the metatarsal heads. The fibular head should be well padded within the cast to minimize the risk of entrapment of the peroneal nerve.

Fig. 12.31 This child has been placed in a 1½ hip spica cast to stabilize a fracture of the proximal femur. Note the opening for personal hygiene and the additional diagonal support bar incorporated between the short and long sections of the cast.

A hip spica cast, which encases the hip and pelvis in addition to the lower extremity, is necessary for effective control of fractures of the proximal femur and of the hip joint[139] (Fig. 12.31). The hip spica cast is the primary method of treatment of femoral fractures in children under 5 years of age and is used in adults when a prefabricated hip orthosis is not appropriate. Several variations of the hip spica cast are available. In a single hip spica cast, the plaster or synthetic cast material is anchored around the entire pelvis and lower trunk but immobilizes only the hip and knee of the involved side, allowing fairly unrestricted hip motion of the opposite limb. In a 1½ hip spica cast, the cast encases the entire lower extremity on the affected side, as well as the lower trunk, pelvis, and thigh on the uninvolved side. Usually the knee on the affected side is completely immobilized; however, an articulated knee joint can be incorporated if specific circumstances so dictate. In most instances, the hip joint of the affected limb is immobilized in 30 degrees of flexion and 30 degrees of abduction, and the perineal edges are trimmed back to allow for personal care and hygiene. The knee is usually positioned in 30 degrees of flexion. The proximal cast encases the lower to middle trunk (to the level of the costal margin or nipple line), depending on the amount of spinal immobilization required. The 1½ hip spica cast is often reinforced by the incorporation of a lightweight diagonal bar between the short and long extremity segments. Ambulation is possible but often quite challenging, requiring significant upper body strength to manage the adapted crutch-walking gait that the cast position makes necessary.

Cast Removal

A cast cutter or saw with a vibrating disk is used to cut the cast during cast removal. Modern cast cutter blades reciprocate back and forth approximately ⅛ inch in either direction. The vibrating blade easily cuts rigid materials such as metal, wood, plaster, or synthetic cast materials but does not cut through materials that are elastic or mobile. If used properly, a cast cutter does not cut skin. Incorrect or inappropriate use of a cast cutter can seriously cut or burn a patient. To reduce the risk of injury, the blade should not directly contact the patient's skin. Friction between the blade and cast significantly heats the blade, creating a potential for burns. A sharp new blade has less potential for burning the patient than a blade that has become dull or worn out. The noise of the cast cutter can be quite frightening to children or other particularly anxious patients. A careful explanation and a demonstration of the cast cutter's action are the first steps in the process of cast removal.

To remove a cast safely, the cutter is used in a repetitive in-out motion, to progressively open the cast, instead of sliding the blade through the cast. This strategy reduces the risk of a cut or burn on the patient's skin.[140] Safety strips may be incorporated into the cast at the time of application to allow for a safe path for the saw blade to penetrate through without damaging skin. These strips are especially important when friable liners like Gore-Tex are used under the cast. Safe technique involves the operator's thumb serving as a fulcrum on the cast as downward pressure is applied through the wrist. The thumb also controls the depth of the blade. Care is taken to avoid positioning the cast cutter in areas where skin is vulnerable: over a bony prominence or where significant edema or fragile healing skin is present. As the blade breaks through the inner wall of the cast, the sensation of reduced resistance to downward pressure, as well as a change in sound, occurs. Once an area of cast has been cut, the blade is repositioned farther along the cast and the process is repeated until the cast can be pried open completely. Bandage scissors are used to cut through padding and stockinet, and the limb is then extracted from the open cast. For infants and young children with small limbs, an alternative strategy can be used: A plaster of Paris cast can be removed by soaking it in water. This method works particularly well when a corrective clubfoot cast is removed from an infant's limb.

HYBRID CAST BRACES

Hybrid cast braces were first developed as a method of management of proximal tibial and distal femoral fractures near the knee just after World War I but then fell out of use until the mid-1960s (Fig. 12.32).[141–143] In some centers, the cast brace is the method of choice for the management of nondisplaced tibial plateau fractures. The cast brace is often used for additional support of fractures near the knee or of the femur that have been stabilized via ORIF surgery for external fixation (Fig. 12.33). This method is also used to control motion after knee ligament injury or reconstruction.

Cast braces incorporate orthotic components (e.g., hinge joints, range of motion locks) into a plaster or synthetic cast in an effort to provide additional stability to a healing limb.[144–152] The cast brace can be applied using either plaster of Paris or synthetic cast materials. Depending on the nature of the fracture and its stability, the orthotic knee joints incorporated into the cast brace may be chosen to provide limited, controlled, or free-knee range of motion. Because the anatomical center rotation of the knee moves in an arc centered over the femoral condyles, it is essential that the mechanical joints be carefully aligned with the anatomical knee joint to reduce the abnormal stress that occurs across the joint and fracture site.[153,154]

Many orthotists and orthopedic surgeons choose a polycentric orthotic knee joint because its motion more closely follows anatomical motion and reduces the torque-related stress that results from a single-axis mechanical joint. Palpating the condyles on a patient who has had recent trauma about the knee is difficult; the midpatella is a somewhat less precise alternative landmark for alignment. A properly placed polycentric metal joint will be proximal to the joint line and slightly posterior to the midline. Orthotic knee joints are positioned close to but not quite contacting skin. This is especially important medially, where contact between the knees during functional activity is likely.

Fig. 12.32 A tibial cast brace with polycentric adjustable range of motion hinges. The patient has undergone an open reduction with internal fixation surgery after fracture of the tibial plateau. Note that synthetic cast tape is available in a wide variety of colors and patterns.

Fig. 12.33 This cast brace provides medial/lateral stability for a comminuted grade 3 open tibial fracture. The length of the tibia is being maintained by an external fixation device. The patient also sustained a closed femoral fracture, which has been supported by an intramedullary rod fixation. Because the proximal portion of the cast must not terminate near a fracture line, the femoral portion of the cast has been extended up to the level of the trochanter to avoid stress on the femoral fixation.

Medial and lateral uprights are incorporated into the cast above and below the orthotic knee joint to provide protection against unwanted varus and valgus stress and to help control anteroposterior displacement of the tibia or femur.

The distal tibial cast holds the ankle in a neutral position and extends distally to encompass the metatarsal heads. The proximal trimline of the tibial cast is typically at the tibial tubercle, and the distal trimline of the femoral cast is an equal distance from the midpatella. Posteriorly, both tibial and femoral casts are trimmed to permit at least 90 degrees of knee flexion. If warranted, a slight varus or valgus stress can be applied at the time of cast brace application, or a varus/valgus strap can be added to aid in unloading a knee compartment. For persons with fractures of the upper tibia and knee, the proximal component encases the lower two-thirds of the femur. If fracture of the femur has occurred, the proximal component extends upward to the level of the greater trochanter. To be effective, careful molding of the proximal portion of the cast around the trochanter and medial wall is required. For fractures of the mid to upper femur, an orthotic hip joint and pelvic band must be added to ensure alignment and stability.

FRACTURE ORTHOSES

A custom-fabricated or custom-fit fracture orthosis is designed to maintain a body part in an optimal anatomical position, limit joint motion, and unload weight-bearing forces.[155–158] The major advantage of a fracture orthosis, as compared with a cast brace, is that the orthosis can be removed for wound or skin care. Fracture orthoses are fabricated from high-temperature thermoplastic materials. They are designed to provide total contact, circumferential control of a fracture while allowing the individual with a healing fracture to have functional mobility. Fracture stability is enhanced in two ways: by hydrostatic pressure forces created as the rigid walls of the orthosis compress soft tissue and muscles in the extremity and by the lever arm created by extension of the orthosis above and below the fracture site. Fracture orthoses do not entirely unload the lower extremity during weight bearing. If complete unloading or reduced loading is required to protect the fracture site, an appropriate assistive device (crutches or a walker) and a single limb gait pattern must be used.[150]

Two types of fracture orthoses are available: (1) those that are custom fabricated from a mold of the patient's limb and (2) prefabricated orthoses that are custom fit to match the patient's needs. Because of the wide variation in anatomical characteristics among individuals, it is not always possible to use a prefabricated orthosis. Likewise, because of anatomical similarities in the human skeleton, it is not always necessary to create a custom-fabricated device. In certain instances, an orthosis must be precisely fit to provide the desired stabilization of the fracture; in other cases, the orthosis must be heavily padded so that a precise fit is less important. The orthotic prescription must clearly designate the motions to be permitted and controlled, the corrective forces to be applied, and a precise diagnosis and description of the fracture.

Types of Fracture Orthoses

Fracture orthoses are named by the joints they encompass and the motion that they are designed to control. An AFO with an anterior shell is used to control ankle and distal tibia motion (Fig. 12.34). It encases the injured limb completely, limiting motion of the foot or ankle for patients with distal tibial or fibular fractures. The AFO fracture orthosis has two advantages: It can be removed for wound care and hygiene, and it can be worn with standard lace-up shoes if weight bearing is permitted. The application of a cushion heel and rocker sole may be necessary on the shoe to compensate for limited heel, ankle, and toe rocker motion during gait. Because total contact is essential, this thermoplastic orthosis is vacuum molded over a positive impression of the patient's limb. The anterior shell may be lined with soft-density foam to accommodate bony deformity or insufficient soft tissue. Perforated thermoplastic material is often used for the anterior section as a means of ventilation for

Fig. 12.34 Ankle-foot fracture orthosis with a patellar tendon-bearing design incorporated to protect the tibia for bending moments during weight bearing. This orthosis is typically utilized to encourage healing for fractures of the middle third of the tibia. This orthosis is typically with a shoe as orthosis has a low-profile footplate to prevent distal migration of orthosis. (Courtesy Alimed.)

Fig. 12.35 An example of a commercially available short leg walker with a rocker bottom sole that can be used for individuals with Achilles tendon repair, stable healing fractures of the distal tibia/fibula, ankle, or foot, or with severe ankle sprains. (Courtesy DJO Global)

patient comfort. The proximal anterior trimline is at the tibial tubercle. Adequate clearance must be provided for the head of the fibula and the peroneal nerve. The distal posterior section usually extends to just beyond the metatarsal heads on the plantar surface, whereas the anterior section is trimmed just proximally. A stocking or thin sock is worn to protect the skin and for comfort. The anterior section is held in place with a series of hook-and-loop material straps. Shoes must be worn if weight bearing is permitted.

A number of prefabricated short leg walkers are also commercially available; these devices are designed to substitute for a short leg cast and are intended to be removable by the patient. They are heavily padded and, if properly fit, provide excellent immobilization of the distal tibia, ankle, rear foot, and forefoot (Fig. 12.35). The various designs are similar, but manufacturers' instructions should be followed to maximize their effectiveness. The short leg walker's advantage is that it can be removed for wound and skin care. Its disadvantage may be slightly less effective immobilization. The ankle is positioned at a neutral (90-degree) angle. Some designs have an adjustable orthotic ankle joint that permits a controlled, limited range of motion, to assist forward progression during walking. The components of a short leg walker include a rigid foot piece that is attached to a pair of metal or thermoplastic uprights and a proximal cuff that helps to suspend a foam liner. Short leg walkers are manufactured in various styles and sizes. To ensure proper fit, the manufacturer's recommendations must be followed carefully.

The PTB fracture orthosis is the removable version of the PTB cast, providing significant protection from bending and rotatory torque for the tibia during weight-bearing activities. This thermoplastic orthosis is most often vacuum molded over a positive mold of the patient's limb for optimal total contact fit. Ankle position within the orthosis is often in slight dorsiflexion, once again to minimize hyperextension moment at the knee during the stance phase of gait. Trimlines are similar to those of an AFO with anterior shell, with the proximal trimline extending somewhat more proximally to the proximal pole of the patella anteriorly, medially, and laterally. The posterior trimline should permit free knee flexion beyond 90 degrees. Hook-and-loop material straps are used to secure the anterior and posterior sections together. The anterior and the posterior sections can be hinged at the proximal edge for improved anteroposterior control.

The purpose of the knee-ankle-foot fracture orthosis is to provide long-term protection for fractures of the distal to middle femur or for fractures about the knee. This orthosis is often used as an alternative to a hybrid cast brace for persons who have had ORIF for fractures of the proximal tibia, knee, or distal femur. The orthosis is removable for wound care and personal hygiene and when protection is not required. Depending on the location of the fracture, the orthosis can be designed to limit range of motion or to permit full motion of the knee. Drop locks can be used to stabilize the knee in full extension during ambulation. The design of the orthosis also protects the knee from excessive mediolateral and anteroposterior shear stress during ambulation. If maximum stability is necessary, a solid-ankle design can be incorporated; if mobility of the ankle is desired, an articulated ankle joint with an appropriate motion stop mechanism can be used. The orthosis requires total contact within the femoral and tibial components. Proximal trimlines follow the anatomical contours of the proximal femur to the greater trochanter to provide femoral protection. To stabilize the knee or proximal tibia, encasement of the lower two thirds of the femur is sufficient. The orthosis alone cannot effectively unload the

Fig. 12.36 A hip section has been utilized with this fracture knee ankle foot fracture orthosis to provide better control of hip abduction/adduction and rotation. This may be beneficial for complex injuries of lower extremity that may include a proximal femur fracture. Lateral stability from metal uprights helps to support femur in ambulation. Orthotic hip joints may be utilized to limit hip flexion and extension as well as adjust for abduction/adduction. (Courtesy Orthomerica Products.)

femur, tibia, or foot: If axial unloading is desired, appropriate assistive devices (crutches or walker) must be used.

For individuals with proximal femoral fractures, a hip joint and pelvic band are often incorporated into a total contact KAFO (Fig. 12.36) in an effort to control motion and rotational forces through the femur. Depending on the patient's specific needs, hip flexion/extension motion can be restricted or free; abduction/adduction is usually restricted. The placement of the orthotic hip joint is approximately 1 cm anterior and 1 cm proximal to the tip of the greater trochanter in most adults. Knee and ankle motion can be free or limited, given the location and stability of the fracture. A variety of single-axis or polycentric orthotic hip joints can be incorporated. A pelvic belt is used to maintain the orthotic hip joint in proper functional position. The belt should fit midway between the crest of the ilium and the greater trochanter.

EXTERNAL FIXATION DEVICES

External fixation devices have evolved primarily to care for initial management of complex open or severely comminuted, unstable fractures that are most often the result of high-energy injury or multiple trauma (see Figs. 12.28 and 12.33).[159–163] In particular, external fixation is used for severe metaphyseal fractures, severe intraarticular fractures, when there has been nonunion, in cases of substantial bone loss with allograft, and for fractures in osteoporotic bone.[161,164] They are particularly useful when fracture disrupts pelvic stability.[165–167]

Pins are placed into bone on either side of the fracture and then clamped onto lightweight rods in an external frame. The external frame can be a single rod, a set of articulated rods that cross the joint axis, circumferential, or a combination of these options.[168–172] The goal is to provide optimal skeletal alignment while providing visual access to healing skin and muscle. The external fixator permits active range of motion of the joint above and below the fracture. It is removed when soft tissues have adequately healed and radiographs demonstrate healing of the fracture. Casts or orthoses can be used to provide immobilization after fixator removal to support and protect the fracture until healing is complete.

POSTFRACTURE MANAGEMENT AND POTENTIAL COMPLICATIONS

The postfracture issues and complications that are of concern to the managing physician and rehabilitation team include vascular injury, compartment syndrome, appropriate weight-bearing status, loss of reduction, delayed or nonunion, infection, implant failure (for ORIF), compression neuropathy, and skin breakdown. Each patient who presents to the emergency department with a fracture must be assessed for potential vascular injury and risk of developing compartment syndrome by careful physical examination. Whether a splint, cast, surgical ORIF, or placement of external fixators has been used to stabilize the fracture, the condition of the extremity must be monitored carefully by the physician, rehabilitation professional, patient, and family caregivers.

Fractures or dislocations around joints may have a concomitant arterial injury that can bruise or completely disrupt an artery, compromising or completely interrupting blood flow beyond the site of fracture.[173–175] This creates a grave situation: The physician has a window of less than 6 to 8 hours in which to restore blood supply and nutrition to the distal muscle and bone before significant tissue death occurs. The longer the period of ischemia, the greater the likelihood of delayed healing, infection, and necrosis. This is commonly seen in patients with blunt trauma due to the associated injuries, fractures, and dislocations. Severe damage may lead to amputation of injured limb.[176]

Compartment syndrome evolves when bleeding or inflammation exceeds the expansive capacity of semirigid muscle or soft tissue anatomical spaces (compartments) of the fractured limb.[177–179] Once interstitial pressure exceeds a critical level, blood vessels and muscles are compressed, and oxygen supply to the muscles is significantly compromised. Irreversible muscle or nerve damage occurs if compartment syndrome continues for longer than 6 to 8 hours. Presenting signs and symptoms include extreme pain and significant swelling of the extremity with taut skin. Passive motion of the fingers or toes causes excruciating

pain. Compartment syndrome is considered a medical emergency: The treating physician must be notified immediately so that a fasciotomy can be performed to relieve excessive compartment pressures. All health professionals who are involved in the treatment of extremity trauma should be aware of the signs and symptoms of compartment syndrome. If unrecognized and untreated, compartment syndrome has devastating results.

One of the most important considerations for lower extremity fractures is weight-bearing status. A patient's weight-bearing status (full weight bearing, weight bearing as tolerated, partial weight bearing, toe-touch weight bearing, or non–weight-bearing) is determined by the physician on the basis of the stability of the fracture and the immobilization method used. Once a patient is stable after an operation or a cast has been applied and is properly set, rehabilitation professionals work with the patient and family on mobility and gait training. The rehabilitation professional selects the appropriate assistive device for a patient's weight-bearing status, given the patient's physical and cognitive status and the characteristics of his or her usual living environment. Communicating quickly to the referring physician any signs of developing complications or difficulty with compliance that might put the fracture site at risk is important.

Loss of reduction of the fracture is a serious complication and can occur whether a splint, cast, ORIF, or external fixator has been used to realign and stabilize the limb.[169,179–181] A progressive angular deformity or abnormal position of the limb suggests loss of reduction and must be quickly reported to the managing physician. Even if reduction appears to be appropriate, inadequate immobilization within a splint or cast can lead to delayed union, nonunion (nonhealing), or malunion (healing in an abnormal position).

Any patient who has sustained an open fracture is at risk of developing infection of skin, deep tissue and muscle, or even bone. Both intravenous and local antibiotics are administered in the emergency department and operating room to minimize likelihood of infection from contamination sustained at the time of injury.[182–186] Infections may also be iatrogenic.[183,187] An infection is a serious complication that requires aggressive antibiotic treatment or debridement, or both. If an infection occurs after ORIF, the implanted hardware may have to be removed and an external fixation device applied. For individuals with external fixation, the pins provide a tract for infectious organisms directly into bone.[188] Appropriate wound and pin care is essential to minimize the risk of infection.[189] Osteomyelitis, or infection of bone, is a serious situation that can result in deformity; joint destruction; and, in some circumstances, amputation.[189–192] Patients who have undergone ORIF are at risk of implant failure if repeated loading causes fatigue and ultimately exceeds the strength of the implant material and design.[193–195] Loosening or breakage of implanted screws, plates, or other devices also indicates excessive motion of the fracture site and increases the risk of delayed healing or nonunion. The patient's ability to function within weight-bearing limits established by the physician must be carefully assessed and monitored to reduce the risk of implant failure.

Complications also occur in patients whose fractures are managed by casting. The patient's neurovascular function is documented before cast application and carefully monitored while the cast is in place. In the distal lower extremity, the peroneal nerve is susceptible to prolonged pressure (compression-induced peroneal palsy) as it wraps around the head of the fibula.[119,196,197]

Complaints of edge pressure or toes being squeezed can be solved with cast modifications; however, excessive pressure and discomfort inside the cast often require removal and reapplication of a new cast.[198] On initial application, a cast is designed to have a snug but not tight fit. Signs of distal vascular compromise such as delayed capillary refill on compression of the nail bed suggest that the cast may be excessively tight.[119,198] It is not uncommon for cast fit to loosen over time as a result of several factors: initial edema resolves, compressive forces modify soft tissue composition, disuse atrophy occurs, and cast padding compresses over time. Fit must be carefully monitored over time: A loose cast provides less control of the skeleton, and fracture reduction may be lost. Pistoning of a loose cast on the extremity is likely to lead to skin breakdown and shear over bony prominences.

Casts applied postoperatively while the patient is anesthetized are usually univalved (split down the front) to accommodate postoperative swelling.[120] Excessive swelling is accompanied by significant pain. Limb elevation is the first defense against excessive swelling and pain; however, the cast can be opened further or bivalved to relieve extreme pressure.[3] The risk of compartment syndrome must always be considered: If the patient experiences significant pain on passive motion of the fingers or toes, the physician must be contacted immediately. Failure to recognize and appropriately treat a compartment syndrome results in muscle necrosis and possible loss of the limb.[177]

Occasionally, a window can be cut into a cast to inspect a wound or relieve a pressure area. If the limb is edematous, it is likely that soft tissue will begin to protrude through the window, resulting in additional skin irritation and breakdown. For this reason, any piece of cast that is removed to make a window must be reapplied and secured to the cast after modifications have been made.[198]

Patients with foot pain try to reposition the foot within the cast to make it more comfortable. Inappropriate plantar flexion of the foot within the cast creates excessive pressure on the posterior heel and dorsum of the foot. Discomfort can be reduced if the patient is able to push the relaxed foot gently downward while pulling the cast upward, as if pulling on a boot. If this fails to relieve pressure, the cast must be removed and reapplied.[198]

Foreign objects introduced into a cast are the most common cause of discomfort and pressure. In an attempt to relieve itching of dry skin, patients are sometimes tempted to insert coat hangers, rulers, sticks, pens, and similar objects into the cast to scratch the itchy areas. This strategy often leads to displacement of cast padding, creating lumps and bumps where smooth surface contact is essential. Objects can break off or become trapped within the cast as well. The best way to relieve itching is by tapping on the cast or blowing cool air into it.

Another common complication is skin maceration, which is the result of prolonged exposure to water or a moist environment within the cast. Although, ideally, a cast is kept completely dry, many become wet at some point after application. Plaster casts that become wet lose significant stability and must be replaced. Synthetic casts can be towel dried as much as possible and then further dried using a cool setting on a blower or hairdryer.

Summary

In this chapter the reader has discovered that orthoses play an important role in the management of traumatic (e.g., fracture) and developmental (e.g., DDH, LCPD) musculoskeletal conditions. Each member of the interdisciplinary rehabilitation team has a contribution to make to the care of individuals with pathologic conditions of the musculoskeletal system, as well as shared responsibility to monitor for changes in function and potential complications. Although many prefabricated orthoses are available, knowledge of appropriate fit, design, and dynamics of the orthoses is essential so that the device will most closely match the intention of intervention. Precise communication about the goals of the orthosis (e.g., to fully immobilize the limb or to allow joint motion within a restricted range), wearing schedule (e.g., all the time or during particular activities), and weight-bearing status while using the orthosis has a major impact on efficacy of the orthotic intervention. All team members participate in patient and family education about the orthosis and its purpose, maintenance and cleaning, signs that indicate problems, and strategies to put in place should problems arise.

13 Orthoses for Spinal Dysfunction ☆

THERESA E. LEAHY and SHARIDY MACCORD

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to do the following:

1. Identify the nomenclature for spinal orthoses.
2. Describe the basic structural and functional anatomy of the spine and its alignment.
3. Discuss the three-column concept of spine stability as it pertains to spine trauma.
4. Identify the types of injury and pathology for which spinal orthoses are used.
5. List the different types and functional use of spinal orthoses.
6. Describe the potential complications associated with the use of spinal orthoses and methods of prevention.
7. Evaluate different areas of the spine as being amenable to bracing.
8. Discuss indications and contraindications for using spinal orthoses.
9. Describe basic pathophysiology of scoliosis and its implications.
10. Identify common braces used in the treatment of scoliosis.
11. Discuss the prescription process for a spinal orthoses.
12. Value the importance of a multidisciplinary team approach in treating disorders of the spine.

External orthoses are used to manage a variety of spinal conditions. The general purpose of a brace is to limit the motion of a spinal region, decreasing the amount of load applied to the region treated. Orthoses are most frequently used when there is concern that loading the spine may result in deformity (i.e., treating an unstable fracture), when the spine is compromised in a way that requires additional support for healing (i.e., postsurgical management or osteoporosis), when the patient is experiencing low back pain (LBP) that can be relieved by either limiting motion or increasing abdominal support, or there is existing spinal deformity such as scoliosis. Another major function of a spinal orthosis is to serve as a psychologic reminder to restrict trunk or neck motion or at least to encourage the patient to move cautiously.[1]

For spinal conditions, an orthosis is defined as an external device applied to the body to restrict motion in a particular body segment or spinal region. The American Academy of Orthopaedic Surgeons standardized the nomenclature used for describing orthoses in spinal management in 1973 and divided them broadly into five categories (Table 13.1)[2]:

- Sacroiliac
- Lumbosacral
- Thoracolumbosacral
- Cervical thoracic
- Cervical

Orthoses may also be classified by their rigidity (i.e., rigid, semirigid, or flexible) or by a combination of their materials and whether they are prefabricated or custom-fit types. Historically, orthoses have been named according to their inventor or city of invention. This chapter provides an overview of spinal anatomy and biomechanics as they apply to orthotic use, highlights tips to ensure optimal fit and avoid complications, and discusses each of the three major spinal regions that are amenable to orthotic management and the orthoses used in each region as well as the various types of pathology for which brace treatment is used. This chapter describes common spinal orthoses grouped by region (cervical, thoracic, and lumbosacral) and the clinical conditions that are most often assisted by the use of spinal orthoses.

Managing a patient who may benefit from a spinal orthosis requires an interdisciplinary team approach. Direct communication between the patient, physician, orthotist, nurse, physical therapist, and other rehabilitation personnel is necessary to ensure that the health care professionals, the patient, and caregivers all understand the rationale, limitations, and expected outcomes when the prescription and use of an orthosis is being planned. To avoid complications and promote optimal care, specific instructions must accompany the management of a spinal orthosis. Rehabilitation professionals are responsible for designing therapeutic interventions that optimize function while also carefully observing the precautions and the treatment goals relevant to the management of persons using spinal orthoses. Understanding the design of and rationale for the orthosis being used is critical to the overall success of the program.

Anatomy and Biomechanics

The spine consists of 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, 5 sacral vertebrae, and 3 to 4 coccygeal segments. Load-sharing discs are interposed between adjacent vertebrae in the cervical, thoracic, and

☆The authors extend appreciation to Jeff Coppage and S. Elizabeth Ames, whose work in prior editions provided the foundation for this chapter.

LS corset	Lumbosacral corset
DL corset	Dorsolumbar corset
Soft collar	Nonreinforced cervical collars made from foam or any low modulus material

lumbar segments; in the sacral and coccygeal regions, the segments are fused. Two adjacent vertebrae and the intervertebral disc define the functional spinal unit (FSU). Multiple FSUs are combined in a superstructure capable of lateral bending, flexion, extension, and axial rotation. The various levels of the spine differ in their contribution to the spine's overall range of motion (ROM). In the cervical spine, the majority of motion in the sagittal plane (flexion/extension) occurs through Occiput–C2, C4–5, and C5–6.[3] The majority of axial rotation occurs at the level of C1–2 and is made possible by the unique anatomy of the atlantoaxial articulations. Lateral bending of the cervical spine is more evenly distributed, with the upper subaxial cervical spine contributing only slightly more than other regions. Sagittal motion in the thoracic spine increases in a cranial-to-caudal direction. The upper segments provide approximately 4 degrees at each level and the lower segments provide approximately 6 degrees, increasing to approximately 12 degrees per level at the thoracolumbar (TL) junction.[3] Axial rotation is greatest in the upper thoracic spine and gradually decreases caudally. Segmental contribution to lateral bending is fairly well distributed over the length of the thoracic spine. The lumbar spine contributes more flexion/extension but significantly less axial rotation. These regional differences in motion are related to anatomic differences, primarily articular process orientation, between the thoracic and lumbar vertebrae. The ligamentous structures of the spinal column play an important role in spinal kinematics by augmenting overall spinal stability while maintaining flexibility.

The normal spine is essentially vertical in the coronal plane but exhibits four curves in the sagittal plane. The terms *kyphosis* and *lordosis* are used to describe sagittal curves. *Kyphosis* refers to a curve in the sagittal plane with a posterior convexity (forward bend). The thoracic and sacral portions of the spine demonstrate kyphosis. The normal amount of thoracic kyphosis ranges from 20 to 50 degrees.[4] The term *lordosis* describes a curve in the sagittal plane with an anterior convexity (posterior bend). The cervical and lumbar portions of the spine demonstrate lordosis. The mean lordosis in the cervical spine is 35 to 40 degrees.[5,6] The normal range of lordosis in the lumbar spine is from 20 to 60 degrees.[4] Although multiple curves are present, an overall sagittal balance is maintained. The sagittal balance of the spine can be assessed using a plumb-line or gravity-line technique. In a normal balanced spine, a plumb line from the center of the C7 should fall ±2 cm from the sacral promontory in the sagittal plane.[7] These curves, as well as appropriate coronal and sagittal balance, allow for increased flexibility and shock-absorbing capacity while maintaining necessary stiffness and stability.[3]

The major load on the spine under normal physiologic conditions is axial. Axial loading causes compression of the vertebral column and its individual FSUs. The natural kyphotic and lordotic curves of the spine increase in magnitude, and components of individual FSUs (vertebrae and intervertebral discs) deform slightly in response to compression.[3] Soft tissue (ligaments and musculature) as well as bony architecture serve to limit the degree to which the gross architecture of the spine can be deformed, and the properties intrinsic to the vertebrae and intervertebral discs counter the effects of compressive forces. The spine must resist tension and shear forces in addition to axial loads. The properties of the spine conform to the Wolff law, which states that form follows function. Studies of the spine reveal that the spine as a whole can resist higher compressive loads than tension or shear forces.[3] Furthermore, segments of the spine that experience greater compressive loads have been found to be capable of withstanding higher loads before failure. Biomechanical studies demonstrate that the ability of the spine to withstand forces increases in a cephalocaudal direction, such that the lumbar spine, which must withstand the total weight of the body above it, has the greatest compressive strength.[8,9] The vertebral body (anterior column and anterior aspect of the middle column) provides the majority of this resistance to compression, which translates into increased overall stability in fractures in which the vertebral body is intact and a greater likelihood that bracing may not be necessary. This structure-function relationship is vital to understanding the rationale behind bracing and other treatments of back pain, spinal deformity, or spine injury.

The Three-Column Concept

An understanding of spinal injury and stability is vital to understanding the role played by bracing and various orthoses. The concept of the three-column spine was initially described by Denis[10] in 1984 and is widely used in defining spinal stability. Denis used the three-column model as a basis for his classification of traumatic spinal injuries. The three columns are the anterior, middle, and posterior columns (Fig. 13.1). The anterior column consists of the anterior aspect of the vertebral body, anterior annulus fibrosus, and anterior longitudinal ligament. The middle column includes the posterior longitudinal ligament, posterior annulus fibrosus, and posterior aspect of the vertebral body. The posterior column consists of the posterior vertebral arch as well as the supraspinous and interspinous ligaments, facet joints, and ligamentum flavum. There is debate as to whether injury to the posterior column or the middle column is the main factor that destabilizes thoracolumbar spinal fractures[3,11–15]; a combination of both, however, results in a highly unstable spine. Compression fractures and burst fractures are the most common clinical entities where orthoses are considered. Denis defined these types of fractures using the three-column concept (Box 13.1).

Compression fractures are defined as failure and wedging of the anterior column and occur with axial forces combined with spinal flexion about an axis located in

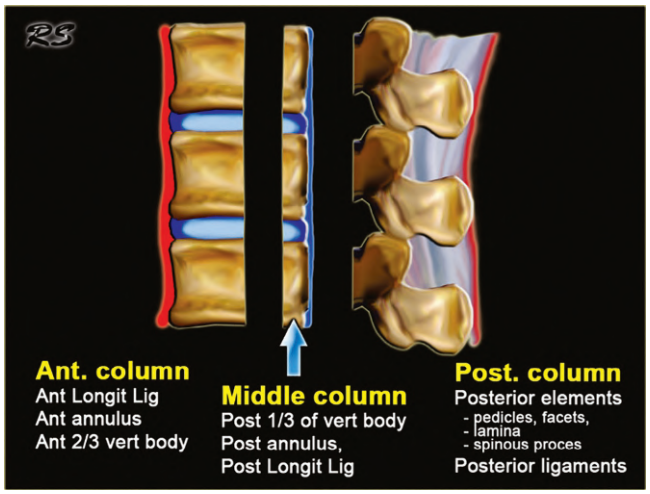

Fig. 13.1 Three-column concept (radiology assistant www.radiologyassistant.nl).

the middle column. The middle column remains intact, which provides stability and prevents retropulsion of bony fragments into the spinal canal. Some degree of partial failure of the posterior ligamentous structures may be present due to the tension forces of the initial forced flexion. Depending on the degree of anterior column failure, some compression fractures may undergo progressive collapse and lead to increasing posttraumatic kyphosis.[16] Compression fractures with greater than a 50% loss of vertebral body height are more likely to have instability due to associated posterior ligamentous involvement, which may result in progressive injury and kyphotic deformity because of the compressive forces conveyed by an upright posture.[3,16]

Burst fractures generally involve failure of the anterior and middle columns due to axial loading with or without additional moments, depending on the fracture pattern.[17] Although these fractures are defined as two-column involvement, Holdsworth[13] described an associated greenstick fracture of the lamina (posterior column). These injuries are referred to as *three-column burst fractures.* Involvement of the middle column is significant because it may lead to retropulsion of bony fragments in the spinal canal and subsequent spinal cord injury. Controversy exists regarding which burst fractures are "stable" and amenable to bracing and which require surgery. A recent randomized trial of hyperextension casting followed by brace management compared with operative management demonstrated that patients treated operatively experienced improved functionality more rapidly than those who were immobilized, but long-term outcomes in terms of deformity, chronic pain, and neurologic status were equivalent.[18]

Fit and Function of the Spinal Orthosis

All spinal orthoses have several common effects on the spinal region they treat. Their primary action is to reduce gross spinal motion, and the degree to which they accomplish this depends on both their materials and design. Secondary effects include the stabilization of individual FSUs, reducing the ROM of one vertebra relative to another. Spinal orthoses also apply closed chain forces designed to counter a deforming force, such as providing hyperextension to a fracture that is vulnerable in flexion. Finally, they reduce loads on the spine itself by preventing specific actions, such as bending and twisting to reduce stress on surgical implants. Each region of the spine has specific needs based on its

Box 13.1 Classification System for Traumatic Fractures of the Thoracolumbar Spine

Compression Fractures (Denis Type 1)

Mechanism of Injury: Spinal Flexion With Compression

Subtype	I-A	Anterior fracture only
	I-B	Anterior fracture with lateral components

Burst Fractures (Denis Type II)

Mechanism of Injury: Spinal Compression With Flexion

Subtype	II-A	Fracture of both end plates or retropulsion, or both, of the posterior wall as a free fragment
	II-B	Fracture of the superior end plate, occasional retropulsion of inferior wall as a free fragment
	II-C	Fracture of the inferior end plate
	II-D	Burst fracture with rotational injury
	II-E	Burst fracture with lateral flexion injury

Seat Belt Injuries (Denis Type III)

Mechanism of Injury: Spinal Flexion With Distraction

Subtype	III-A	(Chance fracture) single segment, posterior or middle column opening
	III-B	(Slice fracture) single segment, posterior and middle column opening through soft and bony tissue
	III-C	Two segments, posterior and middle column opening through soft and bony tissue
	III-D	Two segments, posterior and middle column opening through soft tissue only

Fracture Dislocations (Denis Type IV)

Mechanism of Injury: Translation, Flexion, Rotation, With Shear

Subtype	IV-A	Flexion and rotation injury with disruption through bone or intervertebral disc, or both
	IV-B	Due to shear (anterior-posterior or posterior-anterior) with fracture and dislocation of facet joints
	IV-C	Ligamentous injury to posterior and middle column, with failure (marked instability) of the anterior column
	IV-D	Oblique shear forces resulting in significant instability of involved segment (bone or disc)

predominant motions, loads, anatomic features, and physical condition.

The shape of a spinal orthotic, much like the natural shape of the spine, has an intimate relationship with its desired function. Braces often help to restore or exaggerate natural spinal structure. When thoracolumbar body casts were more commonplace in clinical practice, the casts were applied with patients positioned supine on a casting table with a belt under the lumbar spine such that they were casted in a position of hyperextension.[19] This hyperextension (hyperlordosis) has been used in many types of braces (i.e., Jewett and cruciform anterior spinal hyperextension [CASH] brace) because it removes or decreases the amount of flexion, which reduces compressive force on the fractured vertebral body and limits distraction of the posterior elements. Hyperextension braces achieve the intended positioning by using a three-point mold involving three points of applied force: one posteriorly and two anteriorly, with one located cephalad to the level of the posterior force and one caudal.[3] An analogy to this concept is if one were trying to break a pencil using two hands with the thumbs in the center and fingers located at either end. The resultant bending that would result is analogous to the intended effect of the three-point mold. The desired effect is prevention of the progressive kyphotic deformity associated with significant compression and burst fractures. Another example of three-point molding is seen in corrective braces used for the treatment of scoliosis except that the forces are directed in a coronal instead of a sagittal plane. It is imperative to ensure that the contour and fit of the brace promotes adequate alignment of the spine and avoids potential complications associated with forces applied to the body for long periods of time.

To be effective, an orthosis must have intimate contact with bony prominences.[20] The biomechanical principles of bracing the spine itself can be understood in these terms; in reality, however, using an orthosis to treat a human condition is subject to other variables. Compliance and the psychologic effects of bracing can be significant issues, including the development of a psychologic dependence on the orthosis.[21–26] The financial burden can be significant, with costs ranging from $32 to greater than $5000.[1] Physical issues also apply, particularly in an increasingly obese population. The ability of a brace to apply appropriate forces, either stabilizing or corrective, depends on its ability to act on the structures of the spine. This, in turn, depends on the soft tissue envelope in the contact areas around the spine. Too little or too much pressures transmitted through soft tissues can result in significant physical complications including skin breakdown, loss or reduction of spinal alignment, pain due to the brace, weakening of the immobilized muscles, and soft tissue contractures.[26–32] The prescription and use of a spinal orthotic should always be governed by an appropriate monitoring system and rehabilitation program. Orthoses must be modified periodically, and a comfortable and appropriate fit is critical to preventing skin problems and ensuring compliance.

Compliance with brace wear is a significant clinical issue, particularly because the orthosis is specifically designed to restrict motion, which is neither an accommodating nor pleasant approach to therapy. Studies in adolescent patients with scoliosis wearing "smart braces" that can track wear time indicate compliance rates of 9% to 30%; similar studies have not been done for orthoses used for other conditions. In the current health care environment, most patients with significant spinal conditions recover at home rather than in rehabilitation facilities. Orthosis designs that increase the difficulty of donning or doffing decrease patients' ability to use the brace effectively if they are not supervised and assisted daily. The only orthoses that ensure compliance are fiberglass casts, which are very rarely used today.

REGIONAL ORTHOSES

Cervical

The cervical spine is the most intuitively easy structure to consider bracing in that the bony occiput, mandible, sternum, and clavicles provide appropriate supporting structures. Unfortunately this advantage is offset by the limited surface area available for contact and the fact that the mandibles and clavicles are often in motion during normal activities. The complexity of the cervical soft tissues—vessels, airway, esophagus—is a disadvantage in that significant forces cannot be applied directly to the spine without significant visceral effects. Orthoses for the cervical spine can be limited to the subaxial spine itself—in the form of a cylinder that fits around the neck with a trimline at the occiput, mandible, and sternoclavicular structures—or it may extend proximally and distally (halo vest) or just distally onto the thoracic cage for additional control (cervicothoracic orthosis [CTO]).

Cylindrical cervical braces limit a variable degree of motion, depending on the design, and primarily provide proprioceptive feedback as a reminder to limit the ROM of the neck. Available choices are many, and this list is not exhaustive; commonly used choices include the soft collar, the Stifneck (Laerdal, Armonk, NY), the Philadelphia, the Miami J, and the NecLoc (Össur, Foothill Ranch, CA) (Fig. 13.2).

Soft collars tend to be the most comfortable of the available cervical collars but provide little stability to the cervical spine. The collar is a piece of soft foam rubber covered with stockinette or another gentle fabric with a Velcro-type fastener. These collars have been shown to provide up to 10% restriction to cervical motion in all planes.[33–35] Conversely, Miller et al.[36] analyzed differences in functional motion of the cervical spine between no collar, a soft collar, and a rigid collar during the performance of 15 different activities of daily living[a] (ADLs). The authors found that there was no significant difference in limitation of sagittal ROM between the soft and rigid collars during 13 of the 15 ADLs tested (significant differences were noted while reversing a car and sitting down in a chair). No significant differences were noted during lateral bending, and the difference in restriction of rotational movement was significant only while reversing a car. However, a study examining cervical ROM in 50 healthy adults performing cardinal plane and rotational neck movements while wearing no collar, a soft collar, or a neck brace did find

[a]ADLs tested include standing to sitting, backing up a car, putting on socks, tying shoelaces, reading a magazine in one's lap, cutting food with knife and fork and bringing food to the mouth, rising from a sitting position, washing hands in a standing position, shaving facial hair (men)/applying makeup (women), washing hair in shower, picking up object from floor (bending technique), picking up object from floor (squatting technique), walking, walking up stairs, walking down stairs.

Fig. 13.2 (A) Soft collar. (B) Philadelphia collar. (C) Miami J collar. (D) NecLoc. (© Össur.)

differences between devices in the amount of motion allowed.[37] Whitcroft and colleagues found the soft cervical collar to reduce movement by an average of 17.4%, whereas the cervical brace reduced movement by 62.9%.[37] Differences between the two brace types were least in lateral bending. The authors concluded that a soft cervical collar is not sufficient after a whiplash injury when cervical immobilization is desired. The soft cervical orthosis is used primarily as a comfortable reminder to the patient to limit exaggerated neck movements and may be useful in cases of minor whiplash, cervical spondylosis, or as a postoperative adjunct with a stable spine.[3] Soft collars are inappropriate for an unstable cervical spine.

A great deal more support is required in patients with injuries that compromise spinal stability. This prompted the development of the reinforced cervical collar, which is a commercially produced, prefabricated orthosis that combines some of the soft materials found in soft collars with a semi-rigid contoured plastic external frame. Many different types of reinforced collars are available, such as the Philadelphia, Aspen (Aspen Medical Products, Irvine, CA), Miami J, NecLoc (Össur, Foothill Ranch, CA), and Stifneck. Most reinforced collars have anterior and posterior shells with inner padding and trim; they close around the neck and fasten with Velcro-type fasteners. The collars are contoured such that they abut the sternum, clavicles, trapezius,

and upper thoracic spine inferiorly and the mandible and occiput superiorly, which provides some degree of end-point control. Most have openings anteriorly to accommodate respiratory and ventilator equipment.

Although there are many similarities among the various cervical collars, studies have found significant differences in the degree to which the collars restrict the motion of the cervical spine. The ability of a cervical collar to provide cervical stability is very important in that approximately 3% to 25% of spinal cord injuries occur after the initial spinal injury.[38] Multiple studies have evaluated the various reinforced collars for their ability to promote cervical stability as well as to avoid complications. Askins and Eismont[38] studied five common reinforced cervical collars by using anteroposterior and lateral radiographs to assess the motion of the cervical spine in normal healthy volunteers. They found the NecLoc to be statistically superior with respect to the limitation of cervical motion in all planes, followed by the Miami J collar, as compared with Philadelphia and Aspen collars. Kaufman and colleagues[39] found the NecLoc to provide superior restriction of motion compared with both the Philadelphia collar and a soft collar. Ducker[40] found the NecLoc and Miami J collars to be statistically superior to the Stifneck, Philadelphia, and soft collars. Tescher et al. compared four collars (Aspen, Aspen Vista, Miami J, and Miami J Advanced) for cervical stability and tissue-interface pressure (TIP).[41] These researchers found the Aspen to be more restrictive than the Aspen Vista and Miami J but not significantly different from the Miami J Advanced. They report that, despite statistical difference between the collars, all provided restriction of cervical ROM, and they question the clinical significance of the differences. They further report that TIP increases for all collars with increasing patient body mass index and that the Miami J produced the lowest overall pressures.[41]

In addition to requiring adequate stability in selecting a reinforced cervical collar, the treating physician must consider fit and skin protection. Fisher[29] studied the importance of proper fit of a cervical orthosis and found that an inappropriately fitted collar was equivalent to not wearing any collar at all. Bell and colleagues[32] analyzed the effects that ill-fitted Miami J collars have on the degree of cervical motion restriction. They found that in flexion/extension, braces that were either too large or too small allowed increased motion; however, only extension in the brace that was too large produced a statistically significant increase in allowed motion. Both the too small and too large braces allowed significantly more motion in left and right axial rotation. The too large and too small braces allowed significantly more lateral bending motion to the right, but only the too small brace allowed a significant increase in left lateral bending. Plaisier and colleagues[28] evaluated common cervical collars and the pressures they exerted on craniofacial tissues with respect to capillary closing pressure. The pressure at the collar-skin interface was measured using an electropneumatic sensor placed between the collar and skin. This measurement was compared with a value of 32 mm Hg, which represents capillary closing pressure as defined by Berne and colleagues.[42] Significant differences were found between collars in the amount of pressure exerted on the tissues. The Stifneck collar produced pressures in excess of capillary closing pressure at most collar-tissue interfaces, whereas the Miami J collar exerted pressures well below the capillary closing pressure.

Braces that are required immobilize the occipitocervical spine need fixation to the skull and significant rotational control. The most commonly used example is the halo vest (Fig. 13.3). Facial fracture fixation with traction applied through a skull ring was developed by Bloom during World War II to treat pilots with facial fractures and severe burns. The device was then adapted by Nickel and first reported in 1959.[8] Primary features include a ring anchored to the skull with skeletal pins and connected to a body jacket by four vertical uprights. Changes in material design and advances in plastics technology have allowed significant modifications to the halo vest—molded thermoplastic jackets, radiolucent rings and uprights, shaped rings open posteriorly for patient comfort while supine, and multidirectional adjustments in the connecting mechanisms—but the principles of fixation have remained the same. Six to eight transcranial pins provide secure proximal fixation (end-point control), and full contact support around the thorax and torso provide the distal fixation.

The ring of the halo is positioned 1 cm above the eyebrows and the tips of the ears, with care taken to keep the ring well clear of the skin surface. Four pins are inserted into the outer table of the skull with 6 to 8 lb/in of torque.[43] The anterior pins are placed at the equator (widest point) of the skull above the lateral third of the eyebrow to avoid the frontal sinus, supraorbital and supratrochlear nerves, and temporalis muscle. Posteriorly, pins are placed 1 to 2 cm posterior to the ear diagonally opposite the anterior pins. This provides secure fixation to allow for manipulation in flexion/extension and in translation.

The halo vest itself was originally a plaster cast that fit over the torso with a trim line at or slightly above the inferior costal margin of the last rib.[44] Advances in materials allow for bivalved thermoplastic shells that can be released

Fig. 13.3 Halo vest. (© Össur).

with the patient supine to allow for hygiene, and some designs are fleece-lined. A four-pad halo vest that completely avoids the shoulder girdle has been proposed to avoid scapular movements transferring loads to the neck.[45,46] Two anterior and two posterior rods link the vest to the ring through a series of connectors. Modern connectors allow translation in multiple planes with the ability to lock them into position once reduction has been achieved.

Complications can occur with the use of a halo vest, including pressure sores, loss of reduction (particularly in injuries involving the posterior elements), and pin infection and loosening.[47-51] A higher rate of complications occurs in older patients. In a review of 53 patients with a mean age of 79.9 years, Horn and colleagues[52] recorded 31 complications in 22 patients. Serious complications included respiratory distress and dysphagia; these were the cause of death in 6 of 8 patients who died within the treatment period and were thought to have some relation to the halo treatment. Modern halo vests should always have a wrench attached to the front for quick removal in case of a cardiac emergency.

Studies comparing the halo with other types of cervical bracing in terms of the ability to limit motion have had variable findings. Johnson et al.[53] found that the halo allowed only 4% of normal sagittal motion, 1% of normal rotation, and 4% of lateral bending in normal subjects. A cadaveric study of simulated odontoid fractures demonstrated that the halo was superior in all planes versus a Miami J collar, a Minerva brace, and a soft collar.[34] In studies comparing subjects in various positions and activities, a maximum reduction of sagittal motion of only 30% was demonstrated.[54] A study of injured patients by Benzel et al.[55] demonstrated paradoxically increased movement at the injured levels in the halo versus a Minerva brace, which they attributed to the pull of the neck muscles with attempted flexion or extension against the rigidly fixed head. Ivancic and Telles[56] studied neck motion in a normal versus a loosely applied halo vest in the supine and prone positions using a cadaveric cervical spine between an anthropometric dummy and surrogate head. Results showed significantly increased motion in the loose vest with respect to the normal vest. The authors conclude that such increased motion may play a role in delayed unions and nonunions of cervical spine fractures.

The halo vest is useful in providing reduction and provisional stabilization of injuries or conditions causing instability at the occipitocervical junction, and it can be used to provide additional support after these patients have surgery. It is best used for reducing angular and translational deformities in cervical spinal fractures at the proximal and distal regions of the spine; in the midportion, studies have shown that a halo actually increases the forces on the injured vertebrae.[55] It is commonly used for complex combined C1 and C2 fracture patterns where internal stabilization is not possible without extension to the occiput, which results in severe loss of motion.[57,58] It is used to provide additional stability after complex surgical reconstructions or noninstrumented fusion or wiring constructs after surgery at C1–2 and may be used to supplement instrumented fusions in situations with poor bone quality or significant instability, as in patients with osteoporosis or rheumatoid arthritis.[59] The halo is no longer used as frequently in subaxial (i.e., C3–C7) trauma due to advances in spinal instrumentation. It is still considered the treatment of choice for some types of fractures of the axis (e.g., hangman's fractures) and in some flexion/compression injuries.[60,61] A fracture of the odontoid process at C2 is a common injury in older patients and historically has often been treated with a halo vest.[62–64] Currently the optimal treatment for these patients is controversial, with some authors reporting that simple collar immobilization provides equivalent results.[65-71] Significantly higher mortality has been reported in older patients treated with a halo compared with those treated with a cervical collar.[63,72] Daentzer and Florkemieier[73] performed a retrospective study of 29 patients divided into two groups based on age younger or older than 65 years and found that, although clinical and radiographic results were equivalent between the two groups, the interval to healing and rate of complications were higher in the older-than-65 age group.

Rehabilitation of the patient with a halo is challenging. The fixed head position affects the ability to use visual cues, and the weight of the vest and position of the head combine to change the patient's center of mass. Ambulatory patients in halo vests may exhibit a forward-flexion posture to accommodate this; a cane or walker may be required while the halo is in place. Likewise, there is a readjustment period after the halo has been removed, which may require postural reeducation as part of the rehabilitation strategy.

CERVICOTHORACIC AND THORACIC ORTHOSES

CTOs can be divided into two categories: those that use the thoracic spine to support treatment of a subaxial cervical spine or upper thoracic spine problem and those that support treatment at the upper cervical spine. Examples in the first category include thoracic extensions added to a cylindrical cervical orthosis (i.e., Extended Miami J) or an orthosis that utilizes pads on the chin and occiput to connect to the trunk with four stiff uprights or circumferential supports (i.e., Minerva). The Minerva brace (Fig. 13.4) is the most effective method for immobilizing C1–2 and has been shown to limit flexion/extension by approximately 79%, axial rotation by 88%, and lateral bending by 51%.[74] The cervicothoracic area is a particularly challenging area to immobilize in that it is a transitional area between the very mobile and lordotic cervical spine and the kyphotic thoracic spine. Little data exist in the literature regarding immobilization of the upper thoracic spine; for those conditions not requiring surgery, an extended cervical orthosis can be used.[1] The Minerva brace, Sternal Occipital Mandibular Immobilizer (SOMI) brace (Fig. 13.5), or a custom-molded CTO can be used for conditions extending as far caudally as T5. In general, increasing the length of the orthosis down the trunk enhances its capabilities.[53]

The most common condition that affects the thoracic spine is the vertebral compression fracture (VCF). Approximately 700,000 VCFs occur each year, and it is estimated that 25% of American women will experience at least one VCF in their lifetimes.[75] Most patients will have a benign course, but up to 30% are significantly symptomatic and seek treatment for pain that limits function in either the short or long term.[76] A study of patients with multiple VCFs found significant decreases in trunk extension torque, spinal motion, functional reach, mobility skills, and walking distance compared with the normal age-matched population.[77] The treatment of a VCF is aimed at pain relief

Fig. 13.4 Minerva brace (Otto Bock HealthCare LP, Austin, TX).

Fig. 13.5 SOMI brace (Courtesy of Trulife).

rather than at fracture treatment, as with other types of fracture management. The main objective is to improve quality of life and decrease pain.

Treatment of painful fractures may necessitate a short period of bed rest followed by gradual mobilization. Bracing with an orthosis may be beneficial for the first 6 to 8 weeks until the acute pain resolves. Unfortunately bracing is often poorly tolerated. The efficacy of bracing a VCF has not been established.[78] For osteoporotic women in general, one study demonstrated that wearing a TL orthosis that emphasized postural control for 6 months resulted in improved back extensor and abdominal flexor strength, decreased kyphosis, less pain, greater well-being, and fewer limitations.[79] One study suggested efficacy for this orthosis in patients with VCF and demonstrated potentially better tolerance than other braces.[80] Further study is required to outline optimal general management strategies for using spinal orthoses in this population.[81] Typically a symptomatic patient requesting bracing is trialed in an extended cervical orthosis, a hyperextension TL brace (CASH or Jewett, see later), or a CTO depending on the level involved.[55] If the orthosis is not helpful, it is discarded.

THORACOLUMBAR

The thoracolumbar region is the most common region of the spine affected by traumatic fracture and the most likely region to benefit from orthotic support for the surgically treated spine. The integrity of the vertebral body is of primary importance to resisting compressive forces and axial loads, and this region is a transitional zone that should be neutral in alignment. Fractures involving the anterior body greatly decrease the spine's ability to withstand compressive load and tend to collapse into kyphosis, particularly if the posterior elements are also involved (i.e., a burst fracture). This results in displacement of the patient's sagittal balance, spinal deformity, pain, and, in the worst cases, neurologic deficit. Fractures of this area may be treated with orthoses or surgically, and there is some consensus in the literature for surgical management when the vertebral body is severely comminuted, the patient has a neurologic deficit, or the initial fracture alignment is unacceptable.[78,82] Advances in spinal instrumentation and techniques such as interbody support have improved the surgeon's ability to counteract kyphosis, but at the thoracolumbar junction this requires a combined thoracolumbar surgical approach through the thoracic and abdominal cavities, which carries significant morbidity. Surgeons often choose to use posterior spinal instrumentation alone in these cases. Posterior instrumentation is least effective in resisting kyphosis, so orthoses that reduce kyphotic forces on the thoracolumbar spine may be used to supplement internal fixation techniques.

When an orthosis is used for the management of a thoracolumbar fracture, the same principles apply. Optimal management includes a strategy to resist anterior flexion and therefore the development of a kyphotic deformity. Orthoses are best used for fractures from T10 to L2, although some types of orthoses can be adjusted to control up to T8. Several thoracolumbar hyperextension orthoses are designed to unload the anterior column.[1] The most common types are the Jewett brace (Fig. 13.6A) and the CASH

Fig. 13.6 (A) Jewett brace. (B) Cash brace (Otto Bock HealthCare LP, Austin, TX).

brace (see Fig. 13.6B). Both of these braces are available in prefabricated styles from various manufacturers. The Jewett orthosis has an aluminum frame anteriorly that is stabilized on the pubis, sternum, and lateral midline of the trunk against a posterior pad. The frame is open and is particularly suitable for patients with coexisting abdominal trauma or obesity. Trunk flexion is limited by a single three-point pressure system with posteriorly directed forces at the sternum and pubis opposing an anteriorly directed force applied by the posterior pad. Therefore it is contraindicated in patients with sternal fractures or an inability to tolerate direct pressure from the posterior pad. The goal of the Jewett is to prevent flexion while still allowing active hyperextension. The CASH brace uses the same three-point system. It has an adjustable-length anterior cross with sternal and pelvic pads at the end of the vertical bar and lateral pads on the horizontal bar. It also uses an anteriorly directed force provided by a posterior belt. Both the Jewett and CASH braces are options for those patients who cannot tolerate the constriction of a molded thermoplastic thoracolumbosacral orthosis (TLSO), but they are contraindicated in patients with injuries including significant three-column instability such as the thoracolumbar burst fracture.

The TLSO is the recommended treatment for significant fractures at the thoracolumbar junction that are being treated conservatively. TLSOs can be used to manage fractures from T6 to L4. Molded TLSOs provide total contact designed to restrict ROM in all planes. In one study, a custom-molded thermoplastic TLSO showed 94% restriction in lateral bending and 69% restriction of flexion/extension in the lumbar spine.[83] In the thoracic spine, there was 49% restriction of flexion/extension and 38% restriction of lateral bending. The thoracic spine normally also allows rotation, and a reduction of 60% in total rotation was also shown. The superior trim lines of the TLSO are at the sternal notch and have an anteroinferior trim

line at the groin; they are carefully shaped to envelop the pelvis, arching slightly laterally anteriorly to accommodate the thigh while sitting and trimmed low at the sacrococcygeal junction posteriorly. The superoposterior trim line falls just below the spine of the scapula. The custom molds are made of a ventilated thermoplastic, which may be lined with closed cell foam to increase comfort. They can be bivalved with side closures to facilitate donning and doffing and are generally worn over a light T-shirt for comfort and hygiene. Straps over the shoulders may increase the rigidity, particularly if a semi-flexible or prefabricated model is chosen. TLSOs are also available in prefabricated models, although for maximum control of motion a custom mold is preferred. There is some controversy as to whether the made-to-measure or prefabricated orthoses fit and function as well as the custom-fabricated ones.

LUMBOSACRAL

Immobilization of the lumbosacral spine presents a unique set of challenges. It is a transition zone between the highly mobile lordotic lumbar spine and the rigid sacropelvic structures; it has the largest absolute range of flexion/extension and bears the most load of any of the spinal regions. A rigid lumbosacral orthosis (LSO), which is simply a shorter version of the TLSO described earlier, is appropriate for bracing fractures at L2, L3, and L4; but the FSUs at L4–5 and L5–S1 require special treatment. Fidler and Plasmans[84] found that a unilateral thigh extension is necessary to effectively immobilize L4–5 and L5–S1. A thigh extension is generally a cuff attached by two longitudinal struts that have hinges, allowing a variable degree of flexion at the hip to facilitate toileting and sitting; generally it is set at allowing 20 to 30 degrees of flexion at a maximum. The mean percentage of motion allowed in the brace was 32% at L4–5 and 70% at L5–S1 in a brace without the extension; adding the extension resulted in an additional 15% to 30% reduction of motion.[85,86] At best, restriction at the L5–S1 level still allows 40% of normal range. For this reason fractures at these levels are best treated with surgery (using an orthosis for postoperative support if necessary) if the treating physician desires to mobilize that patient during the healing period.

Up until the last few years, LSOs have commonly been used in the postoperative period. Advances in spinal instrumentation, with the advent of pedicle screws and interbody techniques, now allow many patients to go without bracing postoperatively. Pedicle screws connect the anterior load-bearing portion of the spine with a posterior construct by crossing the middle column and provide better limitation of motion and load sharing than previous hook/rod constructs. Interbody techniques place a block of bone between the vertebral bodies, either through placement by an intra-abdominal approach or with hybrid approaches accessing the disc space from the posterior part of the spine. The placement of bone in the middle and anterior columns facilitates healing because increased surface area and favorable biomechanical conditions allow the bone graft to experience compression forces. A recent randomized trial that assessed the benefit of wearing a lumbar corset for 8 weeks after lumbar fusion did not find a significant advantage or disadvantage with respect to healing rates or patient comfort.[87] Today postoperative bracing is reserved for patients who feel more comfortable with support (a lumbar corset) or those with poor bone quality or technical issues leading to concerns about healing or the stabilization provided by the instrumentation.

Patients with acute LBP may find the additional support and postural reminder of a lumbar corset helpful for pain reduction. Lumbar corsets are generally semi-rigid or flexible braces (Fig. 13.7A). Their function is to reduce gross trunk motion and increase intracavitary pressure in the abdomen by transmitting a three-point pressure system to the lumbar

Fig. 13.7 (A) Lumbar corset (AliMed, Inc. www.alimed.com). (B) Chairback orthosis (Don Joy DJO Global http://djomerchandise.com/).

spine. They are designed to support the trunk in a neutral sagittal alignment and provide a kinesthetic reminder to limit motion. The lumbar corset has little resistance to gross body motion during sitting and standing.[88] Typically the anterior borders of the lumbosacral corset are superior to the symphysis pubis and inferior to the xiphoid process. The posterior borders extend between the sacrococcygeal junction of the pelvis and the inferior angle of the scapulae; some may incorporate shoulder straps. The Chairback Orthosis (see Fig. 13.7B) is an lumbosacral corset with both a thoracic and a pelvic band connected by two paraspinal bars for optimized sagittal control. A pair of lateral bars can also be added for improved coronal control (the Knight orthosis).

The literature on the effectiveness of the corset is conflicting. In 2001, a systematic review of randomized and nonrandomized controlled trials demonstrated no evidence that spinal orthoses were effective in the prevention or management of LBP.[89] An orthosis should be used in conjunction with a rehabilitation program focused on core strengthening and stabilization in these patients.

Spinal orthoses have been found to have a deconditioning effect on the paraspinal muscles and trunk stabilizers. Electromyographic studies have found conflicting results, with some demonstrating a significant reduction in muscle activity in the brace and others finding either unchanged or increased activity.[85,90] An exercise regimen should be maintained when the clinical situation allows and the orthosis should be discontinued as soon as possible.

Cervicothoracolumbosacral

Cases in which patients sustain multiple traumas to the cervical, thoracic, lumbar, and sacral segments of the spine may require the use of more complicated orthotic design. The cervicothoracolumbosacral orthosis (CTLSO) may be used to address the issues of stabilization and motion control involving multiple spinal segments. Use of CTLSOs is not limited to cases of multiple spinal segment trauma. It may also be employed pre- or postoperatively as a supplement to surgical procedures of the cervical spine requiring the level of control provided by a TLSO combined with a cervical component such as the Minerva collar or a SOMI proximal cervical component. Donning, doffing, and skin care issues for CTLSOs are consistent with those for CTOs and TLSOs.

Sacroiliac Joints

Estimates vary regarding the role that the sacroiliac (SI) joints play in the incidence of LBP. Estimates of LBP originating in the SI joints range between 22%[91,92] and 30%[93] of cases. The SI joints are vital links between the spinal column and the lower extremities.[94] They are the critical connection for the successful transference of upper body weight to the legs.[94] The etiology of SI joint pain covers a wide range, including rheumatoid arthritis, osteoarthritis, tumor, infection, pregnancy, and trauma.[95,96] An orthosis for the treatment of SI joint pain is the sacroiliac orthosis (SIO), also known as an SI or pelvic belt. The mechanism involved is a compressive or "squeezing" force across the pelvis that is transferred to the SI joints as a stabilizing force to reduce joint laxity, restrict motion, and thereby reduce pain.[94,97-99] Positioning of the SI belt during donning is key to the successful mitigation of pain related to the SI joint. The SI belt should be positioned and then tightened just proximal to the greater trochanters.[94,99,100] The position of the belt has been found to play a greater role in the reduction of SI joint laxity than the belt's tension.[101]

Scoliosis

Scoliosis is a general term that refers to a three-dimensional spinal deformity characterized by coronal displacement of vertebral bodies away from the axis of gravity combined with abnormal vertebral rotation (Fig. 13.8). There are many types of scoliosis as well as many etiologies. Today, the only type of scoliosis that is typically and frequently managed with a spinal orthosis is the idiopathic curve. Adolescent idiopathic scoliosis (AIS) refers to a curvature and rotational deformity of the spine that develops with growth. It can occur in the upper thoracic, thoracic, thoracolumbar, or lumbar spine or some combination. There is often a primary curve (the curve with abnormal growth) and a compensatory curve, which is a second region of the spine curving in the opposite direction to the primary curve to keep the head centered over the pelvis. The age of the child, the growth remaining, and the curve pattern all have implications for prognosis.

PREVALENCE AND NATURAL HISTORY

Idiopathic scoliosis has been studied and documented for many years and maintains a consistent prevalence of approximately 1% to 2% of school-age children.[102-104] Ninety percent of children have adolescent-onset curves, although this figure may be falsely elevated because younger children are not routinely evaluated.[105] The prevalence of curves that do not require treatment (<20 degrees) is 20 to 30 per 1000, the prevalence of moderate curves amenable to bracing (20–30 degrees) is 3 to 5 per 1000, and the prevalence of large curves likely to go on to surgical management is 2 to 3 per 1000 people.[104] The prevalence of curves is greater in females, particularly with respect to curves over 20 degrees (6.4 F:1 M).[106] The single right thoracic curve is the most prevalent pattern.[107] The most important determinants of the likelihood of progression are those that reflect skeletal maturity: age, menarchal status, and the presence of mature growth centers on

Fig. 13.8 Skeleton with scoliosis trunk shift (Dr. Spivak executivespinesurgery.com).

radiographs of the pelvis (Risser sign) or hand. The likelihood of progression determines the need for treatment; those at highest risk are those with a younger age at diagnosis, a curve that appears before the onset of menstruation, a double curve pattern, and a curve that is documented to change more than 5 degrees on serial radiographs taken at 6-month intervals. Curve magnitude and rotation are both correlated with increased progression rates.[108] This is the basis for the recommendation that curves greater than 50 degrees in a growing child be treated surgically.

BIOMECHANICS

Curves progress when buckling loads change during growth, along with other hormonal and developmental factors. A straight, flexible column fixed at the base and free at the other end subjected to axial forces will buckle, which in the spine results in a combination of curvature and rotation. The loads at which these processes occur are related to the length and rigidity of the spine. The adolescent growth spurt results in a significant increase in spinal length and may result in increased flexibility as well, which contributes to the drastic increases in curve progression commonly observed during the adolescent years. As the curve progresses, a feedforward cycle is created. With curve progression, the spine is subjected to increasingly abnormal force vectors and deviates further from the normal anatomic alignment at which it is best equipped to resist such loading. Braces used for scoliosis are designed to interrupt this feedforward cycle.

There are three primary mechanisms by which an orthosis exerts forces on a developing spine: end-point control, curve correction, and transverse loading.[109] End-point control is the ability of the orthosis to constrain the spine. An example is the neck ring at the proximal end of the Milwaukee brace, which can control the position of the upper thoracic spine relative to the pelvis. Curve correction has the greatest effect because it stiffens the spine and reduces the curve, which in turn decreases the load on the spine and slows the rate of deformation. Transverse loading at the apex is the primary mode of correction within modern orthoses, but it begins to lose efficacy as the curves get larger.[110] It is important to note that brace treatment often does not significantly correct the existing curve but rather prevents it from increasing in size during growth. Some degree of curve correction should be achieved within the brace (ideally 50% or more) because the curve will regress back to its initial magnitude once the brace is removed.[111,112] The overall concept is to halt curve progression.

EVALUATION

The first step in evaluating a child with a spinal curvature is a thorough orthopedic history including age, growth patterns, family history of spinal problems, the age at which the curve was discovered, and any treatment that has previously been used. The primary goal of an orthosis in treating a scoliotic deformity is to control remaining spinal growth so that the spine reaches maturity with an acceptable curvature. There is no role for using an orthosis to prevent scoliosis, and the ability of an orthosis to make a curvature ultimately smaller is limited.[113-115] Scoliosis progresses as the spine grows, so an adolescent at the end of spinal growth has very little risk of progression, and there is no role for bracing a curve that has already reached a size where surgery is indicated.[116] Therefore it is critical to identify children with scoliosis at the early stages. A national screening program has been adopted in many countries for this purpose.

Physical examination and radiographs are used to measure the size, flexibility, and effects of each spinal curvature. The Scoliosis Research Society has adopted a set of terms and definitions to describe scoliosis as well as to describe the multitude of spinal conditions that can lead to scoliosis. Curves can be described either by etiology of the structural changes (Box 13.2) or by the spinal level of the anatomic apex of the curve. In a cervical scoliosis, the apex of the

curve is at or between the vertebral body of C1 and C6. In a cervicothoracic curve, the apex is at C7, C8, or T1. A thoracic curve has an apex at or between T2 and T11. A thoracolumbar curve reaches its apex at the T12 or L1 vertebral body. A lumbar curve occurs at L2, L3, or L4, whereas a lumbosacral curve reaches its apex at L5 or S1. Numerous descriptive terms are also used in the diagnosis, evaluation, and management of scoliosis (Table 13.2). These standards and definitions are used throughout this chapter.

Scoliosis can also be described by etiology. A child or adolescent who develops scoliosis after relatively typical growth and development is diagnosed as having idiopathic scoliosis. An individual who develops scoliosis as a secondary complication of nervous system or muscle disease is described as

Table 13.2 Glossary and Definitions of Terms in Scoliosis

Term	Definition
Adolescent scoliosis	Spinal curvature presenting at or about the onset of puberty and before maturity.
Adult scoliosis	Spinal curvature that develops after skeletal maturity.
Angle of thoracic inclination	The angle between the horizontal plane and inclination plane across the posterior rib cage at the greatest prominence of a rib hump, assessed with the trunk flexed 90 degrees at the hips.
Apical vertebra	The most rotated vertebra in a curve; the most deviated vertebra from the vertical axis of the patient.
Body alignment 1. Alignment of the midpoint of the occiput over the sacrum in the same vertical plane as the shoulders over the hips 2. In radiography, when the sum of the angular deviations of the spine in one direction is equal to that in the opposite direction (also described as balance or compensation)	
Café au lait spots	Light-brown, irregular areas of skin pigmentation; if they are sufficient in number and have smooth margins, they suggest neurofibromatosis.
Cobb angle or method	On radiograph, the uppermost and lowermost vertebrae in the curve are identified; a perpendicular line (curve measurement) is drawn from the transverse axes of these vertebrae, and the angle formed at their intersection (Cobb angle) measures the severity of the curve; if vertebral end plates are poorly visualized, a line through the bottom or top of the pedicles can be used.
Compensatory curve	A curve, which can be structural, above or below the major curve that tends to maintain normal body alignment.
Congenital scoliosis	Scoliosis due to congenitally anomalous vertebral development.
Double major scoliosis	Scoliosis with two structural curves.
Double thoracic curves	Two structural curves within the thoracic spine.
End vertebra 1. Uppermost vertebra of a curve, the superior surface of which tilts maximally toward the concavity of the curve 2. The most caudal vertebra, the inferior surface of which tilts maximally toward the concavity of the curve	
Fractional curve	Compensatory curve that is incomplete because it returns to the erect; its only horizontal vertebra is its caudad or cephalad one.
Full curve	Curve in which the only horizontal vertebra is at the apex.
Gibbus	Sharply angular kyphos.
Hyperkyphosis	Sagittal alignment of the thoracic spine in which more than the normal amount of kyphosis is present (a kyphos).
Hypokyphosis	Sagittal alignment of the thoracic spine in which less than the normal amount of kyphosis is present but not so severe as to be lordotic.
Hysterical scoliosis	Nonstructural deformity of the spine that develops as a manifestation of a conversion reaction.
Idiopathic scoliosis	Structural spinal curvature for which no cause is established.
Iliac epiphysis or apophysis	Epiphysis along the wing of an ilium.
Inclinometer	Instrument used to measure the angle of thoracic inclination or rib hump.
Infantile scoliosis	Spinal curvature that develops during the first 3 years of life.

Continued

Table 13.2 Glossary and Definitions of Terms in Scoliosis—cont'd

Term	Definition
Juvenile scoliosis	Spinal curvature that develops between the skeletal age of 3 years and the onset of puberty (10 years).
Kyphos	Change in alignment of a segment of the spine in the sagittal plane that increases the posterior convex angulation; an abnormally increased kyphosis.
Kyphoscoliosis	Spine with scoliosis and a true hyperkyphosis; a rotatory deformity with only apparent kyphosis should not be described by this term.
Kyphosing scoliosis	Scoliosis with marked rotation such that lateral bending of the rotated spine mimics kyphosis.
Lordoscoliosis	Scoliosis associated with an abnormal anterior angulation in the sagittal plane.
Major curve	Term used to designate the largest structural curve.
Minor curve	Term used to refer to the smallest curve, which is always more flexible than the major curve.
Nonstructural curve	Curve that has no structural component and that corrects or overcorrects on recumbent side-bending radiographs.
Pelvic obliquity	Deviation of the pelvis from the horizontal in the frontal plane; fixed pelvic obliquities can be attributable to contractures either above or below the pelvis.
Primary curve	First or earliest of several curves to appear if identifiable.
Risser sign	Rating system used to indicate skeletal maturity, based on degree of ossification of the iliac epiphysis.
Rotational prominence	In the forward-bending position, the thoracic prominence on one side is usually due to vertebral rotation, causing rib prominence; in the lumbar spine, the prominence is usually due to rotation of the lumbar vertebrae.
Skeletal age (bone age)	Age obtained by comparing an anteroposterior radiograph of the left hand and wrist with the standards of the Greulich and Pyle atlas.
Structural curve	Segment of the spine with a lateral curvature that lacks normal flexibility; radiographically, it is identified by the complete lack of a curve on a supine film or by the failure to demonstrate complete segmental mobility on supine side-bending films.
Vertebral end plates	Superior and inferior plates of cortical bone of the vertebral body adjacent to the intervertebral disc.
Vertebral growth plate	Cartilaginous surface covering the top and bottom of a vertebral body, which is responsible for linear growth of the vertebra.
Vertebral ring apophyses	Most reliable index of vertebral immaturity, seen best in lateral radiographs or in the lumbar region in side-bending anteroposterior views.

having neuromuscular scoliosis. Clinical examination includes an assessment of the patient's posture, noting any asymmetry in trunk alignment, shoulder height, scapular prominence, and pelvic rotation. Special attention is paid to the degree of thoracic kyphosis and lumbar lordosis as well as any tendency toward trunk shift to the right or left (spinal decompensation) (Fig. 13.9A). The Adams forward-bending test assesses the rotation of each curve by the degree of prominence over the apices, and the patient can be flexed laterally while bent forward to assess the degree of curve flexibility (see Fig. 13.9B). Complete neurologic, skin, and cardiac examinations are then performed.

The timing of orthotic treatment is an important determinant of efficacy. The principles have remained the same regardless of the orthosis used. First, treatment should be initiated before skeletal maturity, when there is growth remaining, because bracing is effective only in a growing child; curves less than 20 degrees are generally observed, but once a curve is greater than 20 degrees and/or demonstrates significant progression, bracing is initiated. Second, most braces should be worn full time, which was defined by Blount[117] as 23 hours per day and more recently confirmed by a meta-analysis of available studies.[118] Third, the brace should be worn until skeletal maturity. Last, there should be a weaning period accompanied by a rehabilitation program to rebuild muscle strength once skeletal maturity has been reached. A predictive model using in-brace correction and scoliometer measurements has been created to help identify those individuals who are likely to demonstrate progression of the curvature despite bracing.[119] This tool may be useful in management planning.

TYPES OF BRACES

Milwaukee Brace

In 1944 Blount and Schmidt developed the Milwaukee brace. As a CTLSO, it was initially employed as a postoperative modality but soon found a more important role. Since 1954 it has been used in the nonoperative treatment of idiopathic scoliosis.[120] The brace consists of a pelvic section, which helps to reduce lumbar lordosis, and an attached "superstructure." The superstructure consists of three metal uprights that are attached to a neck ring superiorly. It provides an end point of control to make the spine structurally more rigid and better aligned; it also provides a means of attachment for the spinal pads (Fig. 13.10). This style is considered a full-time brace and should be worn 23 hours a day. The initial design incorporated distraction; however, this has since been modified due to problems with malocclusion of the jaw. Subsequent to the Milwaukee

brace, various low-profile TLSOs have been introduced. Most of these spinal orthoses are named for the city in which they were developed (e.g., Boston brace, Miami orthosis, Wilmington brace, Lyon brace). These spinal orthoses share one characteristic: all control the alignment of the thoracolumbosacral spine but have no superstructure. The Milwaukee brace is mentioned here primarily for its historic significance. It remains the most effective brace for upper thoracic curves but requires a dedicated patient and family for compliance.

Boston Thoracolumbosacral Orthosis

In 1972, in response to patient concerns about the bulkiness and neck ring of the Milwaukee brace, Hall created a lower-profile modular TLSO known as the *Boston brace*.[121] Watts and Hall[122] reported on the Boston brace in 1977. It is a rigid underarm TLSO that, with various modifications, has become the most prevalent type of orthosis used. The original Boston brace consisted of multiple modules that were fabricated in different sizes and could be combined to provide a custom-fitted brace that did not require as much time or expertise on the part of the orthotist.[121] Several studies have demonstrated equivalent results with the use of the Boston brace or its related products compared with the Milwaukee brace, with the possible exception of use for high thoracic curves.[111,112,123-125] Boston braces are popular because of their low-profile and partially open design, which is comfortable and well tolerated.

Charleston Nighttime Brace

This brace was created in 1979 by Reed and Hooper.[121] It is manufactured so that a curvature is maximally corrected while the patient sleeps; the correction is so significant that it is not comfortable when worn in an upright position.[126] Price and colleagues[126] reported on the prevention of progression of curvature in 66% of patients with curves less than 49 degrees and significant growth remaining. One comparative study between the Boston and Charleston orthoses showed the Boston orthosis to be more effective in all curve patterns but the Charleston orthosis to have equal efficacy in 25- to 35-degree single thoracolumbar or lumbar curves.[127] The theoretical advantages of the Charleston orthosis in terms of body image and socialization issues are intuitive but have not been shown in rigorous studies; likewise, compliance problems are similar to those with other braces.

SpineCor

Traditionally, corrective spinal orthoses used in the treatment of adolescent and juvenile scoliosis have been rigid or semirigid devices. Rigid orthoses have been shown to be effective for some patients with AIS but are associated with drawbacks related to cosmesis and physical discomfort, which tend to compromise patient compliance. In the early 1990s, Coillard and Rivard developed the SpineCor brace, a dynamic bracing system that uses nonrigid harness-like bands to apply corrective forces to the patient's torso. The components of the brace include a pelvic base, two thigh bands, two crotch bands, a cotton bolero, and four corrective elastic bands that may be arranged in a number of different configurations depending on the specific deformity being treated. The pelvic base is a belt that includes three pieces of soft thermoplastic material. Fitting patients with the brace is done in a systematic fashion using supplementary computer software; a training course is offered to providers for education on proper fitting technique.

Coillard and Rivard, the developers of the SpineCor brace, published the initial clinical results in 2003.[128] They reported on the treatment results of 195 patients between 6 and 14 years of age with idiopathic scoliosis curves between 15 and 50 degrees and Risser stages 0 to 3. Success in their study was defined as either a correction or stabilization of about 5 degrees or more. Failure was defined as worsening of the curve by more than 5 degrees. The authors found that at 2 years of follow-up, there was an overall correction of greater than 5 degrees in 55% of patients, curve stabilization in 38%, and worsening by greater than 5 degrees in 7% of patients. This equates to 93% success at 2 years. At 4 years of follow-up, the probability of success was 0.88 to 0.92. Coillard and Rivard published results of the same prospective cohort again in 2007 using the Scoliosis Research Society scoliosis research inclusion criteria.[129] A total of 170 patients were included in the study. The authors reported that successful treatment was achieved in 59.4% of patients at the time of brace discontinuation, with 22.9% requiring fusion during the treatment period, at which point 1.2% of patients had curves exceeding 45 degrees at maturity. These initial results reported by the developers of the SpineCor brace were promising; however, further studies by independent investigators have yielded some conflicting results.

Weiss and Weiss[130] published the results of a small study that compared treatment with a SpineCor brace with TLSO bracing. The authors compared 12 SpineCor patients with 15 TLSO patients and found that the SpineCor patients, with a starting Cobb angle of 21 degrees, progressed an average of 10 degrees after 21 months of treatment, versus 0.2 degrees in the TLSO patients who had a starting Cobb angle of 33

degrees. Wong and colleagues[131] compared 22 SpineCor patients with 21 TLSO patients and demonstrated that only 68% of SpineCor patients maintained curve progression of less than or equal to 5 degrees compared with 95% of TLSO patients. Gammon and colleagues[132] compared 35 patients treated with a TLSO with 32 patients treated with the SpineCor brace and found no significant difference between the two outcomes with respect to progression of less than or equal to 5 degrees (60% in TLSO and 53% in SpineCor) or success in avoiding curve progression past 45 degrees (80% in TLSO and 72% in SpineCor). However, a retrospective study of 243 patients with AIS treated with either the SpineCor or the Boston brace revealed greater curve progression in the SpineCor group.[133] A higher percentage of patients in the SpineCor group had curve progression equal to or greater than 6 degrees (76% compared with 55% in the Boston brace group). Additionally the average curve progression was 14.7 degrees (±11.9 degrees) in the SpineCor group compared with 9.6 degrees (±13.7 degrees) in the Boston brace group.[133]

An important aspect of any brace is the degree of physical comfort and cosmetic considerations. As is true with the literature regarding the efficacy of the SpineCor brace versus TLSO bracing, the literature addressing the impact of the SpineCor brace on comfort and cosmesis is scant. In their 2008 study comparing the SpineCor brace with TLSO bracing, Wong and colleagues[131] administered a questionnaire at 3, 9, and 18 months of treatment to gain information about patient acceptance of the brace. The only significant differences noted were problems with toileting (greater in the SpineCor group) and donning/doffing the orthosis (greater in the TLSO group).

Orthotic Prescription

An orthosis should initially improve the magnitude of the curve.[134] An orthosis that provides some correction theoretically decreases the load on the developing vertebrae, increasing the likelihood of long-term control of the deformity.[135] Over time the orthosis should be capable of preventing curve progression for long periods, frequently until the patient reaches skeletal maturity. Finally, an orthosis should be designed to be well tolerated and allow normal social and physical development; even then, compliance with brace wear is a significant issue for adolescents.[136-139] The effectiveness of an orthosis has been shown to be directly related to time spent in the brace, so the patient's willingness to wear the brace is of utmost importance.[118,127,140-142] "Smart braces" that measure compliance have demonstrated that even the most apparently compliant patient spends much less time in the brace than actually prescribed.[137,139,143-146]

The prescribing physician should specify the particular requirements for the orthosis based on the deformity, the goals of treatment, and his or her assessment of the likelihood for compliance. The exact type of brace, generally CTLSO or TLSO, with specifications of thoracic pad placement, lumbar pad placement, need for axillary slings, anterior gussets, trochanteric extensions, kyphosis pads, and the like depends on the type of deformity being treated. Each pad requires a specified location, mediolateral orientation, and placement instructions. The choice between a CTLSO and TLSO is dictated by the location of the curve, with high thoracic curves most effectively treated by the former. A TLSO has a much lower profile and is therefore more socially acceptable. The orthosis may be prefabricated and adjusted to fit or custom-molded for patients who require additional adaptability.

The time in the orthosis is slowly increased over several weeks and then assessed both physically and radiographically by the prescribing physician. Specific pressure point relief and corrective pad adjustments may be required periodically because these patients are in a period of rapid spinal growth. For the youngest patients, multiple braces may be required before growth concludes.

Different goals are applied for patients with scoliosis of a neuromuscular origin such as cerebral palsy or muscular dystrophy. In these cases spinal bracing is frequently ineffective in significantly altering the progression of deformity but may still be useful when surgery is contraindicated.[147] Goals for the use of a spinal orthosis in such patients include maximizing sitting postural control, alleviation of pain, and facilitation of function and daily care.[147]

COMPLICATIONS

Complications with scoliosis orthoses are generally mild from a physical standpoint. However, bracing for AIS has been associated with psychologic stress[148] and decreased pulmonary function.[149,150] Since compliance is a major factor in bracing success, efforts are being made to develop low-profile braces that may reduce wearer stress. A study of 63 adolescent patients demonstrated significantly lower stress levels when they were wearing the Cheneau light brace than when wearing their originally prescribed bulkier braces while obtaining equivalent correction in the brace.[148] Further studies are needed to examine compliance. A meta-analysis of 237 AIS patients determined that patients with thoracic curves who underwent preoperative brace treatment had significantly lower forced vital capacity (FVC) and forced expiration (FEV_1) than those who did not have bracing before surgery.[150] Other potential complications include compression of the abdominal viscera, which can result in increased intragastric pressure, leading to gastroesophageal reflux and potentially esophagitis.[151] Mild to moderate decreases in kidney function have been described but have not been found to have significant long-term consequences.[152] On the other hand, brace treatment in adolescence has been found to produce psychologic disturbances that are measurable into adult life.[153,154] Finally, the successful use of bracing requires a supportive, constructive family and a similar relationship between the physician and the adolescent.

FUTURE DIRECTIONS

The key to scoliosis treatment is to identify which children are likely to develop curve progression, avoiding treating those with curves that will remain in the 25- to 35-degree range through their growth and therefore not require any intervention. Epidemiologic studies and skeletal maturity indicators have traditionally been used for this purpose and continue to be refined.[102,116,155-157] Recently genes

that control the growth of scoliotic curves have been identified.[158-161] With this new information in combination with traditional methods, it may become possible to predict with a high degree of certainty which children will develop significant curves. Surgical treatments that harness asymmetric growth in the spine are also becoming available.[162-170] This combination of techniques may allow intervention before bracing becomes necessary. Meanwhile brace manufacturers are developing many new devices with the goals of decreasing deformity while increasing comfort, compliance, and chest expansion for pulmonary function.

Summary

Spinal orthoses are used to treat patients with a variety of spinal disorders ranging from LBP to complex spinal trauma and deformity. Selection of the appropriate orthosis for a specific patient is based on many factors, such as the indication for bracing and its severity, the age and body habitus of the patient, his or her willingness and ability to commit to a potentially long and difficult treatment course, and the patient's decisions after weighing the risks and benefits of orthotic treatment against other treatment modalities. These challenging treatment decisions are best managed by a multidisciplinary team comprising the treating physician, orthotist, physical and occupational therapists, and patient as well as his or her personal support network. Frequent follow-up and close communication between all members of the treatment team is essential to ensure thorough patient and family education, ensure adequate fit of the orthosis, evaluate for treatment efficacy, monitor for complications, and provide psychosocial support to the patient. Adequately addressing all of the issues surrounding orthotic treatment of spinal disease requires a thorough understanding of the natural history of the pathology being treated, the indications for bracing and use of specific braces, the mechanism of action of the orthosis, potential outcomes of the treatment, and potential complications and methods to minimize them. Comparative studies, long-term outcome analysis, and biomechanical studies have helped to promote understanding of and appropriate and effective use of spinal orthoses. Despite the large body of knowledge about these topics, there are still many unknowns surrounding spinal orthoses and their role in treating disorders of the spine. This chapter provides a brief overview of the basic functional anatomy of the spine, the fundamentals of spinal trauma and scoliosis, the various types of braces and their mechanisms of action and indications, and the potential complications. The ability to use spinal orthoses safely and effectively requires a comprehensive understanding of these topics.
